The Complete System Design Knowledge Base

From first principles to expert practice

Built from the manuscript sources · 56 chapter(s) in this edition

Part I — Foundations of System Design Thinking

Chapter 1 — What Is System Design?

1.1 Learning objectives
1.2 Prerequisites
1.3 Definition of system design
1.4 Software architecture
1.5 High-level vs low-level design
1.6 Functional requirements
1.7 Non-functional requirements (the "-ilities" catalog)
1.8 Architectural decision-making and ADRs
1.9 Why system design matters (cost of wrong decisions)
1.10 How system design is practiced in industry
1.11 How system design interviews work
1.12 Common beginner mistakes
1.13 Summary and revision notes
1.14 Knowledge checkpoint
1.15 Interview questions
1.16 Practical exercises
1.17 Design challenges
1.18 References
1.19 Open verification items

Chapter 2 — How to Think Like a System Designer

2.1 Learning objectives
2.2 Prerequisites
2.3 Decomposition into components
2.4 System boundaries and context diagrams
2.5 Understanding and negotiating requirements
2.6 Identifying bottlenecks
2.7 Making and stating assumptions
2.8 Evaluating trade-offs
2.9 Designing for failure
2.10 Reasoning about scale
2.11 Back-of-the-envelope capacity estimation
2.12 Architecture documentation
2.13 Summary and revision notes
2.14 Knowledge checkpoint
2.15 Interview questions
2.16 Practical exercises
2.17 Design challenges
2.18 References
2.19 Open verification items

Chapter 3 — The System Design Learning Method

3.1 Learning objectives
3.2 Prerequisites
3.3 The ten-step concept-mastery loop

3.4 Active recall, spaced repetition, the Feynman technique, interleaving and deliberate practice
3.5 Reading papers and engineering blogs
3.6 Drawing architecture from memory
3.7 Building simplified implementations
3.8 Beginner methodology: a 12-month path
3.9 Advanced methodology for experienced engineers
3.10 Tracking progress
3.11 Summary and revision notes
3.12 Knowledge checkpoint
3.13 Interview questions
3.14 Practical exercises
3.15 Design challenges
3.16 References
3.17 Open verification items

Chapter 4 — Quantitative Foundations for System Design

4.1 Learning objectives
4.2 Prerequisites
4.3 Exponents, powers of two and powers of ten
4.4 Logarithms
4.5 Units: bits, bytes, rates and prefixes
4.6 Probability essentials
4.7 Statistics: describing measurements
4.8 Percentiles and tail latency
4.9 Basic linear algebra
4.10 Queueing theory
4.11 Little’s Law
4.12 Amdahl’s Law and Gustafson’s Law
4.13 The Universal Scalability Law
4.14 Availability arithmetic
4.15 Reliability: MTBF, MTTR and failure rates
4.16 Durability and replication
4.17 Latency numbers every engineer should know
4.18 Quantitative relationships that recur in system design
4.19 Summary and revision notes
4.20 Knowledge checkpoint
4.21 Interview questions
4.22 Practical exercises
4.23 Design challenges
4.24 References
4.25 Open verification items

Part II — Computer Science Foundations

Chapter 5 — Computer Architecture

5.1 Learning objectives
5.2 Prerequisites
5.3 The CPU: cores, registers, clock and the instruction pipeline
5.4 CPU caches

5.5 RAM and the memory hierarchy
5.6 Storage devices
5.7 I/O operations
5.8 CPU-bound versus I/O-bound workloads
5.9 Memory latency and bandwidth
5.10 NUMA
5.11 SIMD and accelerators
5.12 Throughput versus latency at the hardware level
5.13 Summary and revision notes
5.14 Knowledge checkpoint
5.15 Interview questions
5.16 Practical exercises
5.17 Design challenges
5.18 References
5.19 Open verification items

Chapter 6 — Operating Systems

6.1 Learning objectives
6.2 Prerequisites
6.3 Processes and threads
6.4 Context switching and its cost
6.5 CPU scheduling
6.6 Virtual memory, paging and the page cache
6.7 System calls and the kernel/user boundary
6.8 Concurrency versus parallelism
6.9 Race conditions and critical sections
6.10 Synchronization primitives
6.11 Deadlock, livelock, starvation and priority inversion
6.12 Inter-process communication
6.13 I/O models: from blocking to io_uring
6.14 File systems, journaling and fsync
6.15 Concurrency models in practice
6.16 Summary and revision notes
6.17 Knowledge checkpoint
6.18 Interview questions
6.19 Practical exercises
6.20 Design challenges
6.21 References
6.22 Open verification items

Chapter 7 — Networking Fundamentals

7.1 Learning objectives
7.2 Prerequisites
7.3 OSI and TCP/IP models
7.4 IP addressing, IPv4/IPv6, subnets and CIDR
7.5 Routing basics, BGP and anycast
7.6 DNS: the Internet’s directory
7.7 TCP: reliable byte streams over an unreliable network

7.8 UDP and when to use it
7.9 HTTP/1.1, HTTP/2, HTTP/3 and QUIC
7.10 TLS 1.3 and HTTPS
7.11 WebSockets (introduction)
7.12 Forward proxies and reverse proxies
7.13 NAT
7.14 Firewalls and security groups
7.15 Latency, bandwidth, the bandwidth-delay product and packet loss
7.16 Connection pooling and keep-alive
7.17 Datacenter networking
7.18 What happens when you type a URL
7.19 Summary and revision notes
7.20 Knowledge checkpoint
7.21 Interview questions
7.22 Practical exercises
7.23 Design challenges
7.24 References
7.25 Open verification items

Chapter 8 — Web Application Fundamentals

8.1 Learning objectives
8.2 Prerequisites
8.3 Client–server architecture
8.4 Frontend and backend; SPA, SSR and mobile clients
8.5 The request–response lifecycle end to end
8.6 REST API design
8.7 GraphQL
8.8 gRPC and RPC
8.9 Serialization: JSON, Protocol Buffers, Avro and Thrift
8.10 Cookies and sessions
8.11 Authentication
8.12 Authorization: RBAC, ABAC and ReBAC
8.13 JSON Web Tokens (JWT)
8.14 OAuth 2.0 and OpenID Connect
8.15 API versioning and compatibility
8.16 API documentation: OpenAPI
8.17 Summary and revision notes
8.18 Knowledge checkpoint
8.19 Interview questions
8.20 Practical exercises
8.21 Design challenges
8.22 References
8.23 Open verification items

Chapter 9 — Real-Time Communication

9.1 Learning objectives
9.2 Prerequisites
9.3 Short polling

9.4 Long polling
9.5 Server-Sent Events
9.6 WebSockets in depth
9.7 WebRTC basics
9.8 Mobile push: APNs and FCM
9.9 Connection management at scale
9.10 Choosing a real-time technique
9.11 Summary and revision notes
9.12 Knowledge checkpoint
9.13 Interview questions
9.14 Practical exercises
9.15 Design challenges
9.16 References
9.17 Open verification items

Chapter 10 — Security Fundamentals for System Designers

10.1 Learning objectives
10.2 Prerequisites
10.3 Threat modeling
10.4 Cryptography essentials
10.5 PKI and certificates
10.6 Password storage
10.7 The OWASP Top 10 in architectural terms
10.8 Secrets management
10.9 Encryption at rest and in transit, KMS and envelope encryption
10.10 Network security, zero trust and mTLS
10.11 DDoS basics
10.12 Audit logging and tamper evidence
10.13 A security checklist for every design
10.14 Summary and revision notes
10.15 Knowledge checkpoint
10.16 Interview questions
10.17 Practical exercises
10.18 Design challenges
10.19 References
10.20 Open verification items

Part III — Data Systems

Chapter 11 — Relational Databases

11.1 Learning objectives
11.2 Prerequisites
11.3 The relational model: tables, rows and columns
11.4 Keys: primary, foreign, natural and surrogate
11.5 Normalization and denormalization
11.6 SQL and joins
11.7 Indexes
11.8 B-trees and B+ trees
11.9 Query execution and plans

11.10 Query optimization
11.11 Transactions
11.12 ACID
11.13 Isolation levels and anomalies
11.14 Multi-version concurrency control (MVCC)
11.15 Locking
11.16 PostgreSQL versus MySQL
11.17 Data modeling for a real application
11.18 Summary and revision notes
11.19 Knowledge checkpoint
11.20 Interview questions
11.21 Practical exercises
11.22 Design challenges
11.23 References
11.24 Open verification items

Chapter 12 — NoSQL Databases

12.1 Learning objectives
12.2 Prerequisites
12.3 Why NoSQL emerged
12.4 Key-value stores
12.5 Document databases
12.6 Wide-column stores
12.7 Graph databases
12.8 Time-series databases
12.9 Search engines as databases
12.10 Vector databases
12.11 NewSQL
12.12 Selection framework and SQL versus NoSQL comparison
12.13 Polyglot persistence
12.14 Summary and revision notes
12.15 Knowledge checkpoint
12.16 Interview questions
12.17 Practical exercises
12.18 Design challenges
12.19 References
12.20 Open verification items

Chapter 13 — Storage Engine Internals

13.1 Learning objectives
13.2 Prerequisites
13.3 Pages and blocks
13.4 Buffer pools
13.5 Write-ahead logging and recovery
13.6 B-tree storage engines
13.7 Log-structured storage
13.8 LSM trees: memtables and SSTables
13.9 Compaction strategies

13.10 Bloom filters in storage
13.11 Read, write and space amplification
13.12 Durability: fsync, checksums and torn writes
13.13 Columnar storage
13.14 Case studies: InnoDB, RocksDB and the PostgreSQL heap
13.15 Summary and revision notes
13.16 Knowledge checkpoint
13.17 Interview questions
13.18 Practical exercises
13.19 Design challenges
13.20 References
13.21 Open verification items

Chapter 14 — Database Scaling: Replication, Partitioning and Sharding

14.1 Learning objectives
14.2 Prerequisites
14.3 Read replicas and primary–replica architecture
14.4 Synchronous, asynchronous and semi-synchronous replication
14.5 Multi-primary replication
14.6 Partitioning: range, hash, list and directory-based
14.7 Sharding strategies and choosing shard keys
14.8 Consistent hashing and virtual nodes
14.9 Rebalancing
14.10 Hot partitions and skew
14.11 Secondary indexes in partitioned databases
14.12 Cross-shard queries and distributed transactions
14.13 Connection pooling and proxies
14.14 Summary and revision notes
14.15 Knowledge checkpoint
14.16 Interview questions
14.17 Practical exercises
14.18 Design challenges
14.19 References
14.20 Open verification items

Chapter 15 — Object, Block and File Storage

15.1 Learning objectives
15.2 Prerequisites
15.3 Block, file and object storage compared
15.4 Object storage architecture (the S3 model)
15.5 Distributed file systems: GFS, HDFS, Colossus and Tectonic
15.6 Replication versus erasure coding
15.7 Metadata services
15.8 Multipart upload, chunking and deduplication
15.9 Storage tiers and lifecycle policies
15.10 Summary and revision notes
15.11 Knowledge checkpoint
15.12 Interview questions

15.13 Practical exercises
15.14 Design challenges
15.15 References
15.16 Open verification items

Chapter 16 — Search Systems

16.1 Learning objectives
16.2 Prerequisites
16.3 Inverted indexes
16.4 Tokenization and analysis
16.5 Ranking: TF-IDF and BM25
16.6 Index construction and segment merging
16.7 Distributed search
16.8 Elasticsearch and OpenSearch architecture
16.9 Typeahead and autocomplete
16.10 Near-real-time indexing
16.11 Beyond lexical matching: a bridge to semantic and hybrid search
16.12 Summary and revision notes
16.13 Knowledge checkpoint
16.14 Interview questions
16.15 Practical exercises
16.16 Design challenges
16.17 References
16.18 Open verification items

Chapter 17 — Data Structures and Algorithms for Scale

17.1 Learning objectives
17.2 Prerequisites
17.3 Hash functions at scale
17.4 Bloom filters and cuckoo filters
17.5 HyperLogLog
17.6 Count-Min sketch and heavy hitters
17.7 Skip lists
17.8 Merkle trees
17.9 Geospatial indexing
17.10 Unique ID generation
17.11 Tries
17.12 Reservoir sampling and streaming algorithms
17.13 Summary and revision notes
17.14 Knowledge checkpoint
17.15 Interview questions
17.16 Practical exercises
17.17 Design challenges
17.18 References
17.19 Open verification items

Part IV — Scalability and Performance

Chapter 18 — Scalability

18.1 Learning objectives
18.2 Prerequisites
18.3 Vertical scaling
18.4 Horizontal scaling
18.5 Stateless vs stateful services
18.6 Load distribution
18.7 Bottleneck identification
18.8 Scaling application servers
18.9 Scaling databases (overview)
18.10 The scale cube
18.11 Capacity planning
18.12 Summary and revision notes
18.13 Knowledge checkpoint
18.14 Interview questions
18.15 Practical exercises
18.16 Design challenges
18.17 References
18.18 Open verification items

Chapter 19 — Load Balancing

19.1 Learning objectives
19.2 Prerequisites
19.3 Layer 4 versus layer 7 load balancing
19.4 Load-balancing algorithms
19.5 Health checks
19.6 Session affinity
19.7 Active–passive and active–active balancer pairs
19.8 Balancer failure and redundancy
19.9 DNS and global server load balancing
19.10 Client-side load balancing
19.11 Choosing a load balancer: products compared
19.12 Summary and revision notes
19.13 Knowledge checkpoint
19.14 Interview questions
19.15 Practical exercises
19.16 Design challenges
19.17 References
19.18 Open verification items

Chapter 20 — Caching

20.1 Learning objectives
20.2 Prerequisites
20.3 Cache fundamentals and hit ratio
20.4 CPU cache versus application cache
20.5 Where to cache
20.6 Redis and Memcached internals
20.7 Caching patterns: cache-aside, read-through, write-through, write-back, write-around
20.8 Time to live (TTL)

20.9 Eviction: LRU, LFU, ARC and TinyLFU
20.10 Cache invalidation
20.11 Cache stampede
20.12 Cache penetration
20.13 Cache avalanche
20.14 Distributed caching and consistent hashing
20.15 Hot keys
20.16 Redis versus Memcached
20.17 Summary and revision notes
20.18 Knowledge checkpoint
20.19 Interview questions
20.20 Practical exercises
20.21 Design challenges
20.22 References
20.23 Open verification items

Chapter 21 — Content Delivery Networks

21.1 Learning objectives
21.2 Prerequisites
21.3 CDN architecture
21.4 Edge, mid-tier and origin
21.5 Cache hierarchy and origin shielding
21.6 Cache keys, HTTP caching headers and invalidation
21.7 Static versus dynamic content
21.8 Video delivery
21.9 Edge computing on CDNs
21.10 Netflix Open Connect
21.11 CDN security
21.12 Summary and revision notes
21.13 Knowledge checkpoint
21.14 Interview questions
21.15 Practical exercises
21.16 Design challenges
21.17 References
21.18 Open verification items

Chapter 22 — API and Traffic Management

22.1 Learning objectives
22.2 Prerequisites
22.3 Rate limiting
22.4 Token bucket
22.5 Leaky bucket
22.6 Fixed window
22.7 Sliding window log and sliding window counter
22.8 Distributed rate limiting
22.9 Throttling and load shedding
22.10 Backpressure
22.11 Timeouts and deadlines

22.12 Retries with exponential backoff and jitter
22.13 Circuit breakers
22.14 Bulkheads
22.15 Idempotency and idempotency keys
22.16 Summary and revision notes
22.17 Knowledge checkpoint
22.18 Interview questions
22.19 Practical exercises
22.20 Design challenges
22.21 References
22.22 Open verification items

Chapter 23 — Performance Engineering

23.1 Learning objectives
23.2 Prerequisites
23.3 Performance methodology
23.4 Profiling CPU and memory
23.5 Load testing and benchmarking pitfalls
23.6 Tail latency at scale
23.7 Hedged and tied requests
23.8 Batching, pipelining and compression
23.9 Garbage collection and runtime effects
23.10 Capacity models from measurements
23.11 Summary and revision notes
23.12 Knowledge checkpoint
23.13 Interview questions
23.14 Practical exercises
23.15 Design challenges
23.16 References
23.17 Open verification items

Part V — Distributed Systems

Chapter 24 — Distributed Systems Fundamentals

24.1 Learning objectives
24.2 Prerequisites
24.3 What is a distributed system?
24.4 Why distributed systems exist
24.5 The eight fallacies of distributed computing
24.6 System models: timing and failures
24.7 Network partitions
24.8 Partial failures, gray failures and timeouts
24.9 Physical clocks: drift, NTP, PTP and skew
24.10 Logical clocks: Lamport clocks
24.11 Vector clocks and version vectors
24.12 Hybrid logical clocks
24.13 The FLP impossibility result
24.14 The end-to-end argument
24.15 Summary and revision notes

24.16 Knowledge checkpoint
24.17 Interview questions
24.18 Practical exercises
24.19 Design challenges
24.20 References
24.21 Open verification items

Chapter 25 — Consistency and Availability

25.1 Learning objectives
25.2 Prerequisites
25.3 Linearizability
25.4 Sequential consistency
25.5 Causal consistency
25.6 Session guarantees
25.7 Eventual consistency
25.8 The CAP theorem
25.9 PACELC
25.10 Consistency trade-offs in real databases
25.11 Jepsen-style testing
25.12 Summary and revision notes
25.13 Knowledge checkpoint
25.14 Interview questions
25.15 Practical exercises
25.16 Design challenges
25.17 References
25.18 Open verification items

Chapter 26 — Consensus and Coordination

26.1 Learning objectives
26.2 Prerequisites
26.3 The consensus problem
26.4 Quorums
26.5 Leader election
26.6 Paxos
26.7 Raft
26.8 ZooKeeper and ZAB
26.9 etcd
26.10 Distributed locks
26.11 Leases
26.12 Split brain
26.13 Fencing tokens
26.14 Coordination services in practice
26.15 Summary and revision notes
26.16 Knowledge checkpoint
26.17 Interview questions
26.18 Practical exercises
26.19 Design challenges
26.20 References

26.21 Open verification items

Chapter 27 — Replication and Fault Tolerance

27.1 Learning objectives
27.2 Prerequisites
27.3 Replication strategies overview
27.4 Primary–backup replication
27.5 Chain replication
27.6 Multi-leader replication
27.7 Leaderless replication
27.8 Read and write quorums: R + W > N
27.9 Sloppy quorums and hinted handoff
27.10 Failure detection
27.11 Failover
27.12 Recovery
27.13 Anti-entropy and read repair
27.14 Conflict resolution: LWW, version vectors and CRDTs
27.15 Summary and revision notes
27.16 Knowledge checkpoint
27.17 Interview questions
27.18 Practical exercises
27.19 Design challenges
27.20 References
27.21 Open verification items

Chapter 28 — Distributed Transactions

28.1 Learning objectives
28.2 Prerequisites
28.3 Why distributed transactions are hard
28.4 Two-phase commit
28.5 Three-phase commit
28.6 Sagas: a preview
28.7 Percolator-style transactions
28.8 Spanner and TrueTime
28.9 Calvin and deterministic databases
28.10 Distributed SQL: CockroachDB, YugabyteDB and TiDB
28.11 Choosing a transaction strategy
28.12 Summary and revision notes
28.13 Knowledge checkpoint
28.14 Interview questions
28.15 Practical exercises
28.16 Design challenges
28.17 References
28.18 Open verification items

Chapter 29 — Distributed Data Processing

29.1 Learning objectives
29.2 Prerequisites
29.3 Batch processing concepts

29.4 MapReduce
29.5 Apache Spark
29.6 Partitioning and shuffle
29.7 Data locality
29.8 Stream processing concepts
29.9 Apache Flink
29.10 Lambda and Kappa architectures
29.11 Batch versus stream; Spark versus Flink
29.12 Summary and revision notes
29.13 Knowledge checkpoint
29.14 Interview questions
29.15 Practical exercises
29.16 Design challenges
29.17 References
29.18 Open verification items

Part VI — Messaging and Event-Driven Systems

Chapter 30 — Messaging Fundamentals

30.1 Learning objectives
30.2 Prerequisites
30.3 Synchronous vs asynchronous communication
30.4 Message queues
30.5 Publish/subscribe
30.6 Event-driven architecture
30.7 Event brokers
30.8 Delivery guarantees
30.9 Ordering
30.10 Retries and poison messages
30.11 Dead-letter queues
30.12 Kafka vs RabbitMQ (and SQS, Pulsar)
30.13 Summary and revision notes
30.14 Knowledge checkpoint
30.15 Interview questions
30.16 Practical exercises
30.17 Design challenges
30.18 References
30.19 Open verification items

Chapter 31 — Kafka Deep Dive

31.1 Learning objectives
31.2 Prerequisites
31.3 The log abstraction
31.4 Brokers and clusters: ZooKeeper mode versus KRaft
31.5 Topics and partitions
31.6 Producers
31.7 Consumers and consumer groups
31.8 Offsets
31.9 Replication, ISR and leader election

31.10 Retention and log compaction
31.11 Delivery semantics and transactions
31.12 Rebalancing protocols
31.13 Performance
31.14 Kafka Streams and Kafka Connect
31.15 Operating Kafka
31.16 Summary and revision notes
31.17 Knowledge checkpoint
31.18 Interview questions
31.19 Practical exercises
31.20 Design challenges
31.21 References
31.22 Open verification items

Chapter 32 — Event-Driven Architecture Patterns

32.1 Learning objectives
32.2 Prerequisites
32.3 Event sourcing
32.4 CQRS
32.5 Transactional outbox
32.6 Change data capture
32.7 The saga pattern
32.8 Choreography versus orchestration
32.9 Exactly-once processing and its limits
32.10 Idempotent consumers
32.11 Workflow engines
32.12 Summary and revision notes
32.13 Knowledge checkpoint
32.14 Interview questions
32.15 Practical exercises
32.16 Design challenges
32.17 References
32.18 Open verification items

Part VII — Software Architecture and Design

Chapter 33 — Architecture Patterns

33.1 Learning objectives
33.2 Prerequisites
33.3 Layered architecture
33.4 Monolithic architecture
33.5 Modular monolith
33.6 Service-oriented architecture
33.7 Microservices (overview)
33.8 Event-driven architecture (overview)
33.9 Serverless architecture
33.10 Hexagonal architecture (ports and adapters)
33.11 Clean architecture
33.12 Cell-based architecture

33.13 Monolith versus microservices
33.14 Summary and revision notes
33.15 Knowledge checkpoint
33.16 Interview questions
33.17 Practical exercises
33.18 Design challenges
33.19 References
33.20 Open verification items

Chapter 34 — Microservices

34.1 Learning objectives
34.2 Prerequisites
34.3 Service boundaries
34.4 Domain-driven design
34.5 Bounded contexts and context maps
34.6 API gateways and backends for frontends
34.7 Service discovery
34.8 Inter-service communication
34.9 Distributed tracing (introduction)
34.10 Service mesh
34.11 Data ownership and database-per-service
34.12 Deployment strategies
34.13 Migration from a monolith
34.14 Anti-patterns
34.15 Summary and revision notes
34.16 Knowledge checkpoint
34.17 Interview questions
34.18 Practical exercises
34.19 Design challenges
34.20 References
34.21 Open verification items

Chapter 35 — Object-Oriented Design

35.1 Learning objectives
35.2 Prerequisites
35.3 Classes and objects
35.4 Encapsulation
35.5 Inheritance
35.6 Polymorphism
35.7 Abstraction
35.8 Composition over inheritance
35.9 Interfaces and contracts
35.10 Cohesion and coupling
35.11 Common mistakes
35.12 Summary and revision notes
35.13 Knowledge checkpoint
35.14 Interview questions
35.15 Practical exercises

35.16 Design challenges
35.17 References
35.18 Open verification items

Chapter 36 — SOLID Principles

36.1 Learning objectives
36.2 Prerequisites
36.3 Single Responsibility Principle
36.4 Open/Closed Principle
36.5 Liskov Substitution Principle
36.6 Interface Segregation Principle
36.7 Dependency Inversion Principle
36.8 SOLID at the architecture level
36.9 Summary and revision notes
36.10 Knowledge checkpoint
36.11 Interview questions
36.12 Practical exercises
36.13 Design challenges
36.14 References
36.15 Open verification items

Chapter 37 — Design Patterns

37.1 Learning objectives
37.2 Prerequisites
37.3 Factory
37.4 Abstract factory
37.5 Builder
37.6 Singleton
37.7 Strategy
37.8 Observer
37.9 Adapter
37.10 Decorator
37.11 Proxy
37.12 Command
37.13 Repository
37.14 Dependency injection
37.15 State, Template Method and Chain of Responsibility
37.16 Concurrency patterns
37.17 Choosing a pattern
37.18 Summary and revision notes
37.19 Knowledge checkpoint
37.20 Interview questions
37.21 Practical exercises
37.22 Design challenges
37.23 References
37.24 Open verification items

Chapter 38 — UML and Low-Level Design

38.1 Learning objectives

38.2 Prerequisites
38.3 Class diagrams
38.4 Sequence diagrams
38.5 Component diagrams
38.6 State diagrams
38.7 Activity diagrams
38.8 Object relationships in depth
38.9 The LLD interview method
38.10 LLD exercises
38.11 Summary and revision notes
38.12 Knowledge checkpoint
38.13 Interview questions
38.14 Practical exercises
38.15 Design challenges
38.16 References
38.17 Open verification items

Part VIII — Production Infrastructure and Operations

Chapter 39 — Reliability and Resilience

39.1 Learning objectives
39.2 Prerequisites
39.3 Availability versus reliability
39.4 Fault tolerance and redundancy
39.5 Graceful degradation
39.6 SLI, SLO and SLA
39.7 Error budgets
39.8 Disaster recovery, RTO and RPO
39.9 Backup strategies
39.10 Multi-region architecture (introduction)
39.11 Chaos engineering
39.12 Incident management and blameless postmortems
39.13 Summary and revision notes
39.14 Knowledge checkpoint
39.15 Interview questions
39.16 Practical exercises
39.17 Design challenges
39.18 References
39.19 Open verification items

Chapter 40 — Observability

40.1 Learning objectives
40.2 Prerequisites
40.3 Monitoring versus observability
40.4 Logs
40.5 Metrics
40.6 Traces and distributed tracing
40.7 OpenTelemetry
40.8 Prometheus

40.9 Grafana
40.10 Alerting
40.11 Root cause analysis
40.12 Profiling in production
40.13 Summary and revision notes
40.14 Knowledge checkpoint
40.15 Interview questions
40.16 Practical exercises
40.17 Design challenges
40.18 References
40.19 Open verification items

Chapter 41 — Cloud Computing

41.1 Learning objectives
41.2 Prerequisites
41.3 IaaS, PaaS, SaaS and FaaS
41.4 Regions, availability zones, edge locations and the shared responsibility model
41.5 AWS core services
41.6 Google Cloud core services
41.7 Azure core services
41.8 Compute
41.9 Storage
41.10 Networking
41.11 Managed databases
41.12 Cloud security
41.13 Cost optimization
41.14 Cross-cloud service mapping
41.15 Summary and revision notes
41.16 Knowledge checkpoint
41.17 Interview questions
41.18 Practical exercises
41.19 Design challenges
41.20 References
41.21 Open verification items

Chapter 42 — Containers and Kubernetes

42.1 Learning objectives
42.2 Prerequisites
42.3 Containers: namespaces, cgroups and runtimes
42.4 Docker, images and layers
42.5 Registries
42.6 Kubernetes architecture
42.7 Pods
42.8 Workload controllers
42.9 Networking: CNI and Services
42.10 Ingress and Gateway API
42.11 ConfigMaps and Secrets
42.12 Autoscaling

42.13 Scheduling
42.14 Persistent volumes
42.15 Operators and custom resources
42.16 Kubernetes versus serverless
42.17 Summary and revision notes
42.18 Knowledge checkpoint
42.19 Interview questions
42.20 Practical exercises
42.21 Design challenges
42.22 References
42.23 Open verification items

Chapter 43 — Deployment and Infrastructure

43.1 Learning objectives
43.2 Prerequisites
43.3 CI/CD
43.4 Rolling deployments
43.5 Blue–green deployments
43.6 Canary releases
43.7 Feature flags
43.8 Infrastructure as code
43.9 Terraform
43.10 GitOps
43.11 Secrets management in pipelines
43.12 Infrastructure monitoring
43.13 Database migrations
43.14 Summary and revision notes
43.15 Knowledge checkpoint
43.16 Interview questions
43.17 Practical exercises
43.18 Design challenges
43.19 References
43.20 Open verification items

Part IX — Advanced and Expert Topics

Chapter 44 — Multi-Region and Global Systems

44.1 Learning objectives
44.2 Prerequisites
44.3 Why go multi-region
44.4 Latency physics across regions
44.5 Global traffic management
44.6 Deployment topologies
44.7 Geo-replication
44.8 Conflict handling across regions
44.9 Data residency and sovereignty
44.10 Cell-based and region-isolated architectures at global scale
44.11 Regional failover and evacuation
44.12 Global consistency options and the user-visible consequences

44.13 Summary and revision notes
44.14 Knowledge checkpoint
44.15 Interview questions
44.16 Practical exercises
44.17 Design challenges
44.18 References
44.19 Open verification items

Chapter 45 — Advanced Consistency and Byzantine Fault Tolerance

45.1 Learning objectives
45.2 Prerequisites
45.3 The full consistency hierarchy
45.4 Snapshot isolation versus serializability
45.5 Formalizing histories and checking them
45.6 CRDT theory
45.7 Byzantine faults and why they matter
45.8 BFT lower bounds
45.9 PBFT
45.10 Modern BFT: Tendermint and HotStuff
45.11 Blockchain consensus overview
45.12 Choosing guarantees in practice
45.13 Summary and revision notes
45.14 Knowledge checkpoint
45.15 Interview questions
45.16 Practical exercises
45.17 Design challenges
45.18 References
45.19 Open verification items

Chapter 46 — Distributed Scheduling and Cluster Management

46.1 Learning objectives
46.2 Prerequisites
46.3 The cluster scheduling problem
46.4 Scheduler architectures
46.5 Borg
46.6 The Kubernetes scheduler in depth
46.7 Bin-packing heuristics
46.8 Priorities, preemption and quota
46.9 Fairness
46.10 Gang scheduling and co-scheduling
46.11 GPU and accelerator scheduling
46.12 Batch and HPC schedulers: Slurm
46.13 Autoscaling the cluster itself
46.14 Summary and revision notes
46.15 Knowledge checkpoint
46.16 Interview questions
46.17 Practical exercises
46.18 Design challenges

46.19 References
46.20 Open verification items

Chapter 47 — Multi-Tenant Architecture and Isolation

47.1 Learning objectives
47.2 Prerequisites
47.3 What multi-tenancy is and why
47.4 Tenancy models
47.5 Data isolation patterns
47.6 Tenant-aware sharding and placement
47.7 Noisy neighbors
47.8 Quotas, rate limits and fair share per tenant
47.9 The compute isolation spectrum
47.10 Control plane and data plane
47.11 Observability and cost attribution per tenant
47.12 Security boundaries and cross-tenant attacks
47.13 Tenant lifecycle
47.14 Summary and revision notes
47.15 Knowledge checkpoint
47.16 Interview questions
47.17 Practical exercises
47.18 Design challenges
47.19 References
47.20 Open verification items

Chapter 48 — Edge Computing and Serverless at Scale

48.1 Learning objectives
48.2 Prerequisites
48.3 What “serverless” really means
48.4 Inside a FaaS platform
48.5 Cold starts
48.6 Concurrency and scaling limits
48.7 Serverless data patterns
48.8 Edge runtimes
48.9 Edge data
48.10 What to run at the edge
48.11 Cost at scale
48.12 Operating serverless
48.13 Serverless versus containers: a decision table
48.14 Summary and revision notes
48.15 Knowledge checkpoint
48.16 Interview questions
48.17 Practical exercises
48.18 Design challenges
48.19 References
48.20 Open verification items

Chapter 49 — Large-Scale Data Infrastructure and High-Performance Computing

49.1 Learning objectives

49.2 Prerequisites
49.3 What changes at exabyte scale
49.4 Exabyte storage systems as published
49.5 The modern data platform architecture
49.6 Warehouses at scale
49.7 Data movement at scale
49.8 HPC fundamentals
49.9 MPI
49.10 High-performance networking
49.11 Parallel file systems
49.12 Batch schedulers for HPC
49.13 Convergence of HPC, big data and AI
49.14 Summary and revision notes
49.15 Knowledge checkpoint
49.16 Interview questions
49.17 Practical exercises
49.18 Design challenges
49.19 References
49.20 Open verification items

Chapter 50 — Security Architecture and Privacy Engineering

50.1 Learning objectives
50.2 Prerequisites
50.3 Defense in depth as an architecture
50.4 Zero trust architecture in depth
50.5 Identity architecture
50.6 Software supply-chain security
50.7 Detection and response architecture
50.8 Privacy by design
50.9 GDPR and CCPA engineering
50.10 Data minimization and de-identification
50.11 Differential privacy: an introduction
50.12 Computing on protected data: MPC, homomorphic encryption and confidential computing
50.13 Security architecture review checklist
50.14 Summary and revision notes
50.15 Knowledge checkpoint
50.16 Interview questions
50.17 Practical exercises
50.18 Design challenges
50.19 References
50.20 Open verification items

Chapter 51 — Cost-Aware and Sustainable Architecture

51.1 Learning objectives
51.2 Prerequisites
51.3 Why cost is an architectural property
51.4 Unit economics
51.5 FinOps practice

51.6 Capacity purchasing strategy
51.7 Engineering levers by resource
51.8 Cost modeling and forecasting
51.9 Build versus buy versus managed
51.10 Sustainable computing: energy and carbon basics
51.11 Carbon-aware architecture
51.12 Measuring and reporting
51.13 Trade-offs: cost versus reliability versus latency versus carbon
51.14 Summary and revision notes
51.15 Knowledge checkpoint
51.16 Interview questions
51.17 Practical exercises
51.18 Design challenges
51.19 References
51.20 Open verification items

Part X — Traditional System Design Case Studies

Chapter 52 — Case Studies I: Foundational Services

52.1 Learning objectives
52.2 Prerequisites
52.3 How to use these case studies
52.4 URL shortener
52.5 Pastebin
52.6 Rate limiter (as a distributed service)
52.7 Notification system
52.8 Distributed key-value store
52.9 Distributed job scheduler
52.10 Web crawler
52.11 Summary and revision notes
52.12 Knowledge checkpoint
52.13 Interview questions
52.14 Practical exercises
52.15 Design challenges
52.16 References
52.17 Open verification items

Chapter 53 — Case Studies II: Social and Communication

53.1 Learning objectives
53.2 Prerequisites
53.3 How to use these case studies
53.4 Chat Application
53.5 WhatsApp
53.6 Instagram
53.7 Facebook News Feed
53.8 Twitter/X
53.9 Summary and revision notes
53.10 Knowledge checkpoint
53.11 Interview questions

53.12 Practical exercises
53.13 Design challenges
53.14 References
53.15 Open verification items

Chapter 54 — Case Studies III: Media and Files

54.1 Learning objectives
54.2 Prerequisites
54.3 How to use these case studies
54.4 YouTube
54.5 Netflix
54.6 Spotify
54.7 Google Drive
54.8 Dropbox
54.9 Summary and revision notes
54.10 Knowledge checkpoint
54.11 Interview questions
54.12 Practical exercises
54.13 Design challenges
54.14 References
54.15 Open verification items

Chapter 55 — Case Studies IV: Location, Commerce and Payments

55.1 Learning objectives
55.2 Prerequisites
55.3 How to use these case studies
55.4 Uber: a ride-hailing platform
55.5 Ride matching system
55.6 Google Maps: tiles, routing and live traffic
55.7 Amazon: an e-commerce platform
55.8 Ticket booking system
55.9 Payment system
55.10 Summary and revision notes
55.11 Knowledge checkpoint
55.12 Interview questions
55.13 Practical exercises
55.14 Design challenges
55.15 References
55.16 Open verification items

Chapter 56 — Case Studies V: Data Platforms

56.1 Learning objectives
56.2 Prerequisites
56.3 How to use these case studies
56.4 Search Engine (web-scale)
56.5 Recommendation System (systems view)
56.6 Logging and Monitoring Platform
56.7 Real-time Analytics Platform
56.8 Summary and revision notes

56.9 Knowledge checkpoint
56.10 Interview questions
56.11 Practical exercises
56.12 Design challenges

Part I — Foundations of System Design Thinking

Chapter 1 — What Is System Design?

> **Level:** 1 · **Track:** Shared · **Estimated reading time:** 3.5 h

Every application you have ever used — a photo app, a bank, a search engine — is two things at once. It is *code*, which tells a computer what to do, and it is a *system*, which decides where that code runs, where its data lives, how many copies of each exist, what happens when a machine dies at 3 a.m., and how the whole thing keeps working when ten times more people show up next month. This chapter is about the second thing.

We will follow one fictional product through the whole chapter: **PhotoShare**, a simple photo-sharing app in which people upload photos, follow friends and scroll a feed. PhotoShare starts life on a single rented server with a thousand users. By the end of the chapter it serves ten million daily users across multiple machines and data centers. At every stage you will see *why* the design had to change, *which requirement* forced the change, and *what it cost*. That progression — requirements forcing decisions, decisions carrying costs — is system design.

1.1 Learning objectives

After this chapter you should be able to:

- Define *system design*, *software architecture*, *high-level design* and *low-level design*, and explain how they differ and overlap.
- Distinguish functional requirements from non-functional requirements, and write each in a testable form.
- Name at least fifteen quality attributes (“-ilities”), state a measurable metric for each, and identify common tensions between them.
- Convert an availability target (for example 99.9%) into an allowed-downtime budget, and compute the availability of components in series.
- Estimate average and peak request rates, storage growth and network egress from a user count, using explicit assumptions.
- Write an Architecture Decision Record (ADR) in Nygard’s format and use a weighted decision matrix to compare options.
- Explain why early architectural decisions are expensive to reverse, using a concrete migration-cost calculation.
- Describe how design documents, design reviews and RFC processes work in industry.

- Describe the structure of a 45–60-minute system design interview and what interviewers evaluate.
- Recognize and avoid the twelve most common beginner mistakes in system design.

1.2 Prerequisites

This chapter assumes no prior system design knowledge. Helpful but not required:

- Basic programming in any language — so that “a function”, “a class” and “a web request” are familiar words.
- A rough idea of what happens when a browser loads a web page — treated fully in §8.5 (The request–response lifecycle end to end); here we only need “a client sends a request, a server sends a response”.
- A rough idea of what a database is — treated fully in Ch 11 (Relational Databases); here we only need “a program that stores data durably and answers queries about it”.

Every other term is defined when it first appears.

1.3 Definition of system design

1.3.1 What a “system” is

DEFINITION

Definition — System. A set of interacting **components** (programs, machines, data stores, networks and people) that together deliver a capability no single component delivers alone. Components interact only through **interfaces**: agreed formats and protocols for exchanging requests, responses and data.

DEFINITION

Definition — Component. A unit of a system with a clear responsibility and an interface — for example a web service, a database, a cache, a message queue, a load balancer or a third-party payment provider.

First-principles explanation

Think of a busy restaurant. A single recipe is like a single function in code: it turns inputs (ingredients) into an output (a dish). But a restaurant is not a recipe. It is a *system*: a front-of-house that takes orders, a ticket rail that queues them, stations for grill and salad, a walk-in fridge (storage), a dishwasher (cleanup), a manager who notices when

the grill cook is overwhelmed, and a supplier who delivers flour every Tuesday. The food can be excellent and the restaurant can still fail — because orders get lost, the fridge breaks, or Saturday night brings three times more guests than the kitchen can handle.

Software is the same. The code that resizes a photo can be perfect, and PhotoShare can still fail because the disk filled up, the only server rebooted during a deploy, or a celebrity's post caused a thousand times the normal traffic in ten seconds.

1.3.2 System design

> DEFINITION
>
> **Definition — System design.** The process of deciding the components of a software system, their responsibilities, their interfaces, how data flows and is stored between them, and how they are deployed — so that the system meets its functional requirements *and* its non-functional requirements (performance, scalability, availability, durability, security, cost and others) under stated assumptions about load and failure. The output of the process is also called the *system design*: a set of decisions, diagrams and documents.

Two parts of the definition deserve emphasis.

1. **"So that it meets its requirements."** A design is never good or bad in the abstract — only good or bad *for a stated set of requirements*. A single server is an excellent design for 1,000 users and a terrible one for 10 million.
2. **"Under stated assumptions about load and failure."** Designers must say out loud how much traffic they expect and what kinds of failure they expect to survive. A design that is silent about these is not finished.

Why does this exist?

For most of computing history, a program ran on one machine. Today almost any useful service must handle more data, more users and more failure than one machine can. A modern commodity server fails on the order of once every few years; a fleet of thousands therefore sees failures every day Barroso et al. 2018. Users are spread across continents, and light in optical fiber needs roughly 5 ms per 1,000 km one way, so a single location cannot be fast for everyone (see §7.15 (Latency, bandwidth, BDP, packet loss)). Regulations require some data to stay in certain countries. Each of these forces pushes the system apart into multiple components, and the moment you have multiple components you must decide how they divide the work, how they talk, and what happens when one of them stops. System design exists because those decisions are hard to get right, expensive to get wrong and impossible to avoid.

How it works internally

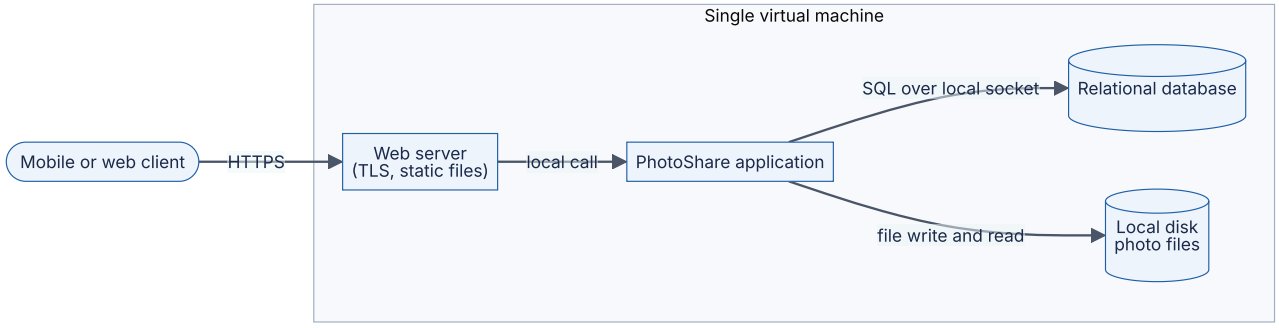
System design is iterative, but in practice most designers follow a loop like this:

1. **Understand the problem.** Who are the users? What must the system do (functional requirements, §1.6)? How well must it do it (non-functional requirements, §1.7)?
2. **Quantify.** Estimate users, request rates, data sizes and growth (back-of-the-envelope estimation; see §2.11 and Ch 89).
3. **Propose a simple design.** Start with the smallest design that could work: a client, a service, a database.
4. **Stress the design against the requirements.** Where does it break first — CPU, memory, disk, network, a single point of failure, a consistency rule? (See §2.6 (Identifying bottlenecks).)
5. **Evolve the design.** Add or change components to fix the weakest point, noting what each change costs.
6. **Record decisions** and their rationale (ADRs, §1.8), and communicate the design (design docs, §1.10).
7. **Validate in production** with monitoring, load tests and incidents, and feed what you learn back into step 1.

Architecture diagram

Here is PhotoShare on launch day. Everything runs on one rented virtual machine.

Figure 1.1 — PhotoShare v0: a single-server design.



Reading the diagram.

- **Components.** A *client* (the mobile app or browser), a *web server* that terminates HTTPS and serves static files, the *PhotoShare application* (business logic: sign-up, upload, feed), a *relational database* holding users, follows and photo metadata, and the *local disk* holding the photo files themselves.
- **Protocols.** The client speaks HTTPS to the web server. Inside the machine, the application talks to the database over a local socket using SQL and reads and writes photo files through the operating system's file system.

- **Direction of data flow.** Uploads flow left to right: client → web server → application → database row plus file on disk. Feed requests flow the same way and responses return along the same path.
- **Synchronous vs asynchronous.** Every arrow is solid: every step is synchronous. The client waits while the application stores the photo and generates any thumbnails.
- **Storage boundaries.** All state — rows and files — lives on one machine's disk. The *subgraph* is the deployment boundary: everything inside shares one fate.
- **Failure points.** The virtual machine is a **single point of failure (SPOF)**: if it reboots, crashes, or its disk fails, PhotoShare is completely down, and photos may be lost if there is no backup.
- **Scaling options.** The only option without redesign is **vertical scaling** — renting a bigger machine (see §18.3). That buys time but has a ceiling and does not remove the SPOF.

This design is not a mistake. For a launch with 1,000 users it is the *right* design: cheap, simple, and easy to change. The rest of the chapter shows which requirements eventually break it.

Mathematical foundations

The first quantitative question in any design is "how much load?" The simplest useful formula converts daily activity into a request rate.

FORMULA

Average and peak request rate

$$\text{RPS}_{\text{avg}} = \frac{\text{DAU} \times r}{86,400} \qquad \text{RPS}_{\text{peak}} = k \times \text{RPS}_{\text{avg}}$$

Symbol	Meaning	Units
RPS_{avg}	Average request rate over a day	requests/second
DAU	Daily active users	users
r	Requests (of the type being estimated) per user per day	requests/user/day
$86,400$	Seconds in a day	seconds/day
k	Peak factor: ratio of the busiest period's rate to the daily average (dimensionless; 2–5 is a common assumption for consumer apps)	—
RPS_{peak}	Request rate during the busiest period	requests/second

RPS (requests per second) is the canonical unit in this book; you will also see **QPS** (queries per second) used as a synonym.

WORKED EXAMPLE

Worked example — PhotoShare on launch day.

Assumptions (stated, as always): 1,000 DAU; each user views 50 photos per day; peak factor $k = 3$.

1. Daily photo views: $1,000 \times 50 = 50,000$ views/day.
2. Average rate: $50,000/86,400 \approx 0.58$ RPS.
3. Peak rate: $3 \times 0.58 \approx 1.7$ RPS.

Interpretation. Under two requests per second at peak. A single small virtual machine running an ordinary web framework typically handles hundreds of such requests per second (an order-of-magnitude assumption; measure your own stack, see §23.10).

Engineering implication. Any design more complex than Figure 1.1 would be *over-engineering* at this scale: more cost, more moving parts, more ways to fail, and no benefit users can feel.

Code example

Estimation is arithmetic, but writing it as a tiny program makes your assumptions explicit and easy to change. The same script is reused in §1.9 when PhotoShare grows.

```
        """Back-of-the-envelope estimator for the PhotoShare running example.

        Uses SI units: 1 MB = 10**6 bytes, 1 TB = 10**12 bytes.
        """
        from dataclasses import dataclass

        SECONDS_PER_DAY = 86_400

        @dataclass
        class Workload:
            dau: int                  # daily active users
            views_per_user: float     # photo views per user per day
            uploads_per_user: float   # photo uploads per user per day
            stored_bytes_per_upload: int  # original + thumbnails, bytes
            served_bytes_per_view: int    # bytes sent to the client per view
            peak_factor: float = 3.0      # peak-hour rate / daily average rate

        def estimate(w: Workload) -> dict:
            views_per_day = w.dau * w.views_per_user
            uploads_per_day = w.dau * w.uploads_per_user
            read_rps = views_per_day / SECONDS_PER_DAY
            write_rps = uploads_per_day / SECONDS_PER_DAY
            storage_per_day = uploads_per_day * w.stored_bytes_per_upload
            egress_bits_per_s = views_per_day * w.served_bytes_per_view * 8 /
SECONDS_PER_DAY
            return {
                "read_rps_avg": read_rps,
                "read_rps_peak": read_rps * w.peak_factor,
                "write_rps_avg": write_rps,
                "write_rps_peak": write_rps * w.peak_factor,
                "storage_TB_per_day": storage_per_day / 1e12,
                "storage_PB_per_year": storage_per_day * 365 / 1e15,
                "egress_Gbps_avg": egress_bits_per_s / 1e9,
                "egress_Gbps_peak": egress_bits_per_s * w.peak_factor / 1e9,
            }

        if __name__ == "__main__":
            for label, dau in [("v0 launch", 1_000), ("v3 scale", 10_000_000)]:
                w = Workload(dau=dau, views_per_user=50, uploads_per_user=0.2,
                             stored_bytes_per_upload=2_500_000,
                             served_bytes_per_view=200_000)
                print(label)
                for key, value in estimate(w).items():
                    print(f"  {key:>20}: {value:,.3f}")
```

What to notice:

- Every assumption is a named field with a unit in the comment. When a reviewer disagrees with “50 views per user”, they change one number, not your reasoning.
- The peak factor is explicit. Systems are sized for the peak, not the average.

- Egress is converted from bytes to **bits** (`* 8`) because network links are rated in bits per second.
- Running it prints about 0.58 average read RPS for v0 and about 5,787 average (17,361 peak) read RPS, 5 TB/day of new storage and about 9.3 Gbit/s average egress for v3. Those v3 numbers drive most of §1.9.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Instagram (2011).** About a year after launch, Instagram's engineering team published a description of its stack: a load balancer in front of Django application servers, PostgreSQL for data (partitioned across multiple database instances, with replicas in a different availability zone), Redis and Memcached for feeds and caching, photos stored in Amazon S3 and served through a CDN, and a task queue for asynchronous work. Their stated principles were to keep things simple, avoid reinventing the wheel, and use proven technologies. The problem (rapid growth with a tiny team) drove an architecture built mostly from well-understood, managed components rather than custom infrastructure. The trade-off: less control and some vendor dependence, in exchange for a very small operations burden. *Evidence: Primary* — Instagram Engineering 2011

Advantages and disadvantages

Treating design as an explicit activity — rather than letting structure emerge from whatever code is written first — has a clear profile. **Advantages:** problems are found on a whiteboard instead of in production; trade-offs are chosen deliberately; teams share a mental model; costs are predictable. **Disadvantages:** design takes time; designs made with poor information can be confidently wrong; and heavy upfront design can delay learning from real users. The practical answer is *proportionate* design: spend design effort in proportion to how expensive a decision would be to reverse (§1.8, §2.8).

Failure scenarios

Table 1.1 — Failure scenarios for the design process itself.

What goes wrong	Why	Detection	Recovery	Prevention
System collapses under launch traffic	Load never estimated; peak factor ignored	Latency and error rate spike; saturated CPU or connections	Emergency vertical scaling; shed load	Estimate peak load before launch (§1.3.2); load-test
Total outage when one machine fails	Single point of failure nobody named	Health checks fail; users report outage	Restore from backup onto a new machine	List SPOFs in every design review (§1.10)
Months spent building infrastructure for users who never arrive	Design sized for imagined scale	Low utilization; slipped launch	Simplify; delete unused components	Design for 10× current load, not 1,000×
Nobody remembers why a component exists	Decisions not recorded	Repeated debates; fear of changing anything	Reconstruct history from commits and people	ADRs (§1.8)

Common misconceptions

COMMON MISTAKE

"System design means drawing boxes and arrows." The diagram is the *output*. The substance is the reasoning: which requirements forced each box, what each arrow carries, what happens when each box fails, and what the design costs. A beautiful diagram with no requirements and no numbers is decoration.

COMMON MISTAKE

"System design only matters at Google scale." A three-person startup still chooses where its data lives, how it backs up, and what happens during a deploy. The decisions are smaller, but the cost of getting the *irreversible* ones wrong (data model, identifiers, storage location of user files) is felt at every scale.

1.4 Software architecture

1.4.1 What architecture is

DEFINITION

Definition — Software architecture. "The set of structures needed to reason about the system, which comprise software elements, relations among them, and properties of both" [Bass et al. 2021]. The international standard for architecture description defines it as the fundamental concepts or properties of a system in its environment, embodied in its elements, relationships, and in the principles of its design and evolution [ISO/IEC/IEEE 42010].

First-principles explanation

Return to the restaurant. Its *architecture* is not the color of the napkins; it is the set of decisions that would be painful to change once the doors open: where the kitchen sits relative to the dining room, how many burners there are, whether orders go through a single ticket rail or directly to stations, whether there is a walk-in fridge or daily deliveries. You can change the menu weekly; moving the kitchen means closing for months.

Martin Fowler summarized the same idea for software: architecture is about "the important stuff — whatever that is", meaning the decisions that are hard to change and that the team must share an understanding of [Fowler 2003]. The parenthetical "whatever that is" is honest: what counts as architectural depends on the system. For PhotoShare, *where photo files live* is architectural (changing it means migrating terabytes); *which image-resizing library we call* is usually not.

Why does this exist?

Large systems are built by many people over many years. Without a shared structure, each person optimizes locally and the whole becomes inconsistent: three ways to authenticate, four copies of the user table, no one able to say what happens if the cache is down. Architecture exists to (1) make the system understandable enough to reason about, (2) make the most important qualities — performance, availability, security, modifiability — achievable by design rather than by luck, and (3) let teams work in parallel along stable boundaries.

How it works internally

An architecture is described by several **views**, because no single picture answers every question. Kruchten's influential "4+1" model proposes four views plus scenarios that tie them together [Kruchten 1995]:

1. **Logical view** — the main abstractions and their responsibilities (users, photos, feeds, follows).
2. **Process view** — what runs concurrently, and how runtime components communicate (requests, queues, threads).
3. **Development view** — how the code is organized into modules, packages and repositories, and which teams own them.
4. **Physical view** — which machines, data centers and networks the software is deployed on.
5. **+1: Scenarios** — a few important use cases ("a user uploads a photo") traced through all four views to validate them.

The C4 model (context, containers, components, code) is a more recent, lightweight alternative used widely in industry; it is covered in §2.12 (Architecture documentation).

Architectures also follow recognizable **styles** or **patterns** — layered, monolithic, modular monolith, microservices, event-driven, serverless — each a reusable answer to a recurring set of forces. They are the subject of Ch 33 (Architecture Patterns) and Ch 34 (Microservices).

KEY CONCEPT

Conway's law. Melvin Conway observed in 1968 that organizations which design systems are constrained to produce designs that copy the organization's communication structure [Conway 1968]. If three teams build a compiler, you tend to get a three-pass compiler. Architecture and team structure therefore co-evolve: choosing service boundaries is partly choosing team boundaries, and vice versa (see §34.3 (Service boundaries)).

1.4.2 Architecture, system design and design: how the words relate

The terms overlap heavily, and different companies use them differently. The working distinction used in this book is in Table 1.2.

Table 1.2 — Overlapping disciplines: architecture, system design and low-level design.

Aspect	Software architecture	System design	Low-level design
What it is	The significant, hard-to-change structures of a system	Choosing components, data flow and deployment to meet requirements at scale	Internal structure of one component
Typical questions	Monolith or services? Which quality attributes dominate?	How many servers? Which database? Where to cache? What if a node fails?	Which classes, interfaces, algorithms, schemas?
Unit of reasoning	Elements, relations, properties	Services, stores, networks, traffic, failures	Classes, functions, tables, state machines
Time horizon	Years	Months to years	Weeks to months
Typical artifacts	Architecture views, principles, ADRs	Design docs, capacity estimates, deployment diagrams	Class/sequence diagrams, API specs, schema DDL
Where in this book	Ch 33–34	Most of Book I; case studies Ch 52–56	Ch 35–38

In everyday industry usage, "system design" usually means the distributed-systems end of architecture: servers, databases, caches, queues, networks and their failure modes. "Software architecture" is the broader discipline that also includes code-level structure

and organizational concerns. This book treats system design as the large-scale, runtime-focused part of architecture.

Real-world industry applications

INDUSTRY EXAMPLE

Architecture as a role. Many companies do not have a job titled "architect"; architectural decisions are made by senior and staff engineers through design documents and reviews (§1.10). Others have dedicated architects who own cross-team standards. In both models the activity is the same — identifying the hard-to-change decisions and making them deliberately — but the accountability differs. *Evidence: Illustrative* — a general description of common industry practice, not a claim about any specific company.

Advantages and disadvantages

An explicit architecture makes systems understandable, supports parallel work, and lets you predict quality attributes before building. Its costs are upfront effort, the risk of an "ivory-tower" architecture that ignores implementation realities, and rigidity if the architecture is enforced long after the requirements that justified it have changed.

Failure scenarios

Table 1.3 — Architecture-level failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
"Big ball of mud" — every module depends on every other	No agreed structure; boundaries eroded under deadline pressure	Small changes break distant features; slow builds	Incremental refactoring toward modules (§33.5)	Explicit module boundaries; dependency checks in CI
Architecture on paper differs from reality	Diagrams never updated	New engineers' mental model is wrong; incidents surprise everyone	Re-derive diagrams from deployment config and traces	Keep diagrams next to code; review in design reviews
Distributed monolith	Split into services without splitting data or ownership	Every release requires coordinating many services	Merge services or re-cut boundaries	Draw boundaries around data ownership (§34.11, §34.14)

Common misconceptions

COMMON MISTAKE

"Architecture is decided once, at the start." Requirements change, traffic grows, teams reorganize. Good architecture is *evolved* deliberately, with decisions revisited when their context changes — which is exactly why ADRs record the context (§1.8).

1.5 High-level vs low-level design

1.5.1 Definitions

DEFINITION

Definition — High-level design (HLD). A description of a system as a set of major components (services, data stores, queues, caches, external dependencies), their responsibilities, the interfaces and protocols between them, data flows, and deployment topology — at a level of detail where each component is a box whose internals are not yet specified.

DEFINITION

Definition — Low-level design (LLD). A description of the internals of one component: its modules, classes or functions, data structures, algorithms, database schemas, API request and response formats, error handling and state transitions — at a level of detail from which an engineer can write code.

First-principles explanation

A city planner decides where the roads, the water mains and the power substations go, and how much traffic and water each must carry. That is high-level design. An architect then draws the plumbing for one particular building: pipe diameters, which tap connects to which riser, where the shut-off valves are. That is low-level design. Both are design; they answer different questions at different zoom levels, and a good HLD makes the LLD of each part *possible* without dictating it.

Why does this exist?

Splitting design by zoom level lets the most consequential decisions (where data lives, how components communicate, how the system survives failures) be made and reviewed first, by people looking at the whole. It then lets each team design its component in detail independently, as long as it respects the interfaces the HLD fixed.

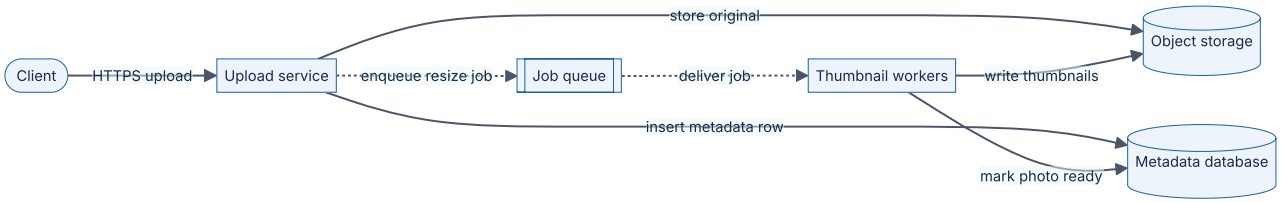
How it works internally

1. The HLD fixes **boundaries and contracts**: which component owns which data and exposes which API.
2. Each component's LLD fills in **internals**: classes, schemas, algorithms, concurrency.
3. LLD work frequently discovers problems the HLD missed (an operation that needs data from two owners; an API that cannot be made idempotent). These flow back to revise the HLD — design is a conversation between zoom levels, not a waterfall.

Architecture diagram

The HLD of PhotoShare's upload path at a later stage (detailed in §1.9) looks like this.

Figure 1.2 — High-level design of the PhotoShare upload path.

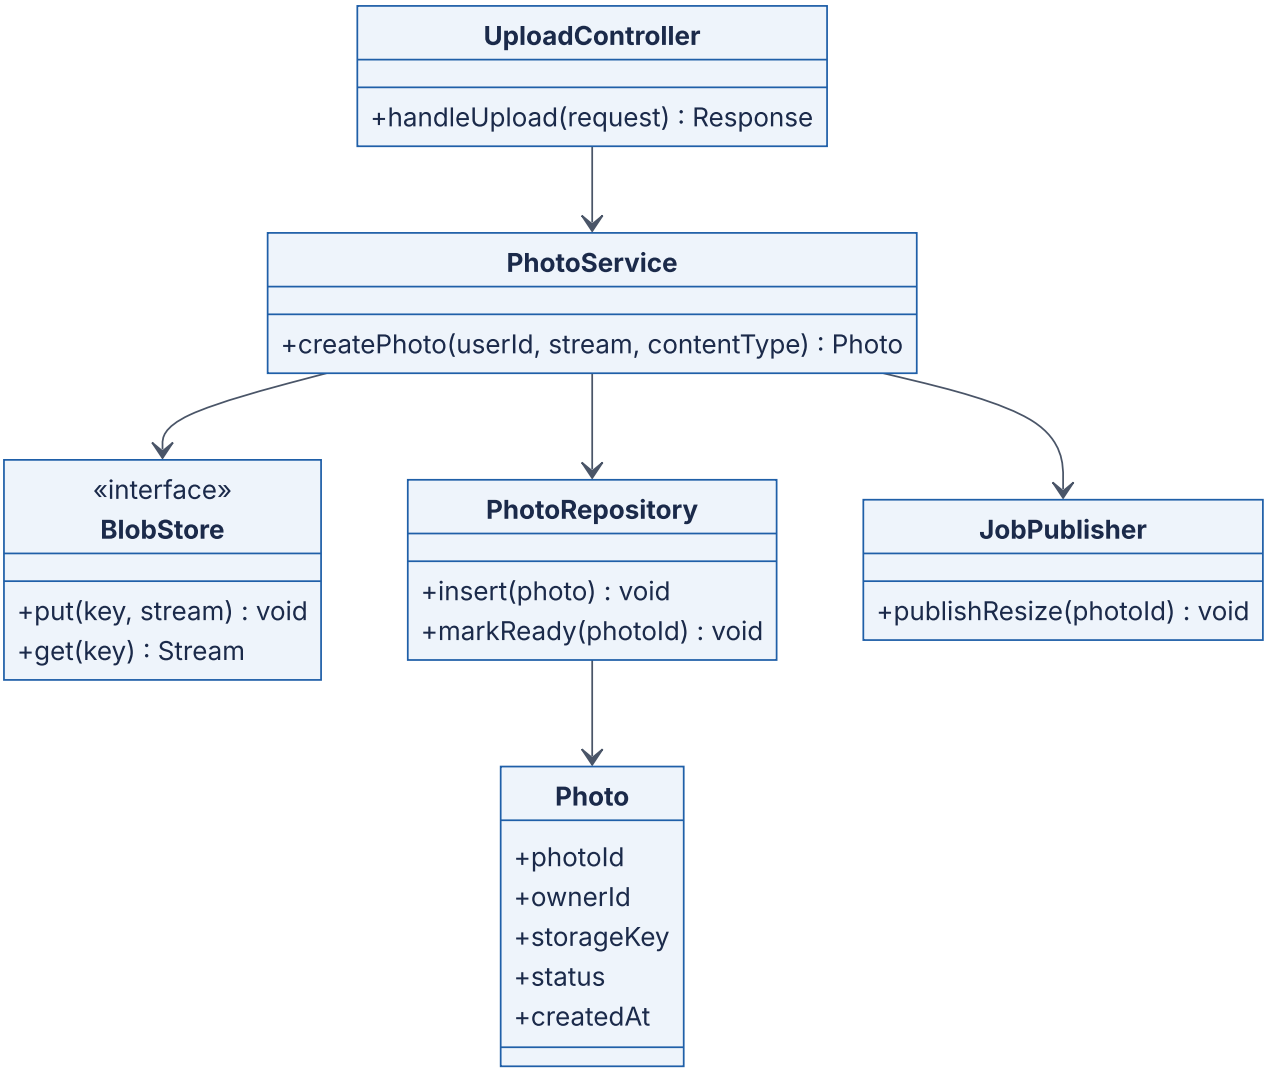


Reading the diagram.

- **Components.** The *upload service* accepts photos; *object storage* holds the image bytes; the *metadata database* holds rows describing each photo (owner, time, status, storage key); the *job queue* buffers work; *thumbnail workers* produce smaller versions of each photo.
- **Protocols.** HTTPS from the client; the object store is typically accessed over an HTTP API; the database over its wire protocol (SQL); the queue over the broker's protocol.
- **Direction and sync/async.** Solid arrows are synchronous: the client waits while the original is stored and the metadata row inserted. Dotted arrows are asynchronous: the resize job is enqueued and processed later, so the client gets a response without waiting for thumbnails.
- **Storage boundaries.** Two stores with different jobs: large immutable blobs in object storage, small mutable rows in the database.
- **Failure points.** If the queue is unavailable, uploads can still succeed but thumbnails are delayed; if workers crash, jobs remain in the queue and are retried. A crash *between* storing the original and inserting the row leaves an orphaned object — a consistency gap the LLD must handle (for example, by a periodic cleanup job).
- **Scaling options.** Upload service and workers scale horizontally by adding instances; the queue absorbs bursts so workers can be sized for average rather than peak load.

Notice what the HLD does *not* say: how the upload service validates file types, which class generates storage keys, or what the table columns are. That is LLD.

Figure 1.3 — Low-level design of the upload component (class view).



Reading the diagram.

- **Components.** `UploadController` handles HTTP concerns (parsing, authentication result, response codes). `PhotoService` holds the business rule "store bytes, record metadata, request thumbnails". `BlobStore` is an *interface*, so the same code can target local disk in tests and object storage in production. `PhotoRepository` wraps database access. `JobPublisher` wraps the queue. `Photo` is the data record.
- **Direction.** Arrows show dependency: the controller depends on the service, which depends on three abstractions. Nothing depends on the controller.
- **Sync/async and storage boundaries.** All calls in this diagram are synchronous in-process calls; the asynchrony from Figure 1.2 is hidden behind `JobPublisher`.
- **Failure points.** `createPhoto` performs three external operations that can each fail; the LLD must define ordering (store bytes first, then the row, then the job) and com-

pensation (a cleanup for orphaned objects). A `status` field (`PENDING` → `READY`) makes partial progress visible.

- **Scaling options.** Scaling is not decided here; this component is stateless, which is what allows the HLD to run many copies of it. Object-oriented principles behind this structure are covered in Ch 35 (Object-Oriented Design) and Ch 36 (SOLID Principles).

Alternatives and trade-offs

Table 1.4 — High-level design vs low-level design.

Aspect	High-level design	Low-level design
What it is	Components, data flows, deployment	Internals of one component
How it works	Boxes, arrows, contracts, capacity numbers	Classes, schemas, algorithms, state machines
Main concern	Quality attributes: scale, availability, latency, cost	Correctness, clarity, testability, extensibility
Typical diagrams	Flowchart/deployment, sequence across services	Class, sequence within a service, state, ER
Cost of a wrong decision	High — often needs data migration	Lower — usually a refactor within one team
Who reviews	Senior engineers across teams	The owning team
Interview format	"Design Instagram" (Ch 87–88, 91)	"Design a parking lot" (Ch 38)
Choose this zoom when	Deciding what to build and where it runs	Deciding how one part is written

Common misconceptions

COMMON MISTAKE

"HLD is for architects, LLD is for junior engineers." Both require skill. A clumsy LLD (no idempotency, no error handling, a schema that cannot be indexed) can sink a sound HLD. Senior engineers move fluidly between levels — and recognizing *when* an LLD detail is actually an HLD concern (for example, a schema choice that blocks partitioning, see §14.7) is a hallmark of seniority.

COMMON MISTAKE

"Once the HLD is approved, it is fixed." LLD routinely uncovers HLD flaws. Treat the HLD as a hypothesis that implementation tests.

1.6 Functional requirements

1.6.1 What functional requirements are and how to write them

> DEFINITION
>
> **Definition — Functional requirement (FR).** A statement of a behavior the system must provide: an input, action or event, and the observable result. Functional requirements describe *what* the system does — for example, "a signed-in user can upload a JPEG or PNG photo up to 20 MB, and it appears in their followers' feeds".

First-principles explanation

A restaurant's functional requirements are its menu and services: it serves pasta, takes reservations, offers takeaway. They say nothing about how fast the food arrives or how many guests fit — those are non-functional (§1.7). If you forget a functional requirement ("we also do delivery"), you build the wrong kitchen.

Why does this exist?

Every design decision is justified by some requirement. If you do not write the functional requirements down, two things happen: the team builds features nobody needs (and designs infrastructure for them), and it misses features that change the design fundamentally. "Users can delete their account and all their photos" sounds minor, but it forces you to be able to *find and erase every copy* of a user's data — in replicas, caches, backups, CDN edges and analytics pipelines — which is an architectural property, not a button.

How it works internally

1. **Identify actors.** Who interacts with the system? For PhotoShare: viewers, posters, moderators, advertisers, internal services.
2. **List use cases** per actor, as verb phrases: *upload photo*, *follow user*, *view feed*, *like photo*, *report photo*.
3. **Make each one testable**: specify inputs, limits and the observable outcome. "Upload photos" becomes "upload a JPEG/PNG/HEIC up to 20 MB; on success, return a photo ID within the latency target".
4. **Prioritize** — for example with **MoSCoW**: *Must*, *Should*, *Could*, *Won't (this time)*.
5. **Write the non-goals.** An explicit "out of scope" list prevents the design from silently growing.
6. **Sketch the API.** A rough interface for each must-have use case (detailed API design is §8.6) catches ambiguities early.

Table 1.5 — PhotoShare functional requirements (v1 scope).

ID	Requirement (testable form)	Priority
FR-1	A user can sign up and sign in with email and password	Must
FR-2	A signed-in user can upload a JPEG, PNG or HEIC photo up to 20 MB with an optional caption up to 2,200 characters	Must
FR-3	A user can follow and unfollow another user	Must
FR-4	A user can view a home feed of photos from followed users, newest first, 20 per page	Must
FR-5	A user can like a photo and see the like count	Should
FR-6	A user can delete a photo; it disappears from all feeds	Must
FR-7	A user can delete their account and all associated data	Must (legal)
FR-8	A user can comment on a photo	Could
—	Video, direct messages, stories, search, ads	Won't (v1 non-goals)

An API sketch for the must-haves might read:

```
POST   /v1/photos                (multipart: image, caption)  -> 201 {photoId}
DELETE /v1/photos/{photoId}                                   -> 204
PUT    /v1/users/{userId}/followers/me                        -> 204
DELETE /v1/users/{userId}/followers/me                        -> 204
GET    /v1/feed?cursor={cursor}&limit=20                      -> 200 {items,
nextCursor}
```

What to notice:

- The feed uses a **cursor** rather than a page number, because new photos arrive constantly and page numbers would skip or repeat items (pagination is detailed in §8.6).
- Follow is modeled as an idempotent `PUT`: repeating it has no further effect, which makes client retries safe (see §22.15 (Idempotency)).

Failure scenarios

Table 1.6 — Functional-requirement failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
A late "small" feature forces redesign	Requirement with architectural impact discovered late (e.g., account deletion, data export)	Feature estimate is months, not days	Retrofit data inventory and deletion pipeline	Ask about lifecycle, legal and admin use cases up front
Scope creep	No non-goals list	Design keeps growing; launch slips	Re-prioritize with MoSCoW	Write non-goals explicitly
Ambiguous requirement built two ways	"Feed" never defined (chronological? ranked?)	Teams' implementations disagree	Agree a definition; rework one side	Testable phrasing with examples

Common misconceptions

COMMON MISTAKE

"Functional requirements are the product manager's job, not the designer's." Product managers own *which* features matter; designers must interrogate each feature for architectural consequences. "Newest first" and "ranked by relevance" are one word apart in a requirements document and an entire ML system apart in architecture (see Ch 68 (Recommendation and Ranking Systems Architecture)).

1.7 Non-functional requirements (the "-ilities" catalog)

1.7.1 What non-functional requirements are

DEFINITION

Definition — Non-functional requirement (NFR). A requirement on *how well* the system performs its functions, or on constraints under which it operates, expressed as a measurable target — for example "p99 feed latency ≤ 300 ms at 2,000 RPS" or "monthly availability ≥ 99.9%". NFRs are also called **quality attributes** or, informally, the **"-ilities"** (scalability, availability, durability, …).

First-principles explanation

Two restaurants can serve the identical menu. One seats 20 and serves each dish in 40 minutes; the other seats 400 and serves each dish in 12 minutes, never runs out of bread, and passes every health inspection. Same functional requirements, completely different buildings, staff and suppliers. The difference is non-functional — and it is the non-functional requirements that determine the *architecture*.

Why does this exist?

Functional requirements can usually be met by a single program on a single machine. It is the non-functional requirements — serve 17,000 requests per second, never lose a photo, survive a data-center outage, cost less than $0.01 per user per month — that force systems to be distributed, replicated, cached and partitioned. Bass, Clements and Kazman make this the central thesis of software architecture: architecture is driven primarily by quality attributes, not by functionality [Bass et al. 2021]. Kleppmann similarly frames reliability, scalability and maintainability as the three central concerns when building data-intensive applications [Kleppmann 2017].

How it works internally

An NFR is only useful if it is **measurable**. Vague words — “fast”, “scalable”, “highly available” — cannot be tested and therefore cannot guide decisions. A reliable technique is the **quality attribute scenario** [Bass et al. 2021], which has six parts:

1. **Source** — who or what generates the stimulus (users, an attacker, a failing disk).
2. **Stimulus** — the event (a feed request, a node crash, a login attempt).
3. **Environment** — the conditions (normal load, peak load, during a deploy).
4. **Artifact** — the part of the system affected (feed service, metadata database).
5. **Response** — what the system does.
6. **Response measure** — the number that decides pass or fail.

Example: “**When** an availability zone fails (source/stimulus) **during** peak traffic (environment), the PhotoShare feed service (artifact) continues serving requests from the remaining zones (response) with **no more than 60 seconds** of elevated errors and **p99 latency ≤ 500 ms** after failover (response measure).”

In production, measurable NFRs become **service level indicators (SLIs)** — the measured quantity, such as the fraction of successful requests — and **service level objectives (SLOs)** — the target value for an SLI over a window [Beyer et al. 2016]. A **service level agreement (SLA)** is a contract with consequences (often financial) if an SLO-like target is missed. These are developed fully in §39.6 (SLI, SLO, SLA) and §39.7 (Error budgets).

> DEFINITION
>
> **Definition — Percentile latency (p50, p95, p99, p99.9).** The latency value below which the given percentage of requests fall. If p99 latency is 300 ms, 99% of requests completed in 300 ms or less and 1% took longer. p50 is the median.

Percentiles matter more than averages because users experience the slow requests, and a single page that fans out to many backend calls is slowed by the *slowest* of them [Dean

and Barroso 2013] (fan-out amplification is quantified in §4.8).

1.7.2 The catalog

The catalog is split into qualities observable while the system runs (Table 1.7) and qualities that matter as the system is built, changed and paid for (Table 1.8). Each row gives a measurable metric and a PhotoShare target.

Table 1.7 — Runtime quality attributes.

Attribute	What it means	Typical metric	PhotoShare example target	Deep dive
Latency (performance)	Time to complete one operation	p50/p99 in ms	Feed API p99 ≤ 300 ms	§4.8, Ch 23
Throughput	Work completed per unit time	RPS; MB/s	2,000 feed RPS at peak	Ch 23
Scalability	Ability to handle more load by adding resources	Cost or nodes per 1,000 RPS as load grows	10× users with ≤ 10× cost	Ch 18
Availability	Fraction of time the system serves correctly	% successful requests per 30 days	≥ 99.9% monthly	§4.14, Ch 39
Reliability	Probability of correct operation over time	Error rate; MTBF	< 0.1% failed uploads	Ch 39
Durability	Probability stored data is not lost	Annual object-loss probability	No acknowledged photo lost	§4.16, Ch 15
Consistency	Guarantees about what reads see after writes	Model name; staleness bound in s	Own uploads visible to self immediately; to followers within 5 s	Ch 25
Fault tolerance / resilience	Continued service despite component failure	Failures tolerated; recovery time	Survive loss of one zone	Ch 27, Ch 39
Recoverability (disaster recovery)	Ability to restore after disaster	RTO (time to restore); RPO (data loss window)	RTO 4 h; RPO 15 min	§39.8
Security	Protection of confidentiality, integrity, availability	Vulnerability count; time to patch; auth coverage	All traffic TLS; private photos never served to non-followers	Ch 10, Ch 50
Privacy	Appropriate handling of personal data	Deletion completed within N days; data minimized	Account deletion propagates in ≤ 30 days	Ch 50
Usability / accessibility	Ease and inclusiveness of use	Task success rate; accessibility conformance level	Screen-reader alt text on all photos	—
Elasticity	Speed of adapting capacity to load	Time to add capacity	Scale out in ≤ 5 min	§42.12

Table 1.8 — Development-time and business quality attributes.

Attribute	What it means	Typical metric	PhotoShare example target	Deep dive
Maintainability	Ease of understanding and fixing	Time to fix a bug; onboarding time	New engineer ships in week 1	Ch 35–36
Modifiability / extensibility	Ease of adding features	Number of modules touched per feature	Adding video touches ≤ 3 services	Ch 33
Testability	Ease of verifying behavior	Test coverage of critical paths; test run time	Full test suite ≤ 10 min	Ch 36
Deployability	Ease and safety of releasing	Deploy frequency; change-failure rate	Daily deploys; rollback ≤ 5 min	Ch 43
Observability	Ability to understand internal state from outputs	% of requests traced; time to diagnose	Every request has a trace ID	Ch 40
Operability	Ease of running in production	Pages per week; manual steps per release	≤ 2 pages per on-call week	Ch 39
Interoperability	Ability to work with other systems	Supported standards and API versions	Public API with versioning	§8.15
Portability	Ability to run in other environments	Effort to move cloud or region	Containerized services	Ch 41–42
Compliance	Conformance to laws and standards	Audit findings	EU users' data stored in the EU	Ch 44, Ch 50
Cost efficiency	Resources consumed per unit of value	$ per 1,000 requests; $ per user per month	≤ $0.01 per MAU per month	Ch 51
Sustainability	Energy and carbon per unit of work	kWh or gCO_2e per request	Track and report	Ch 51

The international quality-model standard ISO/IEC 25010 organizes many of these attributes into a formal hierarchy of characteristics and sub-characteristics; it is a useful checklist when you suspect you have forgotten a category [ISO/IEC 25010].

Mathematical foundations

Availability is the NFR most often stated as a number, and the number hides a surprisingly strict budget.

FORMULA

Availability and downtime budget

$$A = \frac{\text{MTBF}}{\text{MTBF}+\text{MTTR}} \qquad D = (1 - A) \times T$$

Symbol	Meaning	Units
A	Availability: fraction of time the service is up (dimensionless, 0–1)	—
MTBF	Mean time between failures	hours
MTTR	Mean time to repair (restore service)	hours
D	Allowed downtime in the period	minutes (or hours)
T	Length of the period	minutes (or hours)

Table 1.9 — Downtime budgets for common availability targets.

Availability	Downtime per 30-day month	Downtime per 365-day year
99% (“two nines”)	7.2 h	3.65 days
99.9% (“three nines”)	43.2 min	8.76 h
99.95%	21.6 min	4.38 h
99.99% (“four nines”)	4.32 min	52.6 min
99.999% (“five nines”)	25.9 s	5.26 min

WORKED EXAMPLE

Worked example — What does 99.9% allow, and can PhotoShare v0 meet it?

1. Minutes in a 30-day month: $30 \times 24 \times 60 = 43,200$ min.
2. Allowed downtime at 99.9%: $(1 - 0.999) \times 43,200 = 0.001 \times 43,200 = 43.2$ min.
3. PhotoShare v0 (Figure 1.1) is deployed by stopping the application, copying new code and restarting: assume 3 minutes per deploy, and 5 deploys per week ≈ 21.7 deploys per month, giving $21.7 \times 3 \approx 65$ min of planned downtime.
4. Add one unplanned VM failure per quarter with an MTTR of 2 hours, averaging 40 min per month.
5. Total expected downtime $\approx 65 + 40 = 105$ min per month, so $A \approx 1 - 105/43,200 \approx 0.9976$, i.e. 99.76%.

Interpretation. v0 misses 99.9% by more than a factor of two, *before any traffic growth*.

Engineering implication. Meeting 99.9% requires removing deploy downtime (multiple instances behind a load balancer, rolling deploys — §43.4) and shortening MTTR (automatic failover). An availability target, not request volume, is what first forces PhotoShare off a single server.

When a request must pass through several components in sequence, *all* must be up, so availabilities multiply.

FORMULA

Availability of components in series (independent failures)

$$A_{\text{series}} = \prod_{i=1}^{n} A_i$$

Symbol	Meaning	Units
A_{series}	Availability of the whole request path	—
A_i	Availability of component i	—
n	Number of components the request depends on	count

WORKED EXAMPLE

Worked example — A three-tier request path.

A feed request passes through a load balancer ($A = 0.9999$), the feed service ($A = 0.9995$) and the database ($A = 0.9995$).

1. $A_{\text{series}} = 0.9999 \times 0.9995 \times 0.9995$.
2. $0.9995 \times 0.9995 = 0.99900025$.
3. $0.99900025 \times 0.9999 \approx 0.99890$.

Interpretation. About 99.89% — *below* 99.9%, even though every component individually exceeds it.

Engineering implication. Every synchronous dependency you add lowers availability. Designers counter this with redundancy (parallel components; $A_{\text{parallel}} = 1 - \prod (1 - A_i)$ under independence), caching, and making non-critical dependencies asynchronous or optional. The full arithmetic, including the danger of assuming independence, is in §4.14.

Code example

SLOs are increasingly written as configuration that monitoring systems evaluate automatically. The following is illustrative, not the syntax of any specific tool.

```
# illustrative SLO specification for the PhotoShare feed service
service: feed-api
slos:
  - name: feed-availability
    sli: "fraction of GET /v1/feed requests returning non-5xx"
    objective: 0.999          # 99.9 %
    window: 30d               # rolling 30-day window
  - name: feed-latency
    sli: "fraction of GET /v1/feed requests completing in <= 300 ms"
    objective: 0.99           # i.e. p99 <= 300 ms
    window: 30d
```

What to notice:

- A latency SLO is expressed as “the fraction of requests faster than a threshold”, which is equivalent to a percentile target and easier to aggregate across servers.
- The window matters: 99.9% over 30 days allows a single 43-minute outage; 99.9% over every 5-minute window allows almost none.

Real-world industry applications

INDUSTRY EXAMPLE

Google SRE and error budgets. Google's Site Reliability Engineering book argues that 100% is the wrong reliability target for almost everything: users cannot tell the difference beyond a point (their own networks and devices are less reliable), and each additional nine costs disproportionately more. Instead, teams agree an SLO, and the gap between the SLO and 100% becomes an **error budget** that can be "spent" on risky launches; when the budget is exhausted, releases slow down in favor of reliability work. *Evidence: Primary* — [Beyer et al. 2016]

1.7.3 NFRs pull against each other

Quality attributes conflict. Improving one usually costs another, and *naming* the conflict is the heart of design reasoning.

Table 1.10 — Common tensions between quality attributes.

Tension	Why they conflict	Typical resolution	Deep dive
Consistency vs availability (under network partition)	Replicas that cannot communicate must either refuse requests or risk divergent answers	Choose per operation: strong for payments, eventual for like counts	Ch 25
Latency vs consistency (even without partitions)	Coordinating replicas adds round trips	Read from nearby replica; accept bounded staleness	§25.9 (PACELC)
Durability vs write latency	Waiting for multiple disks or zones to confirm takes time	Synchronous replication to a quorum; async to remote region	Ch 27
Availability vs cost	Redundancy means paying for idle capacity	Match nines to business value	Ch 39, Ch 51
Security vs usability	Extra checks add friction	Risk-based authentication	Ch 10
Simplicity (operability) vs scalability	Each scaling technique adds components	Scale only the measured bottleneck	Ch 18
Performance vs modifiability	Optimized code is specialized and harder to change	Optimize hot paths only, after profiling	Ch 23

Failure scenarios

Table 1.11 — Non-functional-requirement failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
System is “fast” in tests, slow for users	Averages measured instead of tail percentiles	p99 dashboards; user complaints	Find tail causes (GC, slow dependencies)	Specify and test p99, not mean
Gold-plated availability	99.999% demanded without business case	Cost far above budget	Renegotiate SLO	Tie each nine to business impact
Data loss despite “replication”	Durability never specified; replicas asynchronous; backups untested	Restore fails during incident	Partial recovery from logs	State RPO; test restores regularly
Privacy breach via forgotten copy	Deletion requirement ignored caches, logs, backups	Audit or regulator finding	Purge pipelines	Data inventory; deletion as an NFR

Common misconceptions

COMMON MISTAKE

“The system must be highly available, scalable and fast.” This is not a requirement; it is a wish. Every system wants these. A requirement has a number, a percentile, a window and a load level: “99.9% of feed requests per 30 days return successfully; p99 ≤ 300 ms at 2,000 RPS”.

COMMON MISTAKE

“Availability and reliability are the same thing.” Availability is the fraction of time the system is *up*; reliability is the probability it operates *correctly* over a period. A system that is up but returns wrong feeds is available and unreliable. See §39.3.

COMMON MISTAKE

“Aim for 100%.” A 100% target is unachievable, makes every change frighteningly risky, and leaves no error budget for shipping features [Beyer et al. 2016].

1.8 Architectural decision-making and ADRs

1.8.1 Architectural decisions

DEFINITION

Definition — Architectural decision. A design choice that addresses an architecturally significant requirement — one that affects structure, quality attributes, interfaces or technology in a way that is costly to change later. Examples: choosing a relational database over a key-value store; storing files in object storage; making photo processing asynchronous.

DEFINITION

Definition — Architecture Decision Record (ADR). A short document that captures one architectural decision: its context, the decision itself, its status, and its consequences. ADRs are numbered, kept in sequence (often in the code repository), and never edited to reverse a decision — a new ADR *supersedes* the old one [Nygard 2011].

First-principles explanation

A court does not just announce “guilty” or “not guilty”; it publishes the reasoning, so later judges can tell whether a new case is similar enough for the ruling to apply. An ADR is a judgment with its reasoning attached. Two years from now, an engineer wondering “why on earth are thumbnails generated asynchronously?” can read the ADR, see that the context was “synchronous resizing pushed upload p99 to 4 seconds”, and decide whether that context still holds.

Why does this exist?

Without records, architectural knowledge lives in people’s heads and leaves when they do. Nygard described the resulting dilemma for a newcomer facing an unexplained decision: either *blindly accept* it (and keep something that may no longer make sense) or *blindly change* it (and possibly break a quality attribute the decision was protecting) [Nygard 2011]. ADRs make a third option possible: read the context, then decide.

How it works internally

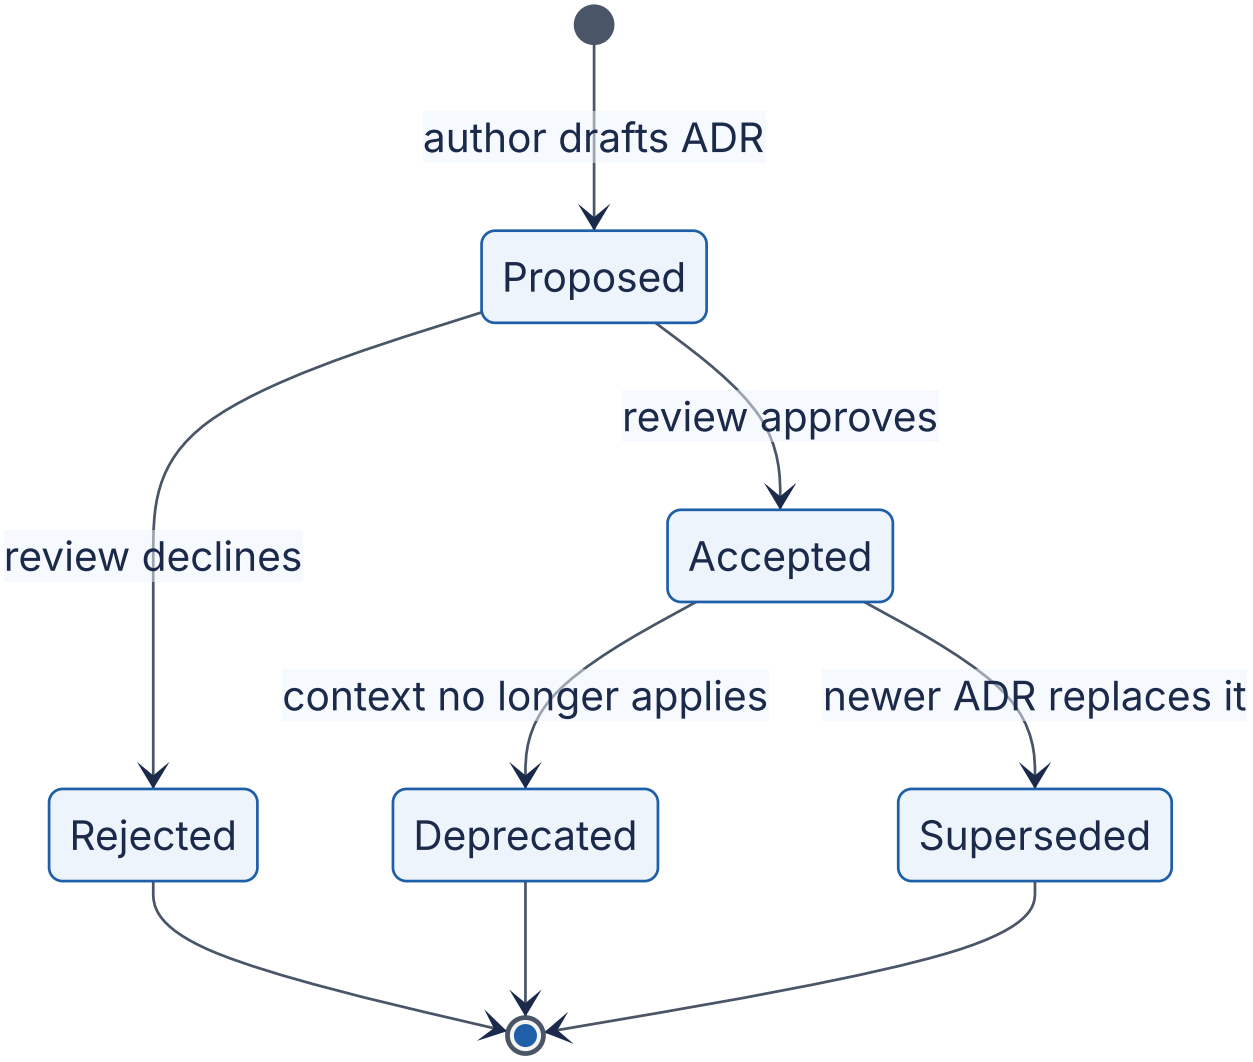
A disciplined decision process looks like this:

1. **Identify the driver.** Which requirement or problem forces a decision now? (For PhotoShare: “the local disk is 80% full and v1 must reach 99.9% availability.”)

2. **Assess reversibility.** Is this a cheap-to-reverse ("two-way door") or expensive-to-reverse ("one-way door") decision? Spend effort proportionally (developed in §2.8).
3. **Enumerate options** — at least two plus "do nothing".
4. **Choose criteria** from the NFRs (§1.7) and weight them.
5. **Evaluate** options against criteria — qualitatively, with a decision matrix, or with a prototype or benchmark when the numbers are uncertain.
6. **Decide and record** the decision as an ADR with status *Proposed*, circulate it, and move it to *Accepted* after review.
7. **Revisit** when the context changes, writing a new ADR that *supersedes* the old one.

Architecture diagram

Figure 1.4 — ADR lifecycle.



Reading the diagram.

- **Components (states).** Each box is the *status* field of an ADR. Nygard's original format lists proposed, accepted, deprecated and superseded; *Rejected* is a common ex-

tension that preserves the record of options the team declined.

- **Transitions.** An ADR starts as *Proposed* and becomes *Accepted* or *Rejected* through review. An accepted ADR is never edited to say the opposite; it becomes *Deprecated* (no longer relevant) or *Superseded* (with a link to the replacing ADR).
- **Direction and sync/async.** This is a state machine, not a data flow; all transitions are human decisions, made asynchronously over days.
- **Storage boundaries.** ADRs typically live as Markdown files in the same repository as the code they govern, so they are versioned and reviewed like code.
- **Failure points.** The common failure is an ADR stuck in *Proposed* forever, or an accepted ADR silently contradicted by code. Design reviews (§1.10) check for both.
- **Scaling options.** At organization scale, teams keep per-repository ADR logs plus a shared log for cross-cutting decisions.

Mathematical foundations

When several criteria matter, a **weighted decision matrix** makes the trade-off explicit and arguable.

FORMULA

Weighted decision score

$$S_j = \sum_{i=1}^{m} w_i \, s_{ij}, \qquad \sum_{i=1}^{m} w_i = 1$$

Symbol	Meaning	Units
S_j	Total score of option j	points (same scale as s_{ij})
w_i	Weight of criterion i (importance; sums to 1)	—
s_{ij}	Score of option j on criterion i (here 1 = poor, 5 = excellent)	points
m	Number of criteria	count

WORKED EXAMPLE

Worked example — Where should PhotoShare store photo files?

Options: (A) keep files on each application server's local disk; (B) a shared network file server (NFS); (C) managed object storage.

Table 1.12 — Decision matrix for photo storage.

Criterion	Weight	A: Local disk	B: NFS server	C: Object storage
Durability	0.30	1	3	5
Scalability	0.25	1	2	5
Operability	0.20	3	2	5
Cost	0.15	5	3	3
Latency	0.10	5	4	3

1. $S_A = 0.30(1) + 0.25(1) + 0.20(3) + 0.15(5) + 0.10(5) = 0.30 + 0.25 + 0.60 + 0.75 + 0.50 = 2.40$.
2. $S_B = 0.30(3) + 0.25(2) + 0.20(2) + 0.15(3) + 0.10(4) = 0.90 + 0.50 + 0.40 + 0.45 + 0.40 = 2.65$.
3. $S_C = 0.30(5) + 0.25(5) + 0.20(5) + 0.15(3) + 0.10(3) = 1.50 + 1.25 + 1.00 + 0.45 + 0.30 = 4.50$.

Interpretation. Object storage wins clearly. A *sensitivity check* matters more than the totals. Suppose a cost-conscious reviewer doubles cost's weight to 0.30 and halves durability's to 0.15:

4. $S_A = 0.15(1) + 0.25(1) + 0.20(3) + 0.30(5) + 0.10(5) = 0.15 + 0.25 + 0.60 + 1.50 + 0.50 = 3.00$.
5. $S_B = 0.15(3) + 0.25(2) + 0.20(2) + 0.30(3) + 0.10(4) = 0.45 + 0.50 + 0.40 + 0.90 + 0.40 = 2.65$.
6. $S_C = 0.15(5) + 0.25(5) + 0.20(5) + 0.30(3) + 0.10(3) = 0.75 + 1.25 + 1.00 + 0.90 + 0.30 = 4.20$.

C still wins by more than a point, so the ranking is robust to this disagreement.

Engineering implication. The matrix does not make the decision; it exposes *which weights* would have to change for the decision to flip, so that reviewers argue about priorities rather than conclusions. Scores of 1–5 are judgments; where a number can be measured (latency, cost per TB), measure it.

Code example

Here is the ADR that records the decision. ADRs are plain Markdown; the block below uses the `text` tag so its content is shown verbatim.

```
# ADR-0003: Store photo binaries in managed object storage

Status: Accepted (2026-03-14). Supersedes ADR-0001 "Store photos on local disk".
Deciders: PhotoShare backend team. Reviewed in design review DR-12.

## Context
- v0 stores photo files on the single VM's local disk (ADR-0001).
- The disk is 80% full; uploads add ~50 GB/day at 100,000 DAU (§1.9 estimate).
- v1 must meet 99.9% monthly availability, which requires at least two
  stateless application servers behind a load balancer. Files on one
  server's local disk are invisible to the other servers.
- There is no off-machine copy of photos; a disk failure loses all photos.

## Decision
Store every original and thumbnail in managed object storage under the key
photos/{photoId}/{variant}. Application servers keep no photo files locally.
Clients download images through the CDN, never directly from app servers.

## Options considered
A. Local disk per server - rejected: blocks horizontal scaling; no durability.
B. Shared NFS server - rejected: new single point of failure; we would
   operate replication and backups ourselves.
C. Managed object storage - chosen (decision matrix score 4.50 vs 2.65, 2.40).

## Consequences
+ Application servers become stateless and can be added or replaced freely.
+ Durability and capacity are the provider's responsibility.
- Upload path gains a network hop (~tens of ms to the object store).
- Storage cost becomes a per-GB monthly bill that grows with users; add a
  lifecycle policy to move old originals to a colder tier (see Ch 15).
- One-time migration of existing files (~2 TB); plan a dual-read period.
- Vendor-specific API; wrap it behind the BlobStore interface (Figure 1.3).
```

What to notice:

- **Context is factual and dated**; it includes the numbers that made the decision necessary. When those numbers change, the ADR tells you the decision may need revisiting.
- **Consequences list negatives**, not only benefits. An ADR with no downsides is advocacy, not a record.
- **Supersession** is explicit in both directions: ADR-0001 should be updated only to change its status to “Superseded by ADR-0003”.
- Nygard’s original format is Title, Status, Context, Decision, Consequences [Nygard 2011]; “Options considered” and “Deciders” are widely used extensions.

Real-world industry applications

INDUSTRY EXAMPLE

Lightweight ADRs in open-source and public-sector projects. After Nygard's 2011 post, the format spread widely; many public repositories contain an ADR numbered 0001 titled "Record architecture decisions", whose decision is simply to adopt ADRs for the project. The appeal is low cost: a page of Markdown reviewed in the same pull-request workflow as code. *Evidence: Secondary* — [Nygard 2011] and the many public repositories that adopt its format; the specific spread is an observation, not a measured statistic.

Advantages and disadvantages

Advantages: cheap to write; versioned with the code; preserves the *why*; speeds onboarding; prevents re-litigating settled questions; forces explicit consequences.
Disadvantages: only as good as team discipline; can become bureaucratic if required for trivial choices; a large ADR log needs an index to remain navigable.

Alternatives and trade-offs

ADRs complement rather than replace design documents (§1.10): a design doc explores a whole problem and may produce several decisions; each significant decision is then distilled into an ADR. Wikis are easier to browse but drift from the code. Commit messages capture *what* changed but rarely the alternatives rejected.

Failure scenarios

Table 1.13 — Decision-making failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Decision re-litigated every quarter	Rationale not recorded	Same debate in multiple meetings	Write the ADR retroactively	ADR for every one-way-door decision
Analysis paralysis	Treating a reversible choice as irreversible	Weeks of debate on a library choice	Time-box; pick and move on	Classify reversibility first (§2.8)
Decision by loudest voice	Criteria never made explicit	Dissenters disengage; later regret	Re-open with an explicit matrix	Agree criteria and weights before scoring
Stale ADR misleads	Context changed, ADR not superseded	Code contradicts accepted ADR	Write a superseding ADR	Review ADR log in design reviews

Common misconceptions

COMMON MISTAKE

“The decision matrix decides.” It structures judgment; it does not replace it. Weights encode values, and a team can make any option win by adjusting them. Its value is making those values visible.

1.9 Why system design matters (cost of wrong decisions)

1.9.1 Decisions differ in their cost of reversal

KEY CONCEPT

The asymmetry of design decisions. Most code-level decisions are cheap to reverse: rename a function, swap a library, redeploy. A few decisions are very expensive to reverse because *data* has been written in their shape: where files live, the primary key format, the partitioning key, the consistency model clients rely on, the public API contract. The job of system design is to spot the expensive few early and decide them deliberately, while keeping everything else cheap to change.

First-principles explanation

Moving furniture is easy; moving a load-bearing wall after the house is built is not. Data is software’s load-bearing wall: once billions of rows or petabytes of files exist in a particular shape, changing that shape means a migration that runs for days or months while the system stays live.

Why does this exist?

Bad design shows up as cost in four currencies: **money** (over-provisioned or emergency hardware), **time** (migrations that consume a team for a quarter), **user trust** (outages, data loss) and **opportunity** (features not built because engineers are fighting fires). Boehm and Basili summarized decades of industry data with the widely quoted observation that fixing a problem after delivery is often far more expensive than fixing it during requirements and design [Boehm and Basili 2001]; the exact multiplier varies greatly between studies and projects, but the direction is consistent.

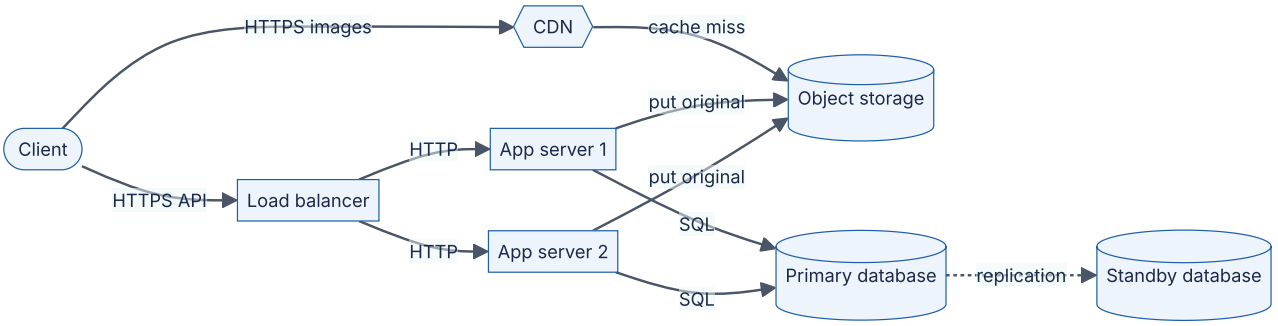
The opposite error — **over-engineering** — has the same currencies. Building a 50-service architecture for 1,000 users spends money and time on problems that do not yet exist, and makes the system harder to change when you learn what users actually want.

How it works internally — PhotoShare grows up

We now evolve PhotoShare from Figure 1.1 through three more stages. Each stage is triggered by a specific requirement that the previous design cannot meet. All estimates come from the script in §1.3.2 with the same assumptions (50 photo views and 0.2 uploads per user per day; 2.5 MB stored per upload; 200 KB served per view; peak factor 3), plus one more: each user loads the feed about 5 times per day, so feed API requests are one-tenth of photo views.

Stage 1 — 100,000 DAU: separate state from compute. Two requirements break v0. The 99.9% availability target cannot be met with deploy downtime (§1.7.2 worked example), and uploads now add $100,000 \times 0.2 \times 2.5$ MB = 50 GB per day to a single local disk. ADR-0003 (§1.8) moves files to object storage; a managed database with a standby replica replaces the local one; two stateless application servers sit behind a load balancer; images are served through a CDN.

Figure 1.5 — PhotoShare v1: stateless application tier and managed storage.



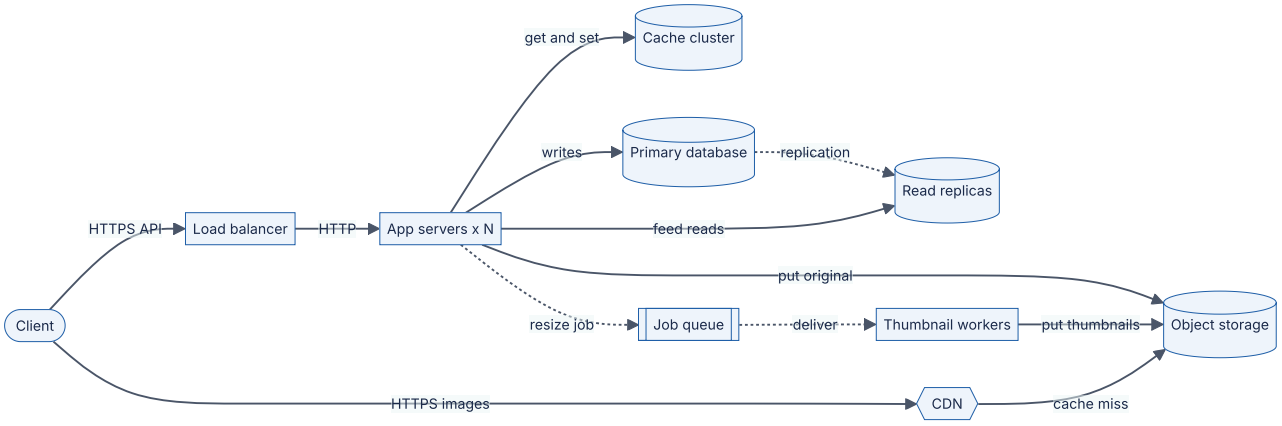
Reading the diagram.

- **Components.** A *load balancer* spreads API requests across two identical *app servers* (see Ch 19 (Load Balancing)). A *primary database* holds metadata, with a *standby* ready to take over. *Object storage* holds image bytes; a *CDN* (an external network of edge caches, drawn as a hexagon) serves images close to users (see Ch 21).
- **Protocols.** HTTPS from clients; plain HTTP inside the private network (or HTTPS, depending on the security model, §10.10); SQL to the database; the object store's HTTP API.
- **Direction and sync/async.** API calls and image fetches are synchronous. Replication from primary to standby is drawn dotted: it is commonly asynchronous, so the standby may lag slightly (replication modes are covered in §14.4).
- **Storage boundaries.** App servers are now **stateless**: they hold no data that cannot be lost. All state lives in the database and object storage. This is what allows any app server to serve any request.

- **Failure points.** Losing one app server halves capacity but keeps the service up. The primary database is still critical: failover to the standby takes time and, with asynchronous replication, may lose the last few seconds of writes.
- **Scaling options.** Add app servers horizontally; scale the database vertically for now.

Stage 2 — 1,000,000 DAU: protect the database. Feed API traffic is now $1,000,000 \times 5 / 86,400 \approx 58$ RPS average and about 174 RPS at peak — modest — but each feed request runs a join across follows and photos, and the database CPU is the bottleneck. Synchronous thumbnail generation pushes upload p99 above 3 seconds. Two additions fix this: a **cache** for feeds, sessions and hot metadata (Ch 20), plus **read replicas** for queries that tolerate slight staleness (§14.3); and an **asynchronous job queue** so uploads return as soon as the original is stored (Figure 1.2; Ch 30).

Figure 1.6 — PhotoShare v2: cache, read replicas and asynchronous processing.



Reading the diagram.

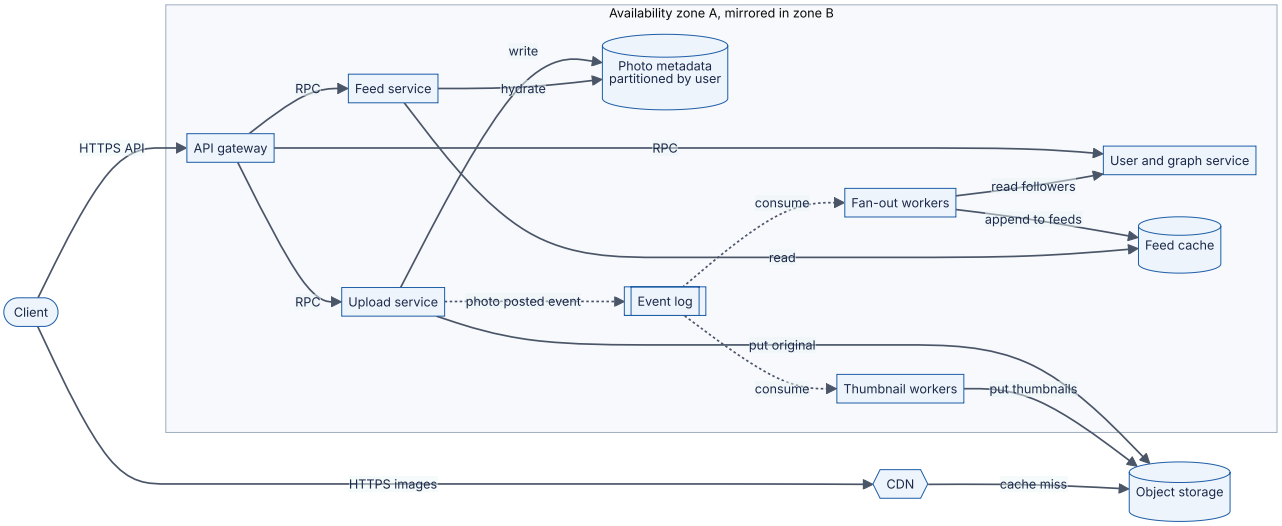
- **Components.** New: a *cache cluster* (in-memory key-value store), *read replicas* of the database, a *job queue* and *thumbnail workers*.
- **Protocols.** The cache uses its own lightweight protocol over TCP; the queue uses the broker's protocol.
- **Direction and sync/async.** Feed reads check the cache first (cache-aside, §20.7) and fall back to a replica on a miss. Uploads are synchronous only until the original is stored and the row written; resizing happens asynchronously (dotted arrows).
- **Storage boundaries.** Data now exists in up to four places — primary, replicas, cache, object storage — so **consistency** becomes a design question: a user who just uploaded may not see the photo if their next read hits a lagging replica. The consistency target in Table 1.7 ("own uploads visible to self immediately") is met by routing a user's reads of their own profile to the primary for a short time after a write (read-your-writes, §25.6).
- **Failure points.** A cache outage sends all reads to the replicas at once and can overload them (a *cache avalanche*, §20.13). A poisoned job that always crashes a worker

must be moved aside to a dead-letter queue (§30.11).

- **Scaling options.** App servers and workers scale horizontally; replicas scale reads; the primary still takes every write.

Stage 3 — 10,000,000 DAU: scale every tier and survive a zone failure. The estimator now gives about 5,800 average and 17,400 peak photo views per second, about 1,700 peak feed API RPS, 5 TB of new photo data per day (1.8 PB per year before replication) and about 9.3 Gbit/s of average image egress (28 Gbit/s at peak). The availability target rises to "survive loss of one availability zone". The design splits into a few services along clear data-ownership lines, partitions the metadata database by user ID (Ch 14), precomputes feeds asynchronously when a photo is posted (*fan-out on write*, examined in §53.7), and runs in at least two zones.

Figure 1.7 — PhotoShare v3: services, partitioned data and multi-zone deployment.



Reading the diagram.

- **Components.** An *API gateway* authenticates and routes requests (§34.6). The *upload*, *feed* and *user and graph* services each own their data. An *event log* (Ch 31) records "photo posted" events; *fan-out workers* insert the new photo ID into each follower's precomputed feed in the *feed cache*; *thumbnail workers* consume the same events. Photo metadata is **partitioned** by user ID across many database nodes.
- **Protocols.** HTTPS at the edge; internal RPC (for example gRPC, §8.8) between gateway and services; the event log's protocol for producers and consumers.
- **Direction and sync/async.** The read path (gateway → feed service → feed cache → metadata) is synchronous and short. The write path returns once the original and metadata are stored; everything else — thumbnails, fan-out — happens asynchronously from the event log, so a user with 100,000 followers does not make the upload slow.

- **Storage boundaries.** Object storage and the CDN are regional or global managed services outside the zone boundary; metadata, the event log and the feed cache are replicated across zones.
- **Failure points.** Loss of a zone: traffic shifts to the mirror zone, which must have spare capacity (≥ 50% headroom with two zones). Fan-out lag: followers see new photos seconds late — acceptable under the "within 5 s" consistency NFR, and visible as event-log consumer lag in monitoring (Ch 40). Celebrity accounts with tens of millions of followers make fan-out on write too expensive; a hybrid with *fan-out on read* for those accounts is the standard fix (§53.7).
- **Scaling options.** Every service is stateless and scales horizontally; metadata scales by adding partitions; the event log by adding partitions and consumers; the CDN absorbs image egress.

Table 1.14 — PhotoShare stages, triggers and costs.

Stage	DAU	Trigger (broken requirement)	Key changes	New cost or complexity
v0 (Fig. 1.1)	1,000	—	One VM	SPOF; no backups
v1 (Fig. 1.5)	100,000	99.9% availability; disk filling	LB, stateless app servers, managed DB plus standby, object storage, CDN	Network hops; managed-service bills; failover semantics
v2 (Fig. 1.6)	1,000,000	DB CPU saturated; upload p99 > 3 s	Cache, read replicas, job queue, workers	Stale reads; cache invalidation; queue operations
v3 (Fig. 1.7)	10,000,000	Zone-failure tolerance; write volume; 28 Gbit/s egress	Services, partitioned metadata, event log, precomputed feeds, multi-zone	Distributed-systems failure modes; more teams and on-call

Mathematical foundations

WORKED EXAMPLE

Worked example — The cost of one wrong early decision.

Suppose PhotoShare had *not* written ADR-0003 and kept files on application-server disks until 1,000,000 DAU, by which time roughly 100 days at 0.5 TB/day had accumulated about 50 TB.

1. Data to move: $50\ \text{TB} = 50 \times 10^{12}$ bytes $= 4 \times 10^{14}$ bits.
2. Available copy bandwidth, without starving production traffic: assume 1 Gbit/s $= 10^{9}$ bit/s.
3. Copy time: $4 \times 10^{14} / 10^{9} = 4 \times 10^{5}$ s ≈ 111 h ≈ 4.6 days of continuous copying.
4. Meanwhile 0.5 TB/day of new uploads keeps arriving, so the migration also needs dual-writes, verification checksums, a cut-over plan and a rollback plan — realistically several engineer-weeks, plus risk of data loss.

Interpretation. Making the decision at v1 with 2 TB took a few hours of copying; deferring it made it 25× larger and turned it into a project.

Engineering implication. Decisions about *where data lives* should be made early and on purpose, even when the system is small. Decisions about *how much compute you run* can safely wait.

Real-world industry applications

INDUSTRY EXAMPLE

Knight Capital (2012). On 1 August 2012, Knight Capital deployed new trading code to its order-routing servers using a manual process; one of eight servers did not receive the new code, and a repurposed configuration flag activated long-unused legacy logic on that server. In about 45 minutes the firm executed millions of unintended trades and lost more than $460 million. The U.S. Securities and Exchange Commission's subsequent order cites, among other failures, the lack of adequate technical controls and written procedures for deployment. The lesson for designers: deployability and operability (Table 1.8) are architectural qualities, not afterthoughts — dead code, reused flags and manual deploys are design decisions with consequences. *Evidence: Primary* — [SEC 2013]

INDUSTRY EXAMPLE

A counter that outgrew its integer. In December 2014 YouTube reported that the view count of the music video “Gangnam Style” had exceeded the maximum value of a signed 32-bit integer (2,147,483,647), and that the counter had been upgraded to a 64-bit integer. Choosing the width of an identifier or counter is a tiny decision on day one and a data migration years later. *Evidence: Secondary* — widely reported at the time; primary source to be confirmed (see §1.19).

Failure scenarios

Table 1.15 — Costly design failure patterns.

What goes wrong	Why	Detection	Recovery	Prevention
Stateful app servers block scaling	Files or sessions stored locally	New servers serve 404s or log users out	Move state to shared stores; migration	Stateless services by default (§18.5)
Identifier overflow	32-bit IDs or counters	Inserts fail at about 2.1 billion	Emergency schema migration	64-bit or globally unique IDs (§17.10)
Premature microservices	Splitting before boundaries are understood	Every feature touches many services	Merge into a modular monolith	Start with a modular monolith (§33.5)
Unplanned celebrity load	Design assumed uniform users	Hot partitions; fan-out lag	Special-case heavy users	Ask about skew in requirements (§14.10)

Common misconceptions

COMMON MISTAKE

“We can always fix the architecture later.” You can always fix *code* later. Fixing data shape, storage location and public contracts later costs migrations that grow with the data. Decide those deliberately; defer the rest.

1.10 How system design is practiced in industry

1.10.1 Design documents

DEFINITION

Definition — Design document (design doc). A written proposal, produced before significant implementation, that states a problem, its goals and non-goals, a proposed design, the alternatives considered, and cross-cutting concerns (security, privacy, operations, cost), so that others can review it while changes are still cheap.

First-principles explanation

Before a building is constructed, its drawings are circulated to the structural engineer, the fire inspector and the client. Each reads for different risks, and each objection costs an eraser rather than a demolition crew. A design doc is the software equivalent: the cheapest place to find a design flaw is in a document.

How it works internally

Practice varies, but a widely cited public description of Google's design-doc culture describes informal documents, written in a collaborative editor, typically containing [Ubl 2020]:

1. **Context and scope** — the landscape the system lives in and what is being built.
2. **Goals and non-goals** — including explicit things the system will *not* do.
3. **The actual design** — often with a system-context diagram, APIs and data storage, emphasizing trade-offs rather than implementation detail.
4. **Alternatives considered** — and why they were rejected.
5. **Cross-cutting concerns** — security, privacy, observability and similar.

The same source describes larger design docs of roughly 10–20 pages and shorter "mini design docs" for smaller changes. *Software Engineering at Google* likewise treats design docs as a standard documentation type [Winters et al. 2020]. Amazon is publicly known for narrative documents instead of slide decks, including the "PR/FAQ" (a mock press release and FAQ written before building a product) described by two former Amazon executives [Bryar and Carr 2021].

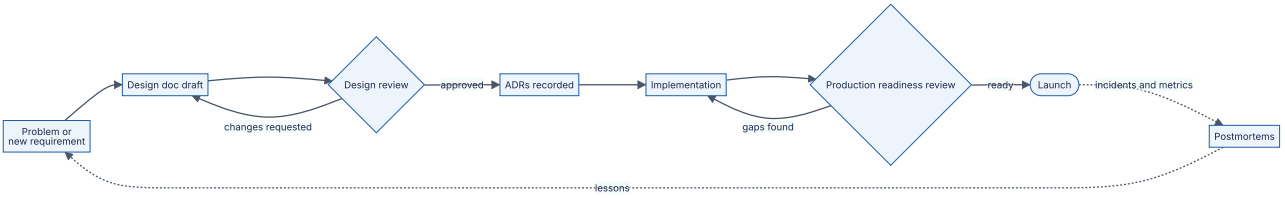
1.10.2 Design reviews and production readiness

A **design review** is a meeting or asynchronous comment thread in which experienced engineers outside the authoring team challenge a design doc. Reviewers typically probe: Are the requirements and numbers right? What are the single points of failure? What hap-

pens under 10× load? How is it deployed and rolled back? How is it monitored? What does it cost? Is there a simpler design?

Close to launch, many organizations run a **production readiness review (PRR)**: a checklist-based assessment that a service is operable — monitoring, alerting, capacity, runbooks, on-call — before it receives production traffic. Google's SRE book describes PRRs as part of how SRE teams engage with services [Beyer et al. 2016]. After incidents, **blameless postmortems** (§39.12) feed lessons back into future designs.

Figure 1.8 — The life of a design in a typical engineering organization.



Reading the diagram.

- **Components.** Activities (rectangles), gates where a decision is made (diamonds) and the launch milestone (stadium).
- **Direction.** Work flows left to right from problem to launch, with two loops back: review feedback to the doc, and readiness gaps to implementation.
- **Sync/async.** Solid arrows are the planned path. Dotted arrows are the slower, asynchronous feedback from production — incidents and metrics — that eventually create new problems to design for.
- **Storage boundaries.** The durable artifacts are the design doc, the ADRs and the postmortems; together they form the organization's architectural memory.
- **Failure points.** Skipping the review gate (designs built unreviewed), a review that becomes a rubber stamp, or postmortem lessons that never feed back into designs.
- **Scaling options.** Large organizations scale review capacity with tiered reviews: lightweight team review for reversible changes, cross-org architecture review for one-way-door decisions.

1.10.3 RFC processes

The term **RFC** ("Request for Comments") comes from the Internet's standards process; RFC 1, "Host Software", was written by Steve Crocker in 1969 [Crocker 1969], and the IETF's current standards process is itself defined in an RFC [Bradner 1996]. Many open-source projects run public proposal processes in the same spirit: Python Enhancement Proposals (PEPs) [Python PEP 1], Rust RFCs [Rust RFCs] and Kubernetes Enhancement Proposals (KEPs) [Kubernetes KEPs]. Inside companies, "RFC" usually means a design doc circulated widely for comment before a decision, often across teams.

Table 1.16 — Design artifacts compared.

Aspect	Design doc	ADR	RFC (company or open source)	PRR
What it is	Proposal for a whole design	Record of one decision	Proposal circulated for broad comment	Operability checklist
When	Before implementation	At decision time	Before cross-team or public change	Before launch
Length	1–20 pages	~1 page	2–20 pages	Checklist
Audience	Team plus reviewers	Future maintainers	Whole organization or community	Operators and SRE
Output	Approved design	Durable rationale	Consensus decision	Launch go/no-go
Choose when	Non-trivial new system or change	Any one-way-door decision	Change affects many teams or users	New service or major change

Real-world industry applications

INDUSTRY EXAMPLE

Open-source RFCs as public design reviews. In the Rust and Python projects, any significant language change is proposed as a document in a public repository, discussed in the open, and accepted or rejected by a designated team, leaving a permanent record of the rationale and alternatives. They are among the best freely available corpora of real design reasoning — and good reading practice (see §3.5). *Evidence: Primary* — [Python PEP 1]; [Rust RFCs]

Failure scenarios

Table 1.17 — Design-process failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Review as rubber stamp	Reviewers lack time or context	Incidents in "reviewed" systems	Postmortem identifies missed risk	Named reviewers with explicit checklists
Design by committee	Every reviewer's preference absorbed	Bloated design; slipped dates	Author re-asserts goals and non-goals	Clear decision owner
Doc written after the fact	Process seen as paperwork	Doc describes code, lists no alternatives	Treat as documentation, not review	Review before implementation starts

1.11 How system design interviews work

1.11.1 Format

DEFINITION

Definition — System design interview. A 45–60-minute interview in which a candidate designs a system from an open-ended prompt (for example, “design a photo-sharing service”) in conversation with an interviewer, who evaluates the candidate’s process, technical judgment and communication rather than a single correct answer.

First-principles explanation

The interview is a compressed design review in which you are the author and the interviewer is a friendly but probing reviewer. There is no single correct answer because real design has none; what is being assessed is whether you would be a good person to have in a real design review.

How it works internally

Formats differ between companies and levels (Ch 90 separates verified public information from general advice), but most follow a shape like Figure 1.9. Popular preparation guides describe a similar sequence — understand the problem and scope, propose a high-level design, dive deep, wrap up [Xu 2020].

Figure 1.9 — A typical 45-minute system design interview.

Reading the diagram.

- **Components.** Six phases, each with a suggested time budget for a 45-minute slot.
- **Direction.** Left to right. The dotted arrow shows that deep dives often send you back to revise the high-level design — that is expected, not a failure.
- **What each phase produces.** A short list of FRs and numeric NFRs; a few key numbers (peak RPS, storage per year); a handful of API calls and core tables; a diagram like Figure 1.6 or 1.7; a deep analysis of one or two components (feed generation, partitioning, consistency); a summary of bottlenecks, failure modes and what you would do next.
- **Failure points.** Spending 20 minutes on requirements, or jumping to the diagram with no requirements at all; going silent; designing for scale nobody asked for.
- **Scaling to longer formats.** In a 60-minute slot, the extra time usually goes to deep dives.

What interviewers evaluate

Table 1.18 — Interview signals: weak vs strong.

Signal	Weak	Strong
Requirements	Starts drawing immediately	Asks targeted questions; states FRs, numeric NFRs and non-goals
Estimation	Skips, or computes to six digits	Order-of-magnitude numbers that drive decisions
Design	Lists technologies by name	Explains what each component is for and why it is needed
Trade-offs	"X is the best"	"X gives A at the cost of B; given our NFRs, that's acceptable"
Depth	Shallow everywhere	Deep on the hardest part of *this* problem
Failure thinking	Assumes nothing breaks	Names SPOFs, failure modes and recovery
Communication	Monologue or silence	Thinks aloud, checks in, adapts to hints

Expectations rise with level: a junior candidate is expected to produce a working design with guidance; a senior candidate to drive the conversation and identify the hard parts unprompted; a staff-level candidate to reason about evolution, organizational and cost concerns, and multiple viable designs (rubrics by level are in Ch 88).

> INTERVIEW TIP
>
> **Interview tip — the first two minutes.** For "design PhotoShare", a strong opening sounds like: *"Let me confirm scope: upload, follow, and a home feed of followed users' photos — chronological, not ranked? I'll leave out video, search and messaging. For scale, shall I assume around 10 million daily users, read-heavy — maybe 50 views per upload? And for quality targets: feed p99 under a few hundred milliseconds, uploads must never be lost, and a few seconds of delay before followers see a new photo is fine?"* In thirty seconds you have stated FRs, non-goals, scale, read/write ratio, latency, durability and consistency — and given the interviewer a chance to redirect.

Variants include **low-level/object-oriented design** interviews (Ch 38), **ML system design** interviews (Ch 92), and product-flavored versus infrastructure-flavored prompts. Full preparation is in Book III (Ch 87–92).

1.12 Common beginner mistakes

Most beginner mistakes are versions of one error: *designing without stating requirements and numbers*. Table 1.19 lists the twelve most common.

Table 1.19 — Common beginner mistakes and their fixes.

#	Mistake	Symptom	Fix	See
1	Jumping to a solution	Diagram before requirements	Spend the first minutes on FRs and NFRs	§1.6–1.7
2	Vague NFRs	“Fast and scalable”	Numbers, percentiles, windows	§1.7
3	No estimation	Arbitrary component counts	Back-of-the-envelope RPS, storage, bandwidth	§1.3.2, Ch 89
4	Over-engineering	Microservices, Kafka and sharding for 1,000 users	Design for ~10× current load; evolve	§1.9
5	Buzzword architecture	Technologies named, purpose unexplained	Justify every box by a requirement	§1.3
6	Ignoring failure	No answer to “what if this node dies?”	Name SPOFs; add redundancy where the NFR demands it	Ch 39
7	Averages instead of tails	p99 never mentioned	Specify and reason in percentiles	§1.7.1, §4.8
8	Stateful app servers	Sessions or files on local disk	Push state into shared stores	§18.5
9	One database for everything, forever	DB is every bottleneck	Cache, replicas, partitioning — when measured	Ch 14, Ch 20
10	Silent trade-offs	Only advantages stated	Always name the cost of each choice	§1.7.3
11	Forgetting the data lifecycle	No deletion, retention or backup plan	Treat deletion, backup and retention as requirements	§1.6, §39.9
12	Forgetting operations	No monitoring, deploy or rollback story	Include observability and deployability	Ch 40, Ch 43

COMMON MISTAKE

The two-sided trap. Mistakes 4 and 9 are opposites, and beginners often swing from one to the other. The cure for both is the same: let *measured or estimated* load and *stated* requirements decide when each component is added. Figure 1.1 was right for v0; Figure 1.7 was right for v3; neither is right for the other.

RECOMMENDATION

A five-question self-check before any design discussion. (1) What must it do? (2) How well — in numbers? (3) How big — in RPS, bytes and growth? (4) What fails, and what happens then? (5) What did I give up, and why is that acceptable?

1.13 Summary and revision notes

SUMMARY

- **System design** is deciding components, responsibilities, interfaces, data flow, storage and deployment so a system meets functional *and* non-functional requirements under stated load and failure assumptions. A design is only good relative to its requirements.
- **Software architecture** is the set of significant, hard-to-change structures of a system; system design is its large-scale, runtime-focused part. Describe architecture with multiple views (4+1, C4).
- **HLD** fixes components, boundaries and contracts; **LLD** fixes the internals of one component. Design moves between the two levels.
- **Functional requirements** say what the system does; write them testably, prioritize them, and list non-goals. Some “small” FRs (account deletion) have large architectural consequences.
- **Non-functional requirements** say how well; they drive the architecture. Make them measurable (number, percentile, window, load) using quality attribute scenarios, SLIs and SLOs.
- 99.9% availability allows 43.2 minutes of downtime per 30 days; components in series multiply availabilities, so each synchronous dependency lowers the total.
- Quality attributes conflict (consistency vs availability, durability vs latency, availability vs cost). Name the tension and choose per operation.
- Record one-way-door decisions as **ADRs** (title, status, context, decision, consequences); supersede, never rewrite. Use weighted matrices to make priorities explicit.
- Decisions about **where data lives and in what shape** are expensive to reverse; decisions about compute quantity are cheap. Avoid both under- and over-engineering.
- Industry practice: **design docs** → **design review** → ADRs → implementation → **production readiness review** → launch → **postmortems**; RFC processes broaden review.
- Interviews compress a design review into 45–60 minutes: requirements, estimation, API and data, high-level design, deep dives, trade-offs.

1.14 Knowledge checkpoint

1. In one sentence each, define *system design* and *software architecture*.
2. Why is “a single server” a good design for PhotoShare v0 but a bad one for v3?
3. Give two things that belong in an HLD and two that belong in an LLD.
4. Rewrite “uploads should be fast” as a measurable NFR.

5. What are the six parts of a quality attribute scenario?
6. How much downtime does 99.95% availability allow in a 30-day month?
7. Three components with availabilities 0.999, 0.999 and 0.9999 are in series. What is the path's availability?
8. Distinguish availability from reliability with an example.
9. Distinguish an SLI, an SLO and an SLA.
10. What are the five sections of Nygard's ADR format?
11. Why is an accepted ADR superseded rather than edited?
12. A product has 2 million DAU, each making 30 API requests per day, with peak factor 3. Estimate average and peak RPS.
13. Which PhotoShare requirement first forced the move off a single server — load or availability? Why?
14. Name the five typical sections of a design doc as described in public accounts of Google's practice.
15. Name four of the twelve beginner mistakes in Table 1.19 and the fix for each.

Answers

1. System design: choosing components, interfaces, data flow, storage and deployment so a system meets its functional and non-functional requirements under stated load and failure. Software architecture: the set of structures needed to reason about a system — its elements, their relations and the properties of both [Bass et al. 2021].
2. At 1,000 DAU the peak load is about 1.7 RPS and simplicity dominates. At 10 million DAU the load (about 17,400 photo views per second at peak, 5 TB/day of new data), the zone-failure requirement and the 99.9% availability target all exceed what one machine — itself a single point of failure — can deliver.
3. HLD: the list of services and data stores; the protocol and sync/async nature of each interaction (also deployment topology, data ownership). LLD: class structure and interfaces; table schemas and indexes (also algorithms, error handling, state machines).
4. For example: "For photos up to 20 MB under normal load at up to 70 uploads per second, 99% of uploads return a photo ID within 2 s, measured server-side over a 30-day window."
5. Source, stimulus, environment, artifact, response, response measure.
6. $(1 - 0.9995) \times 43,200 = 21.6$ minutes.
7. $0.999 \times 0.999 \times 0.9999 = 0.998001 \times 0.9999 \approx 0.99790$, about 99.79%.
8. Availability is the fraction of time the system is up and serving; reliability is the probability it operates correctly over a period. A feed service that responds quickly but sometimes shows other users' private photos is available but unreliable (and insecure).
9. SLI: the measured quantity (fraction of successful requests). SLO: the target for that SLI over a window (≥ 99.9% per 30 days). SLA: a contract with consequences if a stated target is missed.

10. Title, Status, Context, Decision, Consequences.
11. So that the historical reasoning remains intact: future readers can see what was decided, under what context, and what replaced it. Editing would erase the record of why the earlier choice was once right.
12. Requests/day $= 2 \times 10^6 \times 30 = 6 \times 10^7$; average $= 6 \times 10^7 / 86,400 \approx 694$ RPS; peak $\approx 3 \times 694 \approx 2,083$ RPS.
13. Availability. At 100,000 DAU the load was still small, but deploy downtime plus occasional VM failures gave roughly 99.76%, below the 99.9% target; only multiple stateless servers behind a load balancer remove deploy downtime and the single point of failure.
14. Context and scope; goals and non-goals; the actual design; alternatives considered; cross-cutting concerns [Ubl 2020].
15. Any four, e.g. jumping to a solution → clarify FRs and NFRs first; vague NFRs → add numbers, percentiles and windows; over-engineering → design for about 10× current load and evolve; ignoring failure → name SPOFs and the recovery path.

1.15 Interview questions

Basic

Q1. What is the difference between functional and non-functional requirements? Give an example of each for a URL shortener.

Answer. Functional requirements describe behavior — what the system does: “given a long URL, return a short code; visiting the short URL redirects to the long one”. Non-functional requirements describe quality — how well, under what constraints, with numbers: “redirects complete with p99 ≤ 50 ms server-side at 10,000 RPS; the service is available 99.95% per month; a created mapping is never lost”. The NFRs drive the design: the latency and read volume suggest caching (Ch 20), and the durability requirement suggests a replicated store (Ch 27). The full design is in §52.4.

Q2. What is a single point of failure, and how would you find them in a design?

Answer. A component whose failure alone makes the whole system (or a critical function) unavailable. Trace each critical request path end to end and, for every component on it, ask “if this one instance disappears now, what happens?”. Typical SPOFs are a lone database primary, a single load balancer, one availability zone, a shared configuration service, and a person who is the only one able to deploy. Removing a SPOF usually means redundancy plus automatic failover, but each removal costs money and complexity, so remove the ones the availability NFR requires.

Intermediate

Q3. Your product manager asks for “five nines”. How do you respond?

Answer. First translate: 99.999% allows about 26 seconds of downtime per 30-day month — less than a typical database failover and less than most deploy rollbacks. Then ask what the business impact of downtime actually is and which user journeys need the target (checkout, perhaps; profile editing, probably not). Explain the cost: multi-zone or multi-region active–active deployment, automated failover, rigorous change management, and every synchronous dependency must itself exceed five nines because availabilities multiply in series. Propose per-journey SLOs (for example 99.95% for checkout, 99.9% elsewhere) with an error budget, and revisit with data [Beyer et al. 2016].

Q4. When would you introduce a cache, and what new problems does it bring?

Answer. When measurements or estimates show a read-heavy workload where a backing store is the bottleneck or too slow for the latency NFR, and where data can tolerate some staleness or be invalidated reliably — as at PhotoShare v2 (Figure 1.6). New problems: stale reads and invalidation (§20.10); cold-start and stampedes when popular keys expire together (§20.11); a cache outage overwhelming the database (§20.13); memory cost; and a new component to operate. State the expected hit ratio and what happens on a miss and on cache failure.

Advanced

Q5. Walk through how you would evolve a single-server photo-sharing app to 10 million DAU. What triggers each change?

Answer. Estimate first: at 10 million DAU with 50 views and 0.2 uploads per user per day, about 5,800 average and 17,400 peak photo views per second, about 1,700 peak feed API RPS, 5 TB/day of new data and about 28 Gbit/s peak egress. Then evolve by trigger, not by fashion. (1) Availability target and disk growth → stateless app servers behind a load balancer, managed database with standby, object storage and CDN; data location is decided early because it is expensive to change later. (2) Database CPU and upload latency → cache with cache-aside, read replicas with read-your-writes routing, async thumbnail jobs. (3) Zone-failure tolerance and write volume → services split by data ownership, metadata partitioned by user ID, an event log driving fan-out-on-write feed precomputation with a fan-out-on-read path for celebrity accounts, and multi-zone deployment with capacity headroom. At each stage, name the new failure modes (stale reads, cache avalanche, consumer lag, hot partitions) and how you would observe them.

Q6. Two senior engineers disagree about whether to adopt a new distributed database. How would you drive the decision?

Answer. Classify reversibility first: a primary datastore holding production data is a one-way door, so it deserves a design doc and review. Agree the decision drivers (specific NFRs with numbers), criteria and weights *before* scoring options, including "do nothing" and an incremental option (for example partitioning the existing database). Replace opinion with evidence where possible: a time-boxed prototype under representative load, failure-injection tests, and an estimate of migration and operational cost (team skills, on-call burden). Score with a weighted matrix, run a sensitivity check to see which weight changes would flip the result, and record the outcome as an ADR with explicit negative consequences and the conditions under which it should be revisited. The goal is a decision both engineers can commit to even if one disagrees.

1.16 Practical exercises

1. **Run and extend the estimator.** Run the §1.3.2 script. Add fields for feed API requests (5 per user per day) and replication factor (3), and print API RPS and replicated storage per year for 1 million and 10 million DAU.
2. **Write NFRs.** Pick an app you use daily. Write five measurable NFRs, one of them as a full six-part quality attribute scenario.
3. **Availability arithmetic.** A request path has a CDN (99.99%), API gateway (99.95%), service (99.9%) and database (99.95%). Compute the path availability and the monthly downtime it implies. Which component would you make redundant first, and why?
4. **Write an ADR.** Write ADR-0004 for PhotoShare: "Generate thumbnails asynchronously". Include context with numbers, at least two options considered, and at least two negative consequences.
5. **Read a real design record.** Choose one accepted Python PEP or Rust RFC. Identify its context, decision, alternatives and consequences, and compare its structure with Nygard's ADR format.

1.17 Design challenges

1. **PhotoShare goes private.** Add the requirement "accounts can be private; only approved followers can see their photos". Which components in Figure 1.7 change? How do you stop the CDN from serving private photos to anyone with the URL? (Hint: signed URLs with short TTLs; see Ch 21.)
2. **PhotoShare in two regions.** EU regulators require EU users' photos and metadata to stay in the EU. Sketch the changes to Figure 1.7, list the new failure modes, and state which NFR tensions from Table 1.10 become sharper. (See Ch 44.)
3. **Cost ceiling.** The business caps infrastructure cost at $0.01 per monthly active user per month. Using the v3 numbers, identify the two largest cost drivers (con-

sider storage growth and egress) and propose design changes — storage tiers, image formats, CDN cache hit ratio — with estimated savings. (See Ch 51.)

1.19 Open verification items

- [Nygard 2011] and [Ubl 2020]: URLs could not be fetched from the authoring environment (network-restricted); existence and dates confirmed only via search results. Re-check URLs and the Ubl page-length claim (“roughly 10–20 pages”; “mini design docs”).
- [SEC 2013]: confirm release number and URL of the Knight Capital order, and the figures “one of eight servers”, “about 45 minutes” and “more than $460 million”.
- YouTube “Gangnam Style” 32-bit counter (December 2014): locate a primary source (YouTube/Google post) or keep as Secondary.
-
- [Boehm and Basili 2001]: confirm wording of the after-delivery cost-of-fix item; the commonly quoted “100×” multiplier is deliberately not stated.
- [ISO/IEC 25010] and [ISO/IEC/IEEE 42010]: confirm exact current titles of the 2023 and 2022 revisions.

Chapter 2 — How to Think Like a System Designer

> **Level:** 1–2 · **Track:** Shared · **Estimated reading time:** 3 h

Chapter 1 told you *what* system design is. This chapter is about *how* experienced designers think while they do it. It does not cover specific technologies (databases, caches, message brokers). Those come in Parts II–VI. What you get here is a set of thinking tools that apply to every design problem in this book, whether it is a URL shortener, a payment system or a large-language-model serving platform.

To keep the tools concrete, the whole chapter follows one running problem from a vague request to a documented architecture:

> WORKED EXAMPLE
>
> **Running problem — QuickBite.** A start-up asks you to "build the backend for our food-delivery app." Customers browse nearby restaurants, put dishes in a cart, pay, and watch a courier bring the food. Restaurants receive orders on a tablet and mark them ready. Couriers receive delivery jobs on a phone and share their location while driving. QuickBite runs in one country today and wants to grow.
>
> QuickBite is a hypothetical company invented for teaching. Every number attached to it in this chapter is an assumption we make and state openly. None of them is a measurement of any real food-delivery company.

2.1 Learning objectives

After this chapter you should be able to:

- **Decompose** a product description into components with clear responsibilities, using cohesion, coupling and data ownership as criteria.
- **Draw** a system-context diagram that separates what you are building from the people and external systems it depends on.
- **Elicit, quantify and negotiate** functional and non-functional requirements, turning vague wishes ("fast", "real-time", "never down") into testable numbers.
- **Identify the bottleneck** of a request path using the resource model (CPU, memory, disk, network, locks and other software resources), the utilization law and Little's

Law.
- **State assumptions** explicitly, rank them by how much the design depends on them, and plan how to check them.
- **Evaluate trade-offs** with a weighted decision matrix, and judge how much process a decision needs by asking whether it is reversible (a “two-way door”) or not (a “one-way door”).
- **Design for failure** by listing failure modes, limiting blast radius and computing the availability of a dependency chain.
- **Reason about scale** in orders of magnitude, and predict which parts of a design break at 10×, 100× and 1000× the load.
- **Perform** a complete back-of-the-envelope capacity estimate with explicit arithmetic.
- **Document** an architecture with the C4 model, a design document and Architecture Decision Records (ADRs).

2.2 Prerequisites

- Functional vs non-functional requirements — §1.6 and §1.7. This chapter turns them into numbers and negotiates them.
- High-level vs low-level design — §1.5. Decomposition here stays at the high level.
- Powers of ten and units (KB vs KiB) — §4.3 and §4.5. Every estimate in §2.10 and §2.11 depends on them. This chapter uses SI prefixes throughout (1 KB = 10^3 bytes, 1 GB = 10^9 bytes).
- A rough idea of what a server, a database and a network request are. No deeper knowledge is assumed. Every other term is defined when first used.

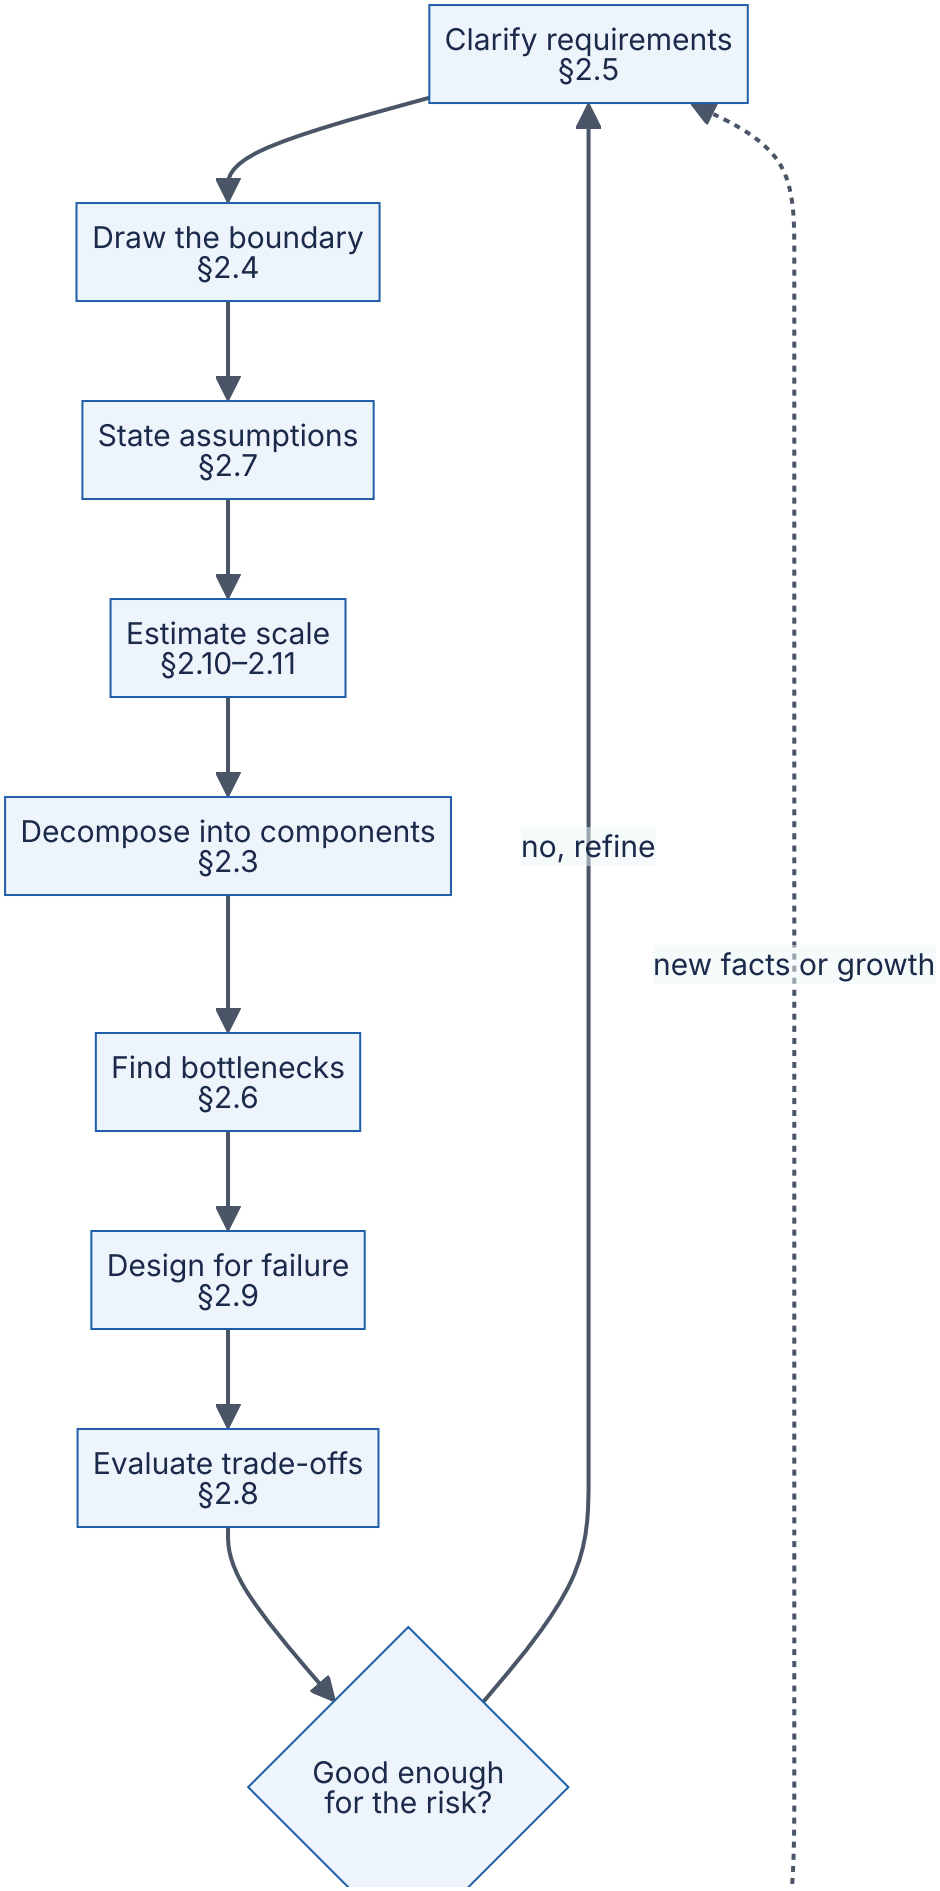
Helpful but optional: Little’s Law (§4.11) and availability arithmetic (§4.14). This chapter introduces both informally and points forward to the full treatment.

2.3 Decomposition into components

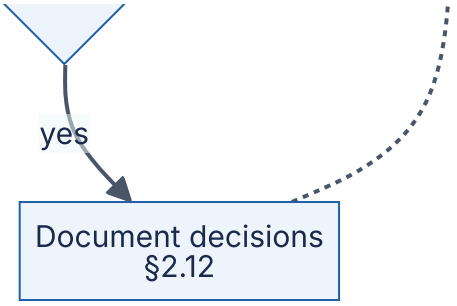
2.3.1 The thinking loop and where decomposition fits

Before the first tool, look at the whole process. Experienced designers do not move in a straight line from requirements to boxes and arrows. They work in a loop. They make a rough pass through every concern, find the riskiest part, and go round again at higher resolution. The sections of this chapter are the tools used at each step of that loop. They are presented one at a time for teaching, but in practice you switch between them constantly.

Figure 2.1 — The system designer’s thinking loop.



Clarify requirements §2.5
Draw the boundary §2.4
State assumptions §2.7
Estimate scale §2.10–2.11
Decompose into components §2.3
Find bottlenecks §2.6
Design for failure §2.9
Evaluate trade-offs §2.8
Good enough for the risk?
no, refine
new facts or growth



Reading the diagram. Each rectangle is a thinking activity, labeled with the section that teaches it. It is not a software component. Solid arrows show the usual order within one pass. The diamond is the decision every designer makes at the end of a pass: is the design good enough *for the risk involved*? A prototype for ten users clears that bar after one rough pass. A payment system may need many passes. The “no, refine” edge returns to requirements because a weak design is very often caused by a misunderstood requirement. The dotted arrow from documentation back to requirements is asynchronous: weeks or months later, production data or business growth disproves an assumption and starts the loop again. Nothing in this loop “fails” in the software sense. The failure to watch for is getting stuck, for example by polishing component diagrams (§2.3) before estimating scale (§2.11). The way to avoid that is to time-box each pass.

2.3.2 What decomposition is

DEFINITION

Definition — Decomposition. Dividing a system into smaller parts (**components**) so that each part has one clear responsibility, a well-defined interface, and as few dependencies on other parts as possible. Each part can then be understood, built, scaled and changed mostly on its own.

First-principles explanation

Think of a restaurant kitchen. Nobody “does the cooking.” There is a grill station, a fry station, a pastry station and a pass where plates are checked before they leave. Each station has its own tools and ingredients and gets work through a narrow interface: the ticket. When the fryer breaks, the grill keeps working. When dessert orders double, you add a pastry cook without touching the grill.

Software decomposition works the same way. You split a big, fuzzy problem (“the food-delivery backend”) into parts. Each part answers one question well (“what is on the menu?”, “where is the courier?”). The parts interact through narrow, explicit interfaces, usually an API or a message.

Why does this exist?

A system nobody can hold in their head cannot be reasoned about. Decomposition gives you four concrete benefits:

1. **Comprehension.** One component fits in one engineer's head.
2. **Independent scaling.** In QuickBite, courier location updates arrive thousands of times per second, but restaurants edit menus a few times per day. Separating them lets each be scaled on its own terms.
3. **Failure isolation.** A bug in the recommendation feature should not stop customers from paying.
4. **Team autonomy.** Different teams can own different components. Conway's observation that organizations produce designs that copy their own communication structures [Conway 1968] means team boundaries and component boundaries end up shaping each other whether you plan it or not.

David Parnas made the classic argument for *how* to choose the parts. Divide a system so that each module hides a design decision that is likely to change, rather than by the steps of a processing flowchart [Parnas 1972]. That principle, **information hiding**, is still the best single test of a good boundary.

How it works internally

A practical decomposition procedure:

1. **List the nouns and verbs.** From the product description: *customer, restaurant, menu, dish, cart, order, payment, courier, delivery, location, notification*. Verbs: *browse, search, add to cart, place order, pay, accept, prepare, assign, pick up, track, deliver, rate*.
2. **Group by data ownership.** Ask "who is the single source of truth for this data?" Menus belong with restaurants. Orders and their states belong together. Courier locations are a separate, high-volume stream.
3. **Group by rate of change and load profile.** Things that change at very different speeds, or see very different traffic, usually belong apart. Menus are read-heavy and rarely written. Location is write-heavy and short-lived.
4. **Group by consistency need.** Money movements need strong guarantees: no double charges. The display of a courier's position can tolerate being a few seconds stale.
5. **Name each component with one sentence of responsibility.** If the sentence needs "and", consider splitting it.
6. **Draw the interactions.** Mark each one as synchronous (the caller waits) or asynchronous (the caller hands off a message and moves on).
7. **Check against scenarios.** Walk the top three user journeys through the diagram. Every step must have exactly one owner.

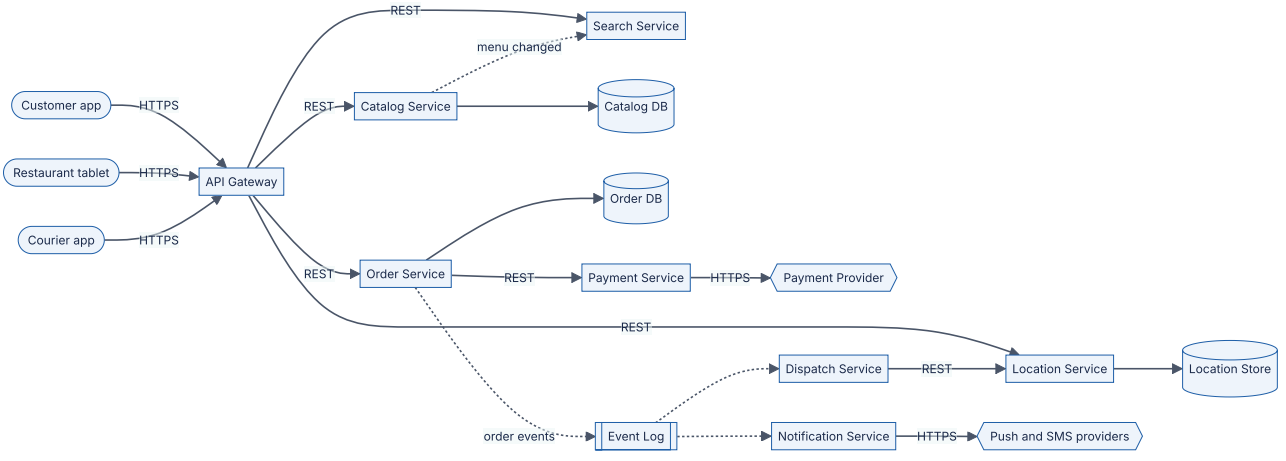
Applying this to QuickBite gives the components in Table 2.1.

Table 2.1 — QuickBite components and their single responsibilities.

Component	Responsibility (one sentence)	Owns data	Load profile	Consistency need
API gateway	Authenticates clients and routes requests	None (stateless)	All traffic	n/a
Catalog service	Serves restaurants, menus and prices	Restaurants, menus	Read-heavy	Minutes of staleness OK
Search service	Finds restaurants by location, cuisine, text	Search index (derived)	Read-heavy	Derived, can lag
Order service	Owns the life cycle of an order	Orders, order items	Moderate writes	Strong
Payment service	Charges and re-funds via a payment provider	Payment records	Low volume	Strong, idempotent
Dispatch service	Assigns couriers to ready orders	Assignments	Bursty	Strong per assignment
Location service	Ingests and serves courier positions	Recent positions	Write-heavy	Seconds of stale-ness OK
Notification service	Sends push, SMS and email	Delivery log	Bursty, async	At-least-once

Architecture diagram

Figure 2.2 — QuickBite first-pass decomposition.



Reading the diagram. Three client types (stadiums) reach the system only through the **API gateway** over HTTPS. The gateway is stateless, so it scales horizontally behind a load balancer (Chapter 19). Solid arrows are synchronous request/response calls. Placing an order calls the order service, which calls the payment service, which calls the external

payment provider (hexagon). That chain is the critical path, and every link in it can fail (§2.9). Dotted arrows are asynchronous. Once an order is committed, the order service publishes an event to the **event log** (subroutine shape; see Chapter 30). The dispatch and notification services consume it at their own pace, so a slow SMS provider cannot slow down checkout. Each cylinder is a storage boundary owned by exactly one service. No service reads another service's database, which keeps data ownership clear (§34.11). The catalog service pushes menu changes asynchronously to the search service, whose index is a *derived* copy that may lag by seconds. The location store is the heaviest write path, as §2.11 will show, so it scales independently, for example with an in-memory store partitioned by city. Likely failure points: the payment provider (external, outside your control), the order database (single source of truth) and the event log (if it stops, dispatch stops). Each needs a mitigation in §2.9.

> NOTE
>
> **Components are logical, not deployment units.** Figure 2.2 shows *logical* components. On day one, QuickBite might deploy all of them as one process: a **modular monolith** (§33.5). Decomposition decides where the *boundaries* are. Deployment decides how many *processes* there are. §2.8 makes that second decision with a decision matrix.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Amazon's move to services.** In a 2006 interview, Amazon's CTO Werner Vogels described how Amazon's early monolithic application was restructured into services. Each service owned its data and could only be reached through a published interface. Direct database access between teams was ruled out. He linked this to team ownership ("you build it, you run it"). The design choice was data ownership behind interfaces, the same rule used in Figure 2.2. The trade-off he acknowledged was added operational and coordination complexity in exchange for team independence and scalability. *Evidence: Primary* — [Gray 2006]

Advantages and disadvantages

Good decomposition makes reasoning, scaling, failure isolation and team ownership easier. It also has costs. Every boundary that crosses a network turns a function call (~nanoseconds) into a remote call (~0.1–0.5 ms or more within a datacenter, see §4.17), and that call can fail independently. Data split across components loses cross-component transactions (Chapter 28). Too many components multiply operational load: more deployments, dashboards and on-call rotations.

Alternatives and trade-offs

Table 2.2 — Ways to choose component boundaries.

Approach	Splits by	Works well when	Main risk
By technical layer	UI / logic / data	Small systems, one team	Every feature change touches every layer
By business capability	Orders, catalog, payments	Most product systems	Needs domain understanding up front
By volatility (Parnas)	Decisions likely to change	Long-lived systems	Requires predicting change
By load profile	Read-heavy vs write-heavy	Very uneven traffic	Can fragment one domain concept
By domain-driven bounded context	Consistent language and model	Large organizations	Heavy analysis cost (§34.4–34.5)

In practice you combine them. QuickBite splits by business capability first, then splits *location* out of *dispatch* because of its very different load profile.

Failure scenarios

Table 2.3 — Decomposition failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Distributed monolith	Services share a database or must deploy together	Every release touches many services; cross-service schema locks	Merge tightly coupled services	Enforce data ownership; review coupling
Chatty interfaces	Boundary cuts through a hot loop	One user request causes dozens of internal calls; high p99	Batch calls or move the boundary	Walk scenarios through the diagram before building
Orphan responsibility	No component owns a step, e.g. refunds	Bugs bounced between teams	Assign an owner explicitly	Step 7 of the procedure: one owner per step
Premature split	Boundaries drawn before the domain is understood	Frequent cross-boundary changes	Re-merge into a modular monolith	Start coarse; split when evidence appears

Common misconceptions

COMMON MISTAKE

“More components means a better design.” The number of boxes is not a quality measure. A good decomposition has *few, cohesive* components with *narrow* interfaces. A useful test: if two components change together in most pull requests, they are probably one component.

COMMON MISTAKE

“Decompose by technology.” “The Redis service” or “the Kafka service” are not responsibilities. Components are named after what they do for the business (“location service”). The technology they use is an internal detail that may change.

2.4 System boundaries and context diagrams

2.4.1 Boundaries and the context diagram

DEFINITION

Definition — System boundary. The line that separates what you are designing and are responsible for from everything outside it: users, other teams’ systems and third-party services. You control what is inside. You can only *depend on* what is outside.

DEFINITION

Definition — Context diagram. A diagram that shows the whole system as a single box, surrounded by the people (actors) and external systems that interact with it, with each interaction labeled. Context diagrams come from structured analysis [DeMarco 1979] and are Level 1 of the C4 model [Brown C4].

First-principles explanation

Before renovating a house, a builder walks the property line. Fences, the street, the neighbor’s tree and the water main are not part of the job, but every one of them constrains it. A context diagram is that walk around the property line. It answers three questions before any internal design starts: *who uses this?*, *what does it depend on?* and *what is not our job?*

Why does this exist?

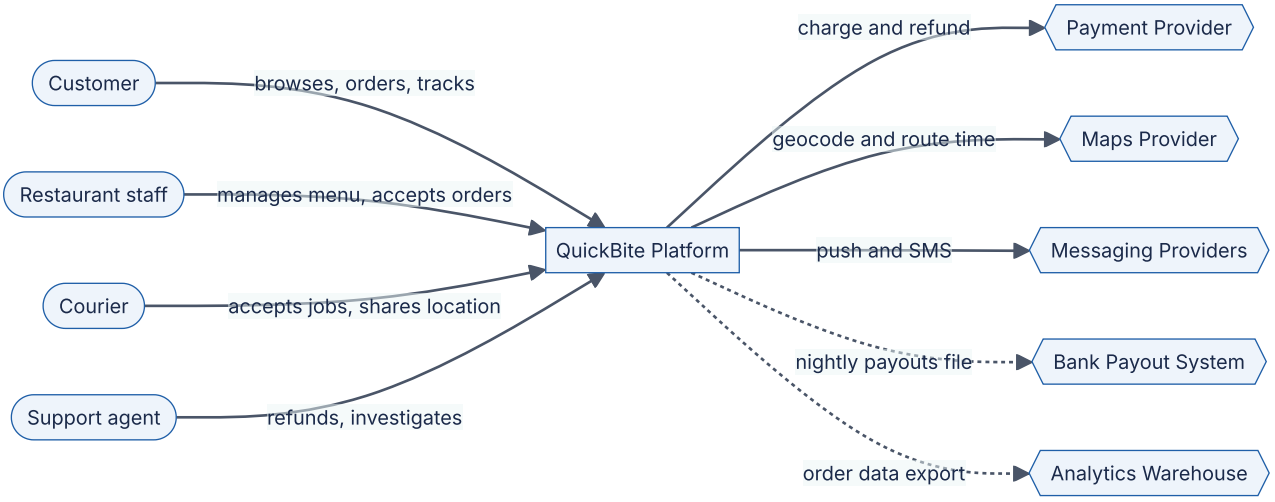
Many expensive design failures are scope failures, not technical ones. A team builds a payment system and finds out late that tax calculation was expected. Or it assumes an external maps API can take 10,000 requests per second when the contract allows 100. Drawing the boundary early brings these surprises to the surface while they are still cheap to fix. It also gives non-engineers, such as product managers, legal and finance, a diagram they can actually check.

How it works internally

1. Draw your system as one box. Resist the urge to draw its insides.
2. Around it, place every **actor** (human role) and every **external system**.
3. Label each interaction with *what* flows (not *how*): “places orders”, “sends card charge”.
4. For every external system, note three facts: its **availability promise** (its SLA, see §39.6), its **rate limits** and its **latency**. These numbers are inherited constraints you do not control.
5. Write down what is explicitly **out of scope**.

Architecture diagram

Figure 2.3 — QuickBite system-context diagram.



Reading the diagram. The single rectangle is the whole QuickBite platform, deliberately shown with no internal detail. Four human actors (stadiums) interact with it. Note the **support agent**, an actor often forgotten in first drafts, who needs refund and investigation tools. Five external systems (hexagons) sit outside the boundary. Solid arrows are synchronous, user-facing interactions. A customer waits while a card charge happens, so the payment provider’s latency and availability become part of QuickBite’s own checkout latency and availability. Dotted arrows are asynchronous batch flows. Payouts to restau-

rants and data exports run nightly and can be retried without users noticing. Each hexagon is a failure point outside your control. The maps provider is especially dangerous because both search (delivery-time estimates) and dispatch depend on it. Hexagons also bring rate limits and per-call costs, so scaling QuickBite may be limited by *contracts* rather than by servers.

WORKED EXAMPLE

Worked example — Inherited constraints from the boundary. Suppose the maps provider's contract allows 500 requests per second and charges $0.005 per route-time request. (These figures are assumptions for QuickBite, not any real provider's price list.)

1. If every restaurant listing in search results needs a live route-time estimate, and search peaks at 2,000 requests per second showing 20 restaurants each, QuickBite would need 2,000 × 20 = 40,000 route requests per second.
2. That is 40,000 / 500 = 80 times the contract limit.
3. Cost at that rate for one peak hour: 40,000 × 3,600 × $0.005 = $720,000.

Interpretation. Calling the maps provider per listing is impossible, regardless of how good the internal architecture is. **Engineering implication:** estimate delivery times internally, for example from precomputed travel-time grids per city zone, and call the provider only once per *placed order*. The boundary diagram exposed this constraint before any code was written.

Real-world industry applications

INDUSTRY EXAMPLE

C4 system-context diagrams. Simon Brown's C4 model makes the system-context diagram its first and most abstract level. It recommends showing the software system as one box with its users and the other software systems it depends on, and states that the diagram should be understandable by non-technical stakeholders. *Evidence: Primary* — [Brown C4]

Failure scenarios and misconceptions

Table 2.4 — Boundary failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Hidden dependency outage	An external system was never listed	Incident traced to an unlisted vendor	Add fallback; add it to the diagram	Inventory every outbound call
Rate-limit wall	Vendor limits not read	HTTP 429 errors at peak	Cache, batch, negotiate a higher tier	Step 4: record limits per external system
Scope creep	Boundary never agreed	Late "but we assumed you'd do X"	Re-plan	Explicit out-of-scope list signed off

COMMON MISTAKE

"External systems are always available." A third-party SaaS API typically promises somewhere between 99.9% and 99.99% availability, as of 2026. At 99.9% that is up to about 43 minutes of downtime per 30-day month. Your design must decide what QuickBite does during those minutes (§2.9).

2.5 Understanding and negotiating requirements

2.5.1 Eliciting and negotiating requirements

DEFINITION

Definition — Requirement. A statement of what the system must do (a **functional requirement**, e.g. "a customer can cancel an order before the restaurant accepts it") or how well it must do it (a **non-functional requirement**, e.g. "99% of order placements complete within 800 ms"). A requirement is **testable** if you could write an automated check or a measurement that proves it is met.

First-principles explanation

A customer asks a tailor for "a nice suit." A bad tailor starts cutting. A good tailor asks: for what occasion? Which climate? What budget? Ready by when? The good tailor is not being difficult. "Nice" can mean a hundred different suits, and only one of them is what the customer actually wants. Requirements gathering is the tailor's questions. **Negotiation** is the conversation that follows: "a hand-stitched suit by Friday for that budget is not possible, but a made-to-measure one is."

Why does this exist?

Vague requirements cause two opposite failures. **Under-engineering** builds a system that falls over on launch day because nobody asked how many users would arrive. **Over-engineering** spends six months building multi-region active–active replication for a prod-

uct with 200 users, because someone said “it must never go down.” Both come from the same root cause: a requirement nobody turned into a number.

Requirements also conflict. “Show the courier’s exact position in real time” pushes against “keep infrastructure costs under budget” and “protect courier privacy.” Someone has to decide how those conflicts are resolved, and the designer’s job is to make that decision *visible and deliberate*.

How it works internally

A reliable elicitation and negotiation procedure:

1. **Identify users and their top journeys.** For QuickBite: *browse and order*, *track delivery*, *restaurant accepts and prepares*, *courier delivers*.
2. **Write functional requirements as user-observable behaviors**, and rank them with **MoSCoW** priorities: Must, Should, Could, Won’t (this time).
3. **For each journey, ask the “-ility” questions** (§1.7): How many users? How fast? How available? How consistent? How durable? How secure? What does it cost?
4. **Quantify every non-functional requirement** as a metric, a threshold and a measurement window. “Fast” becomes “p99 < 800 ms measured over 5-minute windows”. The notation p99 means the 99th percentile: 99% of requests are faster than this value (§4.8).
5. **Differentiate by journey.** Availability and latency targets rarely need to be uniform. Checkout deserves a stricter target than the restaurant’s sales-history report.
6. **Surface conflicts and negotiate.** For each expensive requirement, show its cost and offer a cheaper alternative that still meets the underlying need.
7. **Record what was agreed, and what was explicitly rejected.**

Table 2.5 — QuickBite requirements after negotiation.

ID	Requirement (as first stated)	Negotiated, testable version	Priority
F1	“Customers can order food”	Customer can place an order of 1–30 items from one restaurant and pay by card or wallet	Must
F2	“Real-time tracking”	Courier position shown on a map, refreshed every 5 s; position at most 10 s old at p95	Must
F3	“Restaurants get orders instantly”	New order appears on the restaurant tablet within 5 s at p99	Must
F4	“Smart recommendations”	Deferred to phase 2; phase 1 shows “popular near you”	Won’t (now)
N1	“Never goes down”	Order placement available 99.95% per 30-day month; browsing 99.9%	Must
N2	“Fast”	Place-order p99 < 800 ms excluding payment-provider time; browse p99 < 300 ms	Must
N3	“Never lose an order”	Once the customer sees “order confirmed”, the order survives the loss of any single node or zone (RPO = 0 for orders)	Must
N4	“Never double-charge”	Each order is charged at most once, even if the client retries (idempotency, §22.15)	Must
N5	“Menus always correct”	Menu or price changes visible to customers within 60 s; price is re-checked at order time	Should

Notice what negotiation did to N1. “Never goes down” is impossible: no system reaches 100%. It was also unnecessary for most features. The negotiated version gives each journey its own target and makes the target measurable. RPO in N3 is the *recovery point objective,* the amount of recent data you may lose in a disaster (§39.8).

Mathematical foundations

The most useful number in a negotiation is the downtime a target actually allows.

FORMULA

Allowed downtime for an availability target

$$T_{down} = (1 - A) \times T_{period}$$

Symbol	Meaning	Units
T_{down}	Maximum downtime allowed in the period	minutes
A	Availability target, as a fraction	dimensionless (e.g. 0.9995)
T_{period}	Length of the measurement period	minutes

WORKED EXAMPLE

Worked example — What “three and a half nines” buys QuickBite. A 30-day month has 30 × 24 × 60 = 43,200 minutes.

1. Browsing at 99.9%: T_{down} = (1 − 0.999) × 43,200 = 0.001 × 43,200 = **43.2 minutes per month**.
2. Order placement at 99.95%: (1 − 0.9995) × 43,200 = 0.0005 × 43,200 = **21.6 minutes per month**.
3. A naive “five nines” (99.999%): 0.00001 × 43,200 = **0.43 minutes**, about 26 seconds per month.

Interpretation. Twenty-six seconds a month is less than the time a person takes to notice an alert, open a laptop and log in. Five nines requires fully automated detection and failover across independent zones or regions, which multiplies cost and complexity. **Engineering implication:** for a regional food-delivery start-up, 99.95% on checkout is ambitious but reachable with redundancy inside one region (§39.4). Five nines would be over-engineering, and the payment provider’s own availability probably caps the achievable number anyway (§2.9).

Real-world industry applications

INDUSTRY EXAMPLE

Service level objectives at Google. Google's Site Reliability Engineering book argues that 100% is the wrong reliability target for almost everything. Users cannot tell the difference between very high availability and 100%, because their own devices and networks are less reliable than that. Each extra nine costs a lot. Google's practice is to agree an explicit **service level objective (SLO)** with product owners and treat the remaining unreliability as an **error budget** to be spent on releasing features. This is requirement negotiation turned into an ongoing process (§39.6–39.7). *Evidence: Primary* — [Beyer et al. 2016]

Advantages, alternatives and trade-offs

Up-front negotiation costs meeting time, and stakeholders may not know the answers yet. When they do not, do not block. Make an assumption (§2.7), label it, and design so that it is cheap to change if wrong. In interviews, spend roughly the first five to ten minutes of a 45-minute session on requirements. In industry, requirements live in a design document (§2.12) and get re-negotiated as data arrives.

Failure scenarios

Table 2.6 — Requirements failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Launch-day overload	Peak load never quantified	Errors and latency spike at launch	Emergency scaling, load shedding (§22.9)	Ask "how many, at peak?"
Gold-plating	"Never down" accepted literally	Cost far exceeds the budget; delivery late	Simplify	Translate every adjective into a number
Silent conflict	Two stakeholders want contradictory things	Rework after review	Escalate with options and costs	Step 6: surface conflicts explicitly
Uniform targets	One SLO applied to all features	Expensive redundancy on unimportant paths	Tier the features	Step 5: differentiate by journey

Common misconceptions

COMMON MISTAKE

“Requirements are given to the designer.” In practice they are *discovered and negotiated* by the designer together with stakeholders. A designer who only takes orders will build exactly the wrong thing, very efficiently.

INTERVIEW TIP

Interview tip. Say your negotiated requirements out loud and write them on the board as numbers: “I’ll assume 2 million daily active users, checkout at 99.95%, tracking refreshed every 5 seconds — does that match what you have in mind?” Interviewers reward this because it shows you design *to a target*, not by habit.

2.6 Identifying bottlenecks

2.6.1 The resource model and the bottleneck

DEFINITION

Definition — Bottleneck. The resource whose capacity limits the throughput of the whole system for a given workload. Throughput cannot rise above the bottleneck’s capacity no matter how much the other resources are improved. Formally, it is the resource with the highest **service demand** per request (defined below).

First-principles explanation

Picture a highway that narrows from four lanes to one for a bridge. Widening the highway before or after the bridge to eight lanes changes nothing: cars still cross the bridge one lane at a time. The bridge is the bottleneck. Worse, traffic does not slow down evenly. It piles up in a queue *in front of* the bridge. That is why a system near its bottleneck shows rising latency long before it shows errors.

Two consequences follow, and they explain most performance work:

1. **Improving a non-bottleneck resource gives zero improvement in throughput.** Faster CPUs do not help if the database disk is the limit.
2. **Fixing the bottleneck moves it.** Once the bridge is widened, the next narrowest point becomes the new bottleneck. Performance work is a sequence of “find the bottleneck, relieve it, find the next one.”

Why does this exist?

Systems are made of finite resources. When a QuickBite lunch rush arrives, the first resource to run out decides whether customers see a spinner or an error. If you cannot name that resource, you will add capacity in the wrong place, and pay for servers that make no difference.

How it works internally: the resource model

Every request consumes a small amount of several **resources**. The classical hardware four plus one software category cover almost every case:

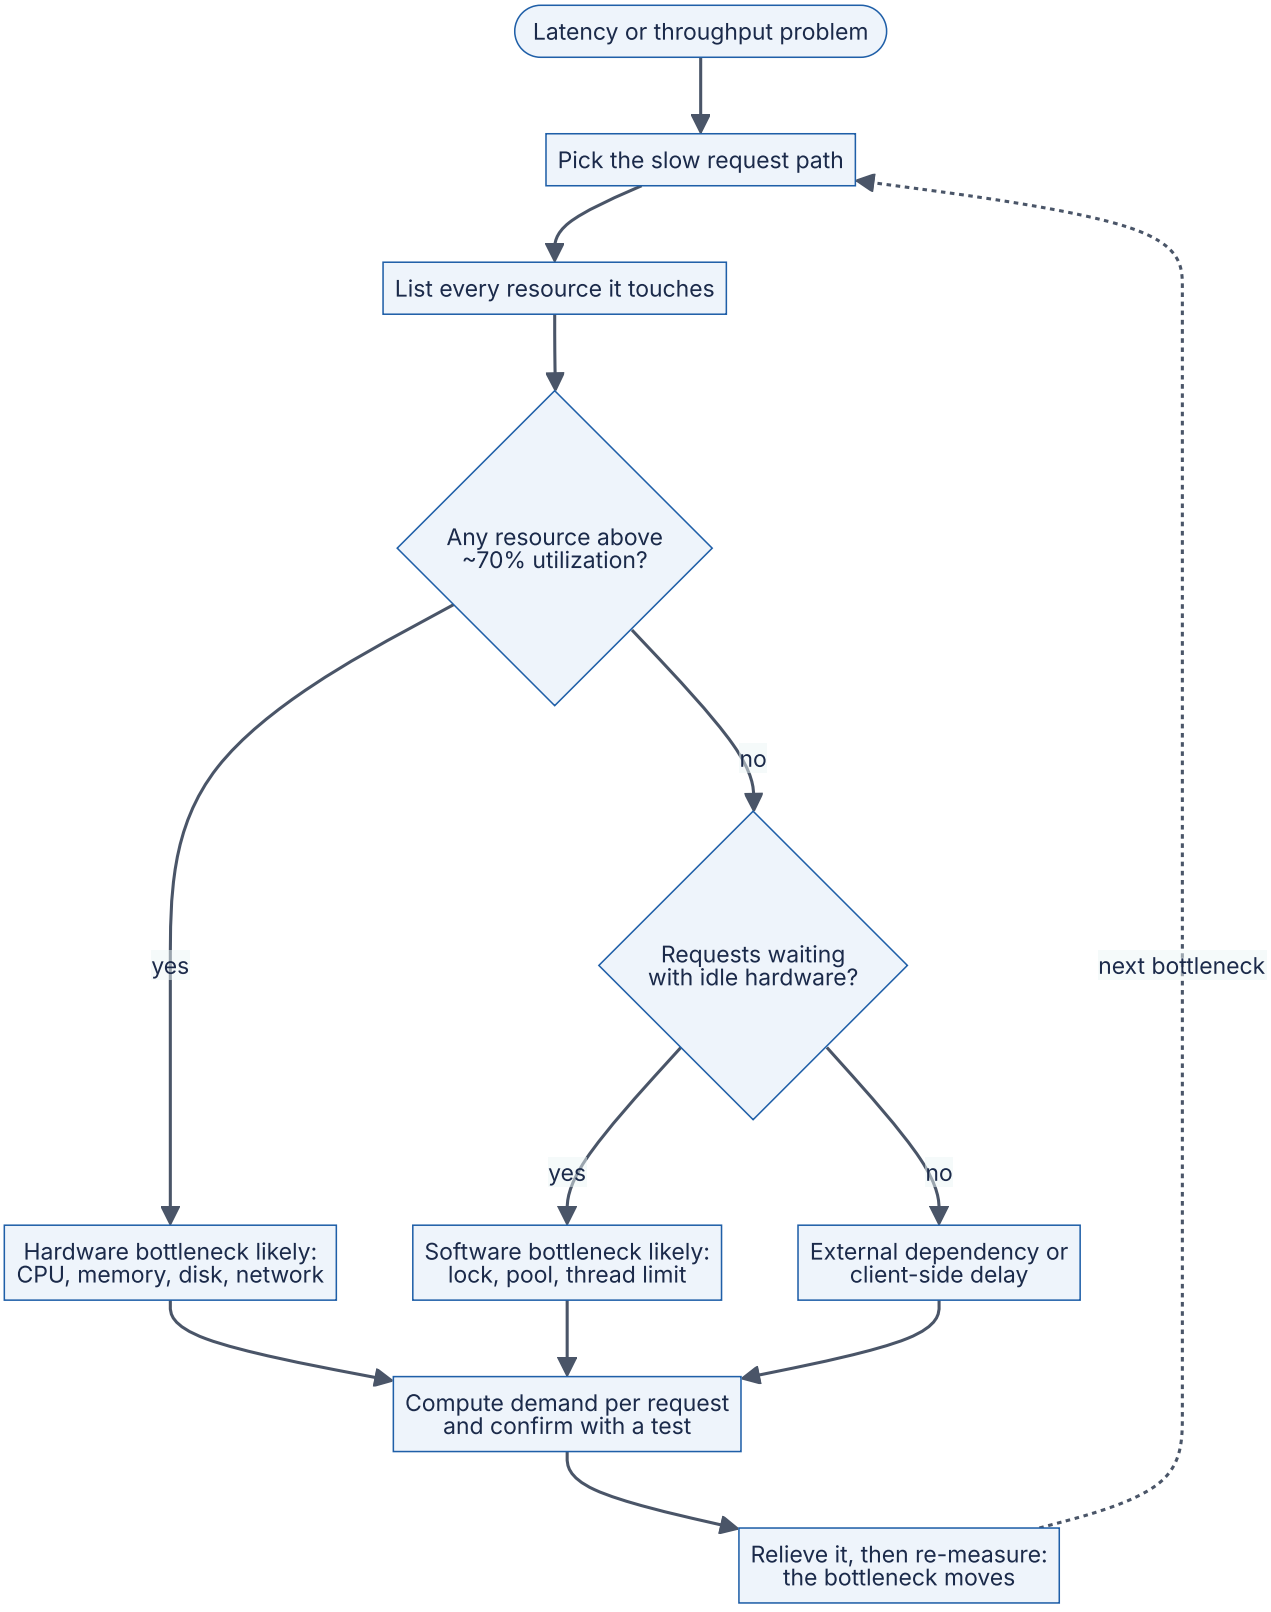
Table 2.7 — The resource model.

Resource	What a request consumes	Utilization signal	Saturation signal	Typical relief
CPU	Cycles for parsing, serialization, business logic, encryption	% busy per core	Run-queue length > core count	Optimize hot code, cache results, add cores or nodes
Memory	Working set, buffers, caches, per-connection state	% used	Swapping, OOM kills, GC pauses	Reduce footprint, add RAM, partition data
Disk	Reads and writes (IOPS), bytes per second, fsync latency	% time busy, IOPS used vs limit	Long I/O queue, rising await time	Cache, batch writes, faster media, partition
Network	Bytes in and out, packets, connections	Bandwidth used vs link capacity	Dropped packets, retransmits	Compress, CDN, bigger links, keep traffic local
Locks and other software resources	Exclusive access to a row, mutex, thread, connection-pool slot, file handle	Fraction of time held	Waiters queued; pool exhausted	Shorten hold time, finer-grained locks, bigger pools, partition the hot item

The last row is the one beginners miss. A **software resource**, such as a database row lock, a thread pool or a connection pool, is just as finite as a CPU. It can be the bottleneck while every hardware dashboard shows idle machines.

The standard diagnostic method is Brendan Gregg's **USE method**: for every resource, check **U**tilization, **S**aturation and **E**rrors [Gregg USE]. Figure 2.4 turns it into a procedure.

Figure 2.4 — Finding the bottleneck with the USE method.



Reading the diagram. This is a reasoning procedure, not a running system. You start from a symptom (stadium) and pick one slow request path, because bottlenecks are workload-specific: browsing and ordering have different ones. The first decision checks hardware utilization. Around 70% is a common warning threshold, because queueing delay grows steeply as utilization approaches 100% (§4.10). The second decision is the key di-

agnostic insight: *requests are waiting while the hardware is idle*. This almost always means a software resource such as a lock or a pool is saturated. If neither applies, the time is being spent outside your servers, for example in a third-party API or on a slow mobile network. Every branch leads to the same discipline: compute the demand per request and confirm the hypothesis with a measurement or load test (Chapter 23). The dotted edge back to the start is the loop that never ends: relieving one bottleneck exposes the next.

Mathematical foundations

Two laws from operational analysis of computer systems [Denning and Buzen 1978] are enough to find most bottlenecks with arithmetic alone.

FORMULA

Service demand, the utilization law and the bottleneck bound

$$D_i = V_i \times S_i \qquad U_i = X \times D_i \qquad X_{max} = \frac{c_i}{D_{max}}$$

Symbol	Meaning	Units
D_i	Service demand: total busy time one request places on resource i	seconds per request
V_i	Visits: how many times one request uses resource i	visits per request
S_i	Service time per visit to resource i	seconds per visit
U_i	Utilization of resource i, per unit of capacity	fraction (0–1)
X	System throughput	requests per second
c_i	Number of parallel units of resource i (e.g. cores)	units
X_{max}	Maximum throughput, set by the resource with the largest demand per unit	requests per second

The utilization law for a resource with c_i parallel units is $U_i = X \times D_i / c_i$. The bottleneck is the resource with the largest D_i / c_i.

FORMULA

Little’s Law (concurrency)

$$L = \lambda \times W$$

Symbol	Meaning	Units
L	Average number of requests in the system (or holding a resource) at once	requests
λ	Average arrival rate	requests per second
W	Average time each request spends in the system (or holds the resource)	seconds

Little’s Law holds for any stable system, regardless of the arrival pattern [Little 1961]. Full treatment in §4.11.

WORKED EXAMPLE

Worked example — Finding QuickBite's checkout bottleneck.

Situation. At dinner peak QuickBite receives 60 order placements per second (this number is derived in §2.11). Customers complain that checkout sometimes spins for 5 seconds and then fails, yet CPU dashboards show the database at only 25% utilization. The order transaction, as first written, does this:

1. Begin a database transaction.
2. Insert the order and its items.
3. Update the restaurant's row in `restaurant_load` to increment `open_orders` (used to stop accepting orders when a kitchen is overwhelmed). This takes a **row lock** until commit.
4. Call the payment service, which calls the payment provider. Average 300 ms.
5. Commit.

Measured per-order demands (assumed values for the exercise):

Table 2.8 — Per-order resource demand in the checkout path.

Resource	Demand per order D_i	Parallel units c_i	D_i/c_i	Max orders/s = $1/(D_i/c_i)$	Utilization at 60/s
API tier CPU	8 ms	32 cores	0.25 ms	4,000	60 × 0.25 ms = 1.5%
Database CPU	5 ms	8 cores	0.625 ms	1,600	3.8%
Database WAL disk (fsync)	2 ms	1 device	2 ms	500	12%
Network (25 KB per order, 10 Gbps link)	0.02 ms	1 link	0.02 ms	50,000	0.1%
DB connection pool (20 connections)	320 ms held	20	16 ms	62.5	96%
Row lock on one popular restaurant	320 ms held	1	320 ms	3.1	see below

Step 1 — Hardware. Every hardware resource is far below 70% utilization. The largest is the WAL disk at 12%, so hardware is not the bottleneck. Following Figure 2.4, "requests waiting with idle hardware" points to a software resource.

Step 2 — Connection pool, by Little's Law. Each order holds a database connection from step 1 to step 5: about 300 ms of payment time plus about 20 ms of database work, so W = 0.32 s. Then $L = \lambda \times W = 60 \times 0.32 =$ **19.2 connections busy on av-**

erage, out of a pool of 20. Utilization is 19.2 / 20 = 96%. Any burst above 62.5 orders/s (20 / 0.32) makes requests queue for a connection, and queueing at 96% utilization is severe (§4.10).

Step 3 — The row lock. A celebrity chef's restaurant runs a promotion and receives 8 orders per second. Each order holds that restaurant's row lock for 0.32 s, so the row can serve at most 1 / 0.32 = **3.1 orders per second**. Arrivals (8/s) exceed capacity (3.1/s), so the queue grows without bound until requests time out at 5 s. That matches the complaint exactly. This is the bottleneck for that workload: a single **hot row**.

Step 4 — Relieve it. Move the slow external call *out of* the database transaction. First authorize the payment, keyed by an idempotency key so retries cannot double-charge (§22.15). Then run a short transaction (insert order, update counter, commit) of about 15 ms. Then capture the payment, or publish an event to do so asynchronously.

Step 5 — Re-compute. Hold time W drops from 0.32 s to 0.015 s.

- Pool: $L = 60 \times 0.015 =$ **0.9 connections busy**, which is 4.5% of the pool.
- Hot row: maximum 1 / 0.015 ≈ **66 orders/s per restaurant**, comfortably above 8.
- The bottleneck has moved. It is now the WAL disk at 500 orders/s, about 8× headroom over today's peak. That is the next thing to watch as QuickBite grows (group commit and partitioning address it, §13.5 and Chapter 14).

Interpretation. Adding database servers or CPUs would have cost money and fixed nothing: the limit was a lock held during a network call. **Engineering implication:** never hold a lock or a pooled connection across a call to a slow or external system. In general, *hold time multiplied by arrival rate* (Little's Law) tells you how many units of any software resource you need.

Code example

A short, runnable script that turns the table above into a bottleneck report. Use it to check your own estimates.

```
        # Bottleneck finder using the utilization law (U = X * D / c).
        resources = {
            # name: (demand per request in seconds, parallel units)
            "api_cpu":   (0.008, 32),
            "db_cpu":    (0.005, 8),
            "wal_disk":  (0.002, 1),
            "network":   (0.00002, 1),
            "db_pool":   (0.320, 20),
            "hot_row":   (0.320, 1),
        }
        arrival_rate = 60.0  # requests per second

        for name, (demand, units) in sorted(
                resources.items(), key=lambda kv: kv[1][0] / kv[1][1], reverse=True):
            max_x = units / demand
            util = arrival_rate * demand / units
            flag = "SATURATED" if util >= 1 else ("HOT" if util >= 0.7 else "ok")
            print(f"{name:9s} max={max_x:9.1f}/s  util@{arrival_rate:.0f}/s={util:7.1%}
{flag}")
```

What to notice:

- Resources are sorted by D_i/c_i, so the first line printed is the bottleneck.
- `hot_row` shows a utilization above 100% (1920%) at 60/s, because the script applies the *whole* arrival rate to one row. That is the worst case where every order goes to a single restaurant. In the worked example only 8/s hit the hot row, which still exceeds its 3.1/s capacity. Edit the script to model per-key arrival rates.
- Changing `0.320` to `0.015` for the pool and the row reproduces Step 5 and shows the bottleneck moving to `wal_disk`.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **The USE method at Netflix and beyond.** Brendan Gregg developed the USE method while working on performance analysis and has published it, together with per-operating-system checklists, as a way to find resource bottlenecks quickly without guessing. It explicitly includes software resources such as mutex locks, thread pools and file descriptors alongside CPUs, memory, disks and network interfaces. *Evidence: Primary* — [Gregg USE], [Gregg 2020]

Alternatives and trade-offs

The USE method is resource-centric. Its complement is the **RED method** (Rate, Errors, Duration per service), which is request-centric and better for spotting *which* service is slow in a microservice graph. The two work well together (§23.3). Profiling (§23.4) finds

which code consumes a resource. Load testing (§23.5) confirms a bottleneck hypothesis empirically. The arithmetic above tells you where to point those tools.

Failure scenarios

Table 2.9 — Bottleneck-analysis failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Scaling the wrong tier	Added servers to a non-bottleneck	Throughput unchanged after scaling	Re-run USE analysis	Compute demand per resource first
Hot key or hot row	Skewed popularity, e.g. a viral restaurant	One key's latency far above the others	Shorten hold time, shard the counter	Model per-key rates, not just totals
Pool exhaustion	Long hold times, often across remote calls	"Timeout acquiring connection" errors with idle DB	Move remote calls out of transactions	Little's Law sizing
Retry amplification	Clients retry into a saturated resource	Load rises as success rate falls	Retry budgets, backoff with jitter (§22.12)	Cap retries; shed load

Common misconceptions

COMMON MISTAKE

"Low CPU means the system has spare capacity." CPU is one resource of five. QuickBite's checkout failed with every machine mostly idle, because the bottleneck was a lock. Always check software resources when latency is high and utilization is low.

COMMON MISTAKE

"Averages are enough." A system can be fine on average and saturated on one hot key, one shard or one minute of the day. Bottleneck analysis must use *peak* rates and *per-partition* rates (§14.10).

2.7 Making and stating assumptions

2.7.1 The assumption register

> DEFINITION
>
> **Definition — Design assumption.** A belief about the workload, the environment or the business that the design depends on but that has not yet been verified, for example “80% of requests are reads” or “the payment provider responds within 1 s at p99”. An assumption is **stated** when it is written down with its value, its source, your confidence in it and how it will be checked.

First-principles explanation

A weather forecaster does not refuse to forecast because tomorrow is unknown. She says “70% chance of rain,” which is an explicit, checkable statement of uncertainty. System designers face the same situation: you never have all the facts before you must design. The professional response is not to wait. It is to assume *out loud*, so that everyone can see which parts of the design rest on which beliefs.

Why does this exist?

Every design rests on assumptions anyway. The only choice is whether they are visible. Hidden assumptions are dangerous because nobody checks them, and when one turns out wrong, nobody knows which parts of the design must change. Stated assumptions turn surprises into planned decision points.

How it works internally

1. **Write each assumption as a number with a source.** “2 M daily active users (marketing forecast for year 1).”
2. **Rate confidence**: high (measured), medium (comparable data exists), low (guess).
3. **Do a sensitivity check.** Ask: *if this is wrong by 10×, does the design change?* Assumptions where the answer is “yes” are **load-bearing**.
4. **Attach a check and a tripwire** to every load-bearing assumption: how you will verify it, and the observed value that will trigger a redesign.
5. **Prefer designs that are robust to the assumptions you are least sure of.**

Table 2.10 — QuickBite assumption register (excerpt).

ID	Assumption	Value	Source	Confidence	Load-bearing?	Check and tripwire
A1	Daily active users	2 M	Business forecast	Low	Yes: sizes every tier	Weekly DAU dashboard; redesign review at 5 M
A2	Orders per DAU per day	0.25	Industry intuition	Low	Yes: order DB and payments	Measure in beta
A3	Busiest hour share of daily orders	20%	Assumed dinner peak	Medium	Yes: peak sizing	Hourly order histogram
A4	Courier location update interval	4 s	Product decision	High	Yes: location write load	Config value, reviewed with product
A5	Payment provider p99 latency	1 s	Vendor documentation	Medium	Moderate: timeouts, pools	Client-side latency histogram
A6	Average menu size	100 items × 1 KB	Sample of 50 menus	Medium	No: menus fit in memory even at 10×	Catalog size metric

The sensitivity column is the payoff. A6 is not load-bearing: all menus total about 5 GB (§2.11), and 50 GB would still fit in a small cache cluster, so being 10× wrong changes nothing structural. A4 *is* load-bearing: halving the interval to 2 s doubles the heaviest write path in the system.

WORKED EXAMPLE

Worked example — Sensitivity of the location tier to assumption A4. Peak active couriers are assumed to be 20,000.

1. Update interval 4 s: 20,000 / 4 = **5,000 writes/s**.
2. Product asks for 1 s “for smoother maps”: 20,000 / 1 = **20,000 writes/s**, 4× the load.
3. At an assumed 200 bytes per update including protocol overhead, ingress rises from 5,000 × 200 = 1 MB/s to 20,000 × 200 = 4 MB/s. That is modest for the network, but 4× the write operations for the store.

Interpretation. Network bandwidth is not the issue. The *write rate* to the location store is. **Engineering implication:** keep the 4 s interval on the server and have the client app *interpolate* the marker’s movement between updates. Customers see smooth motion at a quarter of the cost. The assumption register made this negotiation possible because the cost of the request was visible immediately.

INDUSTRY EXAMPLE

Assumptions in published design-review practice. Google's internal design-doc culture, as described by a Google engineer, asks authors to state context, goals and *non-goals*, and to discuss alternatives and trade-offs, so that reviewers can challenge the premises behind a design and not only its mechanics. *Evidence: Secondary* — [Ubl 2020]

Failure scenarios and misconceptions

Table 2.11 — Assumption failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Stale assumption	The world changed, e.g. a new market launched	Metrics drift past the tripwire	Run the redesign review	Tripwires on load-bearing assumptions
Assumption mistaken for fact	Repeated until nobody remembers it was a guess	Nobody can name its source	Re-label and re-check	"Source" and "confidence" columns
Average-case assumption	Peak and skew ignored	Outages at peaks or on hot keys	Add peak and skew factors	Always state a peak factor

COMMON MISTAKE

"Stating assumptions shows you don't know the answer." The opposite is true. In interviews and design reviews, explicit assumptions signal seniority. They show you know *which* unknowns matter and have a plan for each one.

2.8 Evaluating trade-offs

2.8.1 Weighted decision matrices

DEFINITION

Definition — Trade-off. A situation where improving one desired property of a system makes another worse. Examples: lower latency at higher cost, stronger consistency at lower availability during network partitions, faster delivery at higher operational risk. Every design decision is a trade-off. If you cannot name what an option makes worse, you have not understood it yet.

First-principles explanation

Buying a car means trading price against comfort, fuel economy against power, cargo space against parking ease. No car wins on everything. A sensible buyer decides *which properties matter most to them*, scores the candidates, and also notices how hard the choice is to undo: leasing for a year is easy to reverse, buying a car and selling it a month later loses money. System design decisions have exactly the same two dimensions, **weighted fit** and **reversibility**.

Why does this exist?

Without a method, design decisions are made by whoever argues loudest or by habit ("we always use X"). A structured method makes the criteria and their importance explicit. It lets people disagree about *weights* (a business question) separately from *scores* (an engineering question), and it leaves a record for the ADR (§2.12).

How it works internally: the weighted decision matrix

1. List the **options**, including "do nothing" or "the simplest thing" where it makes sense.
2. List the **criteria** that come from the requirements (§2.5), not from personal taste.
3. Assign **weights** that sum to 1 (or 100%), agreed with stakeholders.
4. **Score** each option against each criterion on a fixed scale, e.g. 1–5, with a one-line justification per score.
5. Compute weighted totals.
6. Run a **sensitivity check**: does the winner change if a weight moves by ±10 percentage points? If it does, the decision is close and the deciding factor should be discussed explicitly.
7. Check **reversibility** before committing (below).

This is a lightweight form of the concept-selection matrices used in engineering design, such as Pugh's method [Pugh 1991].

FORMULA

Weighted decision score

$$S_j = \sum_{i=1}^{n} w_i \times s_{ij}, \qquad \sum_{i=1}^{n} w_i = 1$$

Symbol	Meaning	Units
S_j	Total weighted score of option j	score points (same scale as s_{ij})
w_i	Weight of criterion i	fraction (0–1)
s_{ij}	Score of option j on criterion i	score points, e.g. 1–5
n	Number of criteria	count

WORKED EXAMPLE

Worked example — Modular monolith or microservices for QuickBite v1? The team is eight engineers and must launch in four months. Criteria and weights come from Table 2.5 and from business constraints.

Table 2.12 — Weighted decision matrix for QuickBite's deployment architecture.

Criterion	Weight	Modular monolith	Microservices (8 services)
Time to launch with 8 engineers	0.30	5	2
Operational simplicity	0.20	5	2
Independent scaling of hot paths	0.20	3	5
Failure isolation	0.15	3	4
Team autonomy as headcount grows	0.15	3	5
Weighted total	**1.00**	**3.90**	**3.35**

Arithmetic for the monolith: 0.30×5 + 0.20×5 + 0.20×3 + 0.15×3 + 0.15×3 = 1.50 + 1.00 + 0.60 + 0.45 + 0.45 = **3.90**. For microservices: 0.30×2 + 0.20×2 + 0.20×5 + 0.15×4 + 0.15×5 = 0.60 + 0.40 + 1.00 + 0.60 + 0.75 = **3.35**.

Sensitivity. Move 10 points of weight from time-to-launch to independent scaling (0.20 and 0.30). Monolith: 0.20×5 + 0.20×5 + 0.30×3 + 0.45 + 0.45 = 1.00 + 1.00 + 0.90 + 0.90 = **3.80**. Microservices: 0.20×2 + 0.20×2 + 0.30×5 + 0.60 + 0.75 = 0.40 + 0.40 + 1.50 + 1.35 = **3.65**. The monolith still wins, so the result is robust to a reasonable disagreement about weights.

A hybrid surfaces. The one criterion where the monolith loses badly is independent scaling, and §2.11 shows that the location path dominates write load. Deploying the **location service separately** and everything else as a modular monolith captures most of the scaling benefit at a fraction of the operational cost.

Interpretation. The matrix did not "decide". It made the reasoning inspectable and revealed a better third option. **Engineering implication:** record the matrix and the sensitivity result in the ADR, and name the trigger for revisiting it, for example "more than 30 engineers or more than 3 teams blocked on shared releases."

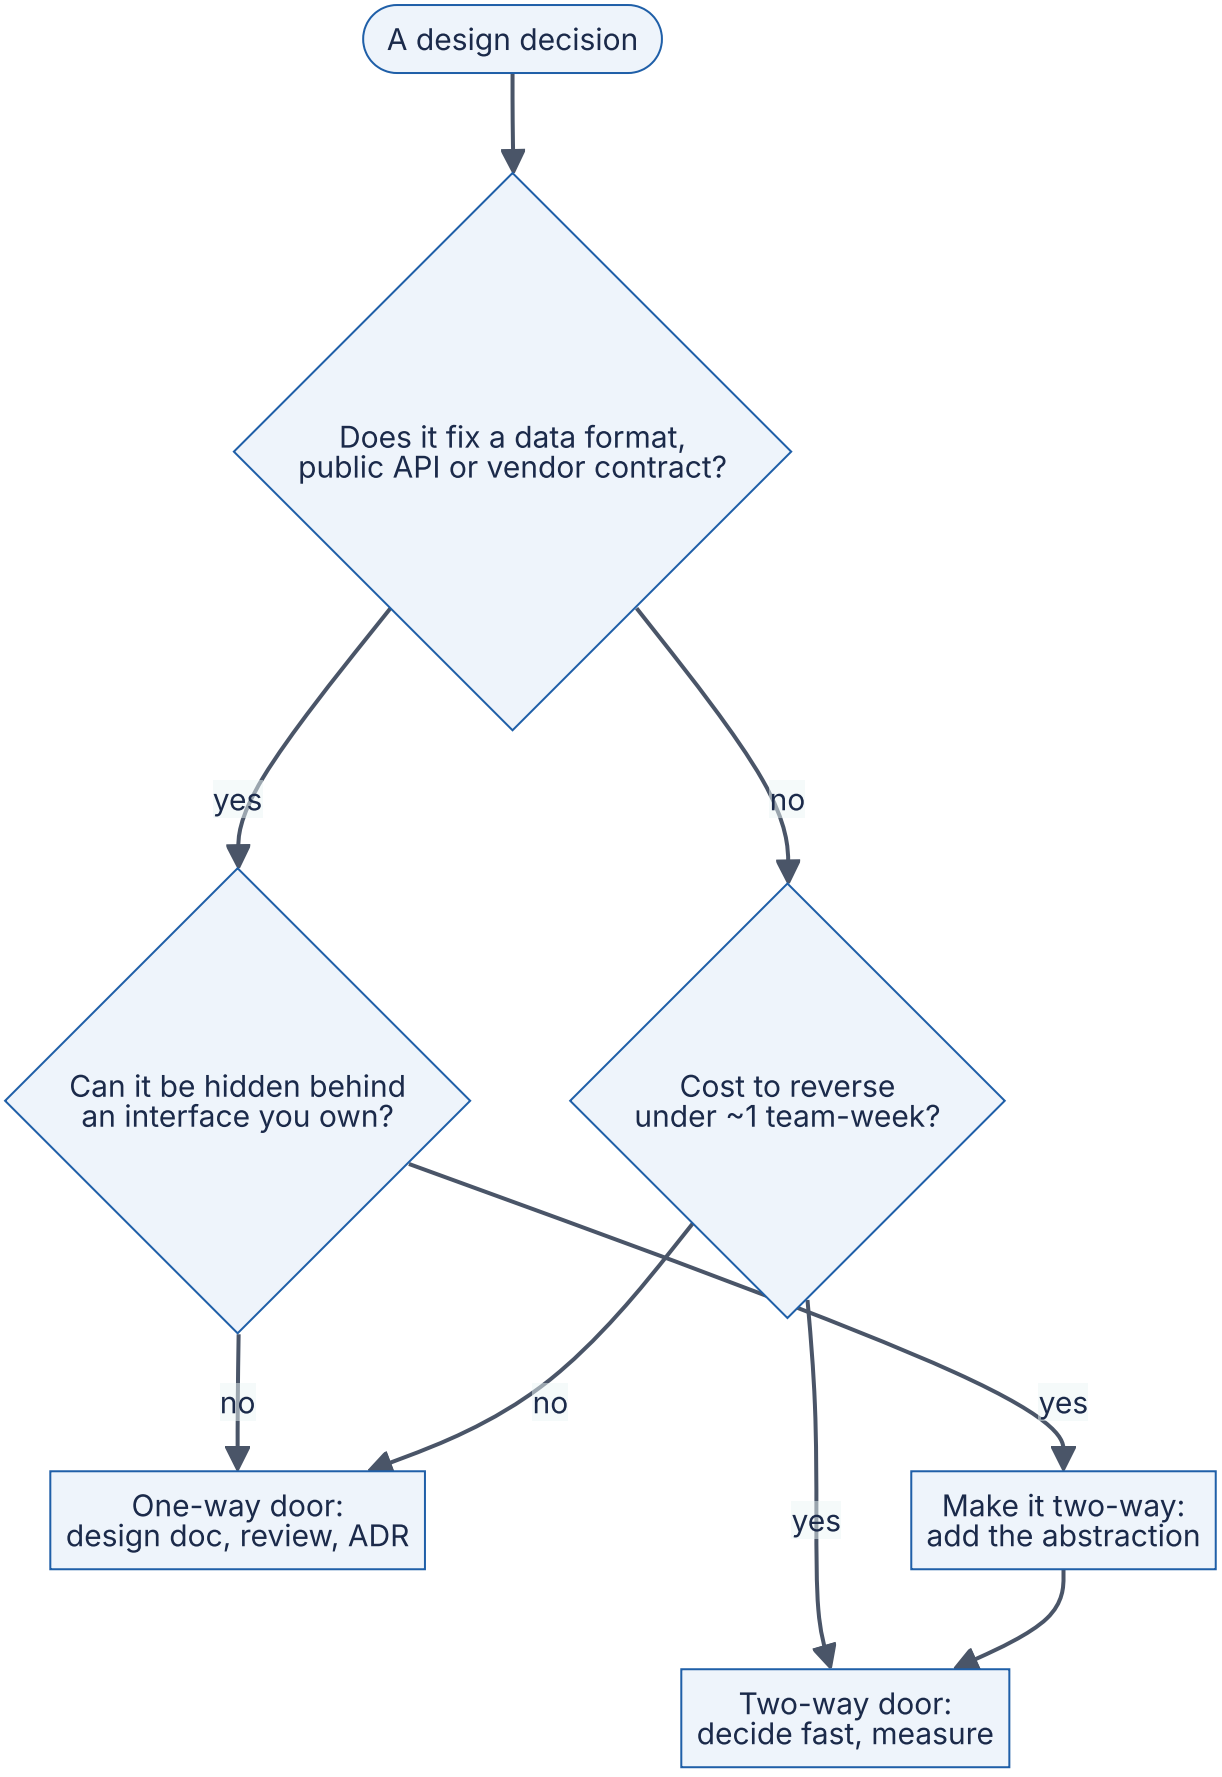
2.8.2 Reversibility: one-way and two-way doors

The matrix measures *fit*. It says nothing about the *cost of being wrong*. In his 2015 letter to shareholders, Jeff Bezos distinguished **Type 1** decisions, which are consequential and irreversible or nearly so ("one-way doors") and deserve slow, careful deliberation, from

Type 2 decisions, which are reversible (“two-way doors”) and should be made quickly by individuals or small groups with good judgment. He warned that large organizations tend to apply the heavyweight Type 1 process to Type 2 decisions, and that this causes slowness and too little experimentation [Bezos 2016].

In architecture, reversibility is mostly about **data and contracts**. Code behind a stable interface is cheap to change. Data formats that have accumulated years of records, and public APIs that thousands of clients depend on, are not.

Figure 2.5 — Choosing the decision process by reversibility.



A design decision
Does it fix a data format, public API or vendor contract?
yes
no
Can it be hidden behind an interface you own?
Cost to reverse under ~1 team-week?
no
no
yes
yes
One-way door: design doc, review, ADR
Make it two-way: add the abstraction
Two-way door: decide fast, measure

Reading the diagram. A decision (stadium) passes through up to three questions (diamonds). The first asks whether the decision fixes something that is costly to change later: stored data formats, public APIs, multi-year vendor contracts. If it does, the second asks whether an interface you own can hide it. A repository layer in front of the database, or an internal payment service in front of the payment provider, turns a one-way door into a two-way one (box T2). That is often the best move available. Decisions that fix nothing durable, and are cheap to reverse, are two-way doors: decide quickly and let measurement correct you. Everything else is a one-way door and earns the full process: a design document, a review and an ADR (§2.12). The "~1 team-week" threshold is a heuristic. Calibrate it to your organization. There is no software data flow here. The failure mode this procedure prevents is organizational: spending weeks debating a two-way door, or rushing a one-way door.

Table 2.13 — QuickBite decisions classified by reversibility.

Decision	Door	Why
Web framework for the catalog service	Two-way	Internal; can be rewritten behind the same API
Cache eviction policy	Two-way	A configuration change
Primary key and ID format for orders	One-way	Embedded in receipts, URLs, partner systems, years of data
Public order-status API shape for restaurant POS partners	One-way	External clients depend on it; versioning needed (§8.15)
Payment provider	One-way unless abstracted	Stored payment tokens are provider-specific
Monolith vs separate location service	Mostly two-way	Modular boundaries make extraction later feasible

INDUSTRY EXAMPLE

Amazon's Type 1 / Type 2 decisions. The two-door model comes from Amazon's 2015 shareholder letter. Bezos presented it as a way for a growing company to keep moving fast: reserve heavyweight deliberation for irreversible choices and push reversible ones down to small groups. *Evidence: Primary* — [Bezos 2016]

Alternatives, failure scenarios and misconceptions

Alternatives to a weighted matrix include simple **pros/cons lists** (fine for two-way doors), **Pugh matrices** (score relative to a baseline option, [Pugh 1991]) and formal methods such as the **Architecture Tradeoff Analysis Method (ATAM)** for large systems, which ties quality-attribute scenarios to architectural decisions [Bass et al. 2021].

Table 2.14 — Trade-off evaluation failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Matrix theater	Scores reverse-engineered to justify a choice already made	Justifications are vague	Re-score independently	Have two people score blind
Missing option	The best option was never listed	A reviewer proposes it late	Add and re-score	Always include "simplest thing" and a hybrid
Analysis paralysis on a two-way door	One process for every decision	Weeks of debate on reversible items	Time-box; pick and measure	Classify reversibility first
Rushed one-way door	Treated like a quick choice	Expensive migration later	Migration project	Figure 2.5 before deciding

COMMON MISTAKE

"There is a best architecture." There is only a best architecture *for a set of weighted requirements and constraints*. Change the team size, the deadline or the load, and the winner changes. This is why the requirements and assumptions behind a decision must be recorded alongside it.

2.9 Designing for failure

2.9.1 Failure as a normal event

DEFINITION

Definition — Designing for failure. Treating component failure as a *normal, expected event* rather than an exception. For every component and dependency, the design states what happens when it is slow, returns errors or disappears, and makes sure the **blast radius** (the set of users and features affected) is as small as possible.

First-principles explanation

Aircraft are not designed on the assumption that engines never fail. They are designed to fly on one engine. Buildings have fire doors that confine a fire to one section. Designing for failure applies the same idea to software: accept that every part *will* fail at some point, and decide in advance how the rest of the system keeps working.

Why does this exist?

At scale, failure is a matter of arithmetic, not bad luck. With 1,000 servers that each fail on average once every three years, the fleet sees roughly one failure a day ($1{,}000 / (3 \times 365) \approx 0.9$). Networks drop packets, disks wear out, deploys ship bugs and third parties

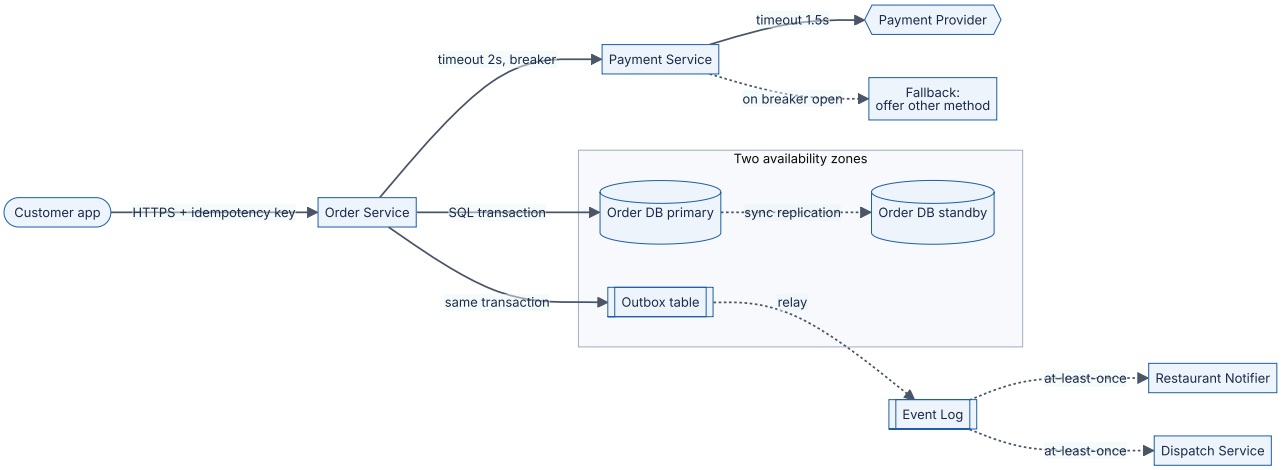
have outages. James Hamilton's widely cited guidance for internet-scale services starts from this premise: expect failures, and design every component so that failures are handled automatically and without drama [Hamilton 2007]. The "fallacies of distributed computing," such as "the network is reliable," catalog the assumptions that make systems brittle (§24.5).

How it works internally

A failure-mode walk-through, sometimes called a lightweight **failure mode and effects analysis (FMEA)**:

1. For each component and each arrow in the decomposition diagram, ask: *what if it is down? Slow? Returning wrong data?*
2. Decide the **desired behavior**: fail fast, retry, degrade gracefully or queue for later.
3. Apply standard mechanisms: **timeouts** on every remote call, **retries with backoff and jitter** only for idempotent operations, **circuit breakers** to stop calling a failing dependency, **bulkheads** to isolate resource pools (all in Chapter 22), **redundancy** across zones (§39.4) and **asynchrony** to take non-essential work off the critical path.
4. Remove things from the **critical path**, the chain of synchronous calls a user must wait for. Each item removed from it raises availability (formula below).

Figure 2.6 — QuickBite checkout designed for failure.



Reading the diagram. The customer's request carries an **idempotency key**, so a retry after a network error cannot create a second order or a second charge (requirement N4). The synchronous critical path is customer → order service → payment service → payment provider. Each hop has an explicit **timeout**, and the payment call sits behind a **circuit breaker**. If the provider is failing, the breaker opens and the customer is offered another payment method within milliseconds, instead of waiting for timeouts (dotted fallback). The order database runs inside a subgraph spanning two **availability zones**: a primary with a synchronously replicated standby, which meets N3 (RPO = 0). Instead of calling

the restaurant notifier and dispatch directly, the order service writes an event to an **outbox table** in the same transaction as the order (§32.5). A relay then publishes it to the event log. Restaurant notification and dispatch are therefore *off the critical path*: if either is down, orders still succeed, and the events are delivered when they recover (at-least-once, so consumers must be idempotent, §32.10). Remaining single points of failure to watch: the payment provider (mitigated by the fallback, or by a second provider later) and the event-log relay (mitigated by running two relays).

FORMULA

Availability of components in series

$$A_{series} = \prod_{i=1}^{n} A_i$$

Symbol	Meaning	Units
A_{series}	Availability of a request path that needs *all* n components	fraction (0–1)
A_i	Availability of component i	fraction (0–1)
n	Number of components on the synchronous path	count

This assumes independent failures. Parallel (redundant) components and correlated failures are treated in §4.14.

WORKED EXAMPLE

Worked example — Taking the restaurant notifier off the critical path. Assumed monthly availabilities: order service 99.95%, order DB 99.95%, payment provider 99.9%, restaurant notifier 99.9%.

1. Notifier called synchronously during checkout: 0.9995 × 0.9995 × 0.999 × 0.999 = 0.9990 × 0.9980 ≈ **0.9970**, i.e. 99.70%. That allows 0.003 × 43,200 ≈ **130 minutes** of checkout failure per month.
2. Notifier asynchronous via the outbox: 0.9995 × 0.9995 × 0.999 ≈ 0.9990 × 0.999 ≈ **0.9980**, i.e. 99.80%, about **86 minutes** per month.
3. Requirement N1 is 99.95%, or 21.6 minutes. Even the improved path misses it, because the payment provider alone allows 43 minutes.

Interpretation. A series chain can never be more available than its weakest link, and every extra synchronous dependency lowers the total. **Engineering implication:** either renegotiate N1 to exclude provider outages (a common SLO definition), or add a second payment provider in parallel. With two independent providers at 99.9% each, the pair is unavailable only when both fail: 1 − (0.001 × 0.001) = 99.9999%. This is a one-way-door-sized decision for a start-up (contracts, token migration), so it goes through Figure 2.5.

INDUSTRY EXAMPLE

Netflix's Chaos Monkey. Netflix publicly described the "Simian Army," starting with Chaos Monkey, a tool that randomly terminates production instances during business hours. Because engineers know instances will disappear, they must build services that tolerate it, and weaknesses are found while engineers are at work rather than at 3 a.m. This is designing for failure enforced by continuous practice (§39.11). *Evidence: Primary* — [Izrailevsky and Tseitlin 2011]

Table 2.15 — Failure scenarios for QuickBite checkout.

What goes wrong	Why	Detection	Recovery	Prevention
Payment provider outage	External dependency	Error rate on provider calls; breaker opens	Fallback method; queue payment capture	Second provider; breaker
Duplicate order on retry	Client retried after a timeout	Two orders with the same cart and customer	Refund the duplicate	Idempotency key (N4)
Order DB primary lost	Hardware or zone failure	Health checks, replication monitor	Automatic failover to standby	Synchronous standby in another zone
Event relay stalls	Bug or crash	Outbox backlog age metric	Restart; events retained in outbox	Two relays; alert on backlog age
Retry storm	Many clients retry at once	Load spikes as success falls	Shed load, open breakers	Exponential backoff with jitter, retry budgets

COMMON MISTAKE

"Redundancy alone makes a system reliable." Two replicas that share a power supply, a configuration push or a software bug fail together. Redundancy only helps against *independent* failures, so look for correlated ones: same zone, same deploy, same dependency.

2.10 Reasoning about scale

2.10.1 Orders of magnitude

DEFINITION

Definition — Order of magnitude. A factor of ten. Two quantities differ by k orders of magnitude when their ratio is about 10^k. Reasoning in orders of magnitude means estimating only the *power of ten* of a quantity (is it 10, 1,000 or 1,000,000 requests per second?) because that, not the exact value, decides the architecture.

First-principles explanation

Cooking dinner for 4 people, for 40 and for 4,000 are not the same task done more times. For 4 you use your home kitchen. For 40 you need a rented hall, borrowed pans and helpers. For 4,000 you need an industrial kitchen, refrigerated trucks, food-safety inspections and shift managers. Each 10× step changes the *kind* of solution, not just its size. Software behaves the same way, and this is why experienced designers first ask "what order of magnitude?"

Why does this exist?

Most design choices are insensitive to a factor of 2 but sensitive to a factor of 10. A single PostgreSQL primary comfortably handles QuickBite's 60 orders per second. At 600 it needs careful tuning and read replicas. At 6,000 it likely needs partitioning (Chapter 14). Knowing the order of magnitude tells you which of these architectures you are in, and how far you are from the next one.

How it works internally

1. Estimate the key rates and sizes to within a factor of about 3 (§2.11).
2. Compare them with reference capacities (Table 2.17 and §4.17) to find which tier is closest to a limit.
3. For each 10× step of growth, ask which components hit a *qualitatively* new problem.

Table 2.16 — What changes for QuickBite at each order of magnitude.

Scale	Orders/day	Peak orders/s	What breaks or changes	Typical response
1× (one city)	5,000	~0.6	Nothing; one server and one DB suffice	Modular monolith, managed DB with standby
10× (region)	50,000	~6	Browse reads dominate; menu queries load the DB	Cache menus, CDN for images (Chapters 20–21)
100× (country)	500,000	~60	Location writes (~5,000/s); hot restaurants; payment pool sizing	Separate location store; short transactions; async events
1000× (multi-country)	5,000,000	~600	Single order-DB write limits; data residency laws; multi-region latency	Partition orders by city or region; regional cells (§33.12, Chapter 44)

WORKED EXAMPLE

Worked example — Where does QuickBite's single order database run out? From §2.6 the WAL disk caps the order DB at about 500 orders/s, assuming 2 ms of fsync demand per order.

1. At 100× (today's design point) peak is 60 orders/s: utilization = 60 / 500 = 12%.
2. At 1000× peak is 600 orders/s: 600 / 500 = 120%, so the database saturates.
3. Group commit, which flushes many transactions in one fsync, might cut per-order disk demand 4× (an assumed factor), giving 2,000 orders/s capacity and 30% utilization at 1000×. That buys roughly one more order of magnitude.

Interpretation. The current design has about 8× headroom on its most constrained resource. **Engineering implication:** no partitioning work is needed now (that would be over-engineering), but partitioning by city should be *designed* before order volume reaches about 5× today's level, giving time to build it.

INDUSTRY EXAMPLE

"Design for 10× growth, plan to rewrite before 100×." Jeff Dean of Google has given talks on building large distributed systems in which he advises designing for about ten times the current scale while expecting a significant redesign before about a hundred times. The point is that one architecture rarely spans more than one or two orders of magnitude gracefully. *Evidence: Secondary* — talk slides; see Open verification items. [Dean 2009]

COMMON MISTAKE

"Design for Google scale from day one." Designing QuickBite v1 for 1000× its launch load would cost months of extra work, and the assumptions it relied on would likely be wrong by the time that scale arrived. Design for the next order of magnitude, keep the one after that *possible*, and use tripwires (§2.7) to know when to start.

2.11 Back-of-the-envelope capacity estimation

2.11.1 The estimation method

DEFINITION

Definition — Back-of-the-envelope estimation. A quick calculation, done with round numbers and stated assumptions, that gives the order of magnitude of a system's load and resource needs (requests per second, storage, bandwidth, memory, number of nodes). The aim is to be within a factor of about 2–3 of the truth with a few minutes of arithmetic. This section introduces the method. Chapter 89 is the full handbook.

First-principles explanation

Enrico Fermi famously estimated quantities such as the number of piano tuners in Chicago by multiplying a chain of reasonable guesses: population, households with pianos, tunings per year, tunings a tuner can do. The individual errors partly cancel out, and the answer lands near the right power of ten. Capacity estimation is the same technique applied to users, requests and bytes.

Why does this exist?

Estimation tells you *which architecture you are in* (§2.10) before you spend money. It also exposes surprises early. In QuickBite's case, the largest write load turns out to be courier GPS updates, not orders, a fact that reshapes the decomposition.

How it works internally

1. Write down the assumptions (they come from the register in §2.7).
2. Convert daily volumes to an **average rate**, then to a **peak rate**.
3. Multiply by **per-request sizes** to get bandwidth, and by **retention** and **copies** to get storage.
4. Divide peak load by **per-node capacity at a target utilization** to get node counts, then add spare capacity for failures.
5. Round sensibly, compare against reference capacities, and name the dominant cost or bottleneck.

FORMULA

Average and peak request rate

$$R_{avg} = \frac{U \times a}{86,400} \qquad R_{peak} = \frac{U \times a \times h}{3,600} \times b$$

Symbol	Meaning	Units
R_{avg}	Average request rate over a day	requests/s
R_{peak}	Design peak request rate	requests/s
U	Daily active users	users
a	Actions of this type per user per day	requests/user/day
h	Share of daily volume in the busiest hour	fraction
b	Burst factor above the busiest-hour average	dimensionless
86,400 / 3,600	Seconds per day / per hour	s

FORMULA

Storage and node count

$$S = n_{day} \times s \times T \times k \qquad N = \lceil \frac{R_{peak}}{c \times u} \rceil + N_{spare}$$

Symbol	Meaning	Units
S	Total storage needed	bytes
n_{day}	Records created per day	records/day
s	Size per record, including indexes and overhead	bytes
T	Retention period	days
k	Number of stored copies (replication)	dimensionless
N	Nodes needed	nodes
c	Throughput one node sustains	requests/s
u	Target utilization, leaving head-room for queueing (§4.10)	fraction
N_{spare}	Extra nodes so a failure or deploy does not overload the rest	nodes

Table 2.17 — Rough reference capacities for estimation (order of magnitude only, as of 2026).

Resource	Rough capacity	Note
Round trip within one datacenter	~0.1–0.5 ms	See §4.17 and Appendix F for dated values
Round trip across a continent	~50–100 ms	Bounded by the speed of light in fiber
Stateless API node, simple JSON requests	~10^3 RPS	Varies by 10× with language and work per request
Relational DB primary, simple indexed writes	~10^3–10^4 writes/s	Depends on fsync, schema, hardware
In-memory key-value store node	~10^5 ops/s	Small values, pipelining helps
1 Gbps network link	125 MB/s	1 Gbps ÷ 8 bits per byte

These numbers are deliberately rough. Measure your own system before relying on any of them.

WORKED EXAMPLE

Worked example — Full capacity estimate for QuickBite (the 100× design point). SI units throughout (1 KB = 10^3 bytes).

Assumptions (from Table 2.10, plus new ones marked "new"). U = 2,000,000 DAU. Orders a = 0.25 per DAU per day. Browse reads 30 per DAU per day (new). Busiest-hour share h = 0.20 for both. Burst factor b = 2 (new; covers promotions). 20,000 couriers active at peak, updating every 4 s. Order record 2 KB including items and status history (new). Average browse response 20 KB with images served separately by a CDN (new).

Step 1 — Orders. - Daily: 2,000,000 × 0.25 = **500,000 orders/day**. - Average: 500,000 / 86,400 ≈ **5.8 orders/s**. - Busiest hour: 500,000 × 0.20 = 100,000 orders in one hour; 100,000 / 3,600 ≈ 27.8 orders/s. - Design peak: 27.8 × 2 ≈ 55.6, rounded up to **60 orders/s**. This is the figure used in §2.6.

Step 2 — Browse reads. - Daily: 2,000,000 × 30 = 60,000,000 reads/day. Average: 60,000,000 / 86,400 ≈ **694 RPS**. - Busiest hour: 60,000,000 × 0.20 / 3,600 ≈ 3,333 RPS. Design peak: × 2 ≈ **7,000 RPS** (rounded up). - Read-to-order ratio at peak: 7,000 / 60 ≈ 117:1. Browsing is read-heavy and highly cacheable.

Step 3 — Courier locations and tracking. - Writes at peak: 20,000 / 4 s = **5,000 writes/s**. That is about 83× the order write rate, so this is the dominant write path. - Orders in the delivery leg at once, by Little's Law (§2.6): arrivals 27.8 orders/s × 900 s average delivery leg (15 min, new assumption) ≈ **25,000 orders**. - Tracking reads: if half of those customers have the app open and it refreshes every 5 s, 25,000 × 0.5 / 5 = **2,500 reads/s**.

Step 4 — Storage. - Orders: 500,000 × 2 KB = 1 GB/day. Over 5 years: 1 GB × 365 × 5 ≈ 1.8 TB. Add 50% for indexes: ≈ 2.7 TB. Two copies (primary + standby): **≈ 5.5 TB**. One database server can hold this. - Locations: assume 6,000 couriers active on average across the day, giving 6,000 / 4 = 1,500 writes/s. Per day: 1,500 × 86,400 = 129.6 million points. At 100 bytes each: ≈ 13 GB/day. Keep 30 days hot: 13 × 30 ≈ **390 GB**, then downsample to an archive. - Menus: 50,000 restaurants × 100 items × 1 KB = **5 GB**, small enough to cache entirely in memory (§20.3).

Step 5 — Bandwidth. - Browse egress at peak: 7,000 × 20 KB = 140 MB/s = 140 × 8 = **1.12 Gbps**, which needs more than one 1 Gbps link or a load balancer tier with 10 Gbps links. - Location ingress: 5,000 × 200 bytes = 1 MB/s = **8 Mbps**, negligible.

Step 6 — API nodes for browsing. With c = 1,000 RPS per node, u = 0.6 and N_spare = 2 (one zone or one deploy batch down): 7,000 / (1,000 × 0.6) = 11.7, rounded up to 12, plus 2 = **14 nodes**.

Step 7 — Interpretation.

Table 2.18 — QuickBite estimate summary (100× design point).

Quantity	Value	Dominant consequence
Peak orders	60/s	One relational primary is enough (§2.6: ~500/s limit)
Peak browse reads	7,000 RPS	Cache menus; ~14 API nodes
Peak location writes	5,000/s	Separate, in-memory, partitioned location store
Tracking reads	2,500/s	Serve from the location store, not the order DB
Order storage (5 years, 2 copies)	~5.5 TB	Single DB cluster fine; plan partitioning at ~5×
Location storage (30 days hot)	~390 GB	Time-partitioned; expire old data with a TTL
Peak egress (API, excluding images)	~1.1 Gbps	CDN for images; 10 Gbps load balancer links

Engineering implication. The estimate confirms the decomposition in Figure 2.2. It also justifies the one deviation from the monolith in §2.8: location must scale independently because it carries about 83× the write rate of orders. Nothing here needs partitioning yet, and that is as important to know as what does.

COMMON MISTAKE

"Estimation needs precise numbers." Round aggressively: 86,400 ≈ 10^5 seconds per day is fine for a first pass. What matters is stating assumptions, keeping units consistent and reaching the right power of ten. Spending ten minutes on the third significant digit while never computing peak load is the classic mistake.

2.12 Architecture documentation

2.12.1 Structure and rationale

DEFINITION

Definition — Architecture documentation. The written and diagrammed record of a system's structure and of the decisions that shaped it. It is written so that people who were not in the room (new team members, reviewers, your future self) can understand *what* the system is and *why* it is that way.

First-principles explanation

A map of a city at one scale cannot answer every question. You need a country map to see where the city is, a city map to see districts, and a street map to find a door. Architecture documentation works the same way: diagrams at several zoom levels for *structure*, and a logbook of decisions for *reasons*. Without the logbook, the next team sees a strange design choice and "fixes" it, reintroducing the problem it solved.

Why does this exist?

Knowledge in heads leaves when people do. Design decisions also tend to be revisited endlessly when their reasons are not written down. Three lightweight artifacts cover most needs:

Table 2.19 — Three architecture documentation artifacts.

Artifact	Answers	Written when	Lifetime
C4 diagrams	What are the parts and how do they connect, at each zoom level?	Before building; updated as the system changes	Living
Design document	What problem, what design, what alternatives, what risks?	Before a significant piece of work	Snapshot, then archived
Architecture Decision Record (ADR)	What did we decide, in what context, with what consequences?	At each significant decision	Immutable; superseded, never edited

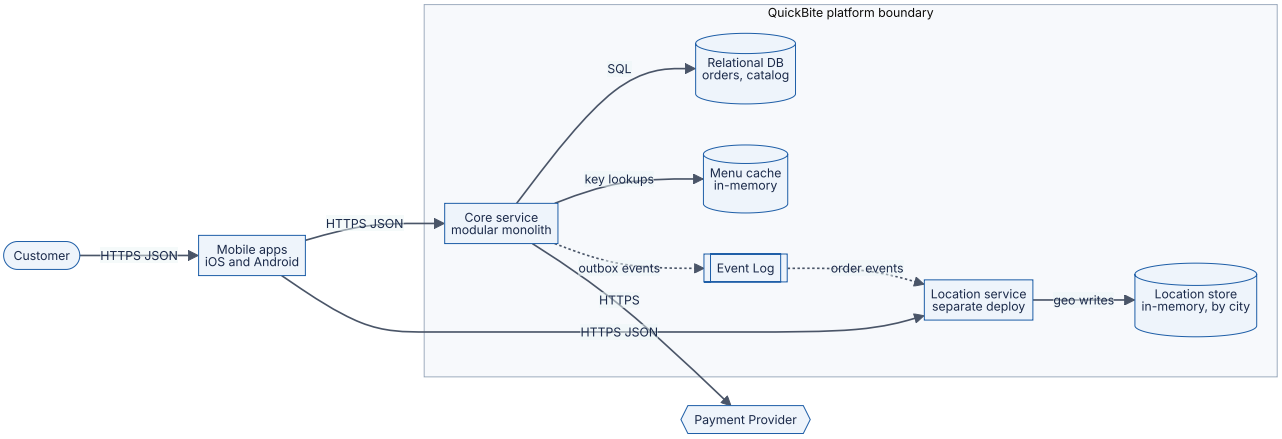
2.12.2 The C4 model

The **C4 model**, created by Simon Brown, describes a software system at four zoom levels [Brown C4]:

1. **Context.** The system as one box, with its users and external systems (Figure 2.3).
2. **Containers.** The separately deployable or runnable units (applications, databases, queues) and the technologies and protocols between them. In C4, "container" means a runtime unit, not specifically a Docker container.
3. **Components.** The major building blocks inside one container.
4. **Code.** Classes and functions. This level is usually generated from code or skipped.

This book draws C4 views with standard flowchart diagrams rather than an experimental C4 diagram syntax (see the style guide).

Figure 2.7 — QuickBite C4 container view, after the §2.8 decision.



Reading the diagram. This is C4 level 2 for QuickBite after the trade-off decision in §2.8. The **mobile apps** are containers too, because they are separately deployed runtime units. The subgraph is the platform's deployment boundary, matching the single box in Figure 2.3. The **core service** is the modular monolith: catalog, orders, payments, dispatch and notifications run in one process with internal module boundaries from Table 2.1. It talks SQL to the relational database (storage boundary for orders and catalog) and does key lookups against an in-memory **menu cache**, which keeps 7,000 browse RPS off the database (§2.11). The **location service** is deployed separately because of its 5,000 writes/s. It stores positions in an in-memory store partitioned by city and learns which courier is on which order from asynchronous order events (dotted). Synchronous paths (solid) are user-facing. Asynchronous paths (dotted) tolerate delay. Failure points match §2.9: the payment provider (external), the relational DB (standby in a second zone) and the event log. Scaling options: add core-service nodes horizontally, add location-store partitions per city, and later extract further modules into services if the tripwires from §2.7 fire.

2.12.3 Design documents

A **design document** (also called an RFC or a tech spec) is written *before* significant work, so that reviewers can find problems while changes are still cheap. Google engineers describe a widely copied structure: context and scope, goals and non-goals, the design itself, alternatives considered, and cross-cutting concerns such as security, privacy and observability [Ubl 2020]. A minimal skeleton:

```
Title, author(s), reviewers, status, date
1. Context and scope        - what exists today, what problem we solve
2. Goals and non-goals      - testable requirements (Table 2.5 style)
3. Assumptions              - register with confidence and tripwires (Table 2.10)
4. Estimates                - capacity numbers (Table 2.18)
5. Design                   - C4 context and container diagrams; APIs; data model
6. Alternatives considered  - decision matrix, reversibility (Table 2.12, Figure 2.5)
7. Failure modes            - FMEA table (Table 2.15)
8. Cross-cutting concerns   - security, privacy, observability, cost
9. Rollout and migration    - phases, flags, rollback plan
10. Open questions
```

What to notice:

- Sections 2–7 map directly onto the thinking tools of this chapter. A design document is the written output of the thinking loop in Figure 2.1.
- “Non-goals” and “Alternatives considered” are the sections reviewers value most, because they show what was rejected and why.

2.12.4 Architecture Decision Records

An **Architecture Decision Record (ADR)** is a short text file recording *one* significant decision. Michael Nygard’s original format has five parts: title, status, context, decision and consequences [Nygard 2011]. ADRs are numbered, stored in the code repository next to the code they affect, and never edited after acceptance. A changed decision gets a *new* ADR that **supersedes** the old one, so the history of reasoning is preserved.

```
ADR-007: Deploy the location service separately from the core monolith

Status: Accepted (2026-10-30). Supersedes: none.

Context: Peak location writes are estimated at 5,000/s, about 83x peak order
writes (design doc section 4). The core service is a modular monolith chosen
by weighted matrix (score 3.90 vs 3.35 for microservices; robust to +/-10 pt
weight changes). Location is the only module whose load profile differs by
more than 10x from the rest.

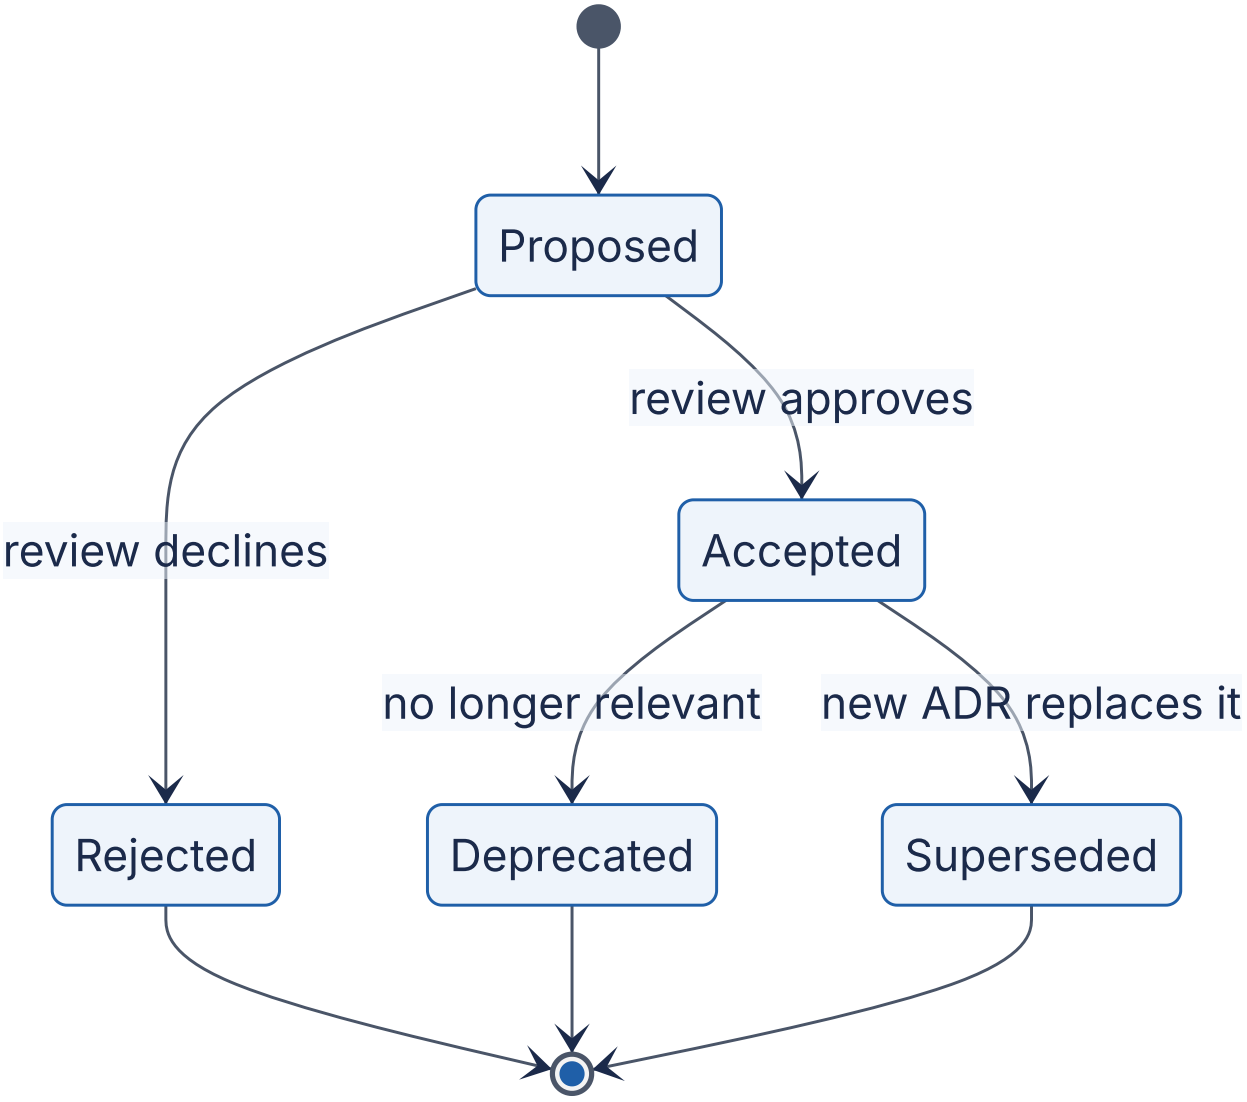
Decision: Run the location module as its own deployable service with its own
in-memory, city-partitioned store. All other modules remain in the monolith.

Consequences: (+) location scales independently; a location outage cannot
block checkout. (-) one more deployment pipeline and on-call surface; courier
assignment data reaches it asynchronously, with seconds of lag.
Revisit if: engineering headcount exceeds 30, or another module's peak load
exceeds 1,000 writes/s.
```

What to notice:

- The **context** carries the numbers and assumptions. Without them, a future reader cannot tell whether the decision is still valid.
- **Consequences** list the downsides honestly. An ADR with only positives is a sales pitch, not a record.
- “Revisit if” turns the assumption tripwires of §2.7 into an explicit trigger.

Figure 2.8 — ADR life cycle.



Reading the diagram. Each state is the *status* field of an ADR, not a running software component. An ADR starts as **Proposed**, often in a pull request, so that review happens with the usual code-review tooling. Review moves it to **Accepted** or **Rejected**. Rejected ADRs are kept, because knowing an option was considered and declined saves future debate. An accepted ADR is never rewritten. When circumstances change it becomes **Superseded**, with a link to the new ADR, or **Deprecated** if the thing it governed no longer exists. All transitions are human, asynchronous actions. The failure mode is decay:

ADRs that are never updated to Superseded make the record misleading, so check ADR status during design reviews.

INDUSTRY EXAMPLE

ADRs and C4 in practice. Nygard's 2011 post proposed ADRs as a lightweight alternative to large architecture documents that nobody reads, and the format has since spread widely, with open-source templates and tooling. Simon Brown's C4 model is likewise published openly with notation guidance and is used to standardize diagrams across teams. *Evidence: Primary* — [Nygard 2011], [Brown C4]

Table 2.20 — Documentation failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Diagram drift	Diagrams not updated with the code	New joiners find components missing	Redraw from the running system	Diagrams in the repo; review with code changes
Lost rationale	Decisions made in chat or meetings	"Why is it like this?" has no answer	Write retroactive ADRs	ADR required for one-way doors
Unreadable tome	80-page document nobody reads	No review comments	Split into C4 views plus ADRs	Keep docs short; link out to details

COMMON MISTAKE

"Documentation slows us down." Writing an ADR takes about half an hour. Re-arguing an undocumented decision, or reversing it by accident, costs days. Document one-way doors always and two-way doors only when they are surprising.

2.13 Summary and revision notes

SUMMARY

- **Design is a loop, not a line** (Figure 2.1): requirements → boundary → assumptions → estimates → decomposition → bottlenecks → failure → trade-offs → documentation, repeated at higher resolution until the design is good enough *for the risk*.
- **Decompose** by business capability, data ownership, load profile and likely change (information hiding). One sentence of responsibility per component. One owner per data store.
- **Draw the boundary first.** External systems bring availability, latency, rate limits and costs you do not control. QuickBite's maps contract ruled out per-listing route calls before any code existed.
- **Turn adjectives into numbers.** "Never down" became 99.95% for checkout (21.6 min/month). "Real-time" became a 5 s refresh with at most 10 s staleness.
- **The bottleneck is the resource with the largest demand per unit of capacity.** Check CPU, memory, disk, network *and* software resources (locks, pools). Utilization law: $U = X \times D/c$. Little's Law: $L = \lambda W$. QuickBite's checkout was limited by a row lock held across a payment call, not by hardware.
- **State assumptions** with source, confidence, sensitivity and a tripwire. A load-bearing assumption is one where a 10× error changes the design.
- **Evaluate trade-offs** with a weighted matrix plus a sensitivity check. Then classify reversibility: one-way doors get deliberation and an ADR, two-way doors get speed.
- **Design for failure.** Timeouts, idempotent retries, circuit breakers, redundancy across zones, and moving work off the critical path. A series path's availability is the product of its parts.
- **Think in orders of magnitude.** Each 10× brings qualitatively new problems. Design for the next 10×, keep the following one possible.
- **Estimate on the back of an envelope.** Average → peak → bandwidth → storage → nodes. QuickBite's heaviest write path is courier location (5,000/s), about 83× its order writes.
- **Document** structure with C4 (context, containers, components, code), plans with design docs, and decisions with immutable, superseding ADRs.

2.14 Knowledge checkpoint

1. Name four criteria for choosing component boundaries.
2. What does a context diagram deliberately leave out, and why?
3. Convert "the site must be fast" into a testable requirement.

4. How many minutes of downtime per 30-day month does 99.95% allow?
5. Which five resource categories make up the resource model?
6. A database is at 20% CPU but requests time out waiting. What class of bottleneck is most likely?
7. Each request holds a pooled connection for 250 ms and 100 requests/s arrive. How many connections are busy on average?
8. What makes an assumption “load-bearing”?
9. Why run a sensitivity check on a weighted decision matrix?
10. Give one example each of a one-way door and a two-way door in system design.
11. Three components in series each have 99.9% availability. What is the path’s availability?
12. 1 million DAU each perform 50 reads per day, 15% of them in the busiest hour. What is the busiest-hour read rate?
13. What are the four levels of the C4 model?
14. Why is an accepted ADR never edited?

Answers

1. Business capability, data ownership, load profile or rate of change, consistency need, and likely future change (information hiding). Any four.
2. The system’s internal structure. It focuses attention on actors, external dependencies and scope, and stays readable for non-technical stakeholders.
3. For example: “p99 latency of the search endpoint below 300 ms, measured over 5-minute windows at up to 7,000 RPS.”
4. $(1 - 0.9995) \times 43{,}200 = 21.6$ minutes.
5. CPU, memory, disk, network, and locks or other software resources (pools, threads, file handles).
6. A software resource: a lock, a connection pool or a thread pool. Requests are waiting while hardware is idle.
7. $L = \lambda W = 100 \times 0.25 = 25$ connections.
8. If it were wrong by about 10×, the design would have to change.
9. To learn whether the winner depends on a contested weight. If small weight changes flip the result, the decision is close and the deciding factor must be discussed explicitly.
10. One-way: the order ID format, a public partner API, the stored data model. Two-way: a cache eviction policy, an internal framework behind a stable API.
11. $0.999^3 \approx 0.997$, i.e. 99.7%.
12. $1{,}000{,}000 \times 50 \times 0.15 / 3{,}600 \approx 2{,}083$ RPS (before any burst factor).
13. Context, Containers, Components, Code.
14. To preserve the history of reasoning. A changed decision gets a new ADR that supersedes the old one, so readers can see what was believed when.

2.15 Interview questions

Basic

Q1. You are asked to “design a food-delivery app.” What do you do in the first five minutes?

Answer. Clarify before designing. Name the users (customers, restaurants, couriers, support) and the top journeys. Agree the functional scope and say explicitly what is out of scope. Then quantify: daily active users, orders per day, peak factor, latency targets per journey, availability for checkout, and consistency needs (“no double charges”). State the assumptions you are making and confirm them with the interviewer. Finish with a quick estimate (orders/s, reads/s, location writes/s) so that the architecture you draw is sized to a target.

Q2. What is a bottleneck, and why does adding servers sometimes not help?

Answer. It is the resource with the largest demand per unit of capacity. It caps throughput for the whole path. Adding capacity anywhere else changes nothing, as with widening a highway before a one-lane bridge. Servers add CPU and memory, but if the limit is a database disk, a hot row lock or a connection pool, throughput stays the same. Find it with the USE method and the utilization law before scaling anything.

Intermediate

Q3. Checkout latency is high at peak but every server’s CPU is below 30%. Walk through your diagnosis.

Answer. Low utilization with high latency points to waiting on a software resource or an external dependency. Look at per-hop latencies in traces. Check pool wait times, lock waits in the database and the latency of external calls. Apply Little’s Law to pools: busy connections = arrival rate × hold time. A common cause is holding a transaction (and therefore a row lock and a connection) across a remote payment call. That gives long hold times, pool exhaustion and hot-row queues. The fix is to shorten the critical section: do the external call outside the transaction, use an idempotency key, and keep transactions to milliseconds. Re-measure afterwards, because the bottleneck moves.

Q4. How do you decide between a modular monolith and microservices for a new product?

Answer. Derive criteria from requirements and constraints: time to market, team size, operational maturity, independent scaling needs, failure isolation. Weight and score them, and run a sensitivity check. For a small team with a deadline, a modular monolith usually wins. Then look for components whose load profile differs by an order of magnitude or

more (QuickBite's location service) and extract only those. Note reversibility: well-kept module boundaries make later extraction a two-way door. Record the decision and its re-visit triggers in an ADR.

Advanced

Q5. Your checkout SLO is 99.95%, but the payment provider guarantees only 99.9%. What are your options?

Answer. In series, the path cannot beat its weakest link, so 99.95% is unreachable as stated. Options: (1) redefine the SLO to exclude declared third-party outages, which is common but must be agreed with the business; (2) add a second provider in parallel, giving roughly $1 - 0.001^2$ for independent failures, at the cost of contracts, token handling and reconciliation, a one-way door; (3) accept the order and defer payment capture (authorize later, queue retries) for trusted customers, trading fraud risk for availability; (4) graceful degradation, such as offering alternative payment methods when the breaker opens. Present the costs and reversibility of each and let the business choose.

Q6. QuickBite expands from one country to ten. What changes, and what would you do first?

Answer. That is roughly 10×, so expect qualitative change. Order writes reach ~600/s and saturate the single primary's WAL disk (§2.10). Data residency laws may require in-country storage. Cross-continent round trips of ~100 ms hurt latency. Payment providers differ by country. First, re-run the estimate and assumption register. Then partition by geography into regional cells, each with its own order database and location store, which addresses scale, residency, blast radius and latency together. Keep a thin global layer for identity and routing only. Treat the partition key (region or city) as a one-way door with a full design doc. Migrate incrementally, one country per cell, with rollback plans.

2.16 Practical exercises

1. **Context diagram.** Draw a system-context diagram for a ride-hailing app. List every external system with an assumed SLA, rate limit and latency, and write three out-of-scope statements.
2. **Requirements negotiation.** Rewrite these as testable requirements and propose a cheaper acceptable alternative for each: "instant search", "zero data loss", "global availability".
3. **Bottleneck arithmetic.** Edit the script in §2.6 so that 10% of orders go to the single most popular restaurant. At what total order rate does the hot row saturate with a 320 ms hold time? With 15 ms?
4. **Estimation.** Repeat the §2.11 estimate for 20 M DAU and a 2 s location update interval. Which tier changes order of magnitude first?

5. **ADR.** Write an ADR for QuickBite's choice of an idempotency-key scheme for payments, including consequences and revisit triggers.

2.17 Design challenges

1. **Grocery delivery variant.** QuickBite adds grocery delivery: orders of 40–100 items, with stock levels that change constantly and substitutions. Rework Table 2.1, the assumption register and the bottleneck analysis. Where does inventory consistency create new locks or hot rows, and how do you keep them short?
2. **Holiday surge.** On one public holiday per year, orders spike to 8× the normal dinner peak for three hours. Compare three strategies: over-provision permanently, autoscale, or queue orders with a "your order is being placed" experience. Use a weighted decision matrix and classify each strategy's reversibility. Estimate the cost difference, stating your price assumptions.

- **[Bezos 2016]** The exact wording and canonical URL (Amazon IR site or SEC exhibit) of the Type 1 / Type 2, “one-way / two-way door” passage. The chapter paraphrases it. sec.gov could not be reached from the authoring session.
- **[Dean 2009]** Confirm that the “design for ~10× growth, plan to rewrite before ~100×” advice appears in the LADIS 2009 keynote slides and not only in other Dean talks (e.g. Stanford, 2007). Hence the label is *Secondary*.
- **[Ubl 2020]** Confirm the publication year and URL. Only secondary summaries were checked.
- **[Gray 2006]** Confirm that “you build it, you run it” and the no-direct-database-access rule appear in this interview.
- **[DeMarco 1979]** The first edition is dated 1978 or 1979 depending on the source.
- **[Izrailevsky and Tseitlin 2011]** Confirm authors and date of the Netflix blog post.
- Table 2.17 capacities and the “99.9–99.99% third-party SLA” range are rough, as of 2026. Reconcile them with Appendix F and §4.17.
- The style guide asks for longer runnable programs in `code/ch02/`. The §2.6 script is short and was not copied there.

Chapter 3 — The System Design Learning Method

> **Level:** 1 · **Track:** Shared · **Estimated reading time:** 3.5 h

System design is a large field. This book covers it in 93 chapters, and the field keeps changing while you read. No one masters it by reading straight through once. Engineers who become strong designers usually have two things: a deep stock of well-understood building blocks, and a reliable way to add new blocks. This chapter gives you that way. It is a *method*, so it applies to every later chapter, from B-trees (Chapter 11) to LLM inference (Chapter 73).

3.1 Learning objectives

After this chapter you should be able to:

- Apply the ten-step concept-mastery loop to any system-design concept and produce the artifact each step requires.
- Explain, with evidence, why retrieval practice and spaced practice beat rereading and highlighting, and schedule reviews to match.
- Read a systems paper using Keshav's three-pass method and judge an engineering blog post's claims by the strength of its evidence.
- Draw a reference architecture from memory, score it against a checklist, and repair the gaps.
- Scope a simplified implementation that keeps the core mechanism and leaves out production concerns.
- Follow a 12-month beginner path through this book, or build a gap-driven plan if you are already experienced.
- Track your progress with a self-assessment rubric, flashcards and a design journal.

3.2 Prerequisites

- **What system design is** — §1.3–§1.5. You need to know what counts as a "concept" or "building block" before you can learn concepts methodically.
- **Trade-off reasoning** — §2.8. Step 6 of the loop asks you to analyze trade-offs. Chapter 2 gives you the vocabulary.

- **Basic Python** — enough to read a 60-line program with a class, a list and a dictionary. Sections 3.3 and 3.4 contain short runnable programs.
- **Hashing (informal)** — you should know that a hash function maps any input to a fixed-size number. Chapter 17 (§17.3) covers hashing in depth; you do not need it yet.

3.3 The ten-step concept-mastery loop

3.3.1 Why a loop rather than a reading list

> DEFINITION
>
> **Definition — Concept-mastery loop.** A fixed sequence of ten learning activities applied to one system-design concept. Each activity produces a concrete artifact (a definition, a diagram, a program, a design). The concept counts as mastered only when you can rebuild every artifact without notes.

First-principles explanation

Think about learning to cook one dish well. Reading the recipe tells you what the dish is. Knowing why each ingredient is there tells you what goes wrong if you leave one out. Watching a chef shows you technique. But you only really know the dish after you have cooked it yourself, burned it once, fixed it, and then cooked it for someone else without the recipe in front of you. The loop applies the same idea to a concept such as caching or consistent hashing.

Why does this exist?

Most engineers learn system design by *exposure*: they read blog posts, watch videos and skim chapters. Exposure feels productive because the material seems familiar on the second reading. Familiarity is not the same as the ability to *use* a concept. Learning researchers call this mismatch an illusion of competence. Rereading and highlighting are among the least effective study techniques measured [Dunlosky et al. 2013]. A design interview or a design review asks you to *produce*: choose a mechanism, draw it, estimate it and defend it. The loop makes production the main activity.

How it works internally

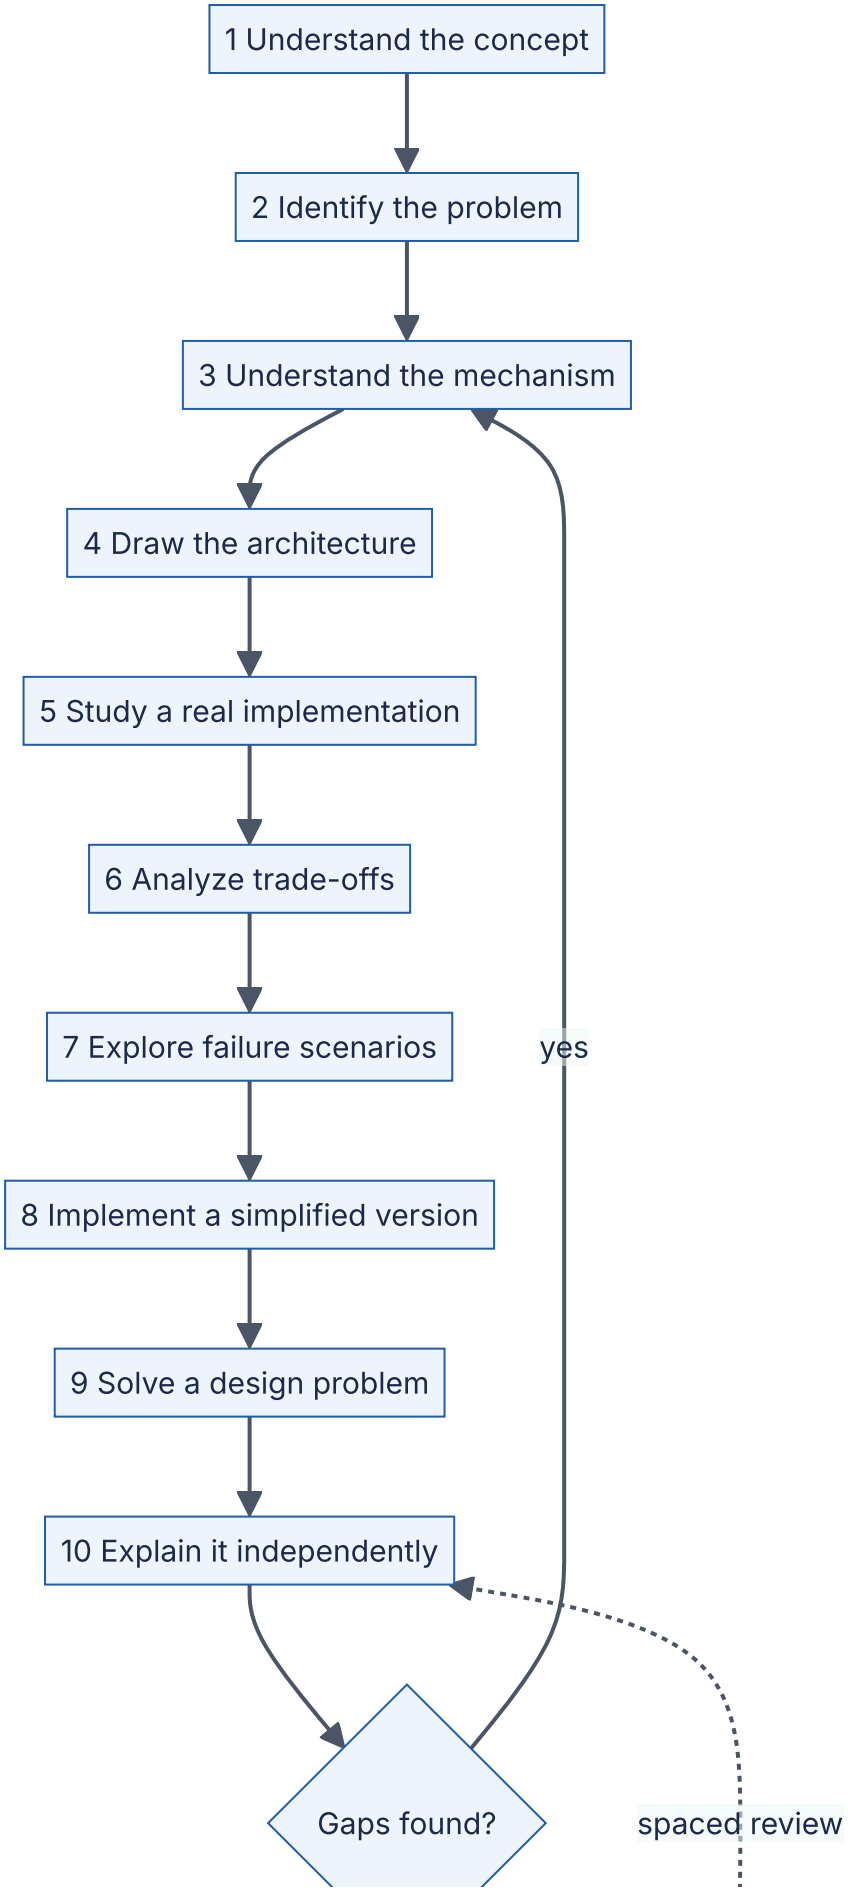
Table 3.1 — The ten steps, the question each answers, and the artifact each produces.

#	Step	Question it answers	Artifact	Typical time (L1–L2)
1	Understand the concept	What is it, in one precise sentence?	Definition in your own words	15 min
2	Identify the problem it solves	What breaks without it?	A “before” scenario with numbers	20 min
3	Understand the mechanism	How does it work, step by step?	Numbered mechanism description	45 min
4	Draw the architecture	Where does it sit and what talks to it?	Diagram drawn from memory	20 min
5	Study an actual implementation	How did a real system build it?	Notes on one paper, docs page or codebase	60–120 min
6	Analyze trade-offs	What does it cost, and versus what?	Comparison table against alternatives	30 min
7	Explore failure scenarios	How does it break?	Failure table (what, why, detect, recover, prevent)	30 min
8	Implement a simplified version	Can I build the core?	Runnable program of 50–300 lines with a measurement	2–4 h
9	Solve a design problem	Can I use it in context?	A small design that uses the concept	45–60 min
10	Explain it independently	Can I teach it without notes?	2–5 minute spoken or written explanation	15 min

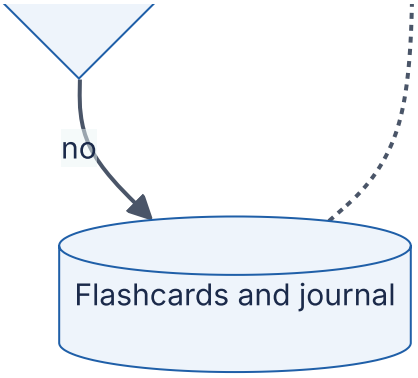
A full pass takes about 6–10 hours for one substantial concept. Plan for that. A concept such as “HTTP status codes” does not need all ten steps. A concept such as consistent hashing, Raft or the KV cache does.

The steps are ordered so that each one gives the next one something to work with. You cannot weigh trade-offs (6) until you know the mechanism (3). You should not implement (8) before you know the failure modes (7), because the failures tell you what your simulation must be able to show. Step 10 then checks all the earlier steps. Wherever your explanation falters, you return to that step. That return is why it is a loop and not a line.

Figure 3.1 — The ten-step concept-mastery loop.



1 Understand the concept
2 Identify the problem
3 Understand the mechanism
4 Draw the architecture
5 Study a real implementation
6 Analyze trade-offs
7 Explore failure scenarios
yes
8 Implement a simplified version
9 Solve a design problem
10 Explain it independently
Gaps found?
spaced review



Reading the diagram. The ten rectangles are learning activities, done in order. The solid arrows mean “finish this before starting the next”. The decision node after step 10 is your self-test. If you cannot explain some part without notes, you go back to step 3 (mechanism), because most gaps turn out to be gaps in the mechanism. If you can, the concept goes into long-term storage: the cylinder represents your flashcard deck and design journal (§3.10). The dotted arrow is asynchronous. Days or weeks later, a scheduled review asks you to repeat step 10 from memory. The weak point in this process is skipping steps 7 and 8, which feel optional but are where most understanding is built. To scale the method across a whole book, run several concepts’ loops interleaved, not one after another (§3.4.5).

Common misconceptions

COMMON MISTAKE

Misconception — “I understood it when I read it, so I know it.” Understanding while reading is recognition: the text is in front of you and gives you the cues. Using a concept in a design is recall: you have to bring it up with no cues. Only steps 4, 8, 9 and 10 test recall. If you skip them, you will not know what you are unable to do.

3.3.2 The loop demonstrated: consistent hashing

The rest of §3.3 runs one concept through all ten steps. It shows the artifacts at the depth we expect from you. We use **consistent hashing** because it is compact enough for one section and still has a real mechanism, real failure modes and real implementations. Chapter 14 (§14.8) and Chapter 20 (§20.14) treat it in full. Treat what follows as a sample of how to study, not the canonical treatment.

Step 1 — Understand the concept

DEFINITION

Definition — Consistent hashing. A way of assigning keys to nodes so that, when a node is added or removed, only about K/N of the K keys change owner, where N is the number of nodes. Both keys and nodes are hashed onto the same circular number space (the **ring**). Each key belongs to the first node found by moving clockwise from the key's position [Karger et al. 1997].

Self-check artifact: one sentence in your own words, with no jargon you cannot define. For example: "It spreads keys over servers so that adding a server moves only that server's fair share of keys."

Step 2 — Identify the problem it solves

Suppose you run four cache nodes and route each key with `node = hash(key) mod 4`. Traffic grows, so you add a fifth node and the rule becomes `hash(key) mod 5`. For most keys, `hash mod 4` and `hash mod 5` point to different nodes. Those keys now live on the wrong node, so nearly every request misses the cache and falls through to the database at the very moment you were trying to add capacity.

FORMULA

Fraction of keys remapped when growing from N to $N+1$ nodes

$$f_{\text{mod}} = 1 - \frac{1}{N+1} = \frac{N}{N+1} \qquad f_{\text{ring}} \approx \frac{1}{N+1}$$

Symbol	Meaning	Units
N	Number of nodes before the change	nodes
f_{mod}	Expected fraction of keys whose owner changes under `hash mod N` (uniform hashing)	dimensionless (0–1)
f_{ring}	Expected fraction of keys whose owner changes under consistent hashing	dimensionless (0–1)

The f_{mod} result comes from a simple observation. A key stays on the same node only if `h mod N` equals `h mod (N+1)`. For uniformly distributed hashes, that happens for about $1/(N+1)$ of keys. Under consistent hashing, the new node takes over only the keys that fall in its arcs of the ring. On average that is its fair share, $1/(N+1)$.

WORKED EXAMPLE

Worked example — Adding a fifth cache node.

1. Setup: $N = 4$, $K = 100,000,000$ cached keys, cache hit ratio 95 %, and 50,000 reads per second (RPS) reach the cache tier.
2. Naive scheme: $f_{\text{mod}} = 4/5 = 0.80$. About $0.80 \times 10^8 = 8 \times 10^7$ keys are now on the wrong node.
3. Ring scheme: $f_{\text{ring}} = 1/5 = 0.20$. About 2×10^7 keys move. They move only *to the new node*, which starts out empty.
4. Database impact right after the change, before the cache refills. Under mod-N, about 80 % of reads miss, plus the normal 5 % on the rest. The database sees about $0.80 \times 50,000 + 0.05 \times 0.20 \times 50,000 = 40,000 + 500 = 40,500$ RPS instead of the usual $0.05 \times 50,000 = 2,500$ RPS. That is a 16× surge. Under the ring, about 20 % of reads miss, plus the normal 5 % on the remaining traffic. The database sees about $0.20 \times 50,000 + 0.05 \times 0.80 \times 50,000 = 10,000 + 2,000 = 12,000$ RPS, a 4.8× surge.

Interpretation. Both schemes cause a miss spike. Consistent hashing makes it about 3.4× smaller ($40,500/12,000$) and limits it to one node's share of keys.
Engineering implication. If your database can absorb about 12,000 RPS, consistent hashing lets you add cache nodes without an outage. With mod-N you would need to warm the new layout ahead of time or add nodes only during low traffic. Chapter 20 (§20.11, cache stampede) covers the remaining spike.

Self-check artifact: a "before" scenario with numbers, like the one above.

Step 3 — Understand the mechanism

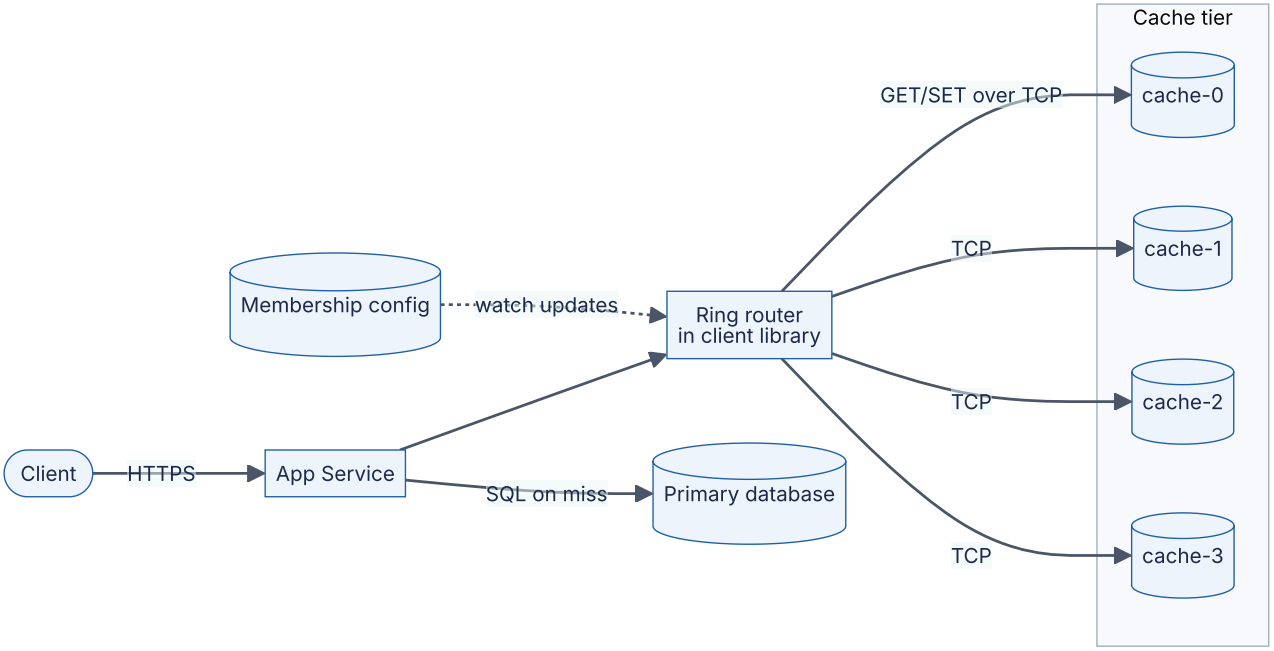
1. Pick a hash function that maps strings to integers in $[0, 2^m)$. Treat that range as a circle in which $2^m - 1$ is next to 0.
2. For each node, compute V positions by hashing distinct labels such as `"cache-2#vn17"`. Each position is a **virtual node** (vnode). Store all $N \times V$ positions in a sorted array, each mapped to its physical node.
3. To look up a key, hash it and binary-search the sorted array for the first position greater than the key's hash. If there is none, wrap around to index 0. The node that owns that position owns the key. A lookup costs $O(\log(NV))$.
4. To add a node, insert its V positions. Each one takes over the arc between its predecessor and itself. Every other key keeps its owner.
5. To remove a node, delete its positions. Each of its arcs goes to the next position clockwise. Because the vnodes are scattered around the ring, the removed node's load is spread over many survivors instead of all landing on one neighbor.
6. For replication, walk clockwise and collect the first R *distinct physical* nodes. Dynamo calls this list the **preference list** [DeCandia et al. 2007].

Why do virtual nodes matter? With $V = 1$, each node owns one arc, and arc lengths from N random points vary widely. One node can easily own two or three times its fair share. With V vnodes, each node's load is the sum of V arcs, and sums of many random lengths stay close to the average. The relative spread shrinks roughly in proportion to $1/\sqrt{V}$. Step 8 measures this.

Step 4 — Draw the architecture

Close the book and draw where consistent hashing sits in a distributed cache. Then compare your drawing with Figure 3.2.

Figure 3.2 — Consistent hashing in a client-routed distributed cache.



Reading the diagram. A client calls the app service over HTTPS. Inside the app service, a client library holds the ring: the sorted vnode positions and their owners. It is in-process, so a lookup is a binary search in memory, typically microseconds. The ring router sends each `GET` / `SET` to exactly one cache node over a TCP connection, such as the Memcached or Redis protocol. All of these are synchronous calls. On a miss, the app service reads the primary database over SQL and fills the cache (cache-aside, §20.7). The dotted arrow from the membership config is asynchronous. A coordination service or config file tells every app instance when nodes join or leave (§26.8–§26.9). There are two storage boundaries: the in-memory cache tier, which is disposable, and the database, which is durable. Failure points: a cache node that dies sends its keys to clockwise successors and causes a miss spike, and app instances that see *different* membership send the same key to different nodes. To scale, add cache nodes (each takes about $1/(N+1)$ of the keys) or raise V to even out the load.

Self-check artifact: your own drawing, annotated with which calls are synchronous and where state lives. If your drawing left out the membership channel, you have found your first gap. Section 3.6 explains how to score drawings like this.

Step 5 — Study an actual implementation

Now read how real systems built it. Pick *one* primary source and read it with the three-pass method (§3.5). For consistent hashing, three sources are worth knowing:

> INDUSTRY EXAMPLE
>
> **Akamai and the original paper.** Karger and colleagues introduced consistent hashing to spread web-cache load without hot spots, in a setting where different clients may see different sets of caches. Their paper defines the properties a good scheme needs. Two of them are *balance*, meaning keys spread evenly, and *monotonicity*, meaning that adding a cache moves keys only onto the new cache, never between old caches. The paper also uses multiple copies of each cache point on the circle to improve balance, which is the idea behind virtual nodes. *Evidence: Primary* — [Karger et al. 1997]

> INDUSTRY EXAMPLE
>
> **Amazon Dynamo.** Dynamo partitions its key space with consistent hashing and assigns each physical node several virtual nodes. This lets a more powerful machine take more vnodes, and it spreads a failed node's load over many survivors. Each key is replicated on the first R distinct physical nodes clockwise, its preference list (the paper calls this count N). The paper compares three strategies for placing tokens. It reports that dividing the ring into equal-sized partitions, decoupled from node placement, gave the best load balance and the smallest membership metadata. *Evidence: Primary* — [DeCandia et al. 2007]

> INDUSTRY EXAMPLE
>
> **Apache Cassandra.** Cassandra's original design hashes keys onto a ring with an order-preserving hash function and assigns each node one position. The paper acknowledges the load imbalance this causes. It handles the imbalance by analyzing load on the ring and moving lightly loaded nodes so they take load from heavily loaded ones. *Evidence: Primary* — [Lakshman and Malik 2010]

When you read an implementation, write down where it *departs* from the textbook mechanism and why. Departures are usually the most instructive part. Dynamo moved from random tokens to fixed equal-sized partitions because random tokens made bootstrapping

and archiving slow. That is an operational reason, not an algorithmic one, and only a real implementation would show it to you.

Step 6 — Analyze trade-offs

Table 3.2 — Key-to-node assignment schemes compared.

Dimension	`hash mod N`	Ring + virtual nodes	Rendezvous (HRW) hashing	Jump consistent hash
What it is	Modulo of key hash	Keys and vnodes on a circle	Each key picks the node with the highest score `hash(key, node)`	Arithmetic function from key to bucket number
Keys moved on add	~$N/(N+1)$	~$1/(N+1)$	~$1/(N+1)$	~$1/(N+1)$
Lookup cost	$O(1)$	$O(\log NV)$	$O(N)$ (scores every node)	$O(\log N)$, no table
Memory	None	$O(NV)$ positions	$O(N)$ node list	None
Load balance	Excellent	Good; improves with V	Excellent	Excellent
Arbitrary node removal	Remaps almost everything	Yes	Yes	No; buckets must be numbered $0..N-1$ and removed from the end
Weighted nodes	Awkward	Natural (more vnodes)	Possible with weighted scores	No
Choose when	N never changes	General-purpose caches and stores	Small N, simple code	Storage shards that only grow

Sources: [Karger et al. 1997], [Thaler and Ravishankar 1998], [Lamping and Veach 2014]. Two further variants are worth knowing by name. **Maglev hashing** builds a fixed-size lookup table for $O(1)$ lookups in load balancers and accepts a little extra disruption in exchange [Eisenbud et al. 2016]. **Consistent hashing with bounded loads** caps every node at $(1+\varepsilon)$ times the average load and sends overflow keys clockwise [Mirrokni et al. 2018].

Self-check artifact: a table like Table 3.2 written from memory, plus one sentence saying which scheme you would pick for a 6-node Redis cache and why.

Step 7 — Explore failure scenarios

Table 3.3 — Failure scenarios for consistent hashing.

What goes wrong	Why	Detection	Recovery	Prevention
One node overloaded	Too few vnodes, so arcs are uneven	Per-node RPS and memory skew	Add vnodes to the others; rebalance	$V \geq 100$; bounded-load variant
Hot key	One key gets a large share of traffic; hashing cannot split one key	Top-K key metrics (§17.6)	Replicate the hot key; add a local cache tier	Key splitting, request coalescing (§20.15)
Successor overload after node death	With $V = 1$, the clockwise neighbor inherits *all* of the dead node's keys	Neighbor CPU and miss-ratio spike	Bring up a replacement node	Virtual nodes spread the load over many successors
Split views of membership	Clients update membership at different times	Same key read from two nodes; inconsistent reads	Converge config; flush the affected range	Single source of truth with watches; versioned ring
Miss storm on resize	New node starts cold	Database RPS spike	Rate-limit fills; serve stale data	Pre-warm; add nodes off-peak; stampede protection (§20.11)
Poor hash function	Clustering of positions	Skewed arc lengths at build time	Change the hash, which remaps everything	Use a well-mixed hash (e.g., MurmurHash, xxHash, MD5 truncated)

The split-view row is the one beginners miss. The algorithm assumes every client has the same ring. Keeping that true is a distributed-systems problem in its own right, and you will meet it again in Chapter 26.

Step 8 — Implement a simplified version

Keep the mechanism and leave out everything else: no networking, no replication, no persistence. The goal is a program that lets you *see* the two properties you studied, minimal movement and load balance.

```
        """Simplified consistent-hashing ring with virtual nodes (teaching version)."""
        import bisect
        import hashlib
        from collections import Counter

        def h(key: str) -> int:
            """Map a string to a 64-bit integer position on the ring."""
            digest = hashlib.md5(key.encode("utf-8")).digest()
            return int.from_bytes(digest[:8], "big")

        class HashRing:
            def __init__(self, nodes=(), vnodes: int = 100):
                self.vnodes = vnodes
                self._positions = []   # sorted ring positions
                self._owner = {}       # position -> physical node name
                for node in nodes:
                    self.add_node(node)

            def add_node(self, node: str) -> None:
                for i in range(self.vnodes):
                    pos = h(f"{node}#vn{i}")
                    bisect.insort(self._positions, pos)
                    self._owner[pos] = node

            def remove_node(self, node: str) -> None:
                for i in range(self.vnodes):
                    pos = h(f"{node}#vn{i}")
                    self._positions.remove(pos)
                    del self._owner[pos]

            def get_node(self, key: str) -> str:
                """Return the first node clockwise from the key's position."""
                if not self._positions:
                    raise LookupError("ring is empty")
                idx = bisect.bisect_right(self._positions, h(key))
                if idx == len(self._positions):  # wrap around past the top
                    idx = 0
                return self._owner[self._positions[idx]]

        def mod_n_node(key: str, nodes: list) -> str:
            """The naive scheme: hash(key) mod N."""
            return nodes[h(key) % len(nodes)]

        if __name__ == "__main__":
            keys = [f"user:{i}" for i in range(100_000)]
            before = [f"cache-{i}" for i in range(4)]
            after = before + ["cache-4"]

            moved = sum(mod_n_node(k, before) != mod_n_node(k, after) for k in keys)
            print(f"mod-N : {moved / len(keys):.1%} of keys moved (4 -> 5 nodes)")

            for v in (1, 100):
```

```
    ring = HashRing(before, vnodes=v)
    old = {k: ring.get_node(k) for k in keys}
    ring.add_node("cache-4")
    moved = sum(old[k] != ring.get_node(k) for k in keys)
    load = Counter(ring.get_node(k) for k in keys)
    spread = max(load.values()) / (len(keys) / len(after))
    print(f"ring vnodes={v:<3}: {moved / len(keys):.1%} moved, "
          f"busiest node at {spread:.2f}x the mean load")
```

Running it with Python 3.8 or later prints:

```
mod-N : 79.9% of keys moved (4 -> 5 nodes)
ring vnodes=1  : 24.4% moved, busiest node at 2.60x the mean load
ring vnodes=100: 21.4% moved, busiest node at 1.08x the mean load
```

What to notice:

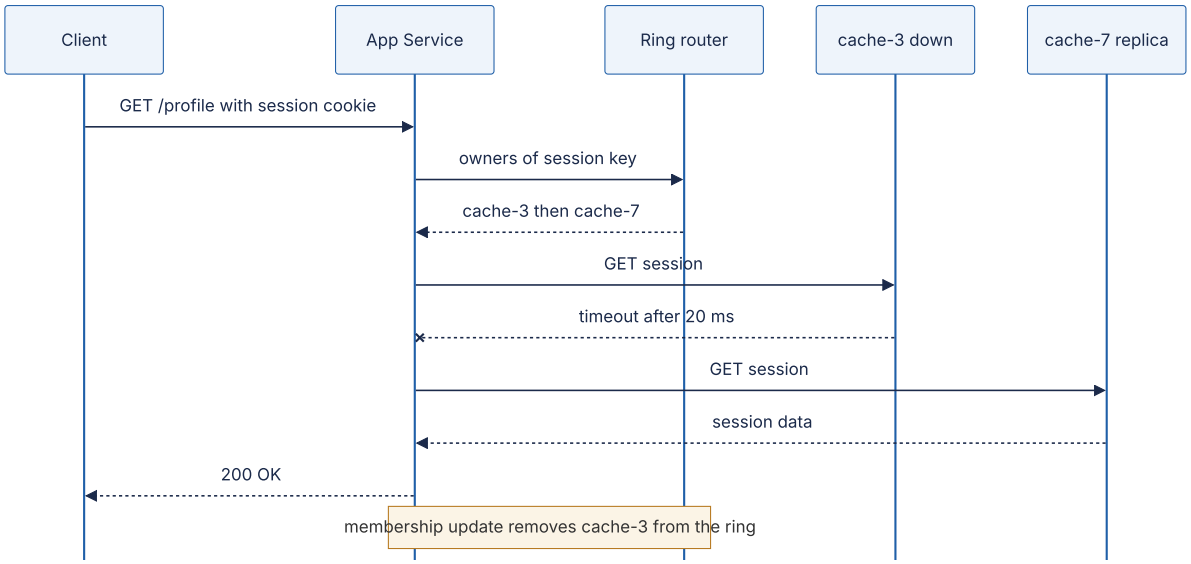
- `h()` uses MD5 only as a *mixing* function, which is fine here because nothing depends on it being cryptographically secure. Python's built-in `hash()` is randomized per process for strings, so two app instances would build different rings. That is exactly the split-view failure from Table 3.3, reproduced by accident.
- `bisect_right` plus the wrap-around check *is* the clockwise walk. Those two lines are the whole algorithm.
- The measurement agrees with the formula. Mod-N moved 79.9 % against a predicted 80 %. The ring moved about 20 % (21.4 % with 100 vnodes).
- With one vnode per node, the busiest node carries 2.6× its fair share. With 100 vnodes it carries 1.08×. You have now *seen* why virtual nodes exist, which is worth more than reading it.
- `bisect.insort` costs $O(NV)$ per insert. That is fine at this scale. A production ring would rebuild a sorted array once per membership change.

Step 9 — Solve a design problem

Use the concept inside a small design. **Problem:** a session store for 20 million concurrently active users. Each session is about 2 KB. Reads run at 200,000 RPS and writes at 20,000 RPS. A cache node may fail without logging out more than about 10 % of users.

A sketch of the solution. Data volume is $2 \times 10^7 \times 2\,\text{KB} = 40\,\text{GB}$ (SI units). With replication factor 2 that is 80 GB. Ten nodes with 16 GB of usable memory each hold it with headroom. Assign keys with a ring of 10 nodes × 150 vnodes. Write each session to the first two distinct physical nodes clockwise. If one node dies, its share (~10 %) has a replica on many different successors thanks to the vnodes, so no user is logged out and no single successor doubles its load. Figure 3.3 shows the read path during that failure.

Figure 3.3 — Session read when the primary owner has failed.



Reading the diagram. The participants are the client, the app service, the in-process ring router, the failed owner (cache-3) and the second replica on the preference list (cache-7). All arrows are synchronous request/response calls. The client uses HTTPS, and the app talks to the cache nodes over TCP. The crossed arrow is the failure: the call to cache-3 times out after a short, explicit deadline (§22.11). The app then tries the next node on the preference list. The cost to the user is one timeout of added latency, here 20 ms. The note shows the asynchronous repair: once failure detection (§27.10) removes cache-3, the router stops trying it and the extra latency goes away. The storage boundary is the cache tier, and each session lives on two nodes. To scale, add nodes. Each one takes about $1/(N+1)$ of the sessions.

Step 10 — Explain it independently

Close everything. Set a timer for three minutes and explain consistent hashing aloud, or in writing, to an imagined colleague who knows what a hash function is but nothing else. A good explanation covers five beats:

1. **The problem**: mod-N remaps about $N/(N+1)$ of keys when N changes.
2. **The trick**: put nodes and keys on the same ring and walk clockwise.
3. **The consequence**: only about $1/(N+1)$ of keys move, and only to or from the changed node.
4. **The refinement**: virtual nodes fix uneven arcs and spread failure load.
5. **The limits**: it does nothing for hot keys, and every client must share the same membership view.

Record yourself if you can. Then mark each beat as “fluent”, “hesitant” or “missing”. Each beat you marked “hesitant” or “missing” sends you back to the matching step: beats 1–2 to steps 2–3, beat 4 to step 8, beat 5 to step 7. Then turn the shaky beats into flash-cards (§3.10.2).

RECOMMENDATION

Recommendation — Keep the artifacts. Store all ten artifacts for each concept in one folder or journal entry (§3.10.3). Months later, rebuilding a concept from your own artifacts is far quicker than the first loop was. That folder becomes your personal edition of this book.

3.4 Active recall, spaced repetition, the Feynman technique, interleaving and deliberate practice

The loop tells you *what* to do with a concept. This section explains *how to practice* so that what you learn lasts. The techniques come from cognitive psychology. They were tested mostly on facts, vocabulary, science texts and mathematics, not on architecture, so applying them to system design is a reasonable extrapolation rather than a measured result.

3.4.1 What the evidence says, in one table

Dunlosky and colleagues reviewed ten widely used study techniques. They rated each one's *utility* by how well it generalized across learners, materials and test conditions [Dunlosky et al. 2013].

Table 3.4 — Study techniques by rated utility, and their system-design form.

Technique	Rated utility	System-design form
Practice testing (retrieval practice)	High	Flashcards; drawing from memory; mock design sessions
Distributed practice (spacing)	High	Scheduled reviews days and weeks apart (§3.4.3)
Elaborative interrogation	Moderate	Asking "why does Dynamo use vnodes rather than one token?"
Self-explanation	Moderate	Step 10 of the loop; the Feynman technique (§3.4.4)
Interleaved practice	Moderate	Mixing caching, queuing and replication problems in one session
Summarization	Low	Writing chapter summaries (useful only with good training)
Highlighting / underlining	Low	Marking up PDFs
Keyword mnemonic	Low	Acronyms for lists of terms
Imagery for text	Low	Picturing a text's content
Rereading	Low	Reading a chapter a second time

The ratings of the top five are the ones that matter. The two techniques that feel most like studying, highlighting and rereading, rated low. The two that feel most like being tested, practice testing and spacing, rated high.

KEY CONCEPT

Key insight — Learning versus performance. How well you do *during* practice is a poor guide to how much you are learning. Conditions that make practice feel harder, such as spacing, interleaving and testing yourself before you feel ready, often produce better long-term retention. Bjork called these **desirable difficulties** [Bjork 1994]; see [Soderstrom and Bjork 2015] for a review. If a study session felt smooth and easy, be suspicious of it.

3.4.2 Active recall (retrieval practice)

DEFINITION

Definition — Active recall. Deliberately retrieving information from memory without looking at the source, for example by answering a question, drawing a diagram or explaining aloud. Its measured benefit for later retention is called the **testing effect**.

In a well-known experiment, students read short prose passages under one of three schedules. They either studied four times (SSSS), studied three times and then took one free-recall test (SSST), or studied once and took three tests (STTT). On a test five minutes later, more studying gave better recall. On a test one week later, the order reversed. The repeated-testing group recalled about 61 % of the idea units, against about 40 % for the repeated-study group, even though the testing group had seen the text only once [Roediger and Karpicke 2006]. A later study found that retrieval practice also beat building concept maps, an “active” elaborative technique, on a test of meaningful learning [Karpicke and Blunt 2011].

Applied to system design. Every reading session should end with retrieval: close the book, and write or draw what you just learned. The checkpoints at the end of each chapter in this book exist for this reason. Answer them before you open the `<details>` block.

3.4.3 Spaced repetition

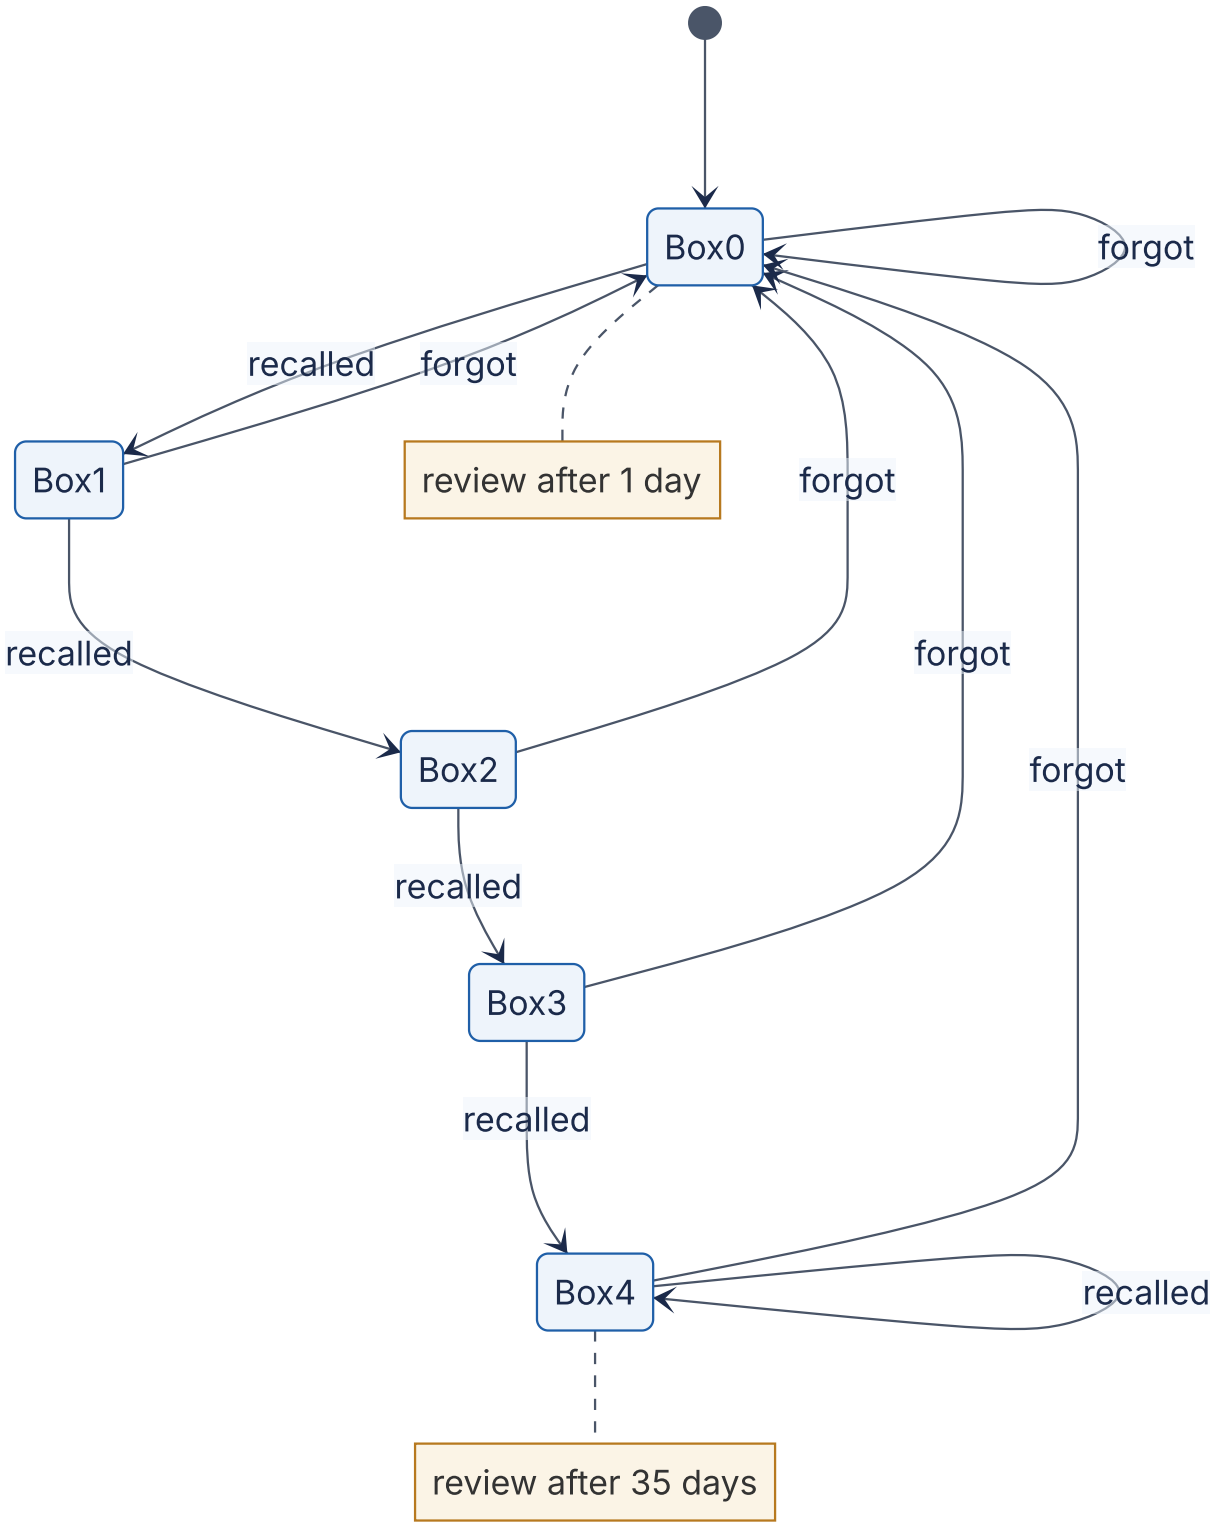
DEFINITION

Definition — Spaced repetition. Reviewing material at increasing intervals, so that each review happens around the time you would otherwise begin to forget it. The underlying finding, that spacing study sessions apart beats massing them together, is the **spacing effect**.

The spacing effect is one of the oldest results in experimental psychology. It goes back to Ebbinghaus's experiments on himself in the 1880s [Ebbinghaus 1885/1913]. A meta-analysis of hundreds of comparisons confirmed that spaced practice beats massed practice for verbal recall [Cepeda et al. 2006]. A follow-up study asked *how far apart* reviews should be. The best gap between study sessions depended on how long you need to remember the material. Expressed as a fraction of that retention interval, the best gap was about 20–40 % for a one-week retention interval and fell to about 5–10 % for a one-year interval [Cepeda et al. 2008].

The practical form of spaced repetition is the **Leitner system**: flashcards move through numbered boxes. A correct answer promotes a card to the next box, which is reviewed less often. A wrong answer sends it back to box 0. Software such as Anki automates the same idea with adaptive intervals.

Figure 3.4 — A five-box Leitner schedule for flashcards.



Reading the diagram. Each state is a box with its own review interval: 1, 3, 7, 16 and 35 days for boxes 0 to 4. The intervals are a reasonable starting point, not an empirically optimal set. Each transition is one review. “Recalled” moves a card one box up, and the top box keeps it there. “Forgot” sends it back to box 0. Data flows one card at a time. All of the state is the box number and due date per card, so a spreadsheet is enough storage.

The failure point is a backlog: if you skip a week, the reviews that were due pile up. The fix is to cap new cards per day, not to skip reviews. The schedule scales because mastered cards cost one review every five weeks or so.

The scheduler itself is small enough to build in a few minutes, which makes it a good first "simplified implementation" (§3.7):

```
        """Minimal Leitner-box scheduler for system-design flashcards."""
        from dataclasses import dataclass, field
        from datetime import date, timedelta

        INTERVALS = [1, 3, 7, 16, 35]  # days until next review, per box (box 0..4)

        @dataclass
        class Card:
            prompt: str
            box: int = 0
            due: date = field(default_factory=date.today)

            def review(self, recalled: bool, today: date) -> None:
                # Success promotes one box; failure sends the card back to box 0.
                self.box = min(self.box + 1, len(INTERVALS) - 1) if recalled else 0
                self.due = today + timedelta(days=INTERVALS[self.box])

        def due_cards(cards, today):
            return [c for c in cards if c.due <= today]

        if __name__ == "__main__":
            start = date(2026, 1, 5)
            card = Card("Why do virtual nodes reduce load imbalance?", due=start)
            today = start
            for ok in [True, True, False, True, True, True]:
                card.review(ok, today)
                print(f"{today}  recalled={ok!s:<5} -> box {card.box}, next {card.due}")
                today = card.due
```

Output:

```
2026-01-05  recalled=True  -> box 1, next 2026-01-08
2026-01-08  recalled=True  -> box 2, next 2026-01-15
2026-01-15  recalled=False -> box 0, next 2026-01-16
2026-01-16  recalled=True  -> box 1, next 2026-01-19
2026-01-19  recalled=True  -> box 2, next 2026-01-26
2026-01-26  recalled=True  -> box 3, next 2026-02-11
```

What to notice:

- `field(default_factory=date.today)` matters. A plain `date.today()` default would be evaluated once, when the class is defined, and every card would share that date. This is the kind of bug you only find by building the thing.
- One failure on 15 January wipes out two promotions. That is harsh by design: a card you forgot needs to be relearned, not just reviewed.
- After six reviews spread over five weeks, the card is due in 16 days. Spaced repetition costs little per item, and the cost keeps falling.

> WORKED EXAMPLE
>
> **Worked example — Daily review load.** You add 5 new cards per study day, 5 days a week, for a year: about $5 \times 5 \times 52 = 1,300$ cards. In the steady state, assume 70 % of cards sit in boxes 3–4 (reviewed about every 16–35 days, call it every 25 days), 20 % in box 2 (every 7 days) and 10 % in boxes 0–1 (every 2 days on average). Daily reviews $\approx 1,300 \times (0.70/25 + 0.20/7 + 0.10/2) = 1,300 \times (0.028 + 0.029 + 0.050) \approx 139$ cards. At about 8 seconds per card that is roughly 19 minutes a day. **Interpretation.** A year of system-design vocabulary stays fresh for under 20 minutes a day, *if* most cards are mastered. **Implication.** Keep cards atomic so they move up the boxes quickly. Cards that bounce between boxes 0 and 1 dominate the load, so rewrite or split them.

3.4.4 The Feynman technique (self-explanation)

The “Feynman technique” is a popular name for a four-step routine. You pick a concept, explain it in plain language as if to a newcomer, find the places where your explanation breaks down or falls back on jargon, and go back to the source to fix those places. Richard Feynman did not publish this method under that name. The label was attached later. The research behind it is the work on **self-explanation**: learners who explain material to themselves while studying understand it better than those who only read it [Chi et al. 1994]. Dunlosky and colleagues rated self-explanation and elaborative interrogation as having moderate utility [Dunlosky et al. 2013].

In system design, the routine is step 10 of the loop, plus one rule: **every “it just handles that” is a gap.** If your explanation of Kafka says “the broker handles durability”, you have not explained durability. You have named it. Push until you reach a mechanism, such as “the leader waits for in-sync replicas to append the record before acknowledging when `acks=all`” (§31.6, §31.9).

3.4.5 Interleaving

DEFINITION

Definition — Interleaving. Mixing different kinds of problems or concepts within one practice session (A B C A C B), instead of finishing all practice on one kind before moving to the next (AAA BBB CCC, called **blocking**).

In one study, students who practiced mixed (shuffled) mathematics problems did worse during practice but much better on a delayed test than students who practiced in blocks [Rohrer and Taylor 2007]. Interleaving also helped people learn to tell categories apart, such as painters' styles, even though most participants *believed* blocking had worked better for them [Kornell and Bjork 2008].

A design problem never tells you which chapter it comes from. Interleaving trains the skill that matters most in a real design: noticing *which* tool a situation calls for. In practice, once you have studied caching, queues and replication, practice with mixed questions such as "this read path is slow; is it a cache problem, a fan-out problem, or a replication-lag problem?" instead of ten caching questions in a row.

3.4.6 Deliberate practice

DEFINITION

Definition — Deliberate practice. Effortful practice designed to improve performance. It targets specific weaknesses, has clear goals, gives immediate feedback and is usually guided by a teacher or coach [Ericsson et al. 1993].

Ericsson and colleagues argued that differences in expert performance largely reflect accumulated deliberate practice. Later work found the picture more mixed. A meta-analysis found that deliberate practice explained about 12 % of the variance in performance across domains, and less in education and professions than in games, music and sports [Macnamara et al. 2014]. The honest conclusion is this: practice that targets weaknesses and comes with feedback helps, but hours alone do not guarantee expertise.

For a system designer, the scarce ingredient is **feedback**. You can get it from mock interviews with a scoring rubric (Chapter 88), from design reviews by senior engineers (§3.9.2), from comparing your design with published ones (Chapters 52–56), and from running your own simplified implementation to see whether it behaves as you predicted.

COMMON MISTAKE

Misconception — “I’m a visual learner, so I should only watch videos.” Matching instruction to self-reported “learning styles” has not been shown to improve outcomes in properly designed experiments [Pashler et al. 2008]. Diagrams do help with system design, but because the *subject* is spatial and structural, not because of your learning style. Everyone should draw.

3.5 Reading papers and engineering blogs

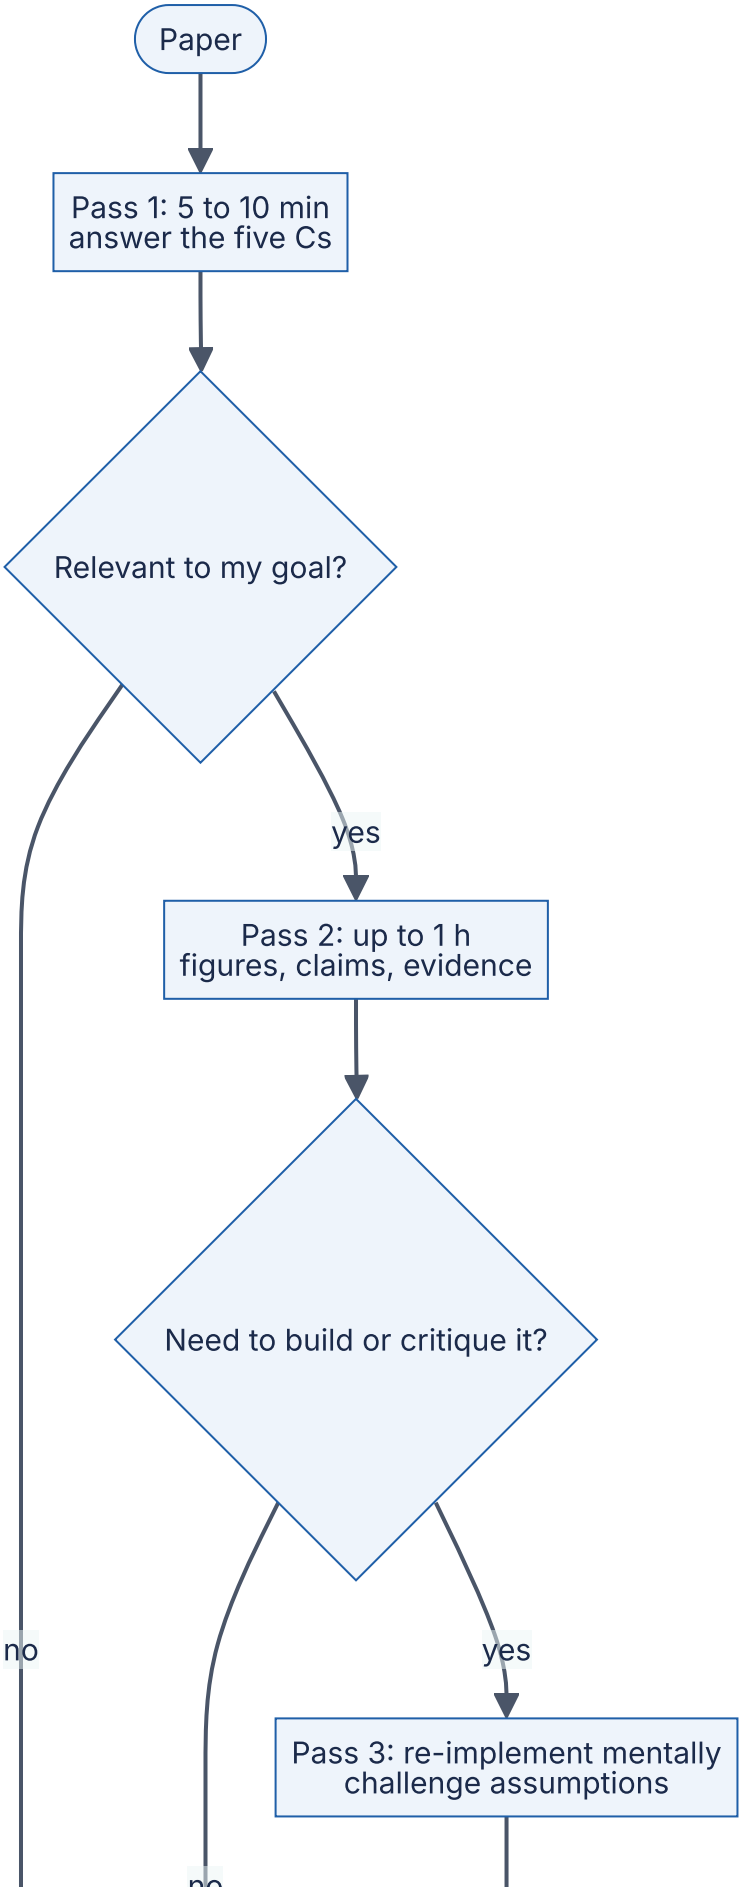
Step 5 of the loop sends you to primary sources. In system design, those are mostly conference papers (SOSP, OSDI, NSDI, USENIX ATC, VLDB, SIGMOD), official documentation and company engineering blogs. Each needs a different way of reading.

3.5.1 Keshav’s three-pass method

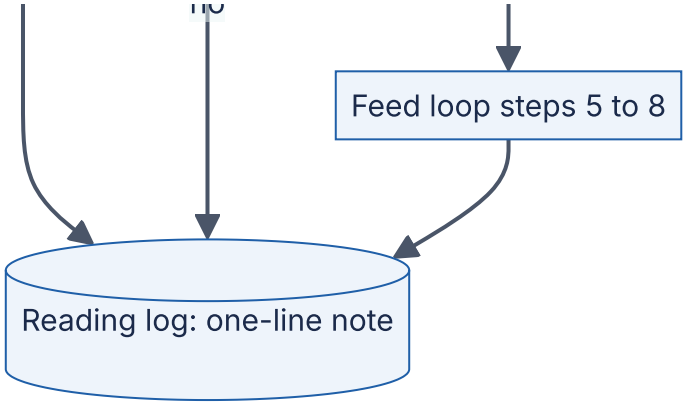
Keshav’s two-page note is the standard advice for reading systems papers. Read a paper in up to three passes, and decide after each pass whether the next one is worth the time [Keshav 2007].

1. **First pass (about 5–10 minutes).** Read the title, abstract and introduction. Read the section headings and nothing under them. Glance at any mathematics, then read the conclusions and scan the references. Afterwards, you should be able to answer the **five Cs**: *Category* (what type of paper is it?), *Context* (which other work does it build on?), *Correctness* (do the assumptions look valid?), *Contributions* (what is new?) and *Clarity* (is it well written?).
2. **Second pass (up to about an hour).** Read carefully but skip proofs. Study the figures, graphs and axes. Mark the references you have not read. Afterwards, you should be able to summarize the paper’s main thrust, with evidence, to someone else.
3. **Third pass (about 4–5 hours for a beginner, about an hour for an experienced reader).** Virtually re-implement the paper. Make the same assumptions, recreate the work, and compare your version with the authors’. This pass exposes hidden assumptions and missing citations.

Figure 3.5 — The three-pass reading decision flow.



Paper
Pass 1: 5 to 10 min
answer the five Cs
Relevant to my goal?
yes
Pass 2: up to 1 h
figures, claims, evidence
Need to build or critique it?
no
yes
Pass 3: re-implement mentally
challenge assumptions



Reading the diagram. A paper enters at the top. Each rectangle is a pass with a time budget, and each diamond is a decision to stop or go deeper. Every path ends at the reading log, the cylinder. Even a paper you rejected after five minutes gets a one-line note, so you will not reread it by accident. Only the third pass feeds steps 5–8 of the loop. The usual failure is starting at the third pass: reading page one in detail and giving up on page four. To scale this across many papers, do many first passes and only a few third passes. For most engineers, about one paper in five deserves the third.

When you apply the method to a *systems* paper, add two questions to the five Cs. **What was the workload?** Dynamo's design follows from Amazon's shopping-cart writes, which had to be "always writeable". **What did they choose not to provide?** GFS gave up a POSIX-compatible interface and offered relaxed consistency [Ghemawat et al. 2003]. A paper's non-goals tell you as much as its goals.

Table 3.5 — A starter reading list mapped to this book.

Paper	Read with	Why this one first
Lamport, *Time, Clocks, and the Ordering of Events* [Lamport 1978]	§24.10	Short; defines "happened-before"
The Google File System [Ghemawat et al. 2003]	§15.5	Clear workload-driven trade-offs
MapReduce [Dean and Ghemawat 2004]	§29.4	Simple model; good first third-pass paper
Dynamo [DeCandia et al. 2007]	§14.8, §27.7	Assembles many chapter concepts in one design
The Chubby Lock Service [Burrows 2006]	§26.14	Engineering lessons, not just algorithms
ZooKeeper [Hunt et al. 2010]	§26.8	Coordination as a service
Kafka [Kreps et al. 2011]	§31.3	The log as a central abstraction
Raft [Ongaro and Ousterhout 2014]	§26.7	Written explicitly to be understandable
The Tail at Scale [Dean and Barroso 2013]	§23.6–§23.7	Magazine-length; shapes how you think about latency
Spanner [Corbett et al. 2012]	§28.8	Advanced; read after Chapters 25–26

3.5.2 Reading engineering blogs critically

Company engineering blogs are where the field's current practice gets written down. They are also written to recruit engineers and to promote the company, and they rarely go through peer review. Read them as **evidence of what one team did under its own constraints**, not as recommendations for you.

Table 3.6 — Critical-reading checklist for engineering posts.

Ask	Why	Red flag
What was the workload and scale?	Solutions depend on the workload	No numbers at all, or only "massive scale"
What was the baseline?	A speed-up needs something to compare against	"10× faster" with no stated "than what"
What did they try that failed?	Shows what the real constraint was	Only a success story
What did it cost?	Every choice costs something	No downsides mentioned
When was it written?	Systems and versions change	No date; describes a deprecated version
Can it be checked?	Separates evidence from narrative	No benchmark method; no code; no follow-up
Who benefits from you believing it?	Vendor posts sell products	"Our product solved it" with no alternatives considered

This book uses the same discipline in its **evidence labels** (§9 of the style guide): Primary, Secondary or Illustrative. Label your own notes the same way. A claim you read in a conference talk summary is Secondary, even if it sounds authoritative.

3.6 Drawing architecture from memory

3.6.1 Why drawing from memory works

Drawing a system from memory is retrieval practice (§3.4.2) on structured material. It also builds what Chase and Simon called **chunks**. In their studies, chess masters reconstructed real game positions from a brief glance far better than novices. On random piece placements, the masters' advantage largely disappeared [Chase and Simon 1973]. Their expertise was stored as meaningful patterns, not as better raw memory. Reference architectures are the chunks of system design: "CDN → load balancer → stateless service → cache → primary/replica database", or "producer → partitioned log → consumer group". Once each of these is a single chunk, your working memory is free to reason about what is *different* in the problem in front of you.

3.6.2 The protocol

1. **Choose a target**: a figure from a chapter you finished at least two days ago.
2. **Draw blind for 10 minutes** on paper or a whiteboard. Use the book's shapes (§6 of the style guide): stadiums for clients, rectangles for services, cylinders for stores, subroutine shapes for queues.
3. **Annotate edges**: protocol, synchronous or asynchronous, direction.
4. **Compare** with the source and score your drawing with Table 3.7.
5. **Write the diff**: every missing component and every wrong edge becomes a flashcard.
6. **Redraw** after the next spacing interval (3 days, then 7, then 16).

Table 3.7 — Scoring rubric for a drawing from memory (0–2 points each, 12 maximum).

Criterion	0	1	2
Components	Major pieces missing	All major pieces present	Also includes supporting pieces (config, discovery, monitoring)
Data flow	Arrows missing or wrong	Correct direction	Read and write paths distinguished
Sync vs async	Not marked	Partly marked	Every edge correct
Protocols	None	Some	Every edge labeled
Storage boundaries	Unclear where state lives	Stores shown	Durability of each store stated
Failure points	None marked	One marked	Each single point of failure plus its mitigation

A score of 10–12 on a figure means you can use that architecture fluently. Below 7 means you should go back to loop step 3 for the components you missed.

INTERVIEW TIP

Interview tip. Interviewers do not score how pretty your diagram is. They notice whether you mark the read and write paths separately and whether you can point at the single points of failure without being asked. Those are the two highest-value rows of Table 3.7, and both can be trained.

3.7 Building simplified implementations

3.7.1 Why build at all

Feynman's blackboard at the time of his death carried the line "What I cannot create, I do not understand." Building a small version of a mechanism forces you to make every decision the prose glossed over: what happens on wrap-around, what a timeout returns, which component owns a piece of state. The consistent-hashing ring in §3.3 and the Leitner scheduler in §3.4.3 each surfaced a bug that reading would not have, a process-randomized `hash()` and a shared default date.

3.7.2 Scoping rules

1. **Keep the mechanism; fake the environment.** Simulate the network with function calls and the clock with a counter. Simulate disks with dictionaries.
2. **One file, under 300 lines.** If it grows past that, you are building a product, not a learning model.

3. **Build in a measurement.** Every simplified implementation should print a number that tests a claim from the chapter: keys moved, hit ratio, p99 latency, messages lost.
4. **Inject one failure.** Kill a node, drop a message or skew a clock, then check whether the behavior matches Step 7's failure table.
5. **Compare with a real system afterwards.** Read the corresponding part of a real codebase or its documentation and list three things it does that yours does not. That list is your map to production concerns.

Table 3.8 — Simplified implementations that pay off, by chapter.

Build	Chapter	The measurement that proves it works
LRU cache with TTL	§20.8–§20.9, §38.10	Hit ratio against cache size on a Zipf-like key stream
Token-bucket rate limiter	§22.4	Accepted rate converges to the refill rate
Consistent-hash ring	§14.8	Keys moved ≈ $1/(N+1)$; max/mean load against vnode count
Bloom filter	§17.4	Measured false-positive rate matches the formula
Append-only log with offsets	§31.3, §31.8	Consumer restarts from its committed offset
Leader election with leases	§26.5, §26.11	At most one leader per lease epoch under clock skew
Raft log replication (simulated network)	§26.7	No committed entry lost when a minority of nodes crash
Retry with exponential backoff and jitter	§22.12	Load on a recovering server, with and without jitter

Chapter 93 turns several of these into full projects with deployment, testing and monitoring. The simplified versions here are the step before that.

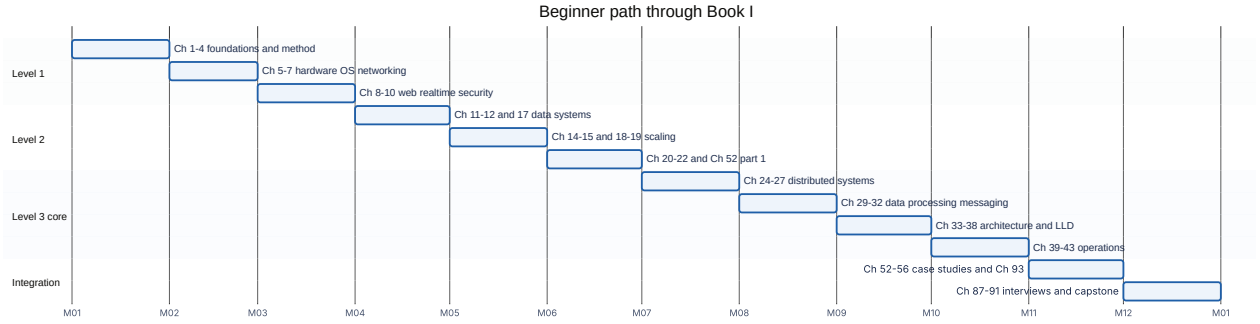
WARNING / TRADE-OFF

Warning — The toy-to-production gap. A 100-line Raft simulation that passes your tests is not a correct Raft. Consensus implementations fail in rare interleavings of events that small tests seldom reach, which is why Jepsen-style testing exists (§25.11). Treat your build as a model of the mechanism, never as evidence that the real problem is easy.

3.8 Beginner methodology: a 12-month path

This path is for readers starting at Level 1: you can program, but you have not designed distributed systems. It assumes 8–10 hours a week. That is enough for about four full concept loops a month plus lighter reading. The target is **Level 2 by month 6 and Level 3 on core Book I material by month 12**. Levels 4 and 5 (senior/staff, principal) depend on production experience that no reading plan can replace. Part IX and §3.9 are where you go next.

Figure 3.6 — The 12-month beginner path (months shown as M01–M12).



Reading the diagram. Each bar is one month of study, and bars run one after another. The `after` dependencies mean that each block assumes you have finished the one before it. The calendar dates are placeholders, so read the axis as month numbers. The three sections match the proficiency levels you should reach by the end of each phase. The fourth section, Integration, combines everything rather than adding new material. The common failure is slipping in months 7–8. Distributed systems is the steepest part of the path, so plan for those two months to take three. There are two ways to scale the plan. At 15+ hours a week, the whole path fits in about eight months. An ML-track reader can swap month 9 for Chapters 57–60 and month 10 for Chapters 66 and 72–75.

Table 3.9 — Month-by-month plan with loop targets and milestones.

Month	Chapters	Full-loop concepts (examples)	Milestone artifact
1	1–4	Latency vs throughput; Little's Law; availability arithmetic	Flashcard deck started; first design journal entry
2	5–7	Memory hierarchy; event loops; TCP handshake; DNS	Request lifecycle drawn from memory (§8.5 preview)
3	8–10	REST design; OAuth 2.0 flow; TLS; threat model	API spec for a URL shortener (§52.4)
4	11–12, 17	B+ tree index; isolation levels; Bloom filter	Bloom filter build (Table 3.8)
5	14–15, 18–19	Replication lag; consistent hashing; L4 vs L7 balancing	Hash ring build (§3.3)
6	20–22; 52.4–52.6	Cache-aside; cache stampede; token bucket	**L2 checkpoint**: rate limiter design (§52.6), timed at 45 min
7	24–27	Lamport clocks; linearizability; Raft; quorums	Raft election simulation
8	29–32	Partitioned log; consumer groups; outbox; saga	Log with offsets build
9	33–38	Modular monolith; bounded contexts; LLD of an LRU cache	LLD exercise from §38.10
10	39–43	SLOs and error budgets; tracing; canary releases	One postmortem study (§3.9.3)
11	52–56; 93.1–93.2	Five case studies through all 16 template sections	One beginner project from Ch 93 deployed
12	87–89, 91	Estimation drills; interview pacing	**L3 checkpoint**: three mock interviews scored with the Ch 88 rubric

Chapters 13, 16, 23 and 28 and all of Part IX are **deferred to year two**. They are L3–L5 material that builds on everything above. Read their introductions when a case study points to them, but do not run full loops on them yet.

RECOMMENDATION

Recommendation — The weekly rhythm. Use two weekday sessions of 2 hours for loop steps 1–7 on one concept, and one weekend session of 3 hours for steps 8–9. Do 15–20 minutes of flashcards on five days. Close the week with a 30-minute review: one drawing from memory of a concept from last month and one journal entry. This rhythm builds in spacing, interleaving and retrieval without any extra planning.

3.9 Advanced methodology for experienced engineers

If you already build production systems, you do not need a path from Chapter 1. You need to know **where your gaps are**. Experience tends to be deep in the systems you have run and thin everywhere else. A payments engineer may know idempotency keys (§22.15) and sagas very well and know little about CDNs or GPU serving.

3.9.1 Gap analysis

Rate yourself from 0 to 4 on each of the book's 19 parts, where 0 means "cannot define the main terms" and 4 means "could teach it and have operated it in production". Set a target for each part from your role or the job you want. Then rank the parts by weighted gap.

FORMULA

Gap priority

$$P_i = (T_i - C_i) \times W_i$$

Symbol	Meaning	Units
P_i	Priority score for part i	points (0–12)
T_i	Target proficiency for part i	0–4 scale
C_i	Current self-rated proficiency (use 0 if $C_i > T_i$ would make P_i negative)	0–4 scale
W_i	Relevance weight: 1 = nice to have, 2 = useful, 3 = essential for role	dimensionless (1–3)

WORKED EXAMPLE

Worked example — A backend engineer moving to an infrastructure role.

Table 3.10 — Gap-analysis scores for one engineer.

Part	T	C	W	$P = (T - C) \times W$
V Distributed systems	4	2	3	$2 \times 3 = 6$
VIII Operations	4	3	3	$1 \times 3 = 3$
IV Scalability and performance	3	2	2	$1 \times 2 = 2$
XIII Training infrastructure	2	0	1	$2 \times 1 = 2$

Interpretation. Part V comes first with a score of 6, three times any other part. Parts IV and XIII tie at 2. Their gaps differ, but weighting by relevance brings them level. **Implication.** Spend the next quarter on Chapters 24–28 with full loops, and keep the others to first-pass reading. Re-rate yourself each quarter, because a self-rating is only a guess until a design review or a mock interview tests it.

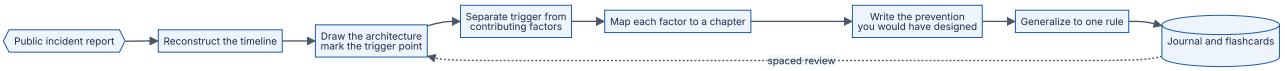
3.9.2 Design reviews as a learning instrument

Design reviews (§1.10) are deliberate practice with expert feedback already built in. Use them on purpose. **As an author**, write a design document for a real change and ask reviewers to challenge specific sections, such as failure modes or capacity numbers. **As a reviewer**, read others' designs with Table 3.7 and Table 3.3 in mind, and write at least one question about failure handling and one about cost. **As an observer**, sit in on reviews outside your team. Hearing how senior engineers question a design teaches you what to ask before you can answer it yourself. After each review, write down in your journal one thing you would have missed.

3.9.3 Postmortem study

Production incidents are the most honest record of how systems fail. Many organizations publish blameless postmortems. The SRE book describes postmortem culture as a way to learn from failure without assigning blame [Beyer et al. 2016]. Curated collections, such as Dan Luu's public list of postmortems, make it easy to find many of them [Luu, postmortems]. Research that analyzes failures across many systems shows patterns that single reports cannot. One study of failures in distributed data-intensive systems found that most catastrophic failures came from incorrect handling of non-fatal errors that the software had already signaled [Yuan et al. 2014]. A study of hundreds of public cloud outage reports cataloged their root causes and how far their impact spread [Gunawi et al. 2016].

Figure 3.7 — The postmortem study loop.



Reading the diagram. The hexagon is an external source, a published report. Each rectangle is an analysis step, done in order. The two most valuable steps are drawing the architecture yourself, since reports rarely include a complete diagram, and separating the *trigger* (what started it) from the *contributing factors* (why it spread and why recovery was slow). Mapping each factor to a chapter turns an anecdote into a lesson you can review. The rule you generalize goes into durable storage, your journal and flashcards. The dotted arrow is a spaced review in which you redraw the architecture from memory. The failure point in this process is stopping at the trigger. “Someone typed the wrong command” is never the whole story.

INDUSTRY EXAMPLE

Amazon S3, US-EAST-1, February 2017. While debugging a billing-system issue, an engineer ran an established playbook command meant to remove a small number of servers. An input was entered incorrectly, and a much larger set of servers was removed, including servers supporting two S3 subsystems: the index subsystem and the placement subsystem. Both needed a full restart, which took longer than expected because those subsystems had not been fully restarted in years while S3 had grown substantially. In response, AWS changed the tool to remove capacity more slowly and to refuse to take any subsystem below its minimum required capacity. It also prioritized splitting the index subsystem into smaller cells. **Lessons mapped to chapters:** guard rails on operational tools (§43.3), blast-radius reduction with cells (§33.12, Chapter 44), and recovery time as a design property (§39.8). *Evidence: Primary* — [AWS 2017]

3.9.4 Reading production incident reports critically

Published reports are edited for a public audience and tend to leave out organizational causes and near misses. Read them with Table 3.6 in mind. Separate **what the report states** from **what you infer**. Look for the **detection gap**, the time from trigger to first alert, which is often more instructive than the bug. Ask what the incident shows about the **design**, not the operator: why could one command remove so much capacity? One report a week gives you about 50 failure case studies a year, and that breadth is a large part of what distinguishes a Level 4 engineer.

3.10 Tracking progress

3.10.1 Self-assessment rubric

Rate yourself each quarter on the seven dimensions below, and ask a peer or mentor to rate you as well. A large gap between their rating and yours is itself useful information.

Table 3.11 — Self-assessment rubric mapped to the five proficiency levels.

Dimension	L1 Beginner	L2 Intermediate	L3 Advanced	L4 Senior/Staff	L5 Principal
Concept knowledge	Defines core terms	Explains building blocks	Explains internals	Knows edge cases and variants	Shapes how the field uses the concepts
Mechanism depth	Describes what it does	Describes how, step by step	Implements a simplified version	Debugs production behavior	Designs new mechanisms
Trade-off reasoning	Names one pro and one con	Compares two options	Compares options with numbers	Weighs cost, organization and time	Sets direction for many teams
Estimation	Needs a template	Estimates RPS and storage	Estimates the bottleneck resource	Builds a capacity model	Owns fleet-level planning
Failure reasoning	Rarely considers failure	Lists failure modes	Designs detection and recovery	Limits the blast radius	Sets reliability strategy
Communication	Describes components	Draws a clear diagram	Leads a 45-minute design discussion	Runs design reviews	Writes standards others adopt
Implementation	Follows tutorials	Builds small services	Builds simplified distributed mechanisms	Ships and operates such systems	Builds platforms others build on

Appendix E gives the full definitions of the levels. Your overall level is roughly the level reached by your *weakest* three dimensions, not your strongest, because a design is only as strong as its weakest reasoning.

3.10.2 Flashcard templates

Make each card **atomic** (one fact or one relationship) and prefer **why** and **when** cards over **what** cards. Six card types cover most of system design:

```
[DEFINITION]  Q: Define linearizability in one sentence.
[MECHANISM]   Q: In a hash ring, which node owns key k?  (answer in two steps)
[NUMBER]      Q: Rough round-trip time within one datacenter? (cite Appendix F, with
year)
[TRADE-OFF]   Q: When would you choose jump hash over a ring with vnodes?
[FAILURE]     Q: A cache node dies under mod-N hashing. What happens to the database,
and why?
[DIAGRAM]     Q: Draw cache-aside read and write paths. (check against Fig. 20.x)
```

Each card should also record its source section (for example `src: §3.3 step 6`), so a failed card leads you straight to the material it came from.

3.10.3 Design journal template

```
Date:              Concept / problem:              Loop steps completed: 1-10
1. One-sentence definition (from memory):
2. Problem it solves, with a number:
3. Mechanism in 5 steps or fewer:
4. Drawing score (Table 3.7): __ / 12   Missing:
5. Source studied + evidence label:
6. Best alternative and when I would pick it:
7. Scariest failure mode and its mitigation:
8. Build: repo/file + the measurement it printed:
9. Design problem used in + what I would change next time:
10. Explanation beats fluent / hesitant / missing:
Cards created:                    Next review date:
```

3.10.4 The concept tracker

Table 3.12 — Concept tracker (example rows).

Concept	Section	Steps done	Drawing score	Last review	Next review	Confidence (1–5)
Consistent hashing	§14.8	1–10	11/12	2027-05-03	2027-05-19	4
Raft leader election	§26.7	1–7	8/12	2027-07-10	2027-07-13	2
Cache stampede	§20.11	1–4, 6–7	9/12	2027-06-02	2027-06-09	3

Look at the tracker every week. Three numbers tell you whether the method is working: **flashcard retention**, meaning the fraction recalled on review, where around 85–90 % is a healthy target; **average drawing score**, which should rise over a quarter; and **loops completed per month**, about four on the beginner path. If retention falls below about 80 %, you are adding cards faster than you are learning them. Slow down. If drawing scores stall, put more time into loop step 3.

3.11 Summary and revision notes

SUMMARY

- Mastery means you can **produce** the concept without notes: define it, draw it, build it, use it and explain it. Recognizing it when you read it does not count.
- The **ten-step loop** turns each concept into ten artifacts. Step 10 (explain independently) checks the other nine, and any gap sends you back to step 3.
- Consistent hashing shows the loop's value. The formula predicts that ~80 % of keys move under mod-N and ~20 % under a ring when going from 4 to 5 nodes. A 60-line build confirmed it and showed that virtual nodes cut the busiest node's load from 2.6× to 1.08× the mean.
- **Retrieval practice** and **spacing** have the strongest evidence. Rereading and highlighting have the weakest [Dunlosky et al. 2013]. Self-explanation and interleaving have moderate support. Deliberate practice helps, but it explains only part of the differences in expertise.
- Read papers in **three passes** [Keshav 2007]. Read blogs as evidence of one team's choices under their own constraints, and label every claim Primary, Secondary or Illustrative.
- **Drawing from memory** builds chunks. Score your drawings out of 12 on components, flows, sync/async, protocols, storage and failure points.
- **Simplified implementations** keep the mechanism, fake the environment, print a measurement and inject a failure.
- Beginners: follow the 12-month path to reach L2 by month 6 and L3 on core Book I material by month 12. Experienced engineers: rank gaps with $P = (T - C) \times W$, use design reviews as deliberate practice and study one incident report a week.
- Track flashcard retention (~85–90 %), drawing scores and loops per month. Judge your level by your weakest dimensions.

3.12 Knowledge checkpoint

1. What artifact does each of loop steps 2, 4, 8 and 10 produce?
2. Why does the loop return to step 3, not step 1, when step 10 reveals a gap?
3. Using the formula, what fraction of keys move when a mod-N cluster grows from 9 to 10 nodes? And under consistent hashing?
4. Why does Python's built-in `hash()` make a poor ring hash for a multi-process service?
5. Name two techniques Dunlosky et al. rated high utility and two they rated low.
6. In Roediger and Karpicke's experiment, which condition did best at five minutes and which at one week?

7. According to Cepeda et al. (2008), does the best review gap, as a fraction of the retention interval, grow or shrink as the retention interval gets longer?
8. What is the difference between interleaved and blocked practice, and why does interleaving suit system design?
9. List Keshav's five Cs.
10. Which pass of the three-pass method feeds loop steps 5–8, and roughly how long does it take a beginner?
11. Give three questions from the blog-reading checklist.
12. What did Chase and Simon's random-position condition show about expertise?
13. State four scoping rules for a simplified implementation.
14. Compute the gap priority for a part with target 3, current 1 and weight 2.
15. In a postmortem study, why separate the trigger from the contributing factors?
16. Your flashcard retention has fallen to 72 %. What should you change?

Answers

1. Step 2: a "before" scenario with numbers. Step 4: a diagram drawn from memory. Step 8: a runnable program that prints a measurement. Step 10: a 2–5 minute explanation given without notes.
2. Most gaps in an explanation are gaps in the mechanism. The definition (step 1) is rarely what is missing.
3. Mod-N: $N/(N+1) = 9/10 = 90\%$. Consistent hashing: about $1/(N+1) = 10\%$.
4. Python randomizes `hash()` for strings in each process, so different processes would build different rings. That is a split-view failure.
5. High: practice testing and distributed practice. Low: any two of rereading, highlighting, summarization, keyword mnemonic and imagery for text.
6. At five minutes, repeated study (SSSS) did best. At one week, repeated testing (STTT) did best, about 61 % against 40 %.
7. It shrinks: from about 20–40 % for a one-week interval to about 5–10 % for a one-year interval.
8. Interleaving mixes problem types within a session, while blocking finishes one type before starting the next. Real design problems do not say which tool they need, and interleaving trains you to choose.
9. Category, Context, Correctness, Contributions, Clarity.
10. The third pass, which takes about 4–5 hours for a beginner.
11. Any three of: What was the workload and scale? What was the baseline? What failed? What did it cost? When was it written? Can it be checked? Who benefits?
12. On random positions, the masters' advantage largely disappeared. Their expertise was stored as meaningful patterns (chunks), not as better general memory.
13. Keep the mechanism and fake the environment; one file under 300 lines; build in a measurement; inject one failure; compare with a real system afterwards.
14. $P = (3 - 1) \times 2 = 4$.

15. The trigger explains how the incident started. The contributing factors explain why it spread and why recovery was slow, and those are what design can change.
16. Add fewer new cards, and rewrite or split the cards that keep falling back to box 0. Cards that are too big or vague cause most of the failures.

3.13 Interview questions

Interviewers sometimes ask how you learn, especially for senior roles. The concept used to demonstrate the loop, consistent hashing, also comes up often in interviews.

Basic

Q1. How do you get up to speed on a technology you have never used? Answer. Describe a method, not a list of resources: find the problem it solves and what came before it; first-pass the official architecture docs or paper; draw the architecture from memory and check it; build a toy that measures something you care about; read its known failure modes or incident reports; and write a one-page summary for your team, which exposes what you do not yet understand.

Q2. Why does `hash(key) mod N` cause problems when you add a cache node? Answer. With uniform hashing, about $N/(N+1)$ of keys change owner, so most of the cache misses at once and the load falls on the database. Consistent hashing moves only about $1/(N+1)$ of keys, all of them to the new node.

Intermediate

Q3. What do virtual nodes fix in consistent hashing, and what do they cost? Answer. With one position per node, arc lengths vary widely, so one node can carry two or three times its share. A dead node's whole load also lands on a single successor. With V vnodes per node, load evens out, the spread shrinking roughly as $1/\sqrt{V}$, and failure load is spread over many nodes. The costs are $O(NV)$ memory for the ring, larger membership metadata and more key ranges to manage during rebalancing.

Q4. Tell me about a postmortem you learned from. Answer. Choose a public report, such as the 2017 S3 disruption. Describe the trigger (a mistyped input to a capacity-removal command), the contributing factors (no minimum-capacity safeguard, and subsystems that had not been fully restarted in years at their current scale), and the design changes (slower removal, capacity floors, cell partitioning). Then say what you changed in your own work because of it.

Advanced

Q5. Your organization's design reviews keep missing failure modes that later cause incidents. How would you change the process? Answer. Require a failure table in the design template (what goes wrong, why, detection, recovery, prevention); give one reviewer the explicit failure-hunting role; link each design to postmortems of similar architectures; and track whether later incidents were or were not anticipated in the design. That is deliberate practice at team scale, with feedback from real outcomes.

Q6. A ring-based cache shows one node at 3× average CPU even with 200 vnodes per node. Diagnose it. Answer. With 200 vnodes, the ring itself should keep the busiest node within roughly 10 % of the mean, so look elsewhere. The likely causes are a hot key, which hashing cannot split; clients with inconsistent membership sending one range to the wrong node; or a heterogeneous node, such as a smaller instance or a noisy neighbor. Check top-K key metrics and compare ring versions across clients. Fixes include replicating hot keys, adding a local cache tier, bounded-load hashing and versioned membership.

3.14 Practical exercises

1. **Run the loop.** Take the cache-aside pattern (§20.7) through all ten steps. Turn in the ten artifacts, and use the journal template (§3.10.3) for at least one of them.
2. **Extend the ring.** Add `get_nodes(key, r)` to the §3.3 `HashRing` so that it returns r distinct physical nodes. Measure the fraction of keys whose replica set changes when you remove a node.
3. **Measure the vnode curve.** For $V \in \{1, 10, 50, 100, 500\}$, plot max/mean load across 10 nodes. Check whether the excess over 1.0 shrinks roughly as $1/\sqrt{V}$.
4. **Three passes.** Read the Dynamo paper with Keshav's method. Turn in the five Cs after pass 1, a one-paragraph summary after pass 2, and, after pass 3, a list of three assumptions that would not hold for a bank ledger.
5. **Critique a post.** Choose a recent engineering blog post about a migration. Score it against Table 3.6 and rewrite its main claim with an evidence label.

3.15 Design challenges

1. **Design your own learning system.** Treat your next six months of study as a system. State requirements (hours per week, target level), components (deck, journal, tracker, build repository), data flows (reading → artifacts → cards → reviews) and failure modes (backlog, burnout, illusion of competence). Add detection and recovery for each failure mode.
2. **A team incident library.** Design a lightweight internal system in which engineers log public and internal postmortems, tag them with this book's chapters and receive

spaced “redraw this architecture” prompts. Estimate storage and request rates for an organization of 2,000 engineers.

3. **Gap-driven onboarding.** Design a 90-day onboarding plan for an experienced engineer joining an ML-infrastructure team from a web-backend background. Use the gap formula, Table 3.11 and specific chapters from Book II.

3.17 Open verification items

- [AWS 2017] URL and wording of the S3 post-event summary could not be fetched from this environment (network restriction); the summary in §3.9.3 is from the author's knowledge of the report and should be checked against the primary text.
- Roediger and Karpicke (2006) Experiment 2 one-week figures (~61 % STTT vs ~40 % SSSS) were confirmed only through secondary summaries; verify against the paper's Figure/Results.
- Macnamara et al. (2014): headline 12 % of variance confirmed; the domain ordering (lower in education and professions than in games, music, sports) is from memory and should be checked.
- Attribution of "What I cannot create, I do not understand" to Feynman's blackboard (Caltech Archives, 1988): widely documented; add an archival citation if one is required.
- Leitner intervals (1, 3, 7, 16, 35 days) are a teaching choice, not an empirically derived schedule; the text says so.
- The "~1/√V" load-spread scaling is stated as an approximation; it is now derived in §14.8.4 (UQ-012, resolved).

Chapter 4 — Quantitative Foundations for System Design

> **Level:** 1–3 · **Track:** Shared · **Estimated reading time:** 6 h

System design is often presented as a drawing exercise: boxes, arrows, a cache here, a queue there. The drawing is the easy part. What separates a design that works from one that merely looks plausible is *arithmetic*. How many machines? How much memory? What happens to latency when traffic doubles? How many nines does the whole system get when every component has three? How likely is it that all three replicas of a file die before you notice the first one is gone?

This chapter gives you the mathematical toolkit to answer those questions, assuming only high-school algebra. Each formula comes with an analogy, its units, a fully worked example and its engineering implication. Short Python programs check formulas against simulation — a habit worth keeping: never trust a formula you have not seen agree with reality at least once.

The tools are grouped into four clusters:

- **Number sense** (§4.3–§4.5): exponents, logarithms and units, the arithmetic of "how big" and "how fast".
- **Uncertainty** (§4.6–§4.9): probability, statistics, percentiles and the small amount of linear algebra you need before the ML chapters.
- **Performance laws** (§4.10–§4.13): queueing theory, Little's Law, Amdahl's and Gustafson's laws and the Universal Scalability Law.
- **Dependability** (§4.14–§4.16): availability, reliability and durability arithmetic.

The chapter closes with the latency numbers that anchor estimation (§4.17) and with the six quantitative relationships that recur throughout the rest of the book (§4.18).

4.1 Learning objectives

After this chapter you should be able to:

- Convert fluently between powers of two and powers of ten, and between bits, bytes, SI prefixes and binary prefixes, stating which convention you use.
- Use logarithms to explain why binary search and B-trees need so few steps, and compute the height of a B-tree for a given fan-out and data size.

- Calculate the probability that at least one of N components fails, the expected number of failures, and the binomial probability of exactly k failures.
- Compute mean, median, variance, standard deviation and percentiles from a sample, and explain why the mean is misleading for heavy-tailed latency distributions.
- Quantify tail-latency amplification under fan-out using $P(\text{all fast}) = p^N$.
- Compute a dot product, a cosine similarity and the floating-point cost of a matrix multiplication.
- Apply the M/M/1 formulas to predict how latency grows with utilization, and explain why a shared queue beats separate queues.
- Size thread pools and database connection pools with Little's Law.
- Predict the limits of parallel speedup with Amdahl's Law, Gustafson's Law and the Universal Scalability Law.
- Compute the availability of components in series, in parallel and in k-of-n configurations, and convert availability targets to downtime budgets.
- Relate MTBF, MTTR, failure rate and availability, and estimate the annual probability of data loss for a replicated store.
- Use dated latency reference numbers to sanity-check designs, and reason quantitatively about six recurring trade-offs.

4.2 Prerequisites

- High-school algebra: fractions, exponents, solving a linear equation — every formula in the chapter is built from these.
- The vocabulary of latency, throughput and availability from §1.7 (Non-functional requirements) — this chapter makes those words measurable.
- Orders-of-magnitude reasoning from §2.10 (Reasoning about scale) — helpful but not required; this chapter supplies the underlying mathematics.
- A Python 3 interpreter (3.10 or later) if you want to run the code examples. All examples use only the standard library.

4.3 Exponents, powers of two and powers of ten

4.3.1 What an exponent is

DEFINITION

Definition — Exponent. In b^n, the **base** b is multiplied by itself n times; n is the **exponent** (or power). By convention $b^0 = 1$ and $b^{-n} = 1/b^n$.

First-principles explanation

Imagine folding a sheet of paper in half repeatedly. After one fold it is 2 layers thick, after two folds 4 layers, after three folds 8. Each fold *doubles* the count, so after n folds there are 2^n layers. After 10 folds you have 1,024 layers; after 20 folds, about a million. Exponential growth is the arithmetic of repeated multiplication, and computers are full of it, because every extra bit in an address or identifier doubles the number of values it can represent.

Three rules do almost all the work in estimation:

FORMULA

Laws of exponents

$$b^m \times b^n = b^{m+n} \qquad \frac{b^m}{b^n} = b^{m-n} \qquad (b^m)^n = b^{mn}$$

Symbol	Meaning	Units
b	Base (2 for binary quantities, 10 for decimal)	dimensionless
m, n	Exponents	dimensionless

WORKED EXAMPLE

Worked example — Multiplying large numbers by adding exponents. A service handles 2×10^4 requests per second (RPS). How many requests is that per day?

1. Seconds per day: $86,400 \approx 8.64 \times 10^4$.
2. Multiply the mantissas: $2 \times 8.64 = 17.28$.
3. Add the exponents: $10^4 \times 10^4 = 10^8$.
4. Result: $17.28 \times 10^8 = 1.728 \times 10^9$ requests per day.

Interpretation. About 1.7 billion requests per day. **Engineering implication.** If each request writes a 1 KB log line, that is $1.7 \times 10^9 \times 10^3 = 1.7 \times 10^{12}$ bytes, roughly 1.7 TB of logs per day — a number that immediately tells you logs need their own retention and sampling plan.

4.3.2 Powers of two

Memory addresses, identifiers, hash spaces and page sizes are all powers of two because hardware is built from binary switches. The key coincidence that makes mental arithmetic possible is

$$2^{10} = 1,024 \approx 10^3.$$

Every additional factor of 2^{10} is therefore “about another factor of a thousand”.

Table 4.1 — Powers of two that every engineer should recognize.

Power	Exact value	Approximately	Binary prefix	Typical meaning
2^{10}	1,024	one thousand (10^3)	kibi (Ki)	1 KiB of memory
2^{16}	65,536	65 thousand	—	Number of TCP/UDP port numbers; max of a 16-bit unsigned integer + 1
2^{20}	1,048,576	one million (10^6)	mebi (Mi)	1 MiB
2^{30}	1,073,741,824	one billion (10^9)	gibi (Gi)	1 GiB
2^{32}	4,294,967,296	4.3 billion	—	IPv4 address space; 32-bit ID space
2^{40}	1,099,511,627,776	one trillion (10^{12})	tebi (Ti)	1 TiB
2^{50}	1,125,899,906,842,624	one quadrillion (10^{15})	pebi (Pi)	1 PiB
2^{60}	1,152,921,504,606,846,976	one quintillion (10^{18})	exbi (Ei)	1 EiB
2^{64}	18,446,744,073,709,551,616	1.8×10^{19}	—	64-bit ID or hash space

Notice that the approximation drifts: 2^{10} is 2.4% larger than 10^3, but 2^{40} is 10% larger than 10^{12} and 2^{60} is 15% larger than 10^{18}. For estimation this is fine; for billing or capacity contracts it is not (see §4.5.2).

WORKED EXAMPLE

Worked example — How long until a 32-bit ID runs out? A table uses a 32-bit unsigned integer as its auto-increment primary key and receives 10,000 inserts per second.

1. ID space: $2^{32} = 4,294,967,296$ values.
2. Seconds to exhaust: $4,294,967,296 / 10,000 = 429,497$ s.
3. Convert to days: $429,497 / 86,400 \approx 4.97$ days.

Interpretation. Under five days. Even at 100 inserts per second the space lasts only about 497 days. **Engineering implication.** Use 64-bit identifiers for any table that grows without bound; at 10,000 inserts per second a 64-bit space lasts $1.8 \times 10^{19} / 10^4 \approx 1.8 \times 10^{15}$ s, roughly 58 million years. Unique ID generation is covered in §17.10.

4.3.3 Powers of ten and scientific notation

Scientific notation writes a number as a mantissa between 1 and 10 times a power of ten: 86,400 becomes 8.64×10^4. In estimation you usually round the mantissa to one significant figure and keep only the exponent honest. Being off by a factor of 2 rarely changes a design decision; being off by a factor of 1,000 always does. The **order of magnitude** of a number is its power of ten, and most back-of-the-envelope reasoning (§2.11, Chapter 89) is order-of-magnitude reasoning.

4.4 Logarithms

4.4.1 What a logarithm is

DEFINITION

Definition — Logarithm. The logarithm base b of x, written $\log_b x$, is the exponent to which b must be raised to give x: if $b^y = x$ then $y = \log_b x$.

First-principles explanation

A logarithm answers the question “how many times do I have to multiply (or divide) to get there?”. Go back to the folded paper: if you want 1,024 layers, how many folds? $\log_2 1024 = 10$. Turn it around: if you have a phone book of 1,024 pages and open it in the middle, then in the middle of the correct half, and so on, how many openings until you reach one page? Also 10. A logarithm counts *halvings*. That is the reason logarithms appear wherever a data structure repeatedly cuts the search space: binary search, balanced trees, B-trees, skip lists, consistent-hash rings with binary-searched tokens.

Why does this exist?

Data sets grow multiplicatively (thousands, millions, billions), and the cost of searching them should not. Logarithms convert the multiplicative growth of n into the additive growth of the step count: multiplying n by 1,000 adds only about 10 steps to a binary search.

4.4.2 Rules and change of base

FORMULA

Logarithm rules and change of base

$$\log_b (xy) = \log_b x + \log_b y \qquad \log_b (x^k) = k \log_b x \qquad \log_b x = \frac{\ln x}{\ln b} = \frac{\log_{10} x}{\log_{10} b}$$

Symbol	Meaning	Units
b	Base of the logarithm ($b > 0$, $b \neq 1$)	dimensionless
x, y	Positive numbers	dimensionless
k	Any real exponent	dimensionless
$\ln$	Natural logarithm, base $e \approx 2.71828$	—

The change-of-base rule means you only need one logarithm on your calculator. Two handy constants: $\log_2 10 \approx 3.32$ and $\log_{10} 2 \approx 0.301$.

WORKED EXAMPLE

Worked example — Binary search over one billion keys. How many comparisons does binary search need to find a key among $n = 10^9$ sorted keys?

1. We need $\log_2 (10^9)$.
2. Change of base: $\log_2 (10^9) = 9 \times \log_2 10 = 9 \times 3.32 = 29.9$.
3. Round up: 30 comparisons.

Interpretation. Thirty comparisons to search a billion items; a linear scan needs on average 500 million. **Engineering implication.** Each comparison in RAM costs on the order of 100 ns if it misses the CPU cache (§4.17), so 30 comparisons take roughly 3 µs. A sorted array or balanced tree in memory is fast enough for almost any lookup workload; the problem only becomes hard when each step requires a disk read, which is exactly the problem B-trees solve.

4.4.3 B-tree fan-out: why databases need only three or four disk reads

A binary tree halves the search space at each node, so a billion keys need about 30 levels. If each level is a random disk read, 30 reads is far too slow. A **B-tree** (detailed in §11.8 and §13.6) instead stores hundreds of keys per node, sized to fill one disk page, so each node splits the search space into hundreds of ranges [Bayer and McCreight 1972]. The number of children per node is the **fan-out** f.

FORMULA

Height of a B-tree

$$h = \lceil \log_f n \rceil = \lceil \frac{\log n}{\log f} \rceil$$

Symbol	Meaning	Units
h	Number of levels from root to leaf (page reads per lookup if nothing is cached)	levels
n	Number of keys indexed	keys
f	Fan-out: child pointers per internal node	children/node
$\lceil \cdot \rceil$	Ceiling: round up to the next integer	—

The derivation is the same counting argument as the paper folds: one root reaches f children, which reach f^2 grandchildren, so h levels reach f^h leaves. We need $f^h \geq n$, so $h \geq \log_f n$.

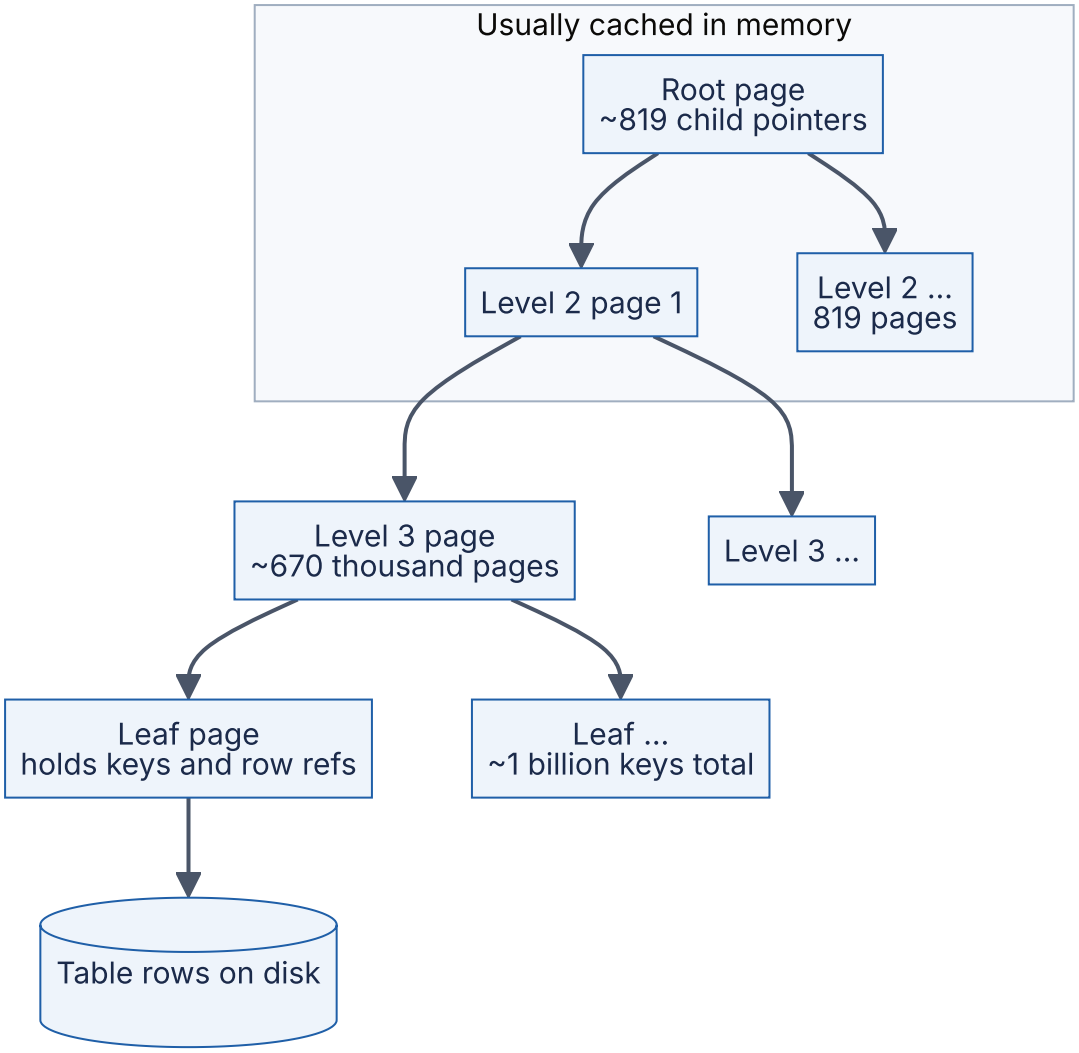
WORKED EXAMPLE

Worked example — Fan-out of a 16 KiB page. A database uses 16 KiB pages (16,384 bytes). Each index entry in an internal node is an 8-byte key plus an 8-byte child pointer = 16 bytes. Assume 20% of each page goes to headers and free space. How tall is the index on 10^9 keys?

1. Usable bytes per page: $16,384 \times 0.8 = 13,107$ bytes.
2. Fan-out: $f = 13,107/16 \approx 819$ children per node.
3. Height: $\log_{819}(10^9) = \frac{\log_{10} 10^9}{\log_{10} 819} = \frac{9}{2.913} = 3.09$.
4. Round up: $h = 4$ levels.
5. Compare: with $f = 1,000$ the height would be exactly $9/3 = 3$; a binary tree needs 30.

Interpretation. Four page reads locate any one of a billion keys. **Engineering implication.** The top two levels contain only $1 + 819 = 820$ pages, about 13 MiB, which fits easily in the buffer pool (§13.4). In practice a point lookup therefore costs one or two real I/Os, around 0.1–0.2 ms on an NVMe SSD (§4.17). Larger keys shrink fan-out: a 100-byte string key gives $f \approx 13,107/108 \approx 121$ and $h = \lceil 9/2.083 \rceil = 5$. Short keys are an index-design decision with measurable latency consequences.

Figure 4.1 — B-tree fan-out turns a billion keys into four levels.



Reading the diagram. Each rectangle is one fixed-size page. A lookup flows top-down synchronously: read the root, binary-search its keys in memory, follow one child pointer, repeat. The number of pages per level multiplies by the fan-out (1 → 819 → about 670,000 → leaves), so the count of *levels* grows only logarithmically. The `Cached` subgraph marks the storage boundary that matters: pages above it are in RAM and cost nanoseconds to microseconds, pages below it may require a disk read. The failure point is a cold cache after a restart, when every level costs an I/O. Scaling the data by another factor of 819 adds only one level.

COMMON MISTAKE

Mistake — "Logarithmic means constant, so the base doesn't matter." Thirty dependent SSD reads at ~100 µs is 3 ms; four is 0.4 ms. The fan-out changes the constant by an order of magnitude.

4.5 Units: bits, bytes, rates and prefixes

4.5.1 Bits versus bytes

DEFINITION

Definition — Bit and byte. A **bit** (symbol b) is a single binary digit, 0 or 1. A **byte** (symbol B) is 8 bits. Storage and memory are conventionally measured in bytes; network link speeds are conventionally measured in bits per second (bps).

The lowercase/uppercase distinction is load-bearing: 1 Gbps (gigabit per second) is one-eighth of 1 GB/s (gigabyte per second). Mixing them up produces an error of exactly 8×, which is large enough to invalidate a design and small enough to escape notice.

FORMULA

Converting link speed to byte throughput

$$R_{\text{B/s}} = \frac{R_{\text{bps}}}{8} \qquad t_{\text{transfer}} = \frac{8 \times S}{R_{\text{bps}}}$$

Symbol	Meaning	Units
R_{bps}	Link rate	bits/second
$R_{\text{B/s}}$	The same rate expressed in bytes	bytes/second
S	Amount of data to transfer	bytes
t_{transfer}	Ideal transfer time, ignoring protocol overhead and congestion	seconds

WORKED EXAMPLE

Worked example — Copying 1 TB across a 1 Gbps link.

1. Convert data to bits: $1\ \text{TB} = 10^{12}$ bytes $= 8 \times 10^{12}$ bits.
2. Divide by the rate: $8 \times 10^{12} / 10^{9} = 8,000$ s.
3. Convert to hours: $8,000 / 3,600 \approx 2.2$ h.
4. At 10 Gbps: 800 s ≈ 13 min.

Interpretation. Even a "fast" link takes hours to move a terabyte; real transfers are slower because TCP/IP headers, TLS and congestion reduce goodput, commonly by 5–10% or more. **Engineering implication.** Rebuilding a failed 20 TB storage node over a single 10 Gbps link takes at least $8 \times 2 \times 10^{13} / 10^{10} = 16,000$ s, about 4.4 hours. That repair window feeds directly into the durability calculations of §4.16, and it is why distributed stores spread re-replication across many source nodes in parallel.

4.5.2 SI versus binary prefixes

Two systems of prefixes coexist. The **SI (decimal) prefixes** k, M, G, T, P, E mean $10^3, 10^6, 10^9, \ldots$ exactly. The **binary prefixes** Ki, Mi, Gi, Ti, Pi, Ei, standardized by the IEC (now in IEC 80000-13) [IEC 80000-13], mean $2^{10}, 2^{20}, 2^{30}, \ldots$ exactly. Operating systems, memory vendors and disk vendors have historically used "GB" for both, which causes the classic "missing" capacity on a new drive.

Table 4.2 — SI versus binary prefixes.

SI name	SI value	Binary name	Binary value	Binary/SI ratio
kilobyte (KB or kB)	10^3	kibibyte (KiB)	2^{10}	1.024
megabyte (MB)	10^6	mebibyte (MiB)	2^{20}	1.049
gigabyte (GB)	10^9	gibibyte (GiB)	2^{30}	1.074
terabyte (TB)	10^{12}	tebibyte (TiB)	2^{40}	1.100
petabyte (PB)	10^{15}	pebibyte (PiB)	2^{50}	1.126
exabyte (EB)	10^{18}	exbibyte (EiB)	2^{60}	1.153

Book convention. Following `terminology.md`, this book uses KB/MB/GB/TB $= 10^3/10^6/10^9/10^{12}$ bytes for estimation and KiB/MiB/GiB when power-of-two precision matters (page sizes, memory allocation). Network rates are always decimal: 1 Gbps $= 10^9$ bits/s.

WORKED EXAMPLE

Worked example — The "missing" 7% on a new drive. A drive sold as 1 TB is shown by an operating system as "931 GB".

1. The vendor means SI: 10^{12} bytes.
2. The operating system divides by 2^{30} but labels the result "GB": $10^{12} / 1,073,741,824 = 931.3$.
3. So the drive holds 931.3 GiB, and nothing is missing.

Interpretation. A 6.9% labeling discrepancy at the tera scale, growing to 12.6% at peta and 15.3% at exa. **Engineering implication.** In a capacity plan for 5 PB of data, confusing PB with PiB means under-provisioning by $5 \times 0.126 = 0.63$ PB. State your units in every capacity document.

4.5.3 Rates and time conversions

Most capacity estimates start from a daily or monthly volume and must become a per-second rate, because servers are sized per second.

Table 4.3 — Time conversions used in estimation.

Period	Seconds (exact)	Handy approximation
1 minute	60	—
1 hour	3,600	3.6×10^3
1 day	86,400	$\approx 10^5$ (overestimates seconds by 16%)
1 week	604,800	$\approx 6 \times 10^5$
1 month (30 days)	2,592,000	$\approx 2.6 \times 10^6$
1 year (365 days)	31,536,000	$\approx \pi \times 10^7$

FORMULA

Average and peak rate from a daily volume

$$\bar{\lambda} = \frac{V_{\text{day}}}{86,400} \qquad \lambda_{\text{peak}} = k \times \bar{\lambda}$$

Symbol	Meaning	Units
V_{day}	Events (requests, writes, messages) per day	events/day
$\bar{\lambda}$	Average rate	events/second
k	Peak-to-average ratio, measured or assumed (often 2–10 for consumer traffic)	dimensionless
λ_{peak}	Rate the system must be sized for	events/second

WORKED EXAMPLE

Worked example — 100 million requests per day.

1. Average: $10^8 / 86,400 = 1,157$ RPS.
2. Shortcut check: $10^8 / 10^5 = 1,000$ RPS (16% low, acceptable for a first pass).
3. Assume a peak-to-average ratio $k = 3$: $\lambda_{\text{peak}} \approx 3,500$ RPS.

Interpretation. “100 million a day” sounds enormous but is a few thousand requests per second at peak. **Engineering implication.** A few application servers can carry this request rate; the harder questions are usually storage growth and tail latency, not raw request rate. The peak factor k is an assumption that must be stated and, once the system is live, measured.

4.6 Probability essentials

4.6.1 Probability, complement and independence

DEFINITION

Definition — Probability. A number between 0 and 1 that measures how likely an event is: 0 means impossible, 1 means certain. If an experiment is repeated many times, the probability of event A, written $P(A)$, is the long-run fraction of repetitions in which A happens.

First-principles explanation

Think of a fleet as a bag of marbles: if 1 in 1,000 is red, a blind draw is red with probability 0.001. Probability in system design is about the *fleet*: a disk with a 2% annual failure probability is rare on its own and a daily event among 100,000 disks.

Two rules carry most of the weight. The **complement rule**: $P(\text{not } A) = 1 - P(A)$; computing "nothing goes wrong" is often far easier than enumerating what can. **Independence**: A and B are independent if knowing one happened tells you nothing about the other; then, and *only* then, $P(A \text{ and } B) = P(A) \times P(B)$. Disks in different datacenters fail nearly independently; disks sharing a power supply do not.

FORMULA

Probability that at least one of N independent components fails

$$P(\text{at least one fails}) = 1 - (1 - p)^N$$

Symbol	Meaning	Units
p	Probability that a single component fails during the period of interest	dimensionless (0–1)
N	Number of independent components	count
$(1 - p)^N$	Probability that *none* fails (complement, multiplied N times by independence)	dimensionless

Derivation. One component survives with probability $1 - p$. By independence, all N survive with probability $(1 - p) \times (1 - p) \times \cdots = (1 - p)^N$. "At least one fails" is the complement of "all survive". A useful approximation for small p: $(1 - p)^N \approx e^{-Np}$, so $P(\text{at least one}) \approx 1 - e^{-Np}$, and when $Np \ll 1$ this is simply $\approx Np$.

WORKED EXAMPLE

Worked example — At least one of 1,000 servers fails today. Each server independently fails on a given day with probability $p = 0.001$ (one failure per thousand server-days). The fleet has $N = 1,000$ servers.

1. Probability one server survives the day: $1 - 0.001 = 0.999$.
2. Probability all survive: 0.999^{1000}. Using the approximation: $e^{-1000 \times 0.001} = e^{-1} = 0.368$. (Exact: 0.3677.)
3. Probability at least one fails: $1 - 0.368 = 0.632$.

Interpretation. A component that almost never fails individually produces a failure on 63% of days at fleet scale. At $N = 10,000$ the probability is $1 - e^{-10} > 0.9999$: a failure *every* day. **Engineering implication.** At scale, failure is not an exception to handle but a steady background rate to design for. This is the quantitative core of "design for failure" (§2.9): automation must detect and replace failed nodes without human intervention, because humans cannot be paged every day for routine events.

4.6.2 Union and intersection

FORMULA

Union (inclusion-exclusion) and intersection

$$P(A \cup B) = P(A) + P(B) - P(A \cap B) \qquad P(A \cap B) = P(A) \times P(B \mid A)$$

Symbol	Meaning	Units
$P(A \cup B)$	Probability that A or B (or both) happens	dimensionless
$P(A \cap B)$	Probability that both happen	dimensionless
$P(B \mid A)$	Conditional probability of B given that A happened; equals $P(B)$ when independent	dimensionless

The subtraction in the union rule avoids counting "both" twice. The conditional form of the intersection rule is how correlation enters: if two replicas share a rack, $P(B \mid A)$ — the probability that the second fails *given* that the first did — can be many times larger than $P(B)$.

WORKED EXAMPLE

Worked example — Two dependencies, independent versus correlated. A request needs both a cache and a database. On a given day, the cache has an outage with probability 0.01 and the database with probability 0.02.

1. If independent: $P(\text{both}) = 0.01 \times 0.02 = 0.0002$.
2. $P(\text{either}) = 0.01 + 0.02 - 0.0002 = 0.0298$.
3. Now suppose they share a network switch, so that given a cache outage the database is also out with probability 0.5: $P(\text{both}) = 0.01 \times 0.5 = 0.005$ — 25 times the independent value.

Interpretation. The probability of "something breaks" barely changes, but the probability of "both break together" rises 25×. **Engineering implication.** Redundancy arithmetic (§4.14, §4.16) assumes independence. Every shared dependency — a rack, a power feed, a software version, a configuration push — breaks that assumption, which is why real systems spread replicas across failure domains.

4.6.3 Expected value

DEFINITION

Definition — Expected value. The probability-weighted average outcome of a random quantity X: $E[X] = \sum_i x_i \, P(X = x_i)$. It is the long-run average over many repetitions.

FORMULA

Expected value and linearity of expectation

$$E[X] = \sum_i x_i \, P(X = x_i) \qquad E[X_1 + X_2 + \cdots + X_N] = E[X_1] + \cdots + E[X_N]$$

Symbol	Meaning	Units
X	A random quantity (failures, latency, cost)	units of the quantity
x_i	A possible value of X	units of the quantity
$P(X = x_i)$	Probability of that value	dimensionless

Linearity is powerful because it holds *even when the components are not independent*. The expected number of failed servers is $N \times p$ whatever the correlation.

WORKED EXAMPLE

Worked example — Expected cost of a retry policy. A call fails with probability 0.05 and is retried once on failure. What is the expected number of calls per request?

1. Outcomes: 1 call with probability 0.95; 2 calls with probability 0.05.
2. $E[\text{calls}] = 1 \times 0.95 + 2 \times 0.05 = 0.95 + 0.10 = 1.05$.

Interpretation. Retries add 5% load in normal operation. But if a dependency is degraded so that 50% of calls fail, the same policy gives $1 \times 0.5 + 2 \times 0.5 = 1.5$ calls per request — a 50% load increase on the struggling dependency. **Engineering implication.** Retries amplify load precisely when the system is weakest. Retry budgets (§22.12) cap this expected amplification.

4.6.4 The binomial distribution

When there are N independent trials, each "failing" with probability p, the number of failures K follows a **binomial distribution**.

FORMULA

Binomial probability of exactly k failures

$$P(K = k) = \binom{N}{k} p^k (1-p)^{N-k}, \qquad \binom{N}{k} = \frac{N!}{k!\,(N-k)!}, \qquad E[K] = Np$$

Symbol	Meaning	Units
N	Number of independent components (trials)	count
k	Number of failures we ask about	count
p	Per-component failure probability in the period	dimensionless
$\binom{N}{k}$	Number of ways to choose which k components fail ("N choose k")	count
$E[K]$	Expected number of failures	count

Derivation. One specific set of k failures and $N-k$ survivals has probability $p^k(1-p)^{N-k}$ by independence. There are $\binom{N}{k}$ such sets, and they are mutually exclusive, so we add them.

WORKED EXAMPLE

Worked example — How many spare servers are enough? Continuing the fleet of $N = 1,000$ servers with daily failure probability $p = 0.001$:

1. Expected failures per day: $E[K] = 1000 \times 0.001 = 1$.
2. $P(K = 0) = 0.999^{1000} = 0.3677$.
3. $P(K = 1) = 1000 \times 0.001 \times 0.999^{999} = 0.3681$.
4. $P(K = 2) = \binom{1000}{2} \times 0.001^2 \times 0.999^{998} = 499,500 \times 10^{-6} \times 0.3685 = 0.1840$.
5. $P(K \geq 3) = 1 - 0.3677 - 0.3681 - 0.1840 = 0.0802$.

Interpretation. On about 8% of days — roughly 29 days per year — three or more servers fail. **Engineering implication.** Provisioning spare capacity for "the average day" (one failure) leaves you short on one day in twelve. Capacity headroom should be chosen against a percentile of the failure distribution, not its mean.

4.7 Statistics: describing measurements

Probability reasons forward from a model to predictions. **Statistics** reasons backward from measurements (latency samples, failure logs) to a description of what is happening.

4.7.1 Mean and median

DEFINITION

Definition — Mean and median. The **mean** (arithmetic average) of n values is their sum divided by n. The **median** is the middle value after sorting (the average of the two middle values when n is even); half of the values are at or below it.

First-principles explanation

If nine people in a café each earn 50,000 a year and a billionaire walks in, the mean income in the room jumps to over 100 million while the median does not move. The mean is sensitive to every value, including extreme ones; the median is sensitive only to rank. Latency data behave like the café: most requests are quick, a few are extremely slow, and the slow ones drag the mean.

FORMULA

Mean, variance and standard deviation

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \qquad \sigma^2 = \frac{1}{n}\sum_{i=1}^{n} (x_i - \bar{x})^2 \qquad \sigma = \sqrt{\sigma^2}$$

Symbol	Meaning	Units
x_i	The i-th measurement	e.g. ms
n	Number of measurements	count
$\bar{x}$	Mean	same as x (ms)
σ^2	Variance: average squared distance from the mean	ms²
σ	Standard deviation: typical distance from the mean	ms

This is the *population* variance (divide by n). When estimating the variance of a larger population from a sample, statisticians divide by $n - 1$ instead (the *sample* variance); for the large samples typical of latency monitoring the difference is negligible.

WORKED EXAMPLE

Worked example — Ten latency measurements with one outlier. Measured latencies in ms: 12, 15, 11, 14, 13, 16, 12, 18, 14, 250.

1. Sum: $12 + 15 + 11 + 14 + 13 + 16 + 12 + 18 + 14 + 250 = 375$. Mean: $375/10 = 37.5$ ms.
2. Sorted: 11, 12, 12, 13, 14, 14, 15, 16, 18, 250. Median: average of 5th and 6th values $= (14 + 14)/2 = 14$ ms.
3. Squared deviations from 37.5: $(12 - 37.5)^2 = 650.25$; similarly 506.25, 702.25, 552.25, 600.25, 462.25, 650.25, 380.25, 552.25, and $(250 - 37.5)^2 = 45,156.25$. Sum $= 50,212.5$.
4. Variance: $50,212.5/10 = 5,021.25$ ms². Standard deviation: $\sqrt{5021.25} = 70.9$ ms.
5. Without the outlier: mean 13.9 ms, median 14 ms, standard deviation 2.1 ms.

Interpretation. One slow request in ten makes the mean 2.7 times the median and inflates the standard deviation 34-fold. The mean (37.5 ms) describes *no actual request*: nine were under 20 ms and one was 250 ms. **Engineering implication.** Report latency as percentiles (§4.8), not as mean ± standard deviation. Mean and standard deviation summarize a distribution well only when it is roughly symmetric and thin-tailed, which latency almost never is.

4.7.2 Distributions: normal, exponential, log-normal and Pareto

A **probability distribution** describes how likely each value is. Four shapes cover most of what you will meet.

The **normal (Gaussian) distribution** is the symmetric bell curve. It arises when many small independent effects add up. About 68% of values lie within 1σ of the mean, 95% within 2σ and 99.7% within 3σ. Extreme values are vanishingly rare: a 6σ event has probability around 10^{-9}.

The **exponential distribution** describes the time between independent random events occurring at a constant average rate λ, such as request arrivals from many independent users, or failures of a component that does not age. Its mean is $1/\lambda$ and $P(T > t) = e^{-\lambda t}$. It is **memoryless**: having waited 5 seconds tells you nothing about how much longer you will wait. It underpins queueing theory (§4.10) and reliability theory (§4.15).

The **log-normal distribution** describes a quantity whose *logarithm* is normal — the result of many small *multiplicative* effects. Request latency often looks roughly log-normal: a long right tail, with the mean above the median. If $\ln X$ has mean μ and standard deviation s, then the median of X is e^{μ} and the mean is $e^{\mu + s^2/2}$.

The **Pareto (power-law) distribution** has $P(X > x) = (x_m/x)^{\alpha}$ for $x \geq x_m$. Its tail decays polynomially, not exponentially, so extreme values are far more common than a normal model predicts. File sizes, object popularity, and per-user activity are frequently described as heavy-tailed (Harchol-Balter 2013 discusses heavy-tailed job sizes in depth). With $\alpha \approx 1.16$ you get the “80/20 rule”: the top 20% of items account for 80% of the total. For $\alpha \leq 1$ the mean is infinite; for $\alpha \leq 2$ the variance is infinite, so sample averages never settle down.

FORMULA

Tail formulas for three skewed distributions

Exponential: $P(T > t) = e^{-\lambda t}$, $E[T] = \frac{1}{\lambda}$ Log-normal: median = e^{μ}, mean = $e^{\mu + s^2/2}$ Pareto: $P(X >$

Symbol	Meaning	Units
λ	Event rate of the exponential distribution	events/second
t	Elapsed time	seconds
μ, s	Mean and standard deviation of $\ln X$ for a log-normal X	ln of the unit of X
x_m	Pareto minimum (scale) value	unit of X (e.g. bytes)
α	Pareto tail index: smaller means heavier tail	dimensionless

Table 4.4 — Four distributions and where they appear in systems.

Distribution	Shape	Tail	Typical system quantity	Mean vs median
Normal	Symmetric bell	Very thin (e^{-x^2})	Aggregates of many small effects; measurement noise	Equal
Exponential	Decaying from zero	Thin (e^{-x})	Inter-arrival times; failures of non-aging parts	Mean ≈ 1.44 × median
Log-normal	Right-skewed	Moderately heavy	Request latency, service times	Mean > median
Pareto	Right-skewed, power law	Heavy (polynomial)	File sizes, key popularity, user activity	Mean ≫ median (may be infinite)

WORKED EXAMPLE

Worked example — Mean versus median for a log-normal latency. Suppose $\ln$ (latency in ms) has mean $\mu = \ln 20 = 2.996$ and standard deviation $s = 1.0$.

1. Median: $e^{\mu} = 20$ ms.
2. Mean: $e^{\mu + s^2/2} = e^{2.996 + 0.5} = 20 \times e^{0.5} = 20 \times 1.649 = 33.0$ ms.
3. The 99th percentile of a normal variable is $\mu + 2.326\,s$, so p99 $= e^{2.996 + 2.326} = 20 \times e^{2.326} = 20 \times 10.24 = 205$ ms.

Interpretation. The p99 is about 10 times the median, and the mean sits 65% above the median. **Engineering implication.** If you set a timeout at the mean (33 ms) you will time out nearly one request in three: $\ln 33 - \ln 20 = 0.50$, which is $0.5\,s$ above μ, and a normal variable exceeds $\mu + 0.5\,s$ with probability 0.31. The Python example in §4.8.2 samples this exact distribution and confirms these values empirically.

4.7.3 Why averages lie

Averages mislead in four recurring ways: **skew** (the mean is pulled toward the tail, as above); **time aggregation** (a day-long average of 50 ms can hide a 10-minute window at 2 s); **averaging percentiles** (a fleet p99 is not the mean of per-host p99s — merge histograms instead, §4.8.3); and **averaging over users** (if 1% of users send 50% of requests, per-request and per-user averages can tell opposite stories).

COMMON MISTAKE

Mistake — "Average latency is 40 ms, so we meet our 100 ms SLO." An SLO is about the fraction of requests that are fast enough. A mean of 40 ms is compatible with 10% of requests taking over a second. SLOs are written in percentiles (§39.6) for exactly this reason.

4.8 Percentiles and tail latency

4.8.1 Definition

DEFINITION

Definition — Percentile. The q-th percentile of a set of measurements is the value at or below which q% of the measurements fall. Latency percentiles are written **p50** (the median), **p95**, **p99** and **p99.9** (also written p999): the 50th, 95th, 99th and 99.9th percentiles.

First-principles explanation

Line up 1,000 runners by finishing time: the p50 is the 500th runner's time, the p99 the 990th's, the p99.9 the 999th's. Percentiles describe what a *fraction of requests* experiences — if your p99 is 2 s, one request in a hundred is painfully slow, and a page making 50 requests will often hit one (§4.8.4).

The region above roughly p99 is called the **tail**, and **tail latency** is the study of why those requests are slow and how to make them faster. Causes include garbage-collection pauses, queueing behind a large request, background compaction, cache misses, retransmitted packets and noisy neighbors [Dean and Barroso 2013].

4.8.2 Computing percentiles from samples

The simplest definition is the **nearest-rank method**.

FORMULA

Nearest-rank percentile

$$r = \lceil \frac{q}{100} \times n \rceil, \qquad \mathrm{p}q = x_{(r)}$$

Symbol	Meaning	Units
q	Desired percentile, $0 < q \le 100$	percent
n	Number of samples	count
r	1-based rank in the sorted list	position
$x_{(r)}$	The r-th smallest sample	e.g. ms

Other definitions interpolate between neighboring samples (NumPy's default does); they differ noticeably only when n is small. With 10 samples, a "p99" is just the maximum, which is why a p99 needs at least several hundred samples and a p99.9 several thousand to mean anything.

WORKED EXAMPLE

Worked example — Percentiles of the ten measurements from §4.7.1. Sorted: 11, 12, 12, 13, 14, 14, 15, 16, 18, 250.

1. p50: $r = \lceil 0.50 \times 10 \rceil = 5 \rightarrow 14$ ms.
2. p90: $r = \lceil 0.90 \times 10 \rceil = 9 \rightarrow 18$ ms.
3. p95: $r = \lceil 0.95 \times 10 \rceil = \lceil 9.5 \rceil = 10 \rightarrow 250$ ms.

Interpretation. p90 and p95 differ by a factor of 14 because with ten samples they land on different single observations. **Engineering implication.** Always report the sample count alongside a high percentile, and alert on percentiles computed over windows large enough to contain hundreds of tail samples.

The following program samples the log-normal distribution of §4.7.2, computes percentiles, and then checks the fan-out formula of §4.8.4 by simulation.

```
        import math
        import random
        import statistics

        def percentile_nearest_rank(samples, p):
            """Return the p-th percentile (0 < p <= 100) using the nearest-rank
method."""
            if not samples:
                raise ValueError("no samples")
            ordered = sorted(samples)
            rank = math.ceil(p / 100 * len(ordered))   # 1-based rank
            return ordered[max(rank, 1) - 1]

        random.seed(42)
        # Log-normal latencies: median ~20 ms, heavy right tail (sigma = 1.0)
        latencies_ms = [random.lognormvariate(math.log(20), 1.0) for _ in
range(100_000)]

        print(f"mean   = {statistics.fmean(latencies_ms):7.1f} ms")
        for p in (50, 90, 99, 99.9):
            print(f"p{p:<5} = {percentile_nearest_rank(latencies_ms, p):7.1f} ms")

        # Fan-out: a request waits for the slowest of N parallel calls
        p99 = percentile_nearest_rank(latencies_ms, 99)
        for n in (1, 10, 100):
            trials = 20_000
            slow = sum(
                max(random.choice(latencies_ms) for _ in range(n)) > p99
                for _ in range(trials)
            )
            print(f"N={n:>3}: simulated P(slow) = {slow/trials:.3f}, "
                  f"formula 1 - 0.99^N = {1 - 0.99**n:.3f}")
```

Output (Python 3.13):

```
mean   =    32.9 ms
p50    =    20.0 ms
p90    =    72.2 ms
p99    =   201.3 ms
p99.9  =   428.4 ms
N=  1: simulated P(slow) = 0.010, formula 1 - 0.99^N = 0.010
N= 10: simulated P(slow) = 0.093, formula 1 - 0.99^N = 0.096
N=100: simulated P(slow) = 0.637, formula 1 - 0.99^N = 0.634
```

What to notice:

- The simulated mean (32.9 ms), median (20.0 ms) and p99 (201 ms) match the closed-form values of §4.7.2 (33.0, 20 and 205 ms) within sampling error.
- `max(...)` models a request that must wait for *all* of its parallel sub-requests; the simulated probability of exceeding the single-server p99 matches $1 - 0.99^N$.
- Sorting 100,000 samples is fine offline, but production systems cannot keep every sample; they use histograms.

4.8.3 Histograms

A **histogram** counts how many samples fall into each of a fixed set of buckets. It uses constant memory regardless of request volume, and two histograms with identical buckets can be merged by adding counts, which makes fleet-wide percentiles possible. Percentiles are read from the cumulative counts, with an error no larger than the bucket width. Libraries such as HdrHistogram use buckets whose width grows with the value (logarithmic or log-linear buckets) so that *relative* error stays bounded across many orders of magnitude [Tene, HdrHistogram].

WORKED EXAMPLE

Worked example — p99 and p99.9 from a histogram. 10,000 requests are counted into buckets (ms): [0,10): 6,000; [10,20): 2,500; [20,50): 1,000; [50,100): 350; [100,200): 120; [200,500): 25; [500,1000): 5.

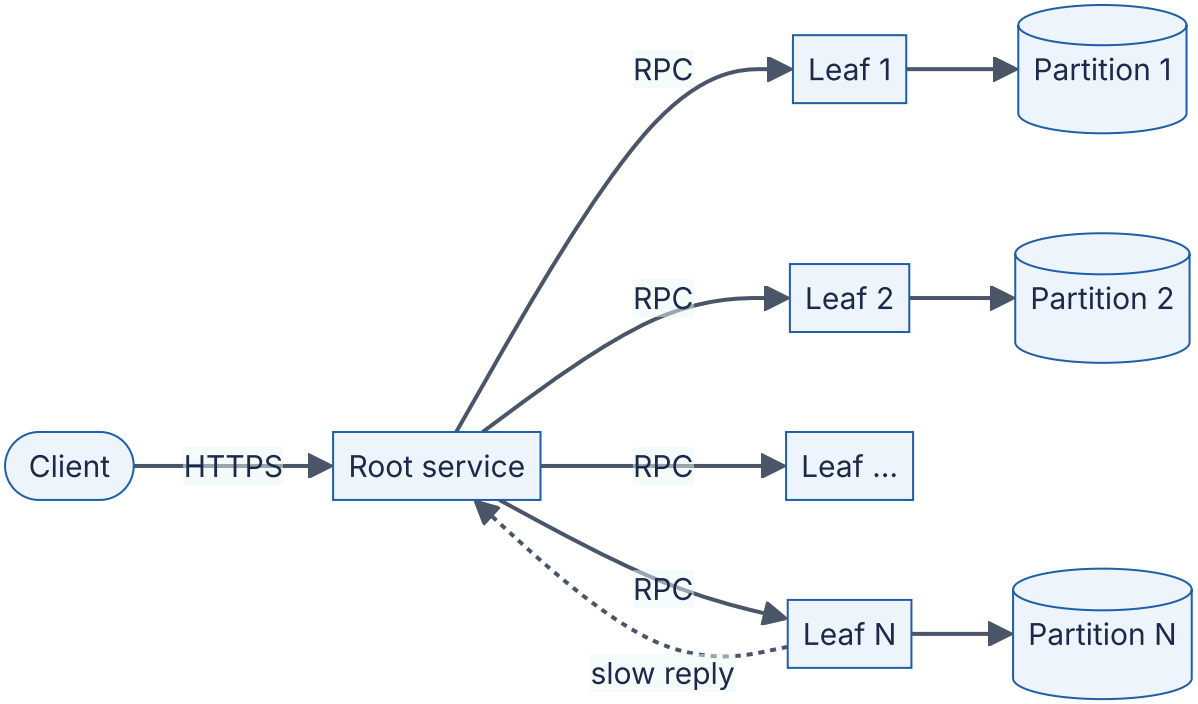
1. Cumulative counts: 6,000; 8,500; 9,500; 9,850; 9,970; 9,995; 10,000.
2. p99 is rank $0.99 \times 10,000 = 9,900$. The cumulative count first reaches 9,900 in the [100,200) bucket (9,850 → 9,970).
3. Interpolate linearly inside the bucket: $(9,900 - 9,850)/120 = 0.417$ of the way through, so p99 $\approx 100 + 0.417 \times 100 = 142$ ms.
4. p99.9 is rank 9,990, inside [200,500) (9,970 → 9,995): $(9,990 - 9,970)/25 = 0.8$, so p99.9 $\approx 200 + 0.8 \times 300 = 440$ ms.

Interpretation. The true p99 is somewhere in [100, 200) ms; interpolation assumes samples are spread evenly inside the bucket. **Engineering implication.** Bucket boundaries should be densest where your SLO thresholds lie. If the SLO is “p99 < 150 ms”, a bucket edge exactly at 150 ms lets you count SLO violations exactly rather than estimate them.

4.8.4 Fan-out amplification

Modern requests are rarely served by one machine. A search query may be scattered to hundreds of index partitions (§16.7); a page render may call dozens of microservices. If a request must wait for *all* of its *N* sub-requests, then it is slow whenever *any* of them is slow.

Figure 4.2 — Fan-out: the slowest leaf determines the response time.



Reading the diagram. The client sends one HTTPS request to a root service, which issues N parallel RPCs to leaf services, each owning one data partition (the cylinders mark storage boundaries). All arrows are synchronous request/response except the dotted arrow, which highlights the one leaf whose reply arrives late. The root cannot answer until every leaf replies (or a deadline fires), so the response time is the *maximum* of N leaf latencies. Every leaf is a failure point for the whole request. Scaling out by adding partitions increases N and therefore makes the tail *worse* unless tail-tolerant techniques are used.

FORMULA

Probability that a fan-out request is fast

$$P(\text{all } N \text{ fast}) = p^N \qquad P(\text{at least one slow}) = 1 - p^N \qquad p_{\text{required}} = P_{\text{target}}^{1/N}$$

Symbol	Meaning	Units
p	Probability that one leaf responds within the threshold (e.g. 0.99 at the leaf's p99)	dimensionless
N	Number of parallel sub-requests the root must wait for	count
P_{target}	Desired probability that the whole request is fast	dimensionless
p_{required}	Per-leaf probability needed to meet P_{target}	dimensionless

This is the complement rule of §4.6.1 again, assuming leaf latencies are independent.

WORKED EXAMPLE

Worked example — 100-way fan-out. Each leaf answers within 10 ms with probability 0.99 (its p99 is 10 ms). The root fans out to $N = 100$ leaves.

1. $P(\text{all fast}) = 0.99^{100} = 0.366$.
2. $P(\text{at least one slow}) = 1 - 0.366 = 0.634$.
3. For 99% of root requests to be fast we need $p = 0.99^{1/100} = 0.99990$: every leaf must meet the 10 ms threshold at its p99.99.
4. With $N = 10$: $0.99^{10} = 0.904$, so 9.6% of requests are slow.

Interpretation. A leaf p99 becomes the root's p37 or so: 63% of user requests see at least one slow leaf. This is the example Dean and Barroso use to open *The Tail at Scale*: with a one-in-a-hundred chance of a slow leaf, 63% of 100-way fan-out requests are slow [Dean and Barroso 2013]. **Engineering implication.** In fan-out architectures you must engineer the leaf p99.9 or p99.99, not the leaf p99, or use tail-tolerant techniques that break the p^N law.

Real-world industry applications

INDUSTRY EXAMPLE

Google — tail-tolerant techniques. Dean and Barroso describe how large fan-out services at Google tolerate latency variability instead of trying to eliminate it. **Hedged requests** send a second copy of a request to another replica if the first has not answered within, for example, the 95th-percentile expected latency, and use whichever reply arrives first; **tied requests** enqueue the request on two servers and let the first to start cancel the other. They report a benchmark reading 1,000 keys from 100 BigTable servers in which hedging after 10 ms cut the p99.9 latency from 1,800 ms to 74 ms while sending only about 2% more requests. Trade-off: hedging spends a little extra load to cut the tail, and must be disabled or rate-limited under overload so it does not amplify it. Chapter 23 (§23.6–§23.7) covers implementation. *Evidence: Primary* — [Dean and Barroso 2013]

Two further traps are covered in Chapter 23: computing a fleet p99 by averaging per-host p99s (merge histograms instead, §4.8.3), and **coordinated omission**, where a load generator that waits for slow replies stops sending during slow periods and so under-samples the tail (§23.5).

COMMON MISTAKE

Mistake — "Our p99 is fine, so only 1% of users suffer." If a user session issues 100 requests, the probability that the session contains at least one request slower than p99 is $1 - 0.99^{100} = 63\%$. Percentiles are per request; user experience is per session.

4.9 Basic linear algebra

This section is a preparation for the ML chapters (Part XI onward), where embeddings, similarity search and matrix multiplication dominate cost. You need only three ideas: vectors, the dot product and matrix multiplication.

4.9.1 Vectors

DEFINITION

Definition — Vector. An ordered list of d numbers, $\mathbf{a} = (a_1, a_2, \ldots, a_d)$, where d is the **dimension**. Geometrically, a vector is an arrow from the origin to a point in d-dimensional space; its **length** (or norm) is $\| \mathbf{a} \| = \sqrt{a_1^2 + \cdots + a_d^2}$.

First-principles explanation

A map location is a 2-dimensional vector (latitude, longitude); a song might be a 3-dimensional vector (tempo, loudness, acousticness). An ML **embedding** is the same idea with hundreds or thousands of learned dimensions, arranged so that similar items point in similar directions. "Find similar items" becomes "find nearby arrows" (Chapter 74).

4.9.2 Dot product and cosine similarity

FORMULA

Dot product and cosine similarity

$$\mathbf{a} \cdot \mathbf{b} = \sum_{i=1}^{d} a_i b_i \qquad \cos\theta = \frac{\mathbf{a} \cdot \mathbf{b}}{\|\mathbf{a}\| \, \|\mathbf{b}\|}$$

Symbol	Meaning	Units
$\mathbf{a}, \mathbf{b}$	Two vectors of the same dimension	(embedding units; dimensionless)
d	Dimension	count
a_i, b_i	i-th components	dimensionless
$\|\mathbf{a}\|$	Length of $\mathbf{a}$	dimensionless
θ	Angle between the vectors	radians or degrees
$\cos\theta$	Cosine similarity: 1 = same direction, 0 = unrelated (perpendicular), −1 = opposite	dimensionless

The dot product multiplies matching components and adds the results. Dividing by both lengths removes the effect of magnitude, so cosine similarity measures *direction only*. If vectors are normalized to length 1 in advance (common for embeddings), cosine similarity *is* the dot product, which is cheaper to compute.

WORKED EXAMPLE

Worked example — Which document is closest to the query? Query $\mathbf{q} = (1, 2, 2)$; document $\mathbf{a} = (2, 1, 2)$; document $\mathbf{b} = (2, 4, 4)$.

1. $\mathbf{q} \cdot \mathbf{a} = 1 \times 2 + 2 \times 1 + 2 \times 2 = 2 + 2 + 4 = 8$.
2. $\|\mathbf{q}\| = \sqrt{1 + 4 + 4} = 3$; $\|\mathbf{a}\| = \sqrt{4 + 1 + 4} = 3$.
3. $\cos\theta_{qa} = 8/(3 \times 3) = 0.889$ (an angle of about 27°).
4. $\mathbf{q} \cdot \mathbf{b} = 2 + 8 + 8 = 18$; $\|\mathbf{b}\| = \sqrt{4 + 16 + 16} = 6$; $\cos\theta_{qb} = 18/(3 \times 6) = 1.0$.

Interpretation. **b** is exactly twice **q**, so it points the same way: cosine 1.0. The raw dot product (18 vs 8) also prefers **b** but would be fooled by long vectors in general. **Engineering implication.** Choose the similarity metric the embedding model was trained with; normalize vectors once at ingestion so that serving-time similarity is a plain dot product.

4.9.3 Matrices and the cost of matrix multiplication

DEFINITION

Definition — Matrix. A rectangular grid of numbers with m rows and n columns (an $m \times n$ matrix). A set of n embeddings of dimension d is naturally stored as an $n \times d$ matrix, one embedding per row.

Multiplying an $m \times k$ matrix A by a $k \times n$ matrix B produces an $m \times n$ matrix C in which each entry C_{ij} is the dot product of row i of A with column j of B. Each of the $m \times n$ entries is a dot product of length k.

FORMULA

Cost of matrix multiplication

$$\text{FLOPs} = 2\,m\,n\,k \qquad \text{arithmetic intensity} = \frac{\text{FLOPs}}{\text{bytes moved}}$$

Symbol	Meaning	Units
m, k	Rows and columns of A	count
k, n	Rows and columns of B (inner dimension k must match)	count
FLOPs	Floating-point operations: one multiply and one add per term	operations
bytes moved	Data read from and written to memory	bytes
arithmetic intensity	FLOPs per byte; low values mean memory-bandwidth-bound, high values compute-bound	FLOP/byte

WORKED EXAMPLE

Worked example — Brute-force similarity search and the value of batching.

Part A: one query against one million embeddings. $n = 10^6$ embeddings of dimension $d = 768$ stored as 4-byte floats.

1. Storage: $10^6 \times 768 \times 4 = 3.07 \times 10^9$ bytes ≈ 3.1 GB.
2. Compute: one dot product per embedding, $10^6 \times 768 = 7.68 \times 10^8$ multiply-adds = 1.54×10^9 FLOPs.
3. Intensity: $1.54 \times 10^9 / 3.07 \times 10^9 = 0.5$ FLOP/byte — every float is loaded once and used once.
4. If memory delivers 20 GB/s to this computation (an illustrative figure), scanning takes $3.07/20 = 0.15$ s per query, regardless of how fast the arithmetic is.

Part B: a neural-network layer. Multiply a batch of m inputs ($m \times 4096$) by a 4096×4096 weight matrix stored in 2-byte (16-bit) floats.

1. Weights: $4096 \times 4096 \times 2 = 33.5$ MB.
2. With $m = 1$: FLOPs $= 2 \times 1 \times 4096 \times 4096 = 3.36 \times 10^7$, intensity ≈ $3.36 \times 10^7 / 3.36 \times 10^7 = 1$ FLOP/byte.
3. With $m = 32$: FLOPs $= 2 \times 32 \times 4096 \times 4096 = 1.07 \times 10^9$; the weights are read once for the whole batch, so intensity ≈ 32 FLOP/byte.

Interpretation. Brute-force search and single-request inference are *memory-bound*: the processor waits for data. Batching reuses each loaded weight for many inputs and raises arithmetic intensity proportionally. **Engineering implication.** At a million vectors and many queries per second, brute force is too slow, which motivates approximate nearest neighbor (ANN) indexes (Chapter 74). For model serving, batching is the main lever for throughput — at a latency cost quantified in §4.18.6.

```
        import math

        def dot(a, b):
            return sum(x * y for x, y in zip(a, b, strict=True))

        def norm(a):
            return math.sqrt(dot(a, a))

        def cosine_similarity(a, b):
            return dot(a, b) / (norm(a) * norm(b))

        def matmul(A, B):
            """Naive matrix multiply: (m x k) times (k x n) -> (m x n)."""
            m, k, n = len(A), len(B), len(B[0])
            assert all(len(row) == k for row in A), "inner dimensions must match"
            return [[sum(A[i][t] * B[t][j] for t in range(k)) for j in range(n)]
                    for i in range(m)]

        query = [1, 2, 2]
        docs = {"doc_a": [2, 1, 2], "doc_b": [2, 4, 4], "doc_c": [-2, 1, 0]}
        for name, vec in docs.items():
            print(f"{name}: dot = {dot(query, vec):3d}, cosine =
{cosine_similarity(query, vec):.3f}")

        # Score all documents at once: (1 x 3) query times (3 x 3) matrix of doc columns
        D = [list(col) for col in zip(*docs.values())]   # 3 x 3, one document per col-
umn
        print("scores via matmul:", matmul([query], D)[0])
```

Output:

```
doc_a: dot =   8, cosine = 0.889
doc_b: dot =  18, cosine = 1.000
doc_c: dot =   0, cosine = 0.000
scores via matmul: [8, 18, 0]
```

What to notice:

- `zip(..., strict=True)` (Python 3.10+) raises an error if dimensions differ, a cheap guard against mixing embeddings from different models.
- `doc_c` is perpendicular to the query (dot product 0): unrelated, not opposite.
- Scoring many documents is one matrix multiplication. The triple loop in `matmul` performs exactly $m \times n \times k$ multiply-adds; production libraries (BLAS, GPU kernels) do the same arithmetic but reorganize it to reuse data in caches.

4.10 Queueing theory

4.10.1 Vocabulary

DEFINITION

Definition — Queueing system. A model in which **jobs** (requests, messages, packets) arrive at a **service center**, wait in a **queue** if all **servers** are busy, receive service, and depart. The **arrival rate** λ is the average number of jobs arriving per second; the **service rate** μ is the average number of jobs one server can complete per second when it is never idle, so the average **service time** is $S = 1/\mu$.

First-principles explanation

Picture a supermarket checkout. Customers arrive at random and take a random time to serve. When the cashier is idle half the time, a queue rarely forms; when the cashier is busy 95% of the time, a long queue is routine, although the cashier is not technically overloaded. **Waiting is caused by variability, and its effect grows without bound as utilization approaches 100%.** With perfectly regular arrivals and service, a cashier at 99% would never have a queue. Every CPU core, disk, thread, connection and network link in a design is a checkout.

Why does this exist?

Capacity plans that ignore queueing assume a server at 90% utilization performs like one at 50%. It does not. Queueing theory, begun by Erlang for telephone exchanges and developed for computer systems from the 1960s onward [Kleinrock 1975; Harchol-Balter 2013], quantifies how much worse it is.

Kendall notation names queue models as A/S/c: arrival process / service-time distribution / number of servers. “M” stands for *Markovian* (memoryless): Poisson arrivals, meaning exponentially distributed gaps between arrivals (§4.7.2), or exponentially distributed service times. **M/M/1** is the simplest model: random arrivals, random service, one server, first-come-first-served, unlimited queue.

4.10.2 The M/M/1 queue

Figure 4.3 — The M/M/1 queue.

Reading the diagram. Jobs flow left to right. Arrivals come from many independent clients at average rate λ (requests/s); the queue (subroutine shape) is a buffer, typically in

memory, with no limit in this model; the single server processes one job at a time at average rate μ. In steady state, departures equal arrivals (λ), so throughput is set by demand, not by the server, as long as $\lambda < \mu$. The failure point is the queue itself: if $\lambda \geq \mu$ it grows without bound until memory or timeouts intervene. Scaling options are a faster server (raise μ), more servers (M/M/c, §4.10.4) or less demand (caching, load shedding).

FORMULA

M/M/1 results

$$\rho = \frac{\lambda}{\mu} \qquad W = \frac{1}{\mu - \lambda} = \frac{S}{1 - \rho} \qquad W_q = \frac{\rho}{\mu - \lambda} \qquad L = \frac{\rho}{1 - \rho} \qquad L_q = \frac{\rho^2}{1 - \rho}$$

Symbol	Meaning	Units
λ	Average arrival rate	jobs/second
μ	Average service rate of the server	jobs/second
$S = 1/\mu$	Average service time	seconds
ρ	Utilization: fraction of time the server is busy (must be < 1)	dimensionless
W	Average time in system (waiting + service), i.e. response time	seconds
W_q	Average time waiting in the queue before service starts	seconds
L	Average number of jobs in the system	jobs
L_q	Average number of jobs waiting in the queue	jobs

Derivation sketch. Because arrivals are memoryless, the number of jobs in the system behaves like a random walk that steps up at rate λ and down at rate μ. Balancing the flow between neighboring states gives $P(n \text{ jobs}) = (1 - \rho)\rho^n$, a geometric distribution. Its mean is $L = \rho/(1 - \rho)$. Little's Law (§4.11) then gives $W = L/\lambda = 1/(\mu - \lambda)$. A further useful fact: in M/M/1 the response time itself is exponentially distributed with rate $\mu - \lambda$, so its q-th percentile is $W \times \ln \frac{1}{1-q}$; the p99 is $W \times \ln 100 = 4.6W$ [Harchol-Balter 2013].

WORKED EXAMPLE

Worked example — One server at increasing load. A service handles requests in 10 ms on average ($\mu = 100$/s).

1. At $\lambda = 50$/s: $\rho = 0.5$; $W = 1/(100 - 50) = 0.020$ s $= 20$ ms; $L = 0.5/0.5 = 1$ request.
2. At $\lambda = 80$/s: $\rho = 0.8$; $W = 1/20 = 50$ ms; $L = 0.8/0.2 = 4$.
3. At $\lambda = 90$/s: $\rho = 0.9$; $W = 1/10 = 100$ ms; $L = 9$; $L_q = 0.81/0.1 = 8.1$; p99 $= 4.605 \times 100 \approx 461$ ms.
4. At $\lambda = 99$/s: $\rho = 0.99$; $W = 1/1 = 1,000$ ms.

Interpretation. Going from 50% to 90% utilization (1.8× the traffic) multiplies mean latency by 5, and the last 9% of traffic (90 → 99/s) multiplies it by another 10.
Engineering implication. Plan latency-sensitive services to run at moderate utilization at peak — often 50–70% for interactive work — and reserve high utilization for batch work whose latency nobody waits for.

Table 4.5 — M/M/1 response time as a multiple of service time.

Utilization ρ	$W/S = 1/(1-\rho)$	W when S = 10 ms	Jobs in system L	p99 when S = 10 ms
0.50	2	20 ms	1	92 ms
0.70	3.3	33 ms	2.3	154 ms
0.80	5	50 ms	4	230 ms
0.90	10	100 ms	9	461 ms
0.95	20	200 ms	19	921 ms
0.99	100	1,000 ms	99	4,605 ms

4.10.3 Why latency explodes near 100% utilization

The factor $1/(1-\rho)$ is the whole story. The distance to saturation, $1-\rho$, is in the denominator, so each halving of the remaining headroom doubles the latency: 0.8 → 0.9 doubles W, 0.9 → 0.95 doubles it again, and so on. The curve is the familiar “hockey stick”. Two practical consequences follow:

- **Small traffic increases near saturation cause large latency increases.** A service at 90% that sees a 5% traffic spike moves to 94.5%, and its mean latency nearly doubles.
- **Overload is not graceful.** At $\rho \geq 1$ there is no steady state: the queue grows for as long as the overload lasts, and every request that joins it waits for all earlier ones. Bounded queues, timeouts and load shedding (§22.9) exist to convert unbounded latency into fast, explicit rejection.

The M/M/1 model assumes exponential service times. Real service times can be more or less variable; the general **Pollaczek–Khinchine** formula for the M/G/1 queue shows that mean queueing delay is proportional to $(1 + C_S^2)/2$, where C_S is the coefficient of variation (standard deviation divided by mean) of the service time [Harchol-Balter 2013]. Exponential service has $C_S = 1$; perfectly constant service ($C_S = 0$) halves the queueing delay; heavy-tailed service ($C_S \gg 1$) multiplies it. The $1/(1 - \rho)$ explosion is present in all of them.

The following simulation checks the M/M/1 formula. It uses the recurrence "a job starts when it arrives or when the previous job finishes, whichever is later".

```
        import random

        def simulate_mm1(lam, mu, n_customers=200_000, seed=1):
            """Simulate a FIFO single-server queue with Poisson arrivals and
            exponential service times. Returns mean time in system (seconds)."""
            rng = random.Random(seed)
            arrival = 0.0          # arrival time of current customer
            server_free_at = 0.0   # time at which the server finishes its current job
            total_time = 0.0
            for _ in range(n_customers):
                arrival += rng.expovariate(lam)            # next arrival
                start = max(arrival, server_free_at)       # wait if server busy
                server_free_at = start + rng.expovariate(mu)
                total_time += server_free_at - arrival     # queueing + service
            return total_time / n_customers

        mu = 100.0  # server completes 100 requests/s on average (10 ms each)
        print(" rho   formula W (ms)   simulated W (ms)")
        for lam in (50, 80, 90, 95, 99):
            formula = 1 / (mu - lam)
            sim = simulate_mm1(lam, mu)
            print(f"{lam/mu:4.2f}   {formula*1000:12.1f}   {sim*1000:14.1f}")
```

Output:

```
 rho   formula W (ms)   simulated W (ms)
0.50           20.0             20.0
0.80           50.0             49.7
0.90          100.0             98.6
0.95          200.0            220.4
0.99         1000.0           1059.1
```

What to notice:

- At moderate utilization 200,000 simulated requests match the formula to within about 1%.
- Near saturation the simulation is noisy (±6–10% here) even with 200,000 requests: the queue drifts through long busy periods, so averages converge slowly. Load tests

near saturation need long runs for the same reason.

- `max(arrival, server_free_at)` is the entire queueing mechanism: waiting happens only when a job arrives before the previous one finishes.

4.10.4 Multiple servers: M/M/c intuition

With c identical servers sharing **one queue** (M/M/c), a job waits only if all c servers are busy. The probability of waiting is given by the **Erlang C** formula; utilization is $\rho = \lambda/(c\mu)$.

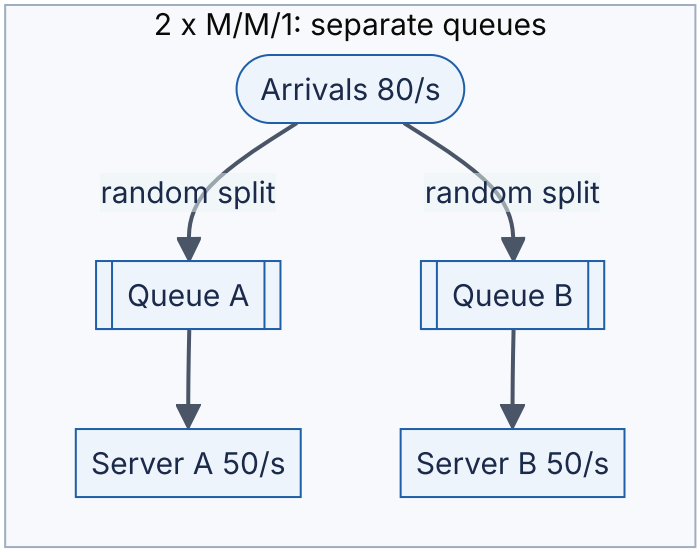
FORMULA

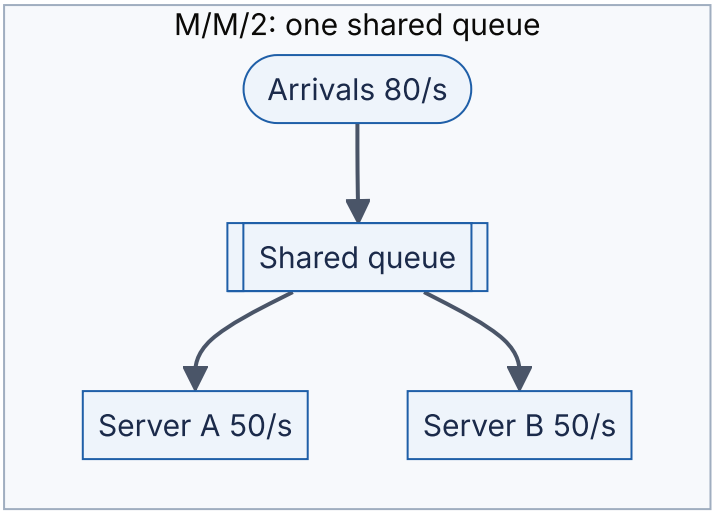
M/M/c (Erlang C)

$$a = \frac{\lambda}{\mu}, \quad \rho = \frac{a}{c}, \quad P_{\text{wait}} = \frac{\dfrac{a^c}{c!\,(1-\rho)}}{\sum_{k=0}^{c-1} \dfrac{a^k}{k!} + \dfrac{a^c}{c!\,(1-\rho)}}, \quad W = \frac{P_{\text{wait}}}{c\mu - \lambda} + \frac{1}{\mu}$$

Symbol	Meaning	Units
c	Number of servers sharing one queue	count
μ	Service rate of *each* server	jobs/second
a	Offered load: average number of busy servers	servers (Erlangs)
ρ	Per-server utilization (< 1)	dimensionless
P_{wait}	Probability an arriving job finds all servers busy	dimensionless
W	Mean response time	seconds

Figure 4.4 — One shared queue versus separate queues.





Reading the diagram. Both subgraphs have the same hardware (two servers at 50 jobs/s) and the same demand (80 jobs/s, $\rho = 0.8$). On the left, any idle server takes the next job from a shared queue. On the right, each job is assigned to a server's private queue at arrival, so one queue can hold waiting jobs while the other server sits idle. All paths are synchronous hand-offs. The failure point on the right is *imbalance*; the scaling lesson is that pooling beats partitioning for latency.

WORKED EXAMPLE

Worked example — Pooling. $\lambda = 80$/s; compare three designs with 100 jobs/s of total capacity.

1. *One fast server* (M/M/1, $\mu = 100$): $W = 1/(100 - 80) = 50$ ms.
2. *Two slow servers, separate queues* (each M/M/1 with $\lambda = 40$, $\mu = 50$): $W = 1/(50 - 40) = 100$ ms.
3. *Two slow servers, shared queue* (M/M/2, $\mu = 50$): $a = 80/50 = 1.6$, $\rho = 0.8$. Numerator: $a^2/(2!\,(1 - 0.8)) = 2.56/0.4 = 6.4$. Denominator: $1 + 1.6 + 6.4 = 9$. $P_{\text{wait}} = 6.4/9 = 0.711$. $W = 0.711/(100 - 80) + 1/50 = 0.0356 + 0.020 = 55.6$ ms.

Interpretation. The shared queue (55.6 ms) is nearly as good as one server twice as fast (50 ms) and almost twice as good as separate queues (100 ms) on identical hardware. **Engineering implication.** Prefer a shared work queue (one listen socket feeding a pool of workers, one broker topic with competing consumers) over static assignment. Load-balancing algorithms such as least-connections and power-of-two-choices (§19.4) approximate a shared queue across machines.

```
        import math

        def erlang_c(c, lam, mu):
            """Probability that an arriving request must wait (M/M/c, Erlang C)."""
            a = lam / mu                # offered load in "servers' worth" of work
            rho = a / c                 # per-server utilization
            if rho >= 1:
                return 1.0
            top = a**c / (math.factorial(c) * (1 - rho))
            bottom = sum(a**k / math.factorial(k) for k in range(c)) + top
            return top / bottom

        def mmc_response_time(c, lam, mu):
            """Mean time in system W for an M/M/c queue (seconds)."""
            wait = erlang_c(c, lam, mu) / (c * mu - lam)
            return wait + 1 / mu

        lam = 80.0
        print(f"One fast server  (M/M/1, mu=100): W = {mmc_response_time(1, lam,
100)*1000:.1f} ms")
        print(f"Two slow servers, shared queue (M/M/2, mu=50 each): "
              f"W = {mmc_response_time(2, lam, 50)*1000:.1f} ms")
        print(f"Two slow servers, separate queues (2 x M/M/1, mu=50, lam=40 each): "
              f"W = {mmc_response_time(1, lam/2, 50)*1000:.1f} ms")
```

Output:

```
One fast server  (M/M/1, mu=100): W = 50.0 ms
Two slow servers, shared queue (M/M/2, mu=50 each): W = 55.6 ms
Two slow servers, separate queues (2 x M/M/1, mu=50, lam=40 each): W = 100.0 ms
```

What to notice: with $c = 1$ the Erlang C function reduces to $P_{\text{wait}} = \rho$ and $W = 1/(\mu - \lambda)$, so the same code covers M/M/1. The `rho >= 1` guard reflects that no steady state exists at or above saturation.

> COMMON MISTAKE
>
> **Mistake — "We are at 85% CPU, so we have 15% headroom."** Headroom in *throughput* is 15%, but latency at 85% is already $1/(1 - 0.85) = 6.7$ times the service time in an M/M/1 model, and every further point of load costs more latency than the last. Express headroom as the latency you will have at the forecast peak, not as spare percentage.

4.11 Little's Law

4.11.1 Statement and intuition

> DEFINITION
>
> **Definition — Little's Law.** For any stable system observed over a long period, the average number of items in the system equals the average arrival rate multiplied by the average time each item spends in the system: $L = \lambda W$ [Little 1961].

First-principles explanation

A café serves 20 customers per hour, and each customer stays for 30 minutes on average. How many customers are inside at a typical moment? Every hour 20 people come in, each contributing half an hour of "presence", so the café accumulates $20 \times 0.5 = 10$ customer-hours of presence per hour: on average 10 people are inside. That is all Little's Law says. Remarkably, it does not depend on the arrival pattern, the service-time distribution, the number of servers or the scheduling order. It needs only that the system is stable (what goes in eventually comes out) and that the three quantities are long-run averages measured over the same boundary.

FORMULA

Little's Law

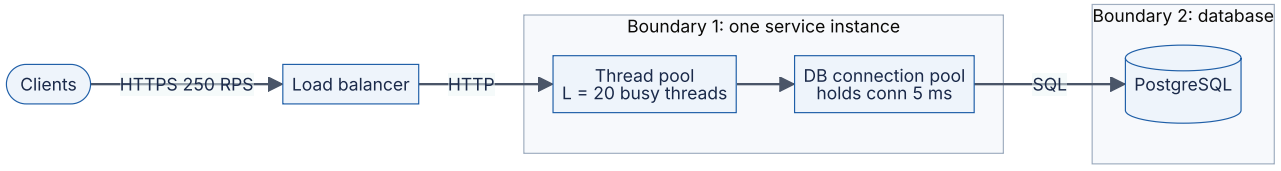
$$L = \lambda \times W$$

Symbol	Meaning	Units
L	Average number of items in the system (concurrency, occupancy, in-flight requests)	items
λ	Average arrival rate (equals throughput in a stable system)	items/second
W	Average time an item spends inside the system boundary	seconds

Derivation intuition. Plot the number of items inside the system, $N(t)$, over a long interval of length T. The area under that curve can be computed two ways. Summed vertically, it is (average height) × (width) $= L \times T$. Summed horizontally, each item contributes a horizontal strip as long as its stay, so the area is (number of items) × (average stay) $= \lambda T \times W$. Equating the two gives $LT = \lambda TW$, i.e. $L = \lambda W$. Little's 1961 paper made this argument rigorous.

Because the law holds for *any* boundary, you can draw the boundary around a thread pool, a connection pool, a broker topic, a whole datacenter or a single CPU, and solve for whichever of the three quantities you do not know.

Figure 4.5 — Choosing the boundary for Little's Law.



Reading the diagram. Clients send HTTPS requests to a load balancer, which forwards plain HTTP to a service instance. Inside the instance (boundary 1) each request occupies a worker thread for its whole duration, and briefly borrows a database connection to issue SQL to PostgreSQL (boundary 2, the storage boundary). All calls are synchronous. Little's Law applies separately to each boundary: threads in use = request rate × request duration; connections in use = query rate × connection hold time. The failure point is any pool whose occupancy L approaches its size, because requests then queue for a thread or connection. Scaling options are more instances (spreading λ), shorter hold times (reducing W) or larger pools (raising the limit on L).

4.11.2 Capacity planning examples

WORKED EXAMPLE

Worked example 1 — Sizing a thread pool. A service receives 2,000 RPS at peak, spread across 8 instances. Each request holds a worker thread for 80 ms on average (mostly waiting on downstream calls).

1. Per-instance arrival rate: $\lambda = 2,000/8 = 250$ RPS.
2. Average busy threads: $L = \lambda W = 250 \times 0.080 = 20$ threads.
3. A pool of exactly 20 would run at 100% utilization and queue without bound (§4.10). Treat the pool as an M/M/c system with c threads, $\mu = 1/0.08 = 12.5$/s per thread and $a = 20$.
4. Using the Erlang C code of §4.10.4: with $c = 25$ ($\rho = 0.80$), 20.9% of requests wait for a thread and mean latency is 83.4 ms; with $c = 30$ ($\rho = 0.67$), 2.5% wait and latency is 80.2 ms; with $c = 35$, 0.16% wait.

Interpretation. Little's Law gives the *average* concurrency (20); queueing theory tells you how much headroom above it buys acceptable waiting. **Engineering implication.** Size the pool around 30 threads per instance, and re-derive it whenever W changes: if a downstream dependency slows from 80 ms to 400 ms, required concurrency jumps to $250 \times 0.4 = 100$ threads, and a 30-thread pool saturates. That is why per-dependency timeouts and bulkheads (§22.11, §22.14) are capacity mechanisms, not just error handling.

WORKED EXAMPLE

Worked example 2 — Sizing a database connection pool. 30 application instances together issue 1,200 queries per second. Each query holds a connection for 5 ms (network round trip plus execution).

1. Connections in use, fleet-wide: $L = 1,200 \times 0.005 = 6$ connections on average.
2. Per instance: $\lambda = 1,200/30 = 40$ queries/s, so $L = 40 \times 0.005 = 0.2$ connections.
3. A common default of 10 connections per instance opens $30 \times 10 = 300$ connections to serve an average demand of 6.
4. Incident case: a missing index makes queries take 500 ms. Now $L = 1,200 \times 0.5 = 600$ connections are needed — more than the 300 that exist, so requests queue for connections, threads block, and the outage spreads upstream.

Interpretation. The pool is 50× oversized in normal operation and still too small during the incident. **Engineering implication.** Oversized pools are not free: in PostgreSQL each connection is a separate server process with its own memory, so hundreds of mostly idle connections waste database resources and let a slow-query incident push far more concurrent work onto an already struggling database. A small pool (here perhaps 2–3 per instance) or a central pooler such as PgBouncer (§14.13), combined with query timeouts, caps concurrency at the database where it matters.

WORKED EXAMPLE

Worked example 3 — Inferring latency from a backlog. A message broker topic holds a backlog of 5,000 messages, and consumers process 1,000 messages per second while producers add messages at the same rate.

1. Rearranging Little's Law: $W = L/\lambda = 5,000/1,000 = 5$ s.

Interpretation. Each message spends about 5 s waiting in the topic before processing. **Engineering implication.** Consumer lag measured in *messages* (the metric most brokers expose) converts to lag in *seconds* — the metric users care about — by dividing by throughput. Alert on the latter.

COMMON MISTAKE

Mistake — Mixing boundaries. Little's Law requires that L, λ and W are measured on the *same* boundary. Using end-to-end request latency (which includes time spent in the database) with the occupancy of the application thread pool is correct only if threads are held for the entire request. If an asynchronous framework releases the thread while waiting for I/O, the thread-holding time W is much smaller than request latency.

4.12 Amdahl's Law and Gustafson's Law

4.12.1 Amdahl's Law

DEFINITION

Definition — Speedup. The ratio of the time a job takes on one processor (or node) to the time it takes on N: $S(N) = T(1)/T(N)$. Perfect, **linear** speedup is $S(N) = N$.

First-principles explanation

Eight friends cook a dinner. Chopping vegetables parallelizes beautifully: eight people chop eight times faster. But the oven takes 40 minutes no matter how many cooks there are. However many friends you add, dinner cannot take less than 40 minutes. Gene Amdahl made this argument in 1967 about parallel computers [Amdahl 1967]: the part of a job that cannot be parallelized sets a hard ceiling on speedup.

FORMULA

Amdahl's Law (fixed problem size)

$$S(N) = \frac{1}{(1 - p) + \frac{p}{N}} \qquad \lim_{N \to \infty} S(N) = \frac{1}{1 - p}$$

Symbol	Meaning	Units
p	Fraction of the single-processor run time that can be parallelized	dimensionless (0–1)
$1 - p$	Serial fraction	dimensionless
N	Number of processors, cores or nodes	count
$S(N)$	Speedup relative to one processor	dimensionless (×)

Derivation. Normalize the one-processor time to 1. The serial part still takes $1 - p$; the parallel part takes p/N on N processors. Speedup is the old time (1) divided by the new time.

WORKED EXAMPLE

Worked example — A 95% parallel job. A batch job spends 5% of its time in a single-threaded setup phase and 95% in work that splits perfectly across cores.

1. On 8 cores: $S = 1/(0.05 + 0.95/8) = 1/(0.05 + 0.11875) = 1/0.16875 = 5.93$.
2. On 64 cores: $S = 1/(0.05 + 0.01484) = 1/0.06484 = 15.4$.
3. Ceiling: $1/0.05 = 20$, however many cores.
4. Efficiency on 64 cores: $15.4/64 = 24\%$.

Interpretation. Moving from 8 to 64 cores (8× the hardware) improves speed only 2.6×. **Engineering implication.** Before buying more parallelism, measure and shrink the serial fraction: a single-threaded coordinator, a global lock, a sequential merge step. Cutting the serial fraction from 5% to 1% raises the ceiling from 20 to 100.

4.12.2 Gustafson's Law

Amdahl assumes a *fixed* problem. In practice, when engineers get more machines they usually tackle *bigger* problems — more data, higher resolution, larger models — in the same wall-clock time. John Gustafson observed in 1988 that under this assumption the serial part stays roughly constant while the parallel part grows with N [Gustafson 1988].

FORMULA

Gustafson's Law (scaled problem size)

$$S_{\text{scaled}}(N) = (1 - p) + pN = N - (1 - p)(N - 1)$$

Symbol	Meaning	Units
p	Fraction of the *parallel run's* time spent in parallel work	dimensionless
$1 - p$	Fraction of the parallel run's time that is serial	dimensionless
N	Number of processors	count
S_{scaled}	How much more work is completed in the same time than one processor could do	dimensionless (×)

WORKED EXAMPLE

Worked example — The same 5% serial fraction, scaled. On 64 processors a job spends 5% of its wall-clock time in serial work.

1. $S_{\text{scaled}} = 0.05 + 0.95 \times 64 = 0.05 + 60.8 = 60.85$.

Interpretation. 64 processors complete about 61 times as much work as one would in the same time, versus Amdahl's 15.4 for a fixed problem. The laws do not contradict each other; they answer different questions ("how much faster?" vs "how much bigger?"). **Engineering implication.** Horizontal scaling of data-parallel systems (MapReduce, Spark, distributed training) mostly lives in Gustafson's world: more nodes handle more data. Latency-sensitive single requests live in Amdahl's world: more nodes do not make one request much faster.

4.13 The Universal Scalability Law

4.13.1 Beyond Amdahl: coordination costs

Amdahl's Law predicts that adding nodes never *hurts*: throughput keeps rising toward a ceiling. Real systems often get *slower* past some size. Neil Gunther's **Universal Scalability Law** (USL) explains why by adding a second penalty: **coherency** (or crosstalk), the cost of nodes keeping each other consistent [Gunther 2007].

First-principles explanation

Return to the kitchen. Contention is the queue for the single oven (Amdahl's serial part). Coherency is the time cooks spend *talking to each other* — "did you already salt this?". If every cook must check with every other cook, the number of conversations grows like $N(N-1)$, roughly N^2. With few cooks this is negligible; with many it dominates, and adding a cook makes dinner later.

FORMULA

Universal Scalability Law

$$C(N) = \frac{N}{1 + \alpha(N - 1) + \beta N(N - 1)} \qquad N^* = \sqrt{\frac{1 - \alpha}{\beta}}$$

Symbol	Meaning	Units
N	Number of nodes, cores, threads or concurrent users	count
$C(N)$	Relative capacity: throughput at N divided by throughput at 1	dimensionless (×)
α	Contention coefficient: serialization on shared resources (queues, locks)	dimensionless (0–1)
β	Coherency coefficient: pairwise coordination cost (cache coherence, consensus, data exchange)	dimensionless (≥ 0)
N^*	Concurrency at which throughput peaks	count

Gunther's later work writes the coefficients as σ (contention) and κ (coherency); the formula is the same. With $\beta = 0$ the USL reduces exactly to Amdahl's Law with serial fraction α. N^* comes from setting the derivative of $C(N)$ to zero.

WORKED EXAMPLE

Worked example — Where adding nodes stops helping. A clustered service is measured and fitted with $\alpha = 0.05$ and $\beta = 0.001$.

1. $C(8) = 8/(1 + 0.05 \times 7 + 0.001 \times 8 \times 7) = 8/(1 + 0.35 + 0.056) = 8/1.406 = 5.69$.
2. $C(32) = 32/(1 + 1.55 + 0.992) = 32/3.542 = 9.03$.
3. $C(64) = 64/(1 + 3.15 + 4.032) = 64/8.182 = 7.82$.
4. Peak: $N^* = \sqrt{(1 - 0.05)/0.001} = \sqrt{950} = 30.8$ nodes.

Interpretation. Throughput peaks around 31 nodes at about 9× a single node; doubling to 64 nodes *loses* 13% of throughput. Amdahl with the same α predicts 15.4× at 64 nodes. **Engineering implication.** If load tests show throughput flattening and then falling as you add nodes or threads, look for coherency costs: all-to-all communication, cache-line ping-pong, distributed locks, broadcast invalidation. The cure is architectural (partitioning so that nodes rarely coordinate), not more hardware.

```
        import math

        def amdahl(p, n):
            """Speedup with n processors when fraction p of the work is parallel."""
            return 1 / ((1 - p) + p / n)

        def gustafson(p, n):
            """Scaled speedup when the parallel part grows with n."""
            return (1 - p) + p * n

        def usl(n, alpha, beta):
            """Relative capacity C(n) under the Universal Scalability Law."""
            return n / (1 + alpha * (n - 1) + beta * n * (n - 1))

        p, alpha, beta = 0.95, 0.05, 0.001
        print("   N  Amdahl  Gustafson   USL")
        for n in (1, 2, 4, 8, 16, 32, 64, 128):
            print(f"{n:4d}  {amdahl(p, n):6.2f}  {gustafson(p, n):9.2f}  {usl(n, alpha,
beta):5.2f}")
        n_star = math.sqrt((1 - alpha) / beta)
        print(f"USL peak at N* = {n_star:.1f}; Amdahl ceiling = {1/(1-p):.0f}")
```

Table 4.6 — Output: three scaling models with a 5% serial fraction.

N	Amdahl	Gustafson	USL (α=0.05, β=0.001)
1	1.00	1.00	1.00
2	1.90	1.95	1.90
4	3.48	3.85	3.44
8	5.93	7.65	5.69
16	9.14	15.25	8.04
32	12.55	30.45	9.03
64	15.42	60.85	7.82
128	17.41	121.65	5.42

The program also prints `USL peak at N* = 30.8; Amdahl ceiling = 20`. What to notice: the three columns agree for small N, which is why a few measurements at low concurrency cannot distinguish the models. Measure out to the concurrency you intend to run. In practice the USL coefficients are fitted by regression to throughput measured at several values of N [Gunther 2007]; Chapter 23 (§23.10) shows the workflow.

COMMON MISTAKE

Mistake — Extrapolating linear scaling from a small test. "Two nodes gave 1.9×, so 100 nodes will give 95×." Every model in Table 4.6 is nearly linear at $N = 2$. Contention and coherency only show up at scale, so linear extrapolation is the most common way capacity plans fail.

4.14 Availability arithmetic

4.14.1 Nines and downtime budgets

DEFINITION

Definition — Availability. The fraction of time (or of requests) for which a system serves correctly: $A = \text{uptime}/(\text{uptime} + \text{downtime})$, or, request-based, $A = \text{successful requests}/\text{valid requests}$. It is commonly quoted in "nines": 99.9% is "three nines".

Table 4.7 — Nines and the downtime they allow (365-day year, 30-day month, 7-day week).

Availability	Nines	Downtime per year	Downtime per month	Downtime per week
90%	1	36.5 days	72 h	16.8 h
99%	2	3.65 days (87.6 h)	7.2 h	1.68 h
99.9%	3	8.76 h	43.2 min	10.1 min
99.95%	3.5	4.38 h	21.6 min	5.04 min
99.99%	4	52.6 min	4.32 min	60.5 s
99.999%	5	5.26 min	25.9 s	6.05 s
99.9999%	6	31.5 s	2.59 s	0.60 s

FORMULA

Downtime budget

$$D = (1 - A) \times T$$

Symbol	Meaning	Units
A	Availability target	dimensionless
T	Length of the period	minutes (or any time unit)
D	Allowed downtime in the period (the error budget, in time)	same unit as T

WORKED EXAMPLE

Worked example — What four nines allows. Target $A = 99.99\%$ over a 30-day month.

1. $T = 30 \times 24 \times 60 = 43,200$ min.
2. $D = 0.0001 \times 43,200 = 4.32$ min.

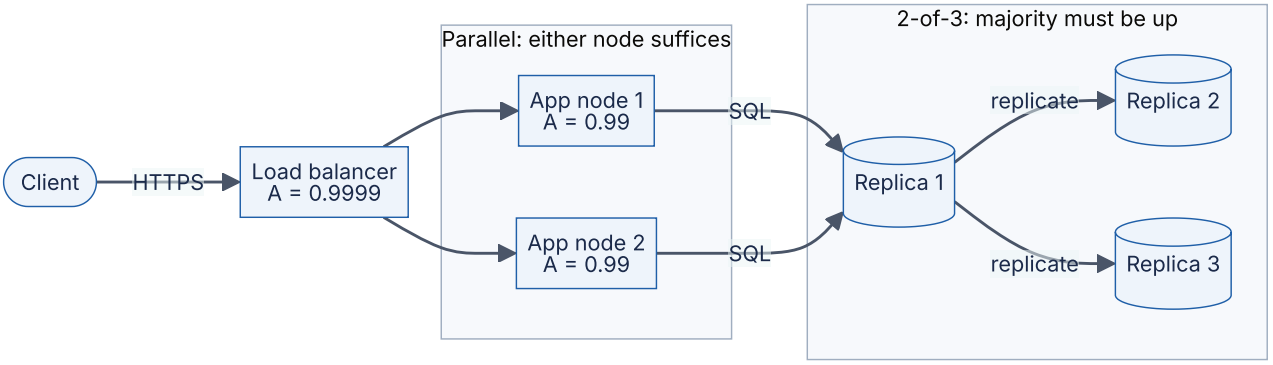
Interpretation. Four minutes and 19 seconds per month, total. **Engineering implication.** A human cannot be paged, wake up, log in and diagnose in four minutes. Four nines therefore implies *automated* detection and failover; five nines (26 s/month) implies the failover itself must be nearly invisible. Each additional nine changes the architecture, not just the effort.

INDUSTRY EXAMPLE

Google SRE — error budgets. Google's SRE practice turns an availability SLO into an **error budget** equal to $1 - \text{SLO}$: a 99.9% SLO allows 0.1% of requests (or time) to fail. While budget remains, teams may ship risky changes; when it is exhausted, releases slow until reliability recovers. The SRE book also argues that 100% is the wrong target, because users cannot distinguish the last nines from failures in their own devices and networks, while each extra nine costs disproportionately more. Error budgets are covered in §39.7. *Evidence: Primary* — [Beyer et al. 2016]

4.14.2 Series and parallel composition

Figure 4.6 — Series, parallel and k-of-n availability.



Reading the diagram. A request flows synchronously left to right: HTTPS from the client to a single load balancer, then to *either* application node, then over SQL to the current leader replica (Replica 1), which replicates each write to the other two and needs a majority (2 of 3) of replicas up to serve, as consensus-based stores do (§26.4); if the leader fails, a surviving replica is elected in its place. The three stages are in **series**: the request fails if any stage fails. Within the middle stage the two nodes are in **parallel**: the stage fails only if both fail. The cylinders are the storage boundary. The single load balancer is the obvious single point of failure; the scaling and availability option is to make it redundant too (§19.8).

FORMULA

Series, parallel and k-of-n availability (independent failures)

$$A_{\text{series}} = \prod_{i=1}^{n} A_i \qquad A_{\text{parallel}} = 1 - \prod_{i=1}^{n} (1 - A_i) \qquad A_{k\text{-of-}n} = \sum_{j=k}^{n} \binom{n}{j} A^j (1 - A)^{n-j}$$

Symbol	Meaning	Units
A_i	Availability of component i	dimensionless
$\prod$	Product over all components	—
n	Number of components	count
k	Minimum number of identical components that must be up	count
A	Availability of each identical component (k-of-n case)	dimensionless

Derivation. *Series:* the system is up only if every component is up; with independence, multiply. *Parallel:* the system is down only if every component is down; the probability all are down is $\prod (1 - A_i)$, and availability is its complement. *k-of-n:* the number of up components is binomial (§4.6.4); add the probabilities of $k, k+1, \ldots, n$ components up.

WORKED EXAMPLE

Worked example — Composing the system of Figure 4.6.

1. *Series of three single components* first, for intuition: LB 99.99%, one app node 99.95%, one database 99.9%: $0.9999 \times 0.9995 \times 0.999 = 0.99840$, i.e. 99.84%, about 14.0 h of downtime per year — worse than the weakest component.
2. *Parallel app tier:* two nodes at 99%: $1 - (0.01)^2 = 1 - 0.0001 = 0.9999$.
3. *2-of-3 database:* $A = 0.99$:
   $\binom{3}{2}(0.99)^2(0.01) + (0.99)^3 = 3 \times 0.9801 \times 0.01 + 0.970299 = 0.029403 + 0.970299 = 0.999702$.
4. *Whole system in series:* $0.9999 \times 0.9999 \times 0.999702 = 0.999502$, about 4.4 h of downtime per year.

Interpretation. Series composition always lowers availability; redundancy raises it dramatically — two 99% nodes give 99.99%. **Engineering implication.** A request path through 10 services, each 99.9% available, is at most $0.999^{10} = 99.0\%$ available. Long synchronous call chains are an availability liability, which is one argument for asynchronous decoupling (Part VI) and for keeping critical paths short.

```
        from math import comb, prod

        def series(*avail):
            """All components must be up (assumes independent failures)."""
            return prod(avail)

        def parallel(*avail):
            """At least one component must be up (independent failures)."""
            return 1 - prod(1 - a for a in avail)

        def k_of_n(k, n, a):
            """At least k of n identical, independent components must be up."""
            return sum(comb(n, i) * a**i * (1 - a)**(n - i) for i in range(k, n + 1))

        def downtime_per_year(a, hours_per_year=365 * 24):
            return (1 - a) * hours_per_year

        web_tier = parallel(0.99, 0.99)          # two app nodes behind a load balancer
        db_quorum = k_of_n(2, 3, 0.99)           # 2-of-3 replicated database
        system = series(0.9999, web_tier, db_quorum)   # LB -> web tier -> DB

        for name, a in [("web tier", web_tier), ("db 2-of-3", db_quorum), ("system",
system)]:
            print(f"{name:10s} A = {a:.6f}  downtime = {downtime_per_year(a):6.2f}
h/year")
```

Output:

```
web tier   A = 0.999900  downtime =   0.88 h/year
db 2-of-3  A = 0.999702  downtime =   2.61 h/year
system     A = 0.999502  downtime =   4.36 h/year
```

What to notice: `series`, `parallel` and `k_of_n` compose — the result of one can be fed into another to model any tree of components. Every function assumes independent failures, so the outputs are *upper bounds* on what a real system with shared dependencies achieves.

WARNING / TRADE-OFF

Warning — Redundancy arithmetic is only as good as its independence assumption. Two app nodes deployed by the same bad configuration push fail together; three replicas on one power feed fail together. Also, parallel redundancy requires *failover to work*: if detecting a failure and rerouting takes 30 s, each failure still costs 30 s of errors. Model failover time explicitly, and place replicas in separate failure domains (racks, zones, regions; §39.4).

4.15 Reliability: MTBF, MTTR and failure rates

4.15.1 Definitions

DEFINITION

Definition — Reliability, MTBF, MTTR and failure rate. Reliability $R(t)$ is the probability that a component operates without failure for a period of length t. The **mean time between failures (MTBF)** is the average operating time from the end of one repair to the next failure (for non-repairable parts the same quantity is called **MTTF**, mean time to failure). The **mean time to repair (MTTR)** is the average time from failure to restored service, including detection, diagnosis and repair. The **failure rate** λ is the average number of failures per unit of operating time.

First-principles explanation

Availability asks “what fraction of the time is it working?”. Reliability asks “how likely is it to keep working for the next hour (or day, or job)?”. A car that breaks down every week but is fixed in five minutes by the roadside is highly *available* and poorly *reliable*; a car that never breaks down for a year but then spends a month in the garage is the opposite. Both properties matter, for different users (§4.18.2).

FORMULA

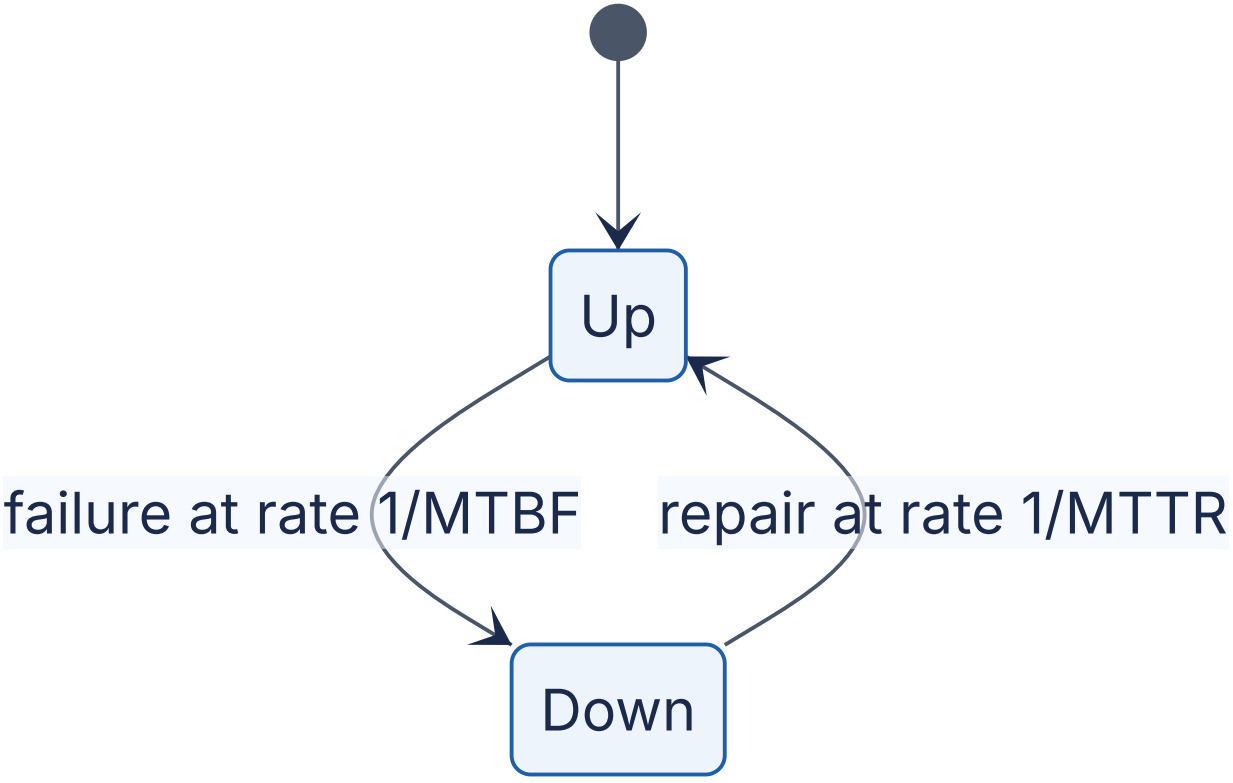
Reliability and availability from MTBF and MTTR

$$\lambda = \frac{1}{\text{MTBF}} \qquad R(t) = e^{-\lambda t} \qquad A = \frac{\text{MTBF}}{\text{MTBF}+\text{MTTR}} \qquad \text{AFR} = 1 - e^{-8760/\text{MTTF}}$$

Symbol	Meaning	Units
MTBF	Mean operating time between failures	hours
MTTR	Mean time to repair (detect + diagnose + fix + restore)	hours
MTTF	Mean time to failure of a non-repairable part	hours
λ	Constant failure rate	failures/hour
t	Mission time: the period we need it to survive	hours
$R(t)$	Probability of no failure during t	dimensionless
A	Steady-state availability	dimensionless
AFR	Annualized failure rate: probability a part fails within a year (8,760 h)	dimensionless (often %)

Derivation. $R(t) = e^{-\lambda t}$ follows from assuming a *constant* failure rate: failures are random events with no memory of age, so the time to failure is exponentially distributed (§4.7.2) with mean $1/\lambda = \text{MTBF}$. Availability is the long-run fraction of each up–down cycle spent up: MTBF out of MTBF + MTTR. The constant-rate assumption is a simplification: real hardware follows a “bathtub curve” with higher failure rates in early life (infant mortality) and at wear-out, and is roughly constant in between.

Figure 4.7 — The up-down cycle of a repairable component.



Reading the diagram. The component alternates between two states. It stays `Up` for an exponentially distributed time with mean MTBF, then moves to `Down`, where it stays for a repair time with mean MTTR. There is no data flow or protocol; the arrows are state transitions. Availability is the fraction of time spent in `Up`. The two levers are visible: make failures rarer (longer MTBF) or make repair faster (shorter MTTR). In distributed systems the second is usually cheaper — automatic failover turns an MTTR of hours into seconds.

WORKED EXAMPLE

Worked example — Two ways to get a nine. A server has MTBF = 1,000 h and MTTR = 1 h.

1. $A = 1000/(1000 + 1) = 0.99900$ (three nines).
2. Option 1, double MTBF to 2,000 h (better hardware): $A = 2000/2001 = 0.99950$.
3. Option 2, cut MTTR to 6 min = 0.1 h (automated failover): $A = 1000/1000.1 = 0.99990$ (four nines).
4. Reliability over a 100-hour batch job: $R(100) = e^{-100/1000} = e^{-0.1} = 0.905$. Over one MTBF: $R(1000) = e^{-1} = 0.368$.

Interpretation. A 10× reduction in MTTR buys a full nine; a 2× increase in MTBF buys half of one. Note that only 37% of components survive to their MTBF: “mean time” is not “typical time”. **Engineering implication.** Invest in detection and automated recovery (health checks, failover, restarts) before investing in more expensive hardware. For long jobs, reliability matters more than availability: a 100-hour job on this server fails about 10% of the time, so it needs checkpointing.

WORKED EXAMPLE

Worked example — Disk failures in a fleet. A disk datasheet quotes MTTF = 1,000,000 h. The fleet has 10,000 disks.

1. AFR $= 1 - e^{-8760/1,000,000} = 1 - e^{-0.00876} = 0.0087 = 0.87\%$.
2. Expected failures per year: $10,000 \times 0.0087 = 87$, about 1.7 per week.

Interpretation. A “million-hour” disk still fails nearly twice a week in a 10,000-disk fleet. **Engineering implication.** Field studies have found real-world replacement rates substantially above datasheet AFRs — Schroeder and Gibson report annual replacement rates typically exceeding 1% and commonly 2–4% across the large populations they studied [Schroeder and Gibson 2007]. Plan with measured fleet data, and use a pessimistic AFR (for example 2–4%) when you have none.

4.16 Durability and replication

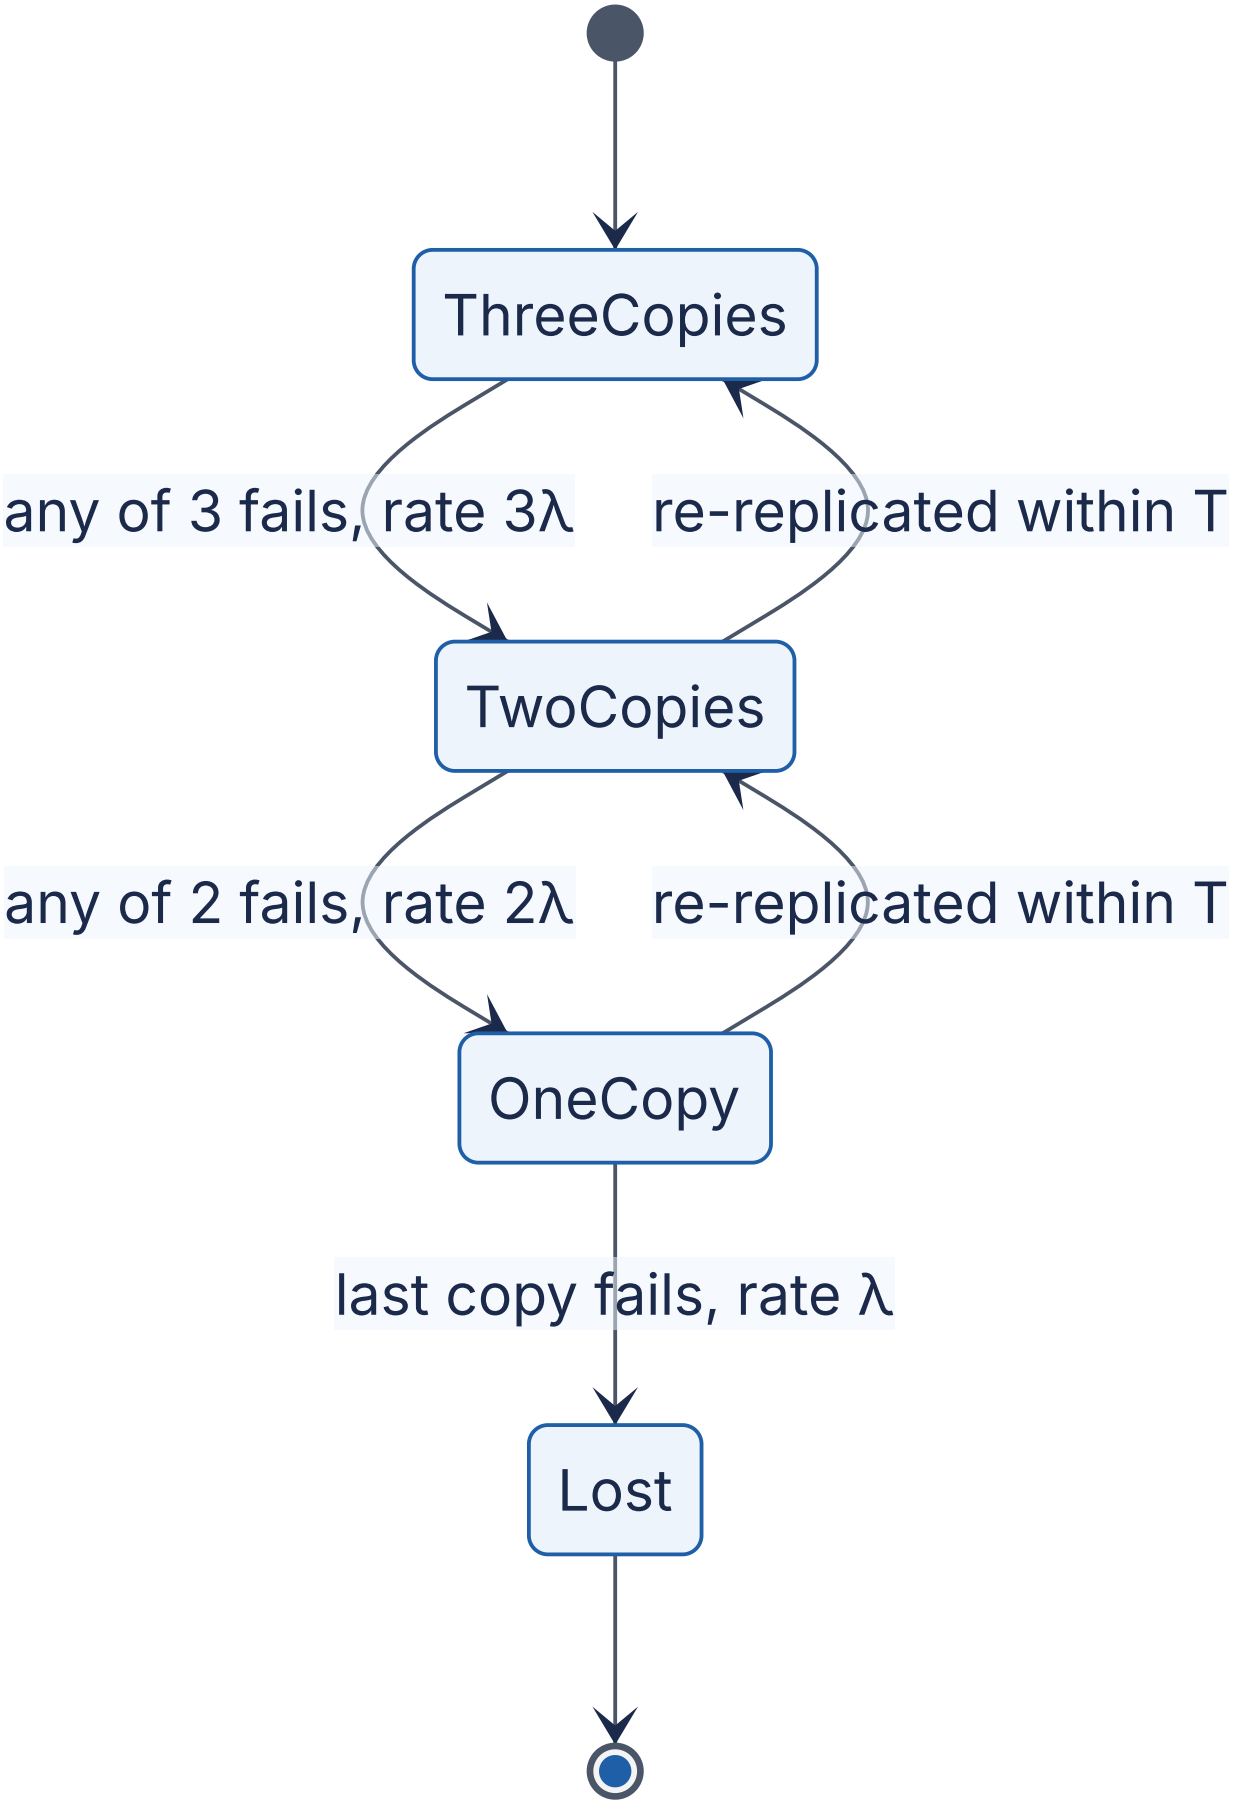
4.16.1 Durability as a probability

DEFINITION

Definition — Durability. The probability that data, once acknowledged as written, is not lost over a given period (usually a year). It is quoted in nines like availability: “eleven nines of durability” means an annual loss probability of 10^{-11} per object.

Durability and availability are different: a storage system can be unavailable for an hour (you cannot read your data) without losing anything, and it can be available while silently having lost an object. Data is lost when *every* copy is destroyed before the system notices and repairs the first loss. Durability is therefore a race between failure and repair.

Figure 4.8 — The replica-loss race for three-way replication.



ThreeCopies
any of 3 fails, rate 3λ
re-replicated within T
TwoCopies
any of 2 fails, rate 2λ
re-replicated within T
OneCopy
last copy fails, rate λ
Lost

Reading the diagram. States count the surviving copies of one piece of data. Each copy fails independently at rate λ, so the rate of leaving a state is (copies) × λ. A failed copy is re-created from a survivor in an average repair time T, which is dominated by detection time and by copy bandwidth (§4.5.1). `Lost` is absorbing: there is no way back. Data is lost only if two more failures occur while the group is still degraded. The failure point is a long repair window; the scaling lever is parallel re-replication, which shrinks T.

FORMULA

Approximate annual probability of losing an n-way replicated item

$$P_{\text{loss/yr}} \approx n!\ \lambda^{n}\ T^{n-1} \times H \qquad \text{valid when } \lambda T \ll 1$$

Symbol	Meaning	Units
n	Number of replicas	count
λ	Per-replica failure rate (AFR / 8,760 for small AFR)	failures/hour
T	Mean time to detect and re-replicate a lost copy	hours
H	Hours per year (8,760)	hours/year
$P_{\text{loss/yr}}$	Annual probability that all n replicas are lost	dimensionless

Derivation (three replicas). First failures in the group occur at rate 3λ. Given a first failure, one of the two survivors fails before repair with probability about $2\lambda T$, and then the last survivor fails before *its* repair completes with probability about λT. Multiply: loss rate $\approx 3\lambda \times 2\lambda T \times \lambda T = 6\lambda^{3}T^{2}$ per hour, and multiply by 8,760 for a year. The same chain for n replicas gives $n!\,\lambda^{n}T^{n-1}$. This is the standard approximation from a Markov model with one repair at a time and independent failures.

WORKED EXAMPLE

Worked example — How many replicas, and how fast must repair be? Disks have AFR = 2%, so $\lambda = 0.02/8760 = 2.28 \times 10^{-6}$ per hour. Repair takes $T = 24$ h, so $\lambda T = 5.48 \times 10^{-5}$.

1. One replica: $P \approx \text{AFR} = 2 \times 10^{-2}$.
2. Two replicas: $2\lambda^2 T \times 8760 = 2 \times 0.02 \times \lambda T = 0.04 \times 5.48 \times 10^{-5} = 2.2 \times 10^{-6}$.
3. Three replicas: $6\lambda^3 T^2 \times 8760 = 3 \times 0.02 \times 2(\lambda T)^2 = 0.06 \times 2 \times 3.00 \times 10^{-9} = 3.6 \times 10^{-10}$.
4. Fleet view: with 10^6 independent three-replica groups, expected losses are $10^6 \times 3.6 \times 10^{-10} = 3.6 \times 10^{-4}$ groups per year.
5. Slower repair, $T = 168$ h (one week): $\lambda T = 3.84 \times 10^{-4}$; three-replica loss $= 0.06 \times 2 \times (3.84 \times 10^{-4})^2 = 1.8 \times 10^{-8}$, which is $7^2 = 49$ times worse.

Interpretation. Each extra replica multiplies durability by roughly $1/(\lambda T)$, here about four orders of magnitude, and for three replicas loss probability grows with the *square* of the repair time. **Engineering implication.** Fast, parallel re-replication is as important as the replica count. These numbers are, however, optimistic upper bounds on durability: they assume independence. In practice correlated failures — a rack losing power, a bad firmware batch, a datacenter-wide event, a software bug that deletes all copies — dominate data loss, which is why durable stores spread replicas across failure domains, keep backups outside the replication system, and checksum data to catch silent corruption (§13.12, §39.9).

Table 4.8 — Annual loss probability per item (AFR 2%, independent failures).

Replicas	T = 1 h	T = 24 h	T = 168 h
1	2×10^{-2}	2×10^{-2}	2×10^{-2}
2	9.1×10^{-8}	2.2×10^{-6}	1.5×10^{-5}
3	6.3×10^{-13}	3.6×10^{-10}	1.8×10^{-8}

INDUSTRY EXAMPLE

Correlated failures in real storage fleets. Ford et al. analyzed a year of availability data from Google's distributed storage and found that failures are often correlated — many nodes failing together in bursts, for example after power or network events — and that models assuming independence can overestimate durability by orders of magnitude; their models incorporate correlated failures and placement across failure domains [Ford et al. 2010]. Cidon et al. showed that with random replica placement across a large cluster, almost *any* simultaneous failure of three nodes destroys some chunk, and proposed limiting the number of distinct replica sets ("copysets") to reduce the frequency of loss events [Cidon et al. 2013]. Amazon S3 documentation states that S3 is designed for 99.999999999% (eleven nines) annual durability of objects, achieved by storing data redundantly across multiple devices and facilities [AWS S3 documentation]. Replication and erasure coding are compared in §15.6. *Evidence: Primary* — [Ford et al. 2010; Cidon et al. 2013; AWS S3 documentation]

4.17 Latency numbers every engineer should know

4.17.1 The table and its history

A table of hardware and network latencies popularized by Jeff Dean around 2009–2010, building on a similar table by Peter Norvig, is the standard estimation reference [Dean 2009; Norvig]. Its value lies in the *ratios* between rows, which change far more slowly than the absolute numbers. Since then SSDs have replaced disks for latency-sensitive data and datacenter networks have moved to 25–100 Gbps and beyond, while memory latency has barely moved. Treat every number as an order-of-magnitude anchor and measure your own hardware.

Table 4.9 — Latency reference numbers (approximate; era-dependent).

Operation	Classic value (as circulated c. 2010)	Approximate order of magnitude, as of 2025	Notes
L1 cache reference	0.5 ns	~1 ns	A few CPU cycles
Branch mispredict	5 ns	~5 ns	Pipeline flush
L2 cache reference	7 ns	~3–5 ns	
Mutex lock/unlock (uncontended)	25 ns	~10–25 ns	Contended locks cost far more
Main memory reference	100 ns	~80–120 ns	Has changed little in 15 years
Compress 1 KB with a fast compressor (Zippy/Snappy)	3 µs	~1–3 µs	
Send 1 KB over a network link	10 µs (1 Gbps)	~1 µs (10 Gbps)	Serialization time only
Read 4 KB randomly from SSD	150 µs (SATA era)	~50–100 µs (NVMe)	
Read 1 MB sequentially from memory	250 µs	~50–100 µs	One thread; depends on bandwidth per core
Round trip within one datacenter	500 µs	~50–500 µs	Kernel bypass can be much lower
Read 1 MB sequentially from SSD	1 ms	~0.15–0.3 ms (NVMe)	
Disk (HDD) seek	10 ms	~4–10 ms	Mechanical; unchanged
Read 1 MB sequentially from HDD	20 ms	~5 ms	~200 MB/s sequential
Packet round trip California ↔ Netherlands	150 ms	~140–150 ms	Bounded by the speed of light in fiber

The modern column is this book's order-of-magnitude estimate for commodity server hardware as of 2025, not a benchmark result; ranges reflect variation across hardware generations. Colin Scott's interactive version of the table extrapolates the values year by year [Scott].

Physics sets the floor

Light in optical fiber travels at about two-thirds of its vacuum speed, roughly 200,000 km/s, or 5 µs per km. The great-circle distance from California to the Netherlands is about 8,800 km, so the round trip cannot take less than $2 \times 8{,}800 / 200{,}000 = 0.088$ s $= 88$ ms, even with perfect routing. No engineering removes that floor; only moving data closer (caching, CDNs, replicas in more regions; Chapters 21 and 44) does.

WORKED EXAMPLE

Worked example — Reading 1 GB from four places, using the classic column.

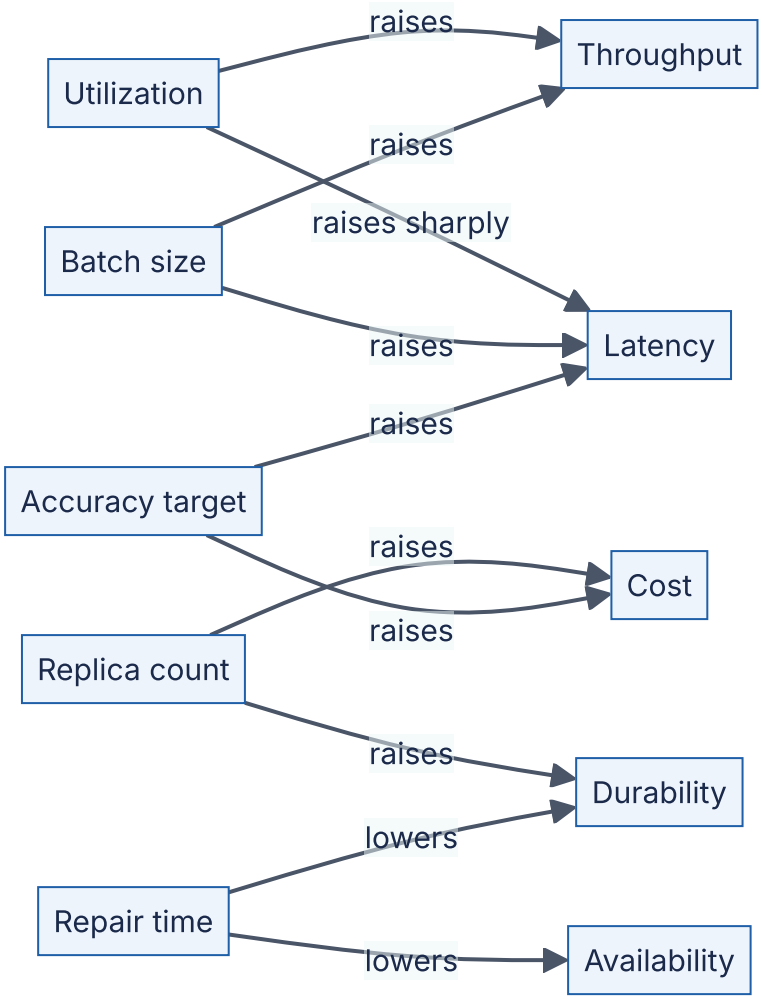
1. From memory: $1,000 \times 250\ \mu s\ = 0.25$ s.
2. From SSD (sequential): $1,000 \times 1$ ms $= 1$ s.
3. From HDD (sequential): $1,000 \times 20$ ms $= 20$ s.
4. Over a 1 Gbps network: $8 \times 10^9 / 10^9 = 8$ s.
5. From HDD with a seek per 4 KB block (random): $250,000$ blocks $\times$ 10 ms $= 2,500$ s ≈ 42 min.

Interpretation. Memory, SSD, network and disk span two orders of magnitude for sequential access, and random disk access is another two orders slower than sequential. **Engineering implication.** Design data layouts for sequential access (log-structured storage, §13.7; columnar files, §13.13), keep hot working sets in memory (Chapter 20), and count cross-region round trips on every user-facing path: five sequential 150 ms round trips is already 750 ms.

4.18 Quantitative relationships that recur in system design

The formulas of this chapter are not independent facts. They describe six trade-offs you will meet in almost every later chapter.

Figure 4.9 — Six recurring quantitative relationships.



Reading the diagram. This is a conceptual map, not a data flow: there are no protocols or storage boundaries. Left-hand nodes are design levers, right-hand nodes are outcomes, and each arrow gives the direction of the effect. Most levers improve one outcome while worsening another — that is what makes them trade-offs. The subsections below quantify each arrow.

4.18.1 Latency ↔ throughput

In a *closed* system, where a fixed number of clients each wait for a reply before sending the next request, Little's Law gives throughput $X = N/R$: concurrency divided by latency. In an *open* system, where requests arrive regardless of how fast earlier ones finish, raising throughput toward capacity raises latency by $1/(1-\rho)$ (§4.10).

WORKED EXAMPLE

Worked example — One connection versus many. A client sends requests one at a time over one connection. Each request spends 1.9 ms on the network round trip and 0.1 ms of server processing, so the server can complete at most 10,000 requests/s, and an unloaded request takes $R = 2$ ms.

1. One connection: $X = N/R = 1/0.002 = 500$ requests/s, no matter how powerful the server is. The server is 5% utilized.
2. Sixteen concurrent connections: ignoring queueing, $X = 16/0.002 = 8,000$ requests/s. But the server would then be 80% utilized, and by the M/M/1 approximation its 0.1 ms becomes $0.1/(1 - 0.8) = 0.5$ ms. Solving $X = 16/R$ and $R = 1.9 + 0.1/(1 - X/10,000)$ ms together gives $X \approx 7,100$ requests/s and $R \approx 2.25$ ms.
3. Sixty-four connections: the naive $64/0.002 = 32,000$ requests/s exceeds capacity, so X approaches 10,000 requests/s and Little's Law forces $R = N/X = 64/10,000 = 6.4$ ms. The extra 4.4 ms is pure queueing.

Interpretation. Throughput is limited by concurrency × (1 / latency) and by capacity; latency rises as throughput approaches capacity. **Engineering implication.** If throughput is low while servers are idle, the bottleneck is client concurrency or round trips (fix with pooling, pipelining, batching); if latency is high while servers are busy, the bottleneck is capacity.

4.18.2 Availability ↔ reliability

WORKED EXAMPLE

Worked example — More available, less reliable. System X fails once a day (MTBF = 24 h) but recovers in 1 s. System Y fails once a year (MTBF = 8,760 h) but takes a day to recover.

1. $A_X = 86,400/86,401 = 0.999988$ (almost five nines).
2. $A_Y = 8,760/8,784 = 0.99727$ (under three nines).
3. Probability of completing a 6-hour job without interruption: $R_X(6) = e^{-6/24} = 0.78$; $R_Y(6) = e^{-6/8760} = 0.9993$.

Interpretation. X is far more available; Y is far more reliable. **Engineering implication.** Interactive services with retries care about availability; long-running jobs, transactions and stateful sessions care about reliability. Choose the metric that matches what the user experiences, and design accordingly (checkpointing for jobs, fast failover for services).

4.18.3 Replication ↔ durability (and cost and write latency)

From §4.16, each extra replica improves durability by about $1/(\lambda T)$ but costs a full copy of storage and, for synchronous replication, adds the slowest acknowledgment to every write.

WORKED EXAMPLE

Worked example — Paying for nines. With AFR 2% and $T = 24$ h (Table 4.8):

1. Two replicas: 2.2×10^{-6} annual loss probability, 2× storage.
2. Three replicas: 3.6×10^{-10}, 3× storage: 50% more storage for about 6,000× better durability.
3. Synchronous write to 3 replicas waiting for all: if each replica acknowledges within 5 ms with probability 0.99, all three do with probability $0.99^3 = 0.970$ — the fan-out law of §4.8.4 applied to writes. Waiting for 2 of 3 (a quorum) instead: $3 \times 0.99^2 \times 0.01 + 0.99^3 = 0.9997$.

Interpretation. Durability is cheap in storage relative to what it buys, but synchronous replication taxes the write tail. **Engineering implication.** Quorum writes (§27.8) capture most of the durability while hiding the slowest replica; erasure coding (§15.6) reaches comparable durability with less storage at the cost of more expensive repair.

4.18.4 Accuracy ↔ latency

Many computations can trade correctness for speed: sampling, approximate algorithms, smaller models, fewer candidates. The statistical baseline is the **standard error** of a mean estimated from n samples, $\sigma/\sqrt{n}$.

FORMULA

Standard error of a sample mean

$$\mathrm{SE} = \frac{\sigma}{\sqrt{n}}$$

Symbol	Meaning	Units
σ	Standard deviation of the quantity being measured	units of the quantity
n	Number of independent samples	count
SE	Typical error of the estimated mean	units of the quantity

WORKED EXAMPLE

Worked example — The square-root tax. Latency has $\sigma = 50$ ms. A monitoring job estimates mean latency from samples.

1. $n = 100$: SE $= 50/\sqrt{100} = 5$ ms.
2. $n = 10,000$: SE $= 50/100 = 0.5$ ms.

Interpretation. Ten times the accuracy costs a hundred times the samples, and so a hundred times the processing time. **Engineering implication.** The same diminishing returns appear elsewhere: an ANN index searched more exhaustively gains recall slowly while latency grows roughly in proportion to the work done (Chapter 74); a ranking stage that scores 5,000 candidates at, say, 20 µs each spends 100 ms versus 10 ms for 500 (an illustrative cost). Decide the accuracy the product needs, then buy exactly that much.

4.18.5 GPU utilization ↔ throughput

For ML workloads, throughput is governed by how much of the accelerator's peak arithmetic is actually used. The **model FLOPs utilization (MFU)** is the achieved model FLOP/s divided by peak FLOP/s. A dense transformer forward pass costs roughly $2P$ FLOPs per token for a model with P parameters [Kaplan et al. 2020].

FORMULA

Compute-bound token throughput

$$X_{\text{tokens}} = \frac{\text{MFU} \times F_{\text{peak}}}{2P}$$

Symbol	Meaning	Units
F_{peak}	Peak accelerator throughput at the precision used	FLOP/s
MFU	Model FLOPs utilization	dimensionless (0–1)
P	Model parameters	count
$2P$	Forward-pass FLOPs per token (approximation)	FLOP/token
X_{tokens}	Tokens processed per second per accelerator	tokens/s

WORKED EXAMPLE

Worked example — Utilization is money. A hypothetical accelerator has $F_{\text{peak}} = 10^{15}$ FLOP/s (1,000 TFLOP/s, the order of magnitude of data-center GPUs at 16-bit precision as of 2024–2025). The model has $P = 7 \times 10^{9}$ parameters, so $2P = 1.4 \times 10^{10}$ FLOP/token.

1. At MFU = 40%: $X = 0.4 \times 10^{15} / 1.4 \times 10^{10} = 28,571$ tokens/s.
2. At MFU = 20%: $X = 14,286$ tokens/s.

Interpretation. Halving utilization halves throughput and doubles the cost per token on the same hardware. **Engineering implication.** Training clusters push MFU as high as possible because they are batch work. Online inference cannot run accelerators at 100% busy for the queueing reasons of §4.10 — latency explodes — so serving systems balance utilization against latency SLOs (Chapters 64, 66 and 73).

4.18.6 Batch size ↔ latency

Batching amortizes a fixed per-batch cost (kernel launch, loading weights from memory, a network round trip, a disk flush) across many items. A simple model: a batch of B items takes $T(B) = t_0 + B\,t_1$.

FORMULA

Batching model

$$T(B) = t_0 + B\,t_1 \qquad X(B) = \frac{B}{t_0 + B\,t_1} \qquad W_{\text{fill}} \approx \frac{B-1}{2\lambda}$$

Symbol	Meaning	Units
B	Batch size	items
t_0	Fixed cost per batch	seconds
t_1	Marginal cost per item	seconds/item
$T(B)$	Time to process one batch	seconds
$X(B)$	Throughput	items/second
λ	Arrival rate of items	items/second
W_{fill}	Average time an item waits for its batch to fill	seconds

WORKED EXAMPLE

Worked example — Choosing a batch size. An inference server has $t_0 = 8$ ms and $t_1 = 0.5$ ms per request; requests arrive at $\lambda = 1,000$/s.

1. $B = 1$: $T = 8.5$ ms; $X = 1/0.0085 = 118$/s — far below demand.
2. $B = 8$: $T = 12$ ms; $X = 8/0.012 = 667$/s — still below demand.
3. $B = 32$: $T = 24$ ms; $X = 32/0.024 = 1,333$/s — meets demand; average fill wait $\approx 31/2000 = 15.5$ ms, so latency $\approx 15.5 + 24 \approx 40$ ms.
4. $B = 64$: $T = 40$ ms; $X = 1,600$/s; fill wait $\approx 63/2000 = 31.5$ ms; latency ≈ 72 ms.

Interpretation. Throughput rises toward the ceiling $1/t_1 = 2,000$/s with diminishing returns, while latency rises roughly linearly with B. **Engineering implication.** Choose the *smallest* batch that meets throughput with headroom, and cap the fill wait with a timeout (dynamic batching) so that low-traffic periods do not wait for full batches. In memory-bound LLM decoding the effect is even stronger: if each decoding step must stream all $7 \times 10^9 \times 2$ bytes = 14 GB of weights from memory at a hypothetical 3 TB/s, a step takes about 4.7 ms whether it serves 1 or 32 sequences, so batch 32 yields about $32/0.0047 \approx 6,800$ tokens/s instead of about 210 (ignoring attention-cache traffic; Chapter 73).

Table 4.10 — The six relationships at a glance.

Relationship	Governing formula	One-line rule
Latency ↔ throughput	$X = N/R$; $W = S/(1-\rho)$	More concurrency raises throughput until queueing raises latency
Availability ↔ reliability	$A = \text{MTBF}/(\text{MTBF} + \text{MTTR})$; $R(t) = e^{-t/\text{MTBF}}$	Fast repair buys availability; only rare failure buys reliability
Replication ↔ durability	$P_{\text{loss}} \approx n!\lambda^n T^{n-1} H$	Each replica adds ~$1/(\lambda T)$; repair speed matters as much
Accuracy ↔ latency	$\text{SE} = \sigma/\sqrt{n}$	10× accuracy often costs 100× work
GPU utilization ↔ throughput	$X = \text{MFU} \cdot F_{\text{peak}}/(2P)$	Throughput and cost per token scale with utilization
Batch size ↔ latency	$X = B/(t_0 + Bt_1)$	Batching buys throughput with latency

4.19 Summary and revision notes

SUMMARY

- **Powers and logs.** $2^{10} \approx 10^3$; carry exponents exactly and mantissas roughly. Logarithms count halvings: binary search over 10^9 keys takes 30 steps; a B-tree with fan-out ~800 needs 4 levels, and the top levels are cached.
- **Units.** Network rates are bits/s, storage is bytes: divide by 8. KB/MB/GB are decimal, KiB/MiB/GiB binary; the gap is 7% at tera and 13% at peta. One day ≈ 86,400 s ≈ 10^5 s.
- **Probability.** $P(\text{at least one of } N \text{ fails}) = 1 - (1-p)^N \approx 1 - e^{-Np}$. Expected values add even without independence. The binomial distribution gives the chance of exactly k failures — size spares against its tail, not its mean.
- **Statistics.** Latency is right-skewed (log-normal or heavier); the mean is pulled up by the tail and describes no real request. Report percentiles with sample counts; never average percentiles — merge histograms.
- **Tail at scale.** Fan-out to N leaves: $P(\text{all fast}) = p^N$. With $N = 100$ and leaf p99, 63% of requests are slow; leaves must be engineered at p99.99 or use hedged/tied requests.
- **Linear algebra.** Cosine similarity compares directions; a matrix multiply costs $2mnk$ FLOPs; brute-force vector search and batch-1 inference are memory-bound; batching raises arithmetic intensity.
- **Queueing.** M/M/1: $W = 1/(\mu - \lambda) = S/(1-\rho)$. Latency doubles each time the remaining headroom halves. Shared queues (M/M/c) beat separate queues on identical hardware.
- **Little's Law.** $L = \lambda W$ on any stable boundary: size thread pools and connection pools from rate × hold time, then add queueing headroom; convert backlog to delay with $W = L/\lambda$.
- **Scaling laws.** Amdahl: ceiling $1/(1-p)$ for fixed problems. Gustafson: near-linear for growing problems. USL adds coherency β, producing a throughput peak at $N^* = \sqrt{(1-\alpha)/\beta}$ and retrograde scaling beyond it.
- **Availability.** Series multiplies availabilities (always worse than the weakest); parallel multiplies unavailabilities; k-of-n is binomial. Four nines = 4.3 min/month and demands automated recovery. All of it assumes independence.
- **Reliability.** $A = \text{MTBF}/(\text{MTBF} + \text{MTTR})$; $R(t) = e^{-t/\text{MTBF}}$. Cutting MTTR is usually the cheapest nine. Only 37% of parts survive to their MTBF.
- **Durability.** Annual loss $\approx n!\lambda^n T^{n-1} \times 8760$: each replica buys ~$1/(\lambda T)$, and repair time enters squared for three replicas. Correlated failures dominate real loss.
- **Latency numbers.** Memory ~100 ns, NVMe random read ~tens of µs, data-center round trip ~0.1–0.5 ms, cross-continent round trip ~100+ ms (physics floor ~5 µs/km of fiber). Use ratios; date your numbers.

- **Trade-offs.** Throughput costs latency near saturation; fast repair buys availability, not reliability; replicas buy durability with storage and write tail; accuracy costs work at a square-root rate; utilization sets cost per token; batching buys throughput with latency.

4.20 Knowledge checkpoint

1. Roughly how many bytes is 2^{40} bytes, and what is its binary-prefix name?
2. How many levels does a B-tree with fan-out 500 need to index 10^9 keys?
3. A 25 Gbps link must copy 50 TB. What is the minimum transfer time?
4. Each of 500 independent servers fails on a given day with probability 0.002. What is the probability that at least one fails today, and the expected number of failures?
5. Why is the median often a better summary of latency than the mean?
6. Using the nearest-rank method, what is the p90 of 1, 2, 3, 4, 5, 6, 7, 8, 9, 100?
7. A root service fans out to 20 leaves, each fast with probability 0.995. What fraction of root requests are fast?
8. Compute the cosine similarity of $(3, 4)$ and $(4, 3)$.
9. An M/M/1 server has a service time of 5 ms. What is the mean response time at 60% and at 95% utilization?
10. A service processes 400 RPS and each request holds a thread for 150 ms. What is the average number of busy threads?
11. A job is 90% parallelizable. What is its maximum speedup under Amdahl's Law, and its speedup on 10 cores?
12. In the USL, what physical effect does β model, and what happens to throughput when $\beta > 0$ and N grows large?
13. A request path calls five services in series, each 99.95% available. What is the path availability, and how much downtime per 30-day month does it allow?
14. A component has MTBF = 500 h and MTTR = 30 min. What is its availability?
15. Why does halving the re-replication time improve the durability of a three-replica system by about 4×?
16. Why is a round trip between California and the Netherlands never faster than about 88 ms?

Answers

1. $2^{40} = 1,099,511,627,776 \approx 1.1 \times 10^{12}$ bytes; one tebibyte (TiB).
2. $\log_{500} 10^9 = 9/\log_{10} 500 = 9/2.699 = 3.33$, so 4 levels.
3. $50 \times 10^{12} \times 8/(25 \times 10^9) = 16,000$ s ≈ 4.4 h (before protocol overhead).
4. $1 - 0.998^{500} \approx 1 - e^{-1} = 0.632$; expected failures $500 \times 0.002 = 1$.
5. Latency is right-skewed; a few very slow requests pull the mean up so that it describes no actual request, while the median reflects the typical request and is ro-

bust to outliers.

6. Rank $\lceil 0.9 \times 10 \rceil = 9$; the 9th value is 9.
7. $0.995^{20} = 0.905$, so about 90.5% fast and 9.5% slow.
8. Dot $= 12 + 12 = 24$; both lengths are 5; cosine $= 24/25 = 0.96$.
9. $W = S/(1 - \rho)$: $5/0.4 = 12.5$ ms at 60%; $5/0.05 = 100$ ms at 95%.
10. $L = 400 \times 0.15 = 60$ threads (size the pool above this for queueing headroom).
11. Ceiling $1/0.1 = 10$; on 10 cores $1/(0.1 + 0.09) = 5.26$.
12. Coherency: pairwise coordination such as cache coherence, consensus or data exchange, growing like N^2. Throughput peaks at N^* and then declines (retrograde scaling).
13. $0.9995^5 = 0.99750$; downtime $0.0025 \times 43,200 = 108$ min per month.
14. $500/500.5 = 0.999$ (three nines).
15. For three replicas annual loss probability is proportional to T^2, so halving T divides it by $2^2 = 4$.
16. The great-circle distance is about 8,800 km; light in fiber travels about 200,000 km/s; $2 \times 8,800/200,000 = 88$ ms. Real routes are longer, so measured RTTs are higher.

4.21 Interview questions

Basic

Q1. Your service averages 50 ms latency. Is that enough to say it meets a "p99 under 200 ms" SLO? Answer. No. The mean says nothing about the tail: a right-skewed distribution can have a 50 ms mean with several percent of requests above 200 ms. You need the p99 itself, computed from a histogram over a window with enough samples (hundreds of requests in the tail), and you should check it at fine time resolution so that bad minutes are not averaged away.

Q2. Estimate the average and peak RPS for 500 million requests per day. Answer. $5 \times 10^8/86,400 \approx 5,800$ RPS on average (or ~5,000 using 10^5 s/day). With an assumed peak-to-average ratio of 2–3, plan for roughly 12,000–17,000 RPS, and say the ratio is an assumption to be replaced by measurement.

Q3. Two independent replicas each have 99% availability. What is the availability of the pair, and what assumptions are you making? Answer. $1 - 0.01^2 = 99.99\%$. Assumptions: failures are independent (no shared rack, power, network, deployment or software bug), failover is instantaneous and automatic, and either replica alone can carry the full load. Each assumption, if false, lowers the real number.

Intermediate

Q4. A database server is at 70% CPU and the team wants to consolidate to fewer servers to reach 90%. What would you tell them? Answer. In an M/M/1 approximation, response time scales as $1/(1-\rho)$: going from 0.7 to 0.9 triples queueing-inclusive latency ($3.3\times$ to $10\times$ the service time), and the tail grows proportionally (M/M/1 p99 $\approx 4.6\times$ mean). For a latency-sensitive OLTP database that is usually unacceptable; for batch analytics it may be fine. I would model the latency at the forecast *peak* after consolidation, and keep enough headroom to absorb a replica failure as well.

Q5. How would you size the connection pool for 40 application instances that together run 3,000 queries/s with a mean connection hold time of 4 ms? Answer. Little's Law: $L = 3,000 \times 0.004 = 12$ connections busy on average across the fleet, 0.3 per instance. A small per-instance pool (2–4) or a shared pooler with on the order of 20–40 server connections gives queueing headroom. The important parts are a query timeout and a cap at the database, because if hold time rises to 200 ms during an incident, demand becomes 600 connections and an uncapped fleet would overload the database.

Q6. A search service fans out to 50 partitions. Leaf p99 is 20 ms. What will the root p99 roughly look like, and what would you do? Answer.
$P(\text{all under 20 ms}) = 0.99^{50} = 0.605$, so 40% of root requests exceed 20 ms; the root p99 will be set by roughly the leaf p99.98 ($0.99^{1/50} \approx 0.9998$), which may be many times 20 ms. Remedies: reduce leaf variability (GC tuning, isolation from background work), hedged or tied requests, per-leaf deadlines with partial results, and fewer, larger partitions if that is feasible.

Advanced

Q7. Load tests show throughput rising to 16 nodes, flat at 32, and falling at 64. Explain using a model, and say what you would investigate. Answer. This is retrograde scaling, which Amdahl's Law cannot produce but the USL can: a non-zero coherency term $\beta N(N-1)$ grows quadratically and eventually dominates. Fitting α and β to the measurements gives $N^* = \sqrt{(1-\alpha)/\beta}$ near 32. I would look for all-to-all interactions: distributed locks, cache invalidation broadcasts, gossip or membership traffic, cross-partition transactions, hot shared rows. The remedy is to partition so that most work needs no coordination, not to add nodes.

Q8. Design the replication policy for a storage system targeting 10^{-9} annual loss probability per object with disks at AFR 3%. Answer. $\lambda = 0.03/8760 = 3.4 \times 10^{-6}$/h. Two replicas with $T = 1$ h give $2 \times 0.03 \times \lambda T \approx 2 \times 10^{-7}$ — not enough. Three replicas with $T = 24$ h give $3 \times 0.03 \times 2(\lambda T)^2 = 0.09 \times 2 \times (8.2 \times 10^{-5})^2 \approx 1.2 \times 10^{-9}$ — borderline, so I would cut repair time (parallel re-replication across many nodes, fast detection) to a few hours, which gives roughly 10^{-11}–10^{-10}. Then I would state the caveat: the independent-failure model is opti-

mistic, so I would place replicas in distinct failure domains, consider erasure coding across zones for cost, add end-to-end checksums and scrubbing for silent corruption, and keep backups against logical deletion.

Q9. An LLM serving team reports 25% MFU and asks whether to raise batch size. How do you reason about it? Answer. Throughput scales with MFU, so raising utilization lowers cost per token. In the decode phase, each step is memory-bandwidth-bound (all weights are streamed per step), so larger batches amortize that fixed cost and raise throughput nearly linearly until compute or KV-cache memory becomes the limit. But per-request latency rises: batch formation time grows with B/λ, and step time grows once compute-bound. I would plot throughput and p99 time per output token against batch size, pick the largest batch that keeps p99 within the SLO, use dynamic batching with a maximum wait, and keep utilization below the knee of the queueing curve for bursty traffic.

4.22 Practical exercises

1. **Percentiles versus means.** Modify the §4.8.2 program to use $\sigma = 0.5$ and $\sigma = 1.5$ for the log-normal. Record mean, p50, p99 and p99.9 for each, and explain how the ratio p99/p50 changes. Check against $e^{2.326\sigma}$.
2. **Coordinated omission.** Write a load generator that sends a request, waits for the reply, then sends the next (closed loop), against a simulated server that pauses for 1 s every 10 s. Compare the p99 it records with that of an open-loop generator that sends at a fixed rate and measures latency from the *intended* send time.
3. **M/M/1 versus M/D/1.** Change `simulate_mm1` so that service times are constant (always $1/\mu$). Verify that mean waiting time in the queue halves, as the Pollaczek–Khinchine formula predicts.
4. **Pool sizing.** Using `erlang_c`, find the smallest thread pool for $\lambda = 500$ RPS and mean hold time 40 ms such that fewer than 1% of requests wait for a thread. Then repeat for a hold time of 200 ms.
5. **Availability of your own system.** List every synchronous dependency on the critical path of a service you know, estimate each one's availability, and compute the series availability with the calculator. Which single change raises it most?
6. **USL fitting.** Measure throughput of a local service (or a multithreaded program) at 1, 2, 4, 8, 16 and 32 threads. Fit α and β by minimizing squared error over a grid, and predict N^*.

4.23 Design challenges

1. **Fan-out search tier.** You must build a search tier over 2 billion documents with a root p99 of 150 ms. Each leaf can hold 20 million documents and has a p50 of 15 ms

and a p99 of 60 ms. Determine the number of leaves, the probability that a root request waits on at least one leaf slower than 60 ms, and a design (replication, hedging, deadlines, partial results) that meets the SLO. Show the arithmetic for every step.

2. **Four-nines checkout.** A checkout path calls an API gateway, an order service, a payment service and a database. The payment provider offers 99.95%. Can the path meet 99.99%? If not, what architectural changes (asynchronous capture, retries with idempotency keys, a second provider in parallel) change the arithmetic, and what new failure modes do they introduce?
3. **Durable object store on a budget.** Design the redundancy scheme for 10 PB of user data with a target of 10^{-11} annual loss probability per object, using drives with an assumed 2–4% AFR and a 10 Gbps network per node. Compute repair times, compare three-way replication with an erasure code of your choice (see §15.6 for the arithmetic), and identify which correlated failures your model ignores.

4.25 Open verification items

- Dean and Barroso (2013) hedged-request benchmark figures (p99.9 from 1,800 ms to 74 ms with ~2% extra requests, 1,000 keys over 100 BigTable servers): confirm exact numbers and wording against the CACM article.
- Schroeder and Gibson (2007) field replacement rates (“typically exceeding 1%, 2–4% common”): confirm against the paper’s abstract.
- Table 4.9 “classic” column: the circulated versions differ (e.g., 1 KB vs 2 KB network send; 20 ms vs 30 ms for 1 MB sequential disk read; SSD rows were added later than Dean’s 2009 talk). Verify each value against Dean’s LADIS 2009 slides and Norvig’s essay, and attribute row by row.
- Table 4.9 “as of 2025” column is the author’s order-of-magnitude estimate; validate against current vendor specifications or measurements before publication.
- AWS S3 durability statement: confirm current wording and add the documentation URL.
- Gunther’s notation (σ, κ in later work vs α, β in *Guerrilla Capacity Planning*): confirm which notation the 2007 book uses.
- IEC 80000-13: confirm the current edition year.
- Copy runnable programs to `code/ch04/` per style guide §8 (not done by this author; out of scope for this file).

Part II — Computer Science Foundations

Chapter 5 — Computer Architecture

> **Level:** 1 · **Track:** Shared · **Estimated reading time:** 3 h

Every distributed system, however large, is built out of single machines. When a database is “slow”, a queue “backs up” or a service “needs more threads”, the real cause almost always comes down to one of a small number of physical facts: it takes about 100 ns to fetch a value from main memory, a spinning disk can perform only about 100 random reads per second, a network card can only move so many bytes per second, and a CPU core can do useful work only when its data is close at hand. This chapter teaches those facts from the ground up. You need no prior knowledge of hardware. By the end you will be able to explain *why* system designers favor sequential I/O, batching, caching and data locality, and you will be able to back those preferences with numbers.

Throughout the chapter we use decimal units for estimation (KB, MB, GB = 10^3, 10^6, 10^9 bytes) and binary units where hardware is built in powers of two (KiB, MiB, GiB = 2^{10}, 2^{20}, 2^{30} bytes), for example cache sizes and page sizes. Hardware numbers are labeled “as of , approximate”. They change every product generation, so learn the **orders of magnitude and the ratios**, which are far more stable than any single figure.

5.1 Learning objectives

After this chapter you should be able to:

- Describe what a CPU core does on every clock cycle, and explain pipelining, branch prediction, superscalar and out-of-order execution, and simultaneous multithreading (hyperthreading) in plain language.
- Calculate CPU execution time from instruction count, cycles per instruction and clock rate, and estimate the cost of branch mispredictions.
- Explain how L1, L2 and L3 caches, cache lines and associativity work, and calculate average memory access time for a multi-level cache.
- Explain cache coherence using the MESI protocol, recognize false sharing in code, and fix it.
- Draw the memory hierarchy from registers to archival storage with dated latency, capacity and cost figures.
- Calculate hard disk access time from seek time, rotational latency and transfer time, and explain why random I/O on a disk is hundreds of times slower than sequential I/O.

- Explain how flash SSDs store data (pages, blocks, erase-before-write), what write amplification is, and why NVMe outperforms SATA.
- Compare programmed I/O, interrupts, DMA, polling and kernel bypass.
- Diagnose whether a workload is CPU-bound or I/O-bound and size a thread pool accordingly.
- Estimate how long it takes to scan 1 GB from RAM, SSD, HDD or the network, and explain the difference between latency and bandwidth.
- Explain NUMA and its effect on multi-socket servers.
- Explain what SIMD and hardware accelerators do and when they matter.
- Map hardware facts to system design decisions: sequential I/O, batching, caching, data locality and queue depth.

5.2 Prerequisites

- Powers of two and powers of ten — §4.3 (cache sizes, addresses and capacities are powers of two).
- Units: bits, bytes, rates and prefixes — §4.5 (we convert between ns, µs, ms and between MB/s and Gbit/s constantly).
- Little's Law — §4.11 (we use it to relate queue depth, latency and throughput for memory and SSDs).
- Latency numbers every engineer should know — §4.17 (this chapter explains the hardware *behind* those numbers).
- Basic programming in any language; the code examples use C and Python, and every line that matters is explained.

5.3 The CPU: cores, registers, clock and the instruction pipeline

5.3.1 What a CPU does

> DEFINITION
>
> **Definition — Central processing unit (CPU).** The hardware that executes a program's **instructions**: simple operations such as "add these two numbers", "load a value from memory address X", or "if this value is zero, jump to instruction Y". A modern CPU package contains several independent **cores**, each of which can execute its own stream of instructions.

First-principles explanation

Imagine a restaurant kitchen. The **chef** is a CPU core. The **recipe** is the program: a numbered list of small steps. The chef's **two hands and the cutting board** are the **regis-**

ters, a tiny number of slots holding the values being worked on right now. The **counter beside the stove** is the cache, the **walk-in fridge** at the back of the kitchen is main memory (RAM), and the **supplier's warehouse across town** is the disk. The chef works at astonishing speed with whatever is in hand, but any trip to the fridge or the warehouse stops the cooking. Most of the techniques in this chapter are tricks for keeping the chef's hands full.

The analogy also explains cores: a kitchen with eight chefs, each following their own recipe, can prepare eight dishes at once — provided they do not keep reaching for the same pan.

Why does this exist?

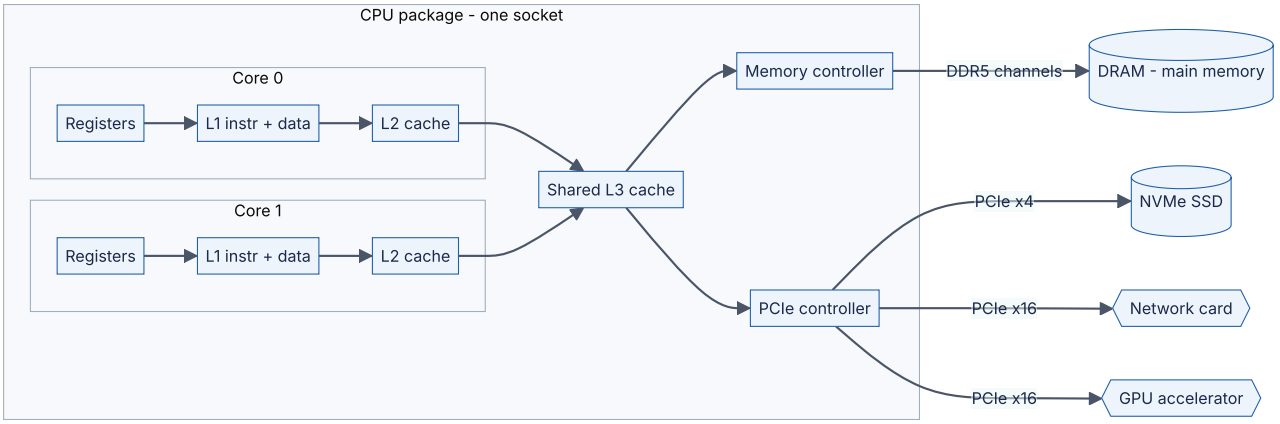
Early computers ran one instruction at a time and memory was about as fast as the processor. Since the 1980s processor speed has grown much faster than memory speed — the so-called **memory wall** [Hennessy & Patterson 2017, ch. 2]. Every feature in a modern core (caches, pipelines, prediction, out-of-order execution) exists to keep a very fast execution engine busy despite slow memory and unpredictable control flow.

How it works internally

At its simplest a core repeats the **fetch–decode–execute cycle**:

1. **Fetch.** Read the next instruction from memory at the address held in the **program counter** (PC) register.
2. **Decode.** Work out what the instruction means: which operation, which registers, which memory address.
3. **Execute.** Perform the operation in an execution unit — the **arithmetic logic unit** (ALU) for integer maths, the floating-point unit for decimals, the load/store unit for memory.
4. **Memory access.** If the instruction reads or writes memory, do so (via the caches, §5.4).
5. **Write back.** Store the result in the destination register and advance the program counter (or jump, if the instruction was a branch).

Figure 5.1 — Inside a single-socket server.



Reading the diagram. The package (the chip you hold in your hand) contains several **cores**; we show two, but server parts in 2025 carry anywhere from 8 to well over 100. Each core has private **registers**, a private **L1 cache** split into an instruction half and a data half, and usually a private **L2 cache**. All cores share an **L3 cache**, which connects to the **memory controller** and the **PCIe controller**. The memory controller drives several **DDR5 channels** to the DRAM modules (main memory). The PCIe controller connects storage (NVMe SSDs), the network card and accelerators such as GPUs over **PCIe lanes** (x4 = four lanes, x16 = sixteen). Arrows point outward from the core because the core initiates requests; data flows back along the same path. All of these paths are synchronous from the core's point of view (an instruction waits for its load), except device I/O, which is asynchronous via DMA and interrupts (§5.7). Every arrow is a potential bottleneck: the further right you go, the higher the latency and the lower the bandwidth per byte of capacity. The storage boundary that matters most is the one between DRAM (volatile, lost on power failure) and the SSD (persistent). The machine scales up by adding cores, memory channels, sockets (§5.10) and PCIe devices; beyond that you scale out across machines, which is the subject of most of this book.

5.3.2 Registers, the clock and the "iron law" of performance

DEFINITION

Definition — Register. A tiny, extremely fast storage slot inside a core, typically 64 bits wide for general-purpose registers. x86-64 exposes 16 general-purpose integer registers to programs; ARMv8-A (AArch64) exposes 31. Reading a register costs essentially nothing beyond the instruction that uses it.

DEFINITION

Definition — Clock rate. The frequency at which a core's internal circuitry steps from one state to the next, measured in hertz (cycles per second). A 4 GHz core has a **cycle time** of $1 / (4 \times 10^9)$ s = 0.25 ns.

The clock is like a metronome in the kitchen: on every tick each part of the core can advance its work by one step. For decades chip makers raised clock rates every year. Around 2005 this stopped: higher frequencies needed more voltage, and power (and therefore heat) grows faster than linearly with voltage and frequency. Clock rates have hovered around 2–6 GHz since (as of 2025, approximate), so the industry turned to doing **more work per cycle** and putting **more cores** on each chip [Hennessy & Patterson 2017, ch. 1]. This “end of free speed-ups” is why concurrency and horizontal scaling dominate modern system design.

How long a program takes is governed by three numbers multiplied together.

FORMULA

CPU execution time (the “iron law”)

$$T_{CPU} = N_{instr} \times CPI \times t_{cycle} = \frac{N_{instr} \times CPI}{f}$$

Symbol	Meaning	Units
T_{CPU}	CPU time to run the program	seconds
N_{instr}	Number of instructions executed	instructions
CPI	Average clock cycles per instruction (its inverse is IPC, instructions per cycle)	cycles/instruction
t_{cycle}	Duration of one clock cycle	seconds/cycle
f	Clock frequency, $1/t_{cycle}$	cycles/second (Hz)

WORKED EXAMPLE

Worked example — Running a program and paying for mispredicted branches.

A program executes $N_{instr} = 4 \times 10^9$ instructions on a 4 GHz core ($t_{cycle} = 0.25$ ns) at an average CPI of 0.5 (the core completes two instructions per cycle on average).

1. $T_{CPU} = 4 \times 10^9 \times 0.5 \times 0.25 \times 10^{-9}$ s $= 0.5$ s.

Now suppose 20% of instructions are branches, 5% of those branches are mispredicted (§5.3.4), and each misprediction costs 15 cycles.

2. Extra CPI from mispredictions $= 0.20 \times 0.05 \times 15 = 0.15$ cycles per instruction.
3. New CPI $= 0.5 + 0.15 = 0.65$.
4. New $T_{CPU} = 4 \times 10^9 \times 0.65 \times 0.25 \times 10^{-9} = 0.65$ s.

Cross-check: $4 \times 10^9 \times 0.2 \times 0.05 = 4 \times 10^7$ mispredictions $\times$ 15 cycles $= 6 \times 10^8$ cycles $= 6 \times 10^8 \times 0.25$ ns $= 0.15$ s extra. ✓

Interpretation. One branch in a hundred instructions going the “wrong way” costs 30% of the run time. **Engineering implication.** Raw clock speed is only one of three factors; CPI — which depends on caches, branches and dependencies — usually varies far more between two versions of the same code than clock rate varies between two CPUs.

5.3.3 The instruction pipeline

DEFINITION

Definition — Instruction pipeline. A technique in which the core splits instruction execution into stages and works on different stages of several consecutive instructions at the same time, like an assembly line.

First-principles explanation

A laundry has a washer, a dryer and a folding table. Doing one load start-to-finish before starting the next wastes the washer while the dryer runs. Instead you start load 2 in the washer the moment load 1 moves to the dryer. Each load still takes as long as before (its **latency** is unchanged), but a load *finishes* far more often (its **throughput** rises). A CPU pipeline is the same idea applied to instructions. This distinction between latency and throughput recurs at every level of system design (§5.12).

How it works internally

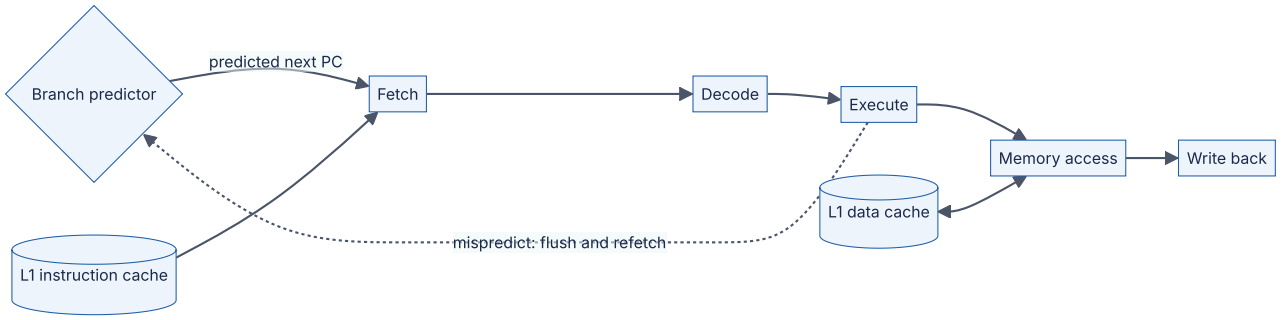
The classic teaching pipeline has five stages: instruction fetch (IF), instruction decode (ID), execute (EX), memory access (MEM) and write back (WB) [Hennessy & Patterson 2017, appendix C]. Real cores have between roughly 10 and 20 stages (as of 2025, approximate), but the principle is identical.

Table 5.1 — Five instructions flowing through a five-stage pipeline.

Cycle →	1	2	3	4	5	6	7	8	9
Instruction 1	IF	ID	EX	MEM	WB				
Instruction 2		IF	ID	EX	MEM	WB			
Instruction 3			IF	ID	EX	MEM	WB		
Instruction 4				IF	ID	EX	MEM	WB	
Instruction 5					IF	ID	EX	MEM	WB

Without pipelining, five instructions would take 5 × 5 = 25 cycles. With it they take 9 cycles, and once the pipeline is full one instruction completes **every** cycle. Each individual instruction still takes 5 cycles.

Figure 5.2 — A pipelined core with a branch predictor.



Reading the diagram. Instructions move left to right through five stages; each arrow is a hand-off on a clock edge, so the whole chain is synchronous. The **fetch** stage reads instructions from the **L1 instruction cache**; the **memory** stage reads and writes the **L1 data cache** (bidirectional arrow). The **branch predictor** tells fetch which instruction comes next before the core actually knows. The dotted arrow is the failure path: when the execute stage discovers that a branch went the other way, the work in all earlier stages is wrong and is thrown away (flushed), and fetching restarts from the correct address. Pipelines fail to deliver one instruction per cycle when an instruction needs a result not yet produced (a **data hazard**), when two instructions need the same unit (a **structural hazard**), or when the next instruction is unknown (a **control hazard**). Designers scale this structure by making it wider (§5.3.5) rather than much deeper, because deeper pipelines make each misprediction more expensive.

5.3.4 Branch prediction

DEFINITION

Definition — Branch prediction. Hardware that guesses the outcome of a conditional jump (a **branch**, e.g. an `if` or a loop condition) before it is computed, so that the pipeline can keep fetching instructions. A wrong guess is a **misprediction** and forces a pipeline flush.

A long pipeline needs to know which instruction to fetch next on every cycle, but a branch's outcome is only known several stages later. Waiting would leave the pipeline empty for 10–20 cycles at every `if`, and typical code has a branch every five to ten instructions. So the core *guesses*. Modern predictors record the recent history of each branch and of the branches before it, and are right well over 95% of the time on typical code (approximate; it depends heavily on the program) [Hennessy & Patterson 2017, ch. 3]. A misprediction costs roughly 15–20 cycles on recent high-performance x86 cores (as of 2025, approximate).

The practical lesson: **predictable code runs faster**. Loops over sorted data, or code whose `if` almost always goes the same way, mispredict rarely. A filter over random data where each element passes with 50% probability mispredicts about half the time. Compilers can sometimes replace such branches with branch-free "conditional move" instructions, and data-processing engines often sort or partition data first precisely to make branches predictable.

5.3.5 Superscalar and out-of-order execution (intuition)

DEFINITION

Definition — Superscalar execution. A core that can issue and complete more than one instruction per cycle by having several execution units working in parallel.

DEFINITION

Definition — Out-of-order (OoO) execution. A technique in which the core executes instructions as soon as their inputs are ready rather than strictly in program order, while still making the results *appear* in program order (it **retires** them in order).

Back to the kitchen. A good chef reading a recipe does not stand idle while the water boils; they skip ahead to chopping onions, which does not depend on the water, and come back when the pot is ready. That is out-of-order execution. And a chef with two hands and

several burners can sear, stir and plate in the same moment; that is superscalar execution.

Internally, the core decodes a window of upcoming instructions — several hundred on recent high-end cores (as of 2025, approximate) — into a buffer called the **reorder buffer**. Each instruction waits in a **scheduler** until its inputs are ready, then dispatches to any free execution unit. Results are held until every earlier instruction has completed and are then retired in order, which preserves the illusion of sequential execution for the programmer. The key algorithmic idea dates to Tomasulo's work at IBM in 1967 [Tomasulo 1967].

Why does this matter to a system designer? Because the main thing OoO hides is **memory latency**. If a loop issues ten independent loads, an OoO core can have all ten outstanding at once and pay roughly one memory latency instead of ten. If each load depends on the previous one — walking a linked list, chasing pointers through a tree — nothing can overlap and the core pays the full latency every time. This is why arrays usually beat linked lists by a wide margin in practice, even when asymptotic complexity is identical, and why B-trees with wide nodes (§11.8) beat binary trees on real hardware.

5.3.6 Multiple cores and simultaneous multithreading (hyperthreading)

DEFINITION

Definition — Multi-core processor. A single chip containing several complete cores, each with its own pipeline and private caches, sharing the last-level cache and memory.

DEFINITION

Definition — Simultaneous multithreading (SMT). A technique in which one physical core runs two (occasionally more) instruction streams at once, interleaving them through the same execution units. Intel markets its implementation as **Hyper-Threading Technology**. Each stream appears to the operating system as a separate **logical CPU** (or **hardware thread**).

Even with out-of-order execution, a single thread often leaves execution units idle — for example while waiting for a cache miss. SMT gives the core a second recipe to work from: when thread A stalls, the core issues instructions from thread B. The core duplicates only the per-thread state (registers, program counter) and shares nearly everything else, so the extra silicon is small. The benefit depends heavily on the workload. Intel's original description reported gains of up to about 30% on some server benchmarks [Marr et al. 2002]; workloads that already saturate the execution units or the caches may gain nothing or even slow down, because two threads now compete for the same L1 and L2.

Three consequences for system design:

- **A "vCPU" in the cloud is usually a hardware thread, not a core.** On most x86 instance types at the major cloud providers, two vCPUs share one physical core (as of 2025; check your provider's documentation per instance family). Do not assume 16 vCPUs give 16 cores' worth of throughput.
- **Benchmarks must state whether SMT is on.** Doubling thread count from 8 to 16 on an 8-core, 16-thread machine will not double CPU-bound throughput.
- **Security.** Because SMT siblings share caches and execution units, they can leak information to each other through timing side channels. Some operators disable SMT for multi-tenant isolation, and some recent client CPUs ship without it (as of 2024).

Failure scenarios

Table 5.2 — CPU-level failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Service throughput flat after doubling vCPUs	vCPUs were SMT siblings; the workload saturates execution units	Per-core utilization near 100%; IPC drops as threads are added	Size by physical cores; scale out	Benchmark with physical-core counts in mind
Hot loop far slower on production data than in tests	Test data was sorted or uniform; production data makes branches unpredictable	`perf stat` shows high branch-miss rate	Sort/partition input; use branch-free code	Benchmark on realistic data distributions
Throttled CPU under sustained load	Thermal or power limits lower the clock rate	Clock frequency drops in telemetry	Improve cooling; spread load	Capacity-plan at sustained, not turbo, frequency

Common misconceptions

COMMON MISTAKE

"A higher GHz number means a faster CPU." Clock rate is only one factor in the iron law. A 3 GHz core with an IPC of 4 completes more work than a 4 GHz core with an IPC of 2. Compare CPUs on benchmarks of your own workload.

COMMON MISTAKE

"The CPU runs my code one line at a time, in order." It overlaps dozens to hundreds of instructions and executes them out of order; only the *visible* results are in order. That is why independent operations can be nearly free while dependent chains are slow.

5.4 CPU caches

5.4.1 Why caches exist

> DEFINITION
>
> **Definition — CPU cache.** A small, fast memory built from SRAM (static RAM) on the processor chip that holds copies of recently used main-memory data, so that most loads and stores do not have to wait for DRAM.

First-principles explanation

Picture a researcher in a library. The book on the **desk** is instantly available. The **shelf behind the chair** holds a few dozen books and takes a few seconds to reach. The **library stacks** on the same floor take a minute. The **off-site depository** takes a day. The researcher keeps the books they are using right now on the desk and the ones they will probably need soon on the shelf. When they fetch a book from the stacks, they bring back its neighbors too, because research tends to move along the shelf.

A CPU cache is that desk and shelf. It works because programs exhibit **locality of reference**:

- **Temporal locality** — data used recently is likely to be used again soon (a loop counter, a hot configuration object).
- **Spatial locality** — data near recently used data is likely to be used soon (the next element of an array, the next field of a struct).

Why does this exist?

A DRAM access costs about 80–120 ns (as of 2025, approximate), which at 4 GHz is 320–480 cycles. A core that could issue several instructions per cycle would spend almost all of its time waiting. Making all of main memory as fast as a register is physically impossible: fast memory (SRAM) needs about six transistors per bit, sits on the expensive processor die, and the longer the wires to it, the slower it gets. So designers build a **hierarchy**: tiny and very fast near the core, larger and slower further away.

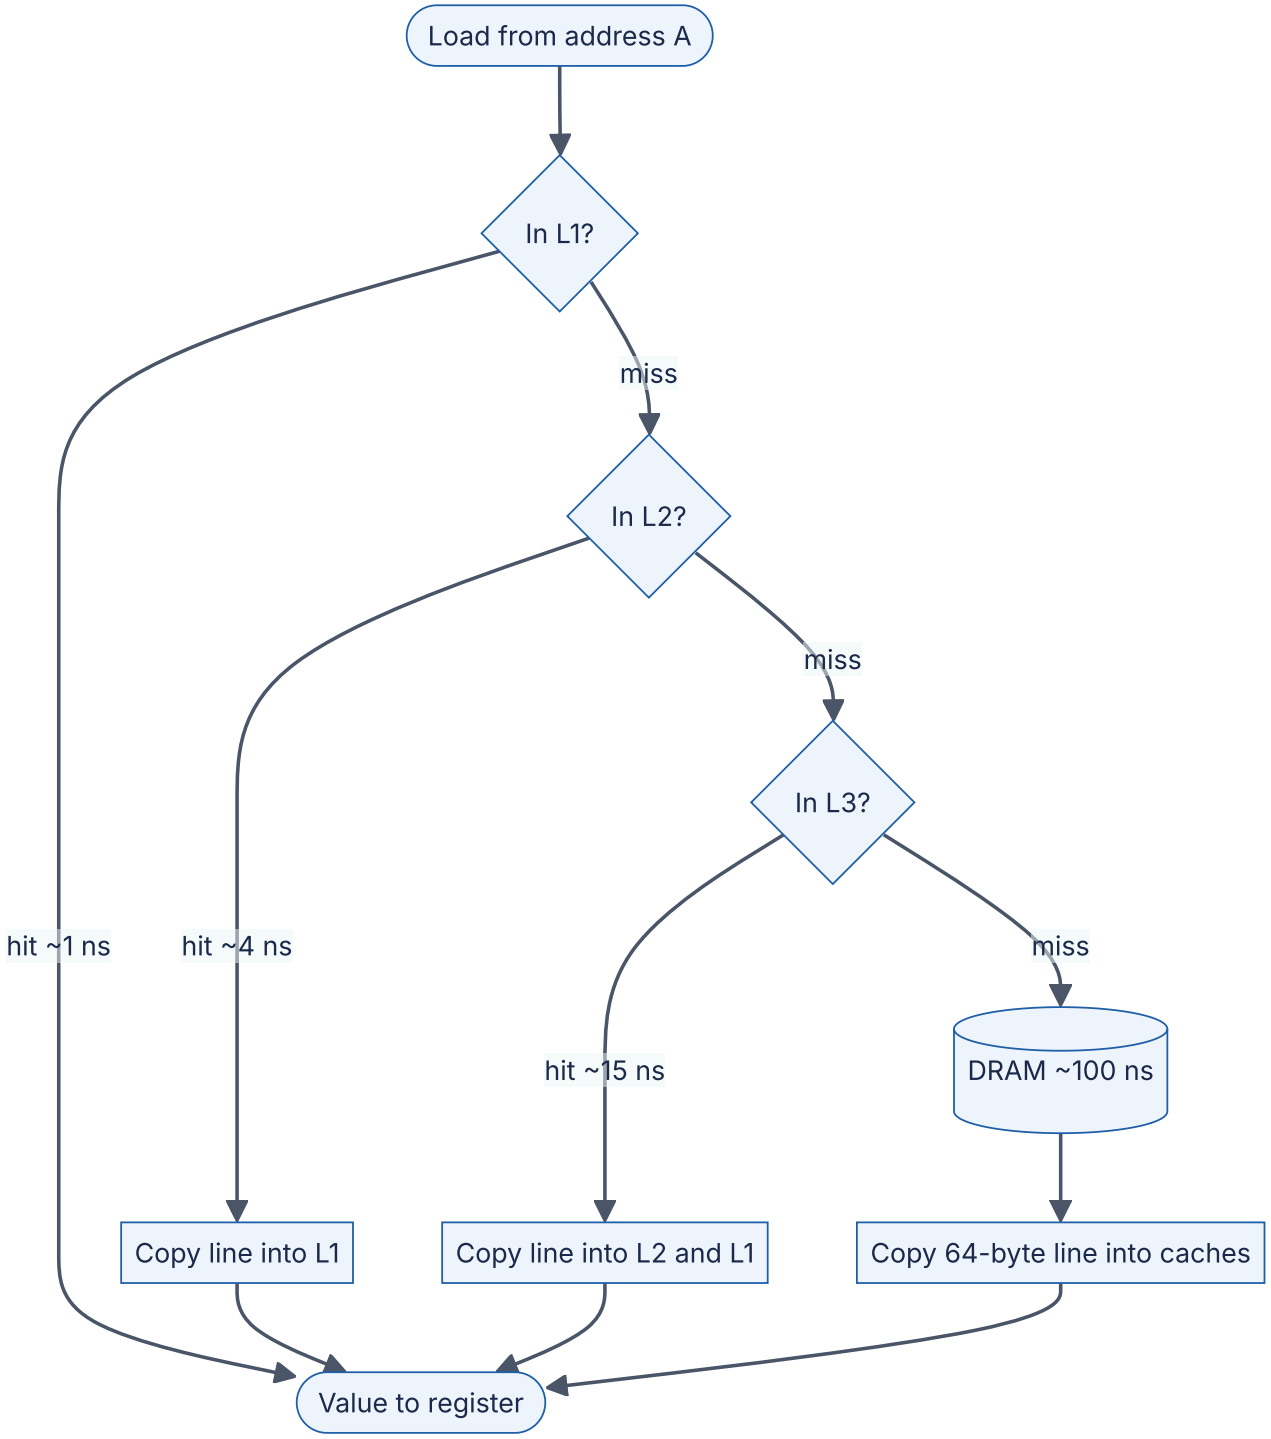
5.4.2 Cache levels

Table 5.3 — Typical CPU cache levels (as of 2024–2025, approximate; sizes and latencies vary by product).

Level	Typical size	Shared by	Latency (cycles)	Latency at ~4 GHz	Analogy
Registers	Tens of 64-bit values visible per thread	One hardware thread	0–1	< 0.3 ns	Hands
L1 data	32–64 KiB	One core	~4–6	~1–1.5 ns	Desk
L2	0.5–3 MiB	One core (usually)	~12–18	~3–5 ns	Shelf behind you
L3 (last-level cache)	8 MiB to several hundred MiB	All cores on the chip or chiplet	~40–80	~10–20 ns	Stacks on your floor
DRAM	GBs to TBs	Whole socket (or machine)	~300–500	~80–120 ns	Off-site depository

Sources for the ranges: vendor optimization manuals and independent measurements summarized in [Hennessy & Patterson 2017, ch. 2] and [Drepper 2007]; check `lscpu` on your own machine. The machine on which this chapter's examples were tested reports 48 KiB L1d and 2 MiB L2 per core.

Figure 5.3 — What happens on a load instruction.



Reading the diagram. A load instruction checks each level in turn. A **hit** returns the data at that level's latency; a **miss** passes the request to the next level. When the data finally arrives it is copied into the faster levels so the next access hits (this is temporal locality at work), possibly **evicting** some other line to make room. Each step is synchronous for the instruction that needs the value, but an out-of-order core keeps running independent instructions while it waits, and several misses can be outstanding at once (§5.9.2). The storage boundary is between L3 (on chip, SRAM) and DRAM (off chip). The main failure mode is a **miss storm**: a working set larger than the caches turns most loads into

100 ns trips. The way to scale is not a bigger cache — you cannot buy one — but a smaller, denser working set and access patterns the hardware can predict.

5.4.3 Cache lines and locality

DEFINITION

Definition — Cache line. The fixed-size unit in which data moves between memory and caches. On x86-64 and most ARM server cores a line is 64 bytes; some designs (for example Apple's M-series cores) use 128 bytes (as of 2024). A load of a single byte brings its whole line into the cache.

Because a whole line arrives at once, reading the first element of an array also brings in the next seven 8-byte elements "for free". Hardware **prefetchers** go further: when they detect that you are walking through memory in a regular pattern, they start fetching the next lines before you ask. Sequential access is therefore the best case in the entire memory system, and random access the worst.

Code example — row-major vs column-major traversal

```c
/* traverse.c — build: gcc -O2 -std=c11 traverse.c -o traverse */
#define _POSIX_C_SOURCE 199309L
#include <stdio.h>
#include <stdlib.h>
#include <time.h>

#define N 8192                /* 8192 x 8192 ints = 256 MiB */

static double now(void) {
    struct timespec t;
    clock_gettime(CLOCK_MONOTONIC, &t);
    return t.tv_sec + t.tv_nsec / 1e9;
}

int main(void) {
    int *m = malloc((size_t)N * N * sizeof *m);
    if (!m) return 1;
    for (size_t i = 0; i < (size_t)N * N; i++) m[i] = 1;

    long long sum = 0;
    double t0 = now();
    for (size_t r = 0; r < N; r++)          /* row-major: consecutive addresses
*/
        for (size_t c = 0; c < N; c++)
            sum += m[r * N + c];
    double t1 = now();
    for (size_t c = 0; c < N; c++)          /* column-major: jumps of N*4 bytes
*/
        for (size_t r = 0; r < N; r++)
            sum += m[r * N + c];
    double t2 = now();

    printf("row-major:    %.3f s\n", t1 - t0);
    printf("column-major: %.3f s\n", t2 - t1);
    printf("checksum: %lld\n", sum);         /* stops the compiler deleting
loops */
    free(m);
    return 0;
}
```

What to notice:

- Both loops add exactly the same 67,108,864 integers; only the **order** differs.
- The row-major loop touches consecutive 4-byte integers, so each 64-byte line serves 16 additions and the prefetcher streams lines ahead of time.
- The column-major loop jumps 8192 × 4 = 32,768 bytes between consecutive accesses, so every access lands on a different line and, because the matrix is 256 MiB, most of those lines have been evicted before the loop comes back for their neighbors.

- On the test machine (a cloud x86-64 VM, 2026) the row-major loop took 0.038 s and the column-major loop 0.667 s — about **17× slower** for identical arithmetic. Your ratio will differ, but the direction will not.
- `sum` is printed so that the optimizing compiler cannot prove the loops are useless and delete them — a classic benchmarking pitfall (§23.5).

5.4.4 Associativity: where a line may live

A cache must find a line quickly, so it cannot search every slot. Instead the memory address decides which **set** (group of slots) a line may occupy.

DEFINITION

Definition — Set-associative cache. A cache divided into S sets of W slots (**ways**). A line at a given address may be stored in any of the W ways of exactly one set. $W = 1$ is a **direct-mapped** cache; a cache with a single set holding every line is **fully associative**.

The analogy is a coat check with numbered racks. Your ticket number decides the rack (the set); within the rack your coat can go on any free hook (any way). If many guests' tickets map to the same rack, that rack overflows even though others are empty — a **conflict miss**.

FORMULA

Address decomposition in a set-associative cache

$$S = \frac{C}{B \times W}, \qquad \text{offset bits} = \log_2 B, \qquad \text{index bits} = \log_2 S$$

$$\text{set index} = \left\lfloor \frac{A}{B} \right\rfloor \bmod S, \qquad \text{tag} = \left\lfloor \frac{A}{B \times S} \right\rfloor$$

Symbol	Meaning	Units
C	Cache capacity	bytes
B	Line (block) size	bytes
W	Associativity (ways per set)	lines
S	Number of sets	sets
A	Memory address	byte address
tag	High-order address bits stored with the line to identify it	—

WORKED EXAMPLE

Worked example — Where does address 0x12345 go in a 32 KiB, 8-way cache with 64-byte lines?

1. Sets: $S = 32\,768/(64 \times 8) = 32\,768/512 = 64$ sets.
2. Offset bits $= \log_2 64 = 6$; index bits $= \log_2 64 = 6$.
3. Address $A = 0x12345 = 74\,565$.
4. Offset within the line $= 74\,565 \bmod 64 = 74\,565 - 1165 \times 64 = 74\,565 - 74\,560 = 5$.
5. Line number $= \lfloor 74\,565/64 \rfloor = 1165$; set index $= 1165 \bmod 64 = 1165 - 18 \times 64 = 13$.
6. Tag $= \lfloor 1165/64 \rfloor = 18$ (0x12).

Check in binary: 0x12345 = `0001 0010 0011 0100 0101`; the low 6 bits `000101` = 5 ✓, the next 6 bits `001101` = 13 ✓, the remaining bits `10010` = 18 ✓.

Interpretation. Addresses that differ by a multiple of $B \times S = 64 \times 64 = 4096$ bytes land in the **same set**. **Engineering implication.** A loop that strides through memory in steps of exactly 4 KiB (for example, reading one field from each of many page-aligned 4 KiB records) can use only one set — 8 lines, 512 bytes — of a 32 KiB cache. Power-of-two strides are a known performance trap; padding a row or record by one cache line often removes it [Drepper 2007, §6.2].

5.4.5 Average memory access time

FORMULA

Average memory access time (AMAT), applied recursively to each level

$$AMAT = t_{L1} + m_{L1} \times (t_{L2} + m_{L2} \times (t_{L3} + m_{L3} \times t_{mem}))$$

Symbol	Meaning	Units
t_{L1}, t_{L2}, t_{L3}	Hit time at each cache level	ns
t_{mem}	DRAM access time	ns
m_{L1}	Fraction of all accesses that miss L1	dimensionless (0–1)
m_{L2}, m_{L3}	**Local** miss rate: fraction of accesses *reaching* that level that miss it	dimensionless (0–1)

The same formula, with two levels, is the **effective access time** of any cache in front of a slower store: $EAT = h \times t_{hit} + (1 - h) \times t_{miss}$, where h is the hit ratio. You will use it again for application caches (§20.3).

WORKED EXAMPLE

Worked example — Good locality versus poor locality.

Assume t_{L1} = 1 ns, t_{L2} = 4 ns, t_{L3} = 15 ns, t_{mem} = 90 ns.

Good locality (array scans, small hot data): m_{L1} = 0.05, m_{L2} = 0.20, m_{L3} = 0.30.

1. L3 term: $15 + 0.30 \times 90 = 15 + 27 = 42$ ns.
2. L2 term: $4 + 0.20 \times 42 = 4 + 8.4 = 12.4$ ns.
3. AMAT $= 1 + 0.05 \times 12.4 = 1 + 0.62 = 1.62$ ns.

Poor locality (random lookups in a large hash table): m_{L1} = 0.30, m_{L2} = 0.60, m_{L3} = 0.70.

1. L3 term: $15 + 0.70 \times 90 = 15 + 63 = 78$ ns.
2. L2 term: $4 + 0.60 \times 78 = 4 + 46.8 = 50.8$ ns.
3. AMAT $= 1 + 0.30 \times 50.8 = 1 + 15.24 = 16.24$ ns.

Interpretation. The same hardware delivers memory ten times slower on average for the second workload. **Engineering implication.** Data layout (compact structs, arrays instead of pointer-linked nodes, hot fields grouped together) can change performance by an order of magnitude without changing the algorithm. The application-level twin of this example: raising a cache hit ratio from 90% to 99% in front of a 100 µs SSD read, with a 1 µs hit, cuts effective access time from $0.9 \times 1 + 0.1 \times 100 = 10.9$ µs to $0.99 \times 1 + 0.01 \times 100 = 1.99$ µs, about 5.5× faster.

5.4.6 Cache coherence and the MESI protocol

DEFINITION

Definition — Cache coherence. The guarantee that all cores observe a single, consistent sequence of values for each memory location, even though each core keeps private copies in its own caches.

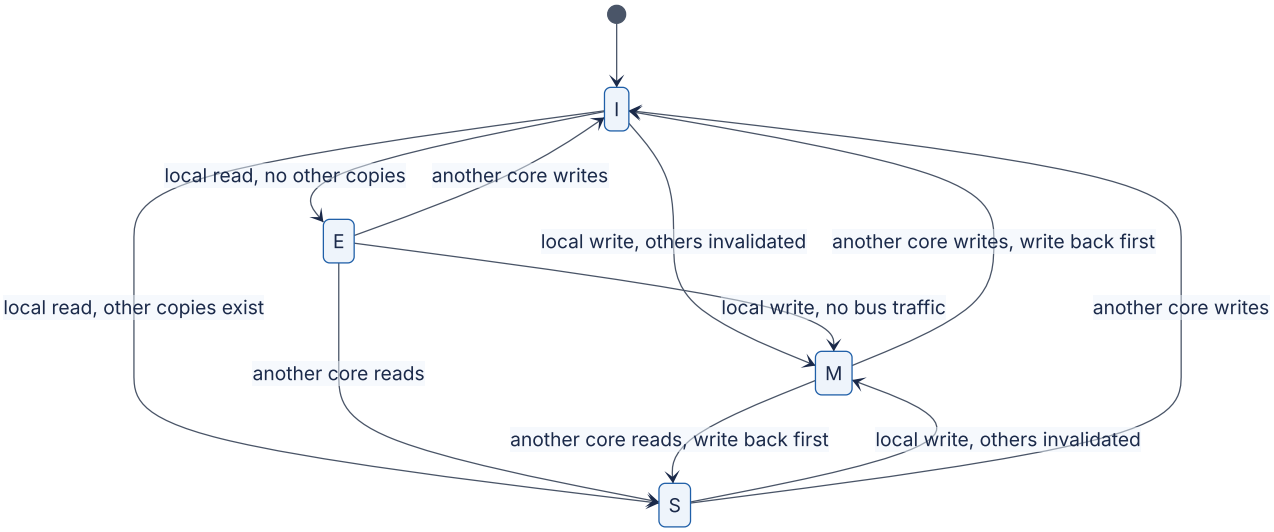
Suppose cores 0 and 1 both cache the variable `x`. Core 0 writes `x = 5`. If core 1 keeps reading its stale copy, the program breaks. Coherence protocols prevent this by tracking, for every cached line, which cores hold it and whether it has been changed. The textbook protocol is **MESI**, named after the four states a line can be in within one core's cache [Papamarcos & Patel 1984; Sorin, Hill & Wood 2011]:

- **Modified (M)** — this core has the only copy and has changed it; memory is stale. The core must write the line back before anyone else may use it.
- **Exclusive (E)** — this core has the only copy, and it matches memory. The core may write to it without telling anyone.

- **Shared (S)** — several cores may hold read-only copies that match memory.
- **Invalid (I)** — this cache does not hold a valid copy.

The analogy is a shared document with a single “edit pen”. Anyone may hold a read-only photocopy (Shared). To write, you must collect every photocopy and shred it (invalidate them), then you hold the pen (Modified). Real processors use extensions — Intel describes MESIF, AMD MOESI — that add states to reduce memory traffic, but the core idea is the same.

Figure 5.4 — MESI state transitions for one cache line in one core’s cache.



Reading the diagram. Each box is the state of *one* 64-byte line in *one* core’s cache; every core runs this machine independently for every line. “Local” events come from this core’s own instructions; “another core” events arrive as coherence messages over the on-chip interconnect (a ring or mesh linking cores, caches and memory controllers) or, between sockets, over the socket-to-socket link. Transitions caused by our own reads and writes are synchronous with the instruction; invalidations and write-backs triggered by other cores arrive asynchronously. Note the two expensive arcs: moving from Shared to Modified requires invalidating every other copy and waiting for acknowledgments, and a remote read of a Modified line forces a write-back. When two cores repeatedly write the same line, it ping-pongs between their caches, each transfer costing tens of nanoseconds on one chip and more across sockets. Coherence traffic is the reason “just add cores” stops scaling for shared, frequently written data.

5.4.7 False sharing

DEFINITION

Definition — False sharing. A performance problem in which threads on different cores write to *different* variables that happen to sit in the *same* cache line, so the coherence protocol bounces the line between cores as if they were sharing data.

Coherence works at the granularity of a whole line, not a variable. Two counters 8 bytes apart, each updated by its own thread, look to the hardware exactly like one heavily contended variable. The program is logically correct and has no locks, yet it scales *negatively*.

Code example — demonstrating and fixing false sharing in C

```c
/* false_sharing.c — build: gcc -O2 -std=c11 -pthread false_sharing.c -o fs */
#define _POSIX_C_SOURCE 199309L
#include <pthread.h>
#include <stdalign.h>
#include <stdatomic.h>
#include <stdint.h>
#include <stdio.h>
#include <time.h>

#define ITERATIONS 50000000ULL   /* 5 x 10^7 increments per thread */
#define CACHE_LINE 64            /* x86-64 line size; check yours */

/* Variant A: two counters 8 bytes apart -> same cache line. */
struct packed {
    _Atomic uint64_t a;
    _Atomic uint64_t b;
};

/* Variant B: each counter starts its own 64-byte cache line. */
struct padded {
    alignas(CACHE_LINE) _Atomic uint64_t a;
    alignas(CACHE_LINE) _Atomic uint64_t b;
};

static struct packed P;
static struct padded Q;

static void *worker(void *arg) {
    _Atomic uint64_t *counter = arg;
    for (uint64_t i = 0; i < ITERATIONS; i++)
        atomic_fetch_add_explicit(counter, 1, memory_order_relaxed);
    return NULL;
}

static double run(_Atomic uint64_t *x, _Atomic uint64_t *y) {
    struct timespec t0, t1;
    pthread_t ta, tb;
    clock_gettime(CLOCK_MONOTONIC, &t0);
    pthread_create(&ta, NULL, worker, (void *)x);
    pthread_create(&tb, NULL, worker, (void *)y);
    pthread_join(ta, NULL);
    pthread_join(tb, NULL);
    clock_gettime(CLOCK_MONOTONIC, &t1);
    return (double)(t1.tv_sec - t0.tv_sec) + (t1.tv_nsec - t0.tv_nsec) / 1e9;
}

int main(void) {
    printf("gap between counters: packed=%td B, padded=%td B\n",
           (char *)&P.b - (char *)&P.a, (char *)&Q.b - (char *)&Q.a);
    printf("packed (false sharing): %.2f s\n", run(&P.a, &P.b));
    printf("padded (separate lines): %.2f s\n", run(&Q.a, &Q.b));
    return 0;
}
```

What to notice:

- Each thread touches **only its own counter**; there is no logical sharing and no lock.
- In `struct packed` the counters are 8 bytes apart, so they share a 64-byte line. In `struct padded`, `alignas(64)` forces each counter onto its own line (the struct grows from 16 to 128 bytes).
- `atomic_fetch_add_explicit` compiles to a locked read-modify-write instruction, which requires the core to hold the line in the Modified state — every increment by one thread therefore steals the line from the other.
- On the 4-vCPU test VM (2026), three runs gave 1.57–1.69 s for the packed layout versus 0.31–0.34 s for the padded layout: about **5× slower purely because of memory layout**. With plain (non-atomic) increments, the effect is smaller and noisier because store buffers and compiler optimizations hide part of it — another reason to measure rather than assume.
- The fix costs memory (112 wasted bytes here). Pad only data that is genuinely written by different threads at high frequency: per-thread counters, queue head and tail indices, per-core statistics.

Real-world industry applications

INDUSTRY EXAMPLE

LMAX Disruptor (low-latency financial exchange). LMAX built an inter-thread messaging library for its trading platform and found that the head and tail sequence counters of a queue, written by different threads, suffered false sharing. The Disruptor pads its sequence counters to occupy their own cache lines and avoids locks on the hot path; the authors attribute a large part of its throughput advantage over conventional bounded queues to this “mechanical sympathy” with the cache hierarchy. Trade-off: padded structures waste memory and the design assumes a known line size. *Evidence: Primary* — [Thompson et al. 2011]

INDUSTRY EXAMPLE

Netflix (JVM service on larger cloud instances). When Netflix moved a stateless Java service to an instance type with three times the vCPUs, throughput rose only about 25% instead of the expected ~3×. Using hardware performance counters, engineers traced the problem to cache-line contention inside the JVM’s type-checking code — first false sharing, then, after a workaround, true sharing of a frequently written cache field. Fixing it brought throughput close to the expected scaling. Trade-off: diagnosing it required low-level counters that are not exposed on every cloud instance type. *Evidence: Primary* — [Filanovsky & Sane 2022]

Runtimes offer help: Java's internal `@Contended` annotation, C++17's `std::hardware_destructive_interference_size`, and explicit padding fields in Go and Rust.

Advantages and disadvantages of caches

Caches make the common case (good locality) almost as fast as registers, with no effort from the programmer. Their disadvantages are that performance becomes **data-dependent and hard to predict**, that coherence traffic limits how well shared, written data scales across cores, and that shared caches create interference between unrelated workloads — one tenant's large scan can evict another tenant's hot data (the **noisy neighbor** problem, Ch 47).

Failure scenarios

Table 5.4 — Cache-related failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Throughput falls as threads are added	False sharing or a hot shared counter	`perf c2c` on Linux; high cross-core cache-to-cache transfers	Pad or shard per-thread state	Per-thread or per-core data; aggregate occasionally
Latency spikes when a batch job runs on the same host	Batch job's scan evicts the service's working set from shared L3	LLC miss rate rises in sync with the batch job	Move the job; pin to other cores	Cache partitioning (e.g., Intel RDT) or separate hosts
Mysterious slowdown at certain array sizes	Power-of-two stride causes conflict misses in one set	Performance cliff at sizes like 4096 or 8192	Pad rows/records	Avoid power-of-two strides in hot loops
Pointer-heavy structure slow despite good big-O	Each hop is a dependent cache miss	Low IPC, high cache-miss counts	Switch to arrays / B-tree-like wide nodes	Design data structures for locality

Common misconceptions

> COMMON MISTAKE
>
> **"Lock-free code always scales."** Lock-free code still writes to shared cache lines. If many cores update the same atomic counter, the line ping-pongs between them and throughput can be *lower* than with one thread. Scalable designs avoid shared writes altogether (per-core counters, sharded state).

COMMON MISTAKE

“Caches only matter to C programmers.” Every language runs on the same hardware. Java object headers, Python object pointers and Go slices all have cache footprints; the gap between “array of values” and “array of pointers to objects” is often several-fold in any language.

5.5 RAM and the memory hierarchy

5.5.1 Main memory (DRAM)

DEFINITION

Definition — DRAM (dynamic random-access memory). The technology used for main memory. Each bit is stored as charge in a tiny capacitor that leaks and must be **refreshed** every few tens of milliseconds. DRAM is **volatile**: its contents are lost when power is removed.

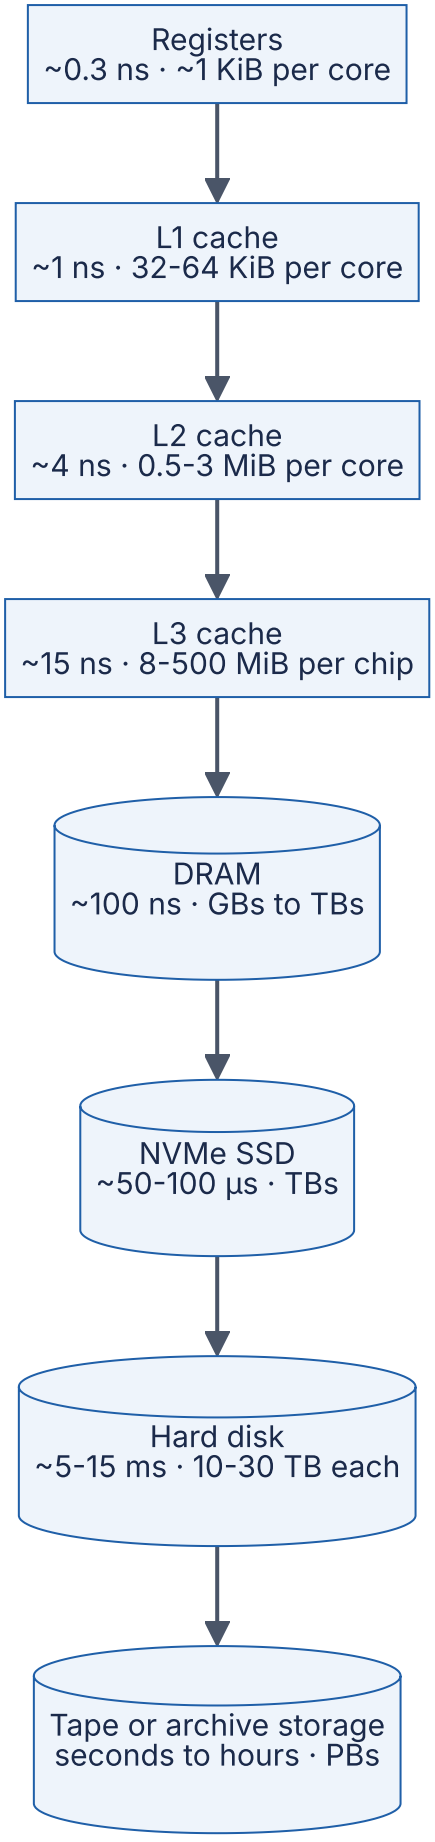
DRAM uses one transistor and one capacitor per bit, versus about six transistors for the SRAM in caches, so it is far denser and cheaper — but slower. Memory chips sit on modules (DIMMs) that plug into **channels**, each an independent 64-bit data path to the CPU’s memory controller (DDR5 splits each module’s path into two 32-bit subchannels, still 64 bits in total). Inside a chip, bits are arranged in banks of rows and columns; reading a row that is already “open” is faster than opening a new one, which is one more reason sequential access is cheaper than random access [Drepper 2007, §2]. Servers use **ECC** (error-correcting code) memory, which stores extra check bits to correct single-bit errors.

5.5.2 The memory hierarchy

DEFINITION

Definition — Memory hierarchy. The layered arrangement of storage technologies in a computer, from small, fast and expensive per byte (registers, caches) to large, slow and cheap per byte (disks, tape), in which each level acts as a cache for the level below it.

Figure 5.5 — The memory and storage hierarchy (as of 2024–2025, approximate).



Registers
~0.3 ns · ~1 KiB per core
L1 cache
~1 ns · 32-64 KiB per core
L2 cache
~4 ns · 0.5-3 MiB per core
L3 cache
~15 ns · 8-500 MiB per chip
DRAM
~100 ns · GBs to TBs
NVMe SSD
~50-100 µs · TBs
Hard disk
~5-15 ms · 10-30 TB each
Tape or archive storage
seconds to hours · PBs

Reading the diagram. Read it top to bottom as “faster, smaller, costlier per byte” turning into “slower, larger, cheaper per byte”. Each arrow means “misses at this level are served by the next level”. The levels above DRAM are managed by hardware automatically; the boundary between DRAM and SSD is managed by software — the operating system’s page cache (§6.6) or your database’s buffer pool (§13.4). The most important storage boundary is **volatility**: everything from DRAM upward vanishes on power loss, so durability requires reaching the SSD, disk or a remote replica (§6.14). Each step down costs roughly 3–1000× in latency. Systems “scale” this pyramid by keeping the working set as high up as possible: more RAM to cache hot data, SSDs instead of disks for random access, and disks or object storage only for cold, sequentially read data.

Table 5.5 — Memory hierarchy numbers (as of 2024–2025, approximate; prices are volatile).

Level	Typical capacity	Random-access latency	Sequential bandwidth	Approx. cost per GB	Persistent?
L1 / L2 / L3 cache	KiB to hundreds of MiB	~1 / ~4 / ~15 ns	Hundreds of GB/s per core (L1)	Not sold separately	No
DRAM (DDR5)	16 GB – several TB per server	~80–120 ns	~38 GB/s per DDR5-4800 channel; ~300–600 GB/s per socket	~$2–5	No
NVMe SSD (TLC flash)	1–30+ TB	~50–100 µs read	~3–7 GB/s (PCIe 4.0 x4); ~10–14 GB/s (PCIe 5.0 x4)	~$0.05–0.15	Yes
SATA SSD	0.25–8 TB	~80–150 µs read	~0.55 GB/s	~$0.05–0.10	Yes
HDD (7200 RPM)	4–30+ TB	~5–15 ms	~0.15–0.28 GB/s	~$0.015–0.03	Yes
LTO-9 tape	18 TB native per cartridge	Seconds to minutes (mount, wind)	~0.4 GB/s native	< $0.01	Yes

Sources: interface limits from the DDR5, PCIe and SATA specifications (bandwidth arithmetic in §5.9); device ranges from vendor datasheets of the period; LTO-9 figures from the LTO Program; general structure from [Hennessy & Patterson 2017, ch. 2] and [Bryant & O’Hallaron 2015, ch. 6]. Prices are retail/street approximations for 2024 and changed sharply in 2025–2026 for DRAM and flash; treat them as ratios, not quotes.

The ratios are the lesson: DRAM costs roughly 30–100× more per GB than flash, and flash roughly 3–5× more than disk, while latency falls by about 1,000× from DRAM to flash and 100× again from flash to disk. Choosing where data lives is an economic decision as much as a technical one.

5.6 Storage devices

5.6.1 Hard disk drives (HDDs)

DEFINITION

Definition — Hard disk drive (HDD). A storage device that records data magnetically on spinning platters, read and written by heads mounted on a moving arm (the **actuator**). Data is organized in concentric **tracks** divided into **sectors** of 512 or 4096 bytes.

First-principles explanation

Think of a record player. To play a particular song, you lift the arm and move it to the right groove (the **seek**), then wait for the start of the song to come round under the needle (**rotational latency**), then listen to the song (**transfer**). Moving the arm and waiting for the platter take milliseconds — millions of CPU cycles — whereas reading the data once the head is in place is fast. An HDD rewards you for reading long runs of adjacent data and punishes you for jumping around.

FORMULA

HDD access time

$$T_{access} = T_{seek} + T_{rot} + T_{transfer}, \qquad T_{rot} = \frac{1}{2} \times \frac{60}{RPM}, \qquad T_{transfer} = \frac{S}{R}$$

$$IOPS_{random} \approx \frac{1}{T_{access}}$$

Symbol	Meaning	Units
T_{seek}	Average time to move the head to the target track	ms
T_{rot}	Average rotational latency: half a revolution	ms
RPM	Spindle speed	revolutions per minute
S	Size of the request	bytes
R	Sustained media transfer rate	bytes/second
$IOPS_{random}$	Random I/O operations per second for one outstanding request	operations/second

WORKED EXAMPLE

Worked example — Random versus sequential reads on a 7200 RPM disk.

Assume T_{seek} = 8.5 ms (a typical desktop-class average), R = 200 MB/s (as of 2024, approximate; outer tracks are faster than inner tracks).

1. One revolution: $60/7200 = 0.008\,33$ s $= 8.33$ ms, so $T_{rot} = 8.33/2 = 4.17$ ms.
2. Transfer of a 4 KiB block: $4096/(200 \times 10^6) = 2.05 \times 10^{-5}$ s $= 0.02$ ms.
3. Random 4 KiB read: $T_{access} = 8.5 + 4.17 + 0.02 = 12.69$ ms.
4. Random IOPS $\approx 1/0.012\,69 \approx 79$ operations/s, so random throughput $= 79 \times 4096 \approx 0.32$ MB/s.
5. Sequential throughput ≈ 200 MB/s, which is $200/0.32 \approx 620\times$ the random throughput.
6. Reading 100 MB contiguously after one positioning: $12.67 + (10^8/2 \times 10^8) \times 1000 = 12.67 + 500 = 512.67$ ms, an effective $10^8/0.512\,67 \approx 195$ MB/s — 97.5% of the maximum.

Interpretation. For small random reads, 99.8% of the time is mechanical positioning (12.67/12.69). **Engineering implication.** On disks, design for large sequential transfers: append-only logs, LSM trees (§13.8), large blocks in distributed file systems (§15.5) and batch scans. Even a 15,000 RPM enterprise disk (T_{rot} = 2 ms, seek ≈ 3.5 ms) reaches only about $1/0.0055 \approx 180$ random IOPS.

HDDs remain the cheapest online storage per byte (Table 5.5), so they still hold most of the world's bulk data in object stores and backup systems — where access is overwhelmingly sequential [Ruemmler & Wilkes 1994].

5.6.2 Solid-state drives (SSDs) and flash memory

DEFINITION

Definition — Solid-state drive (SSD). A storage device with no moving parts that stores data in **NAND flash** memory cells, managed by an on-board controller running a **flash translation layer** (FTL).

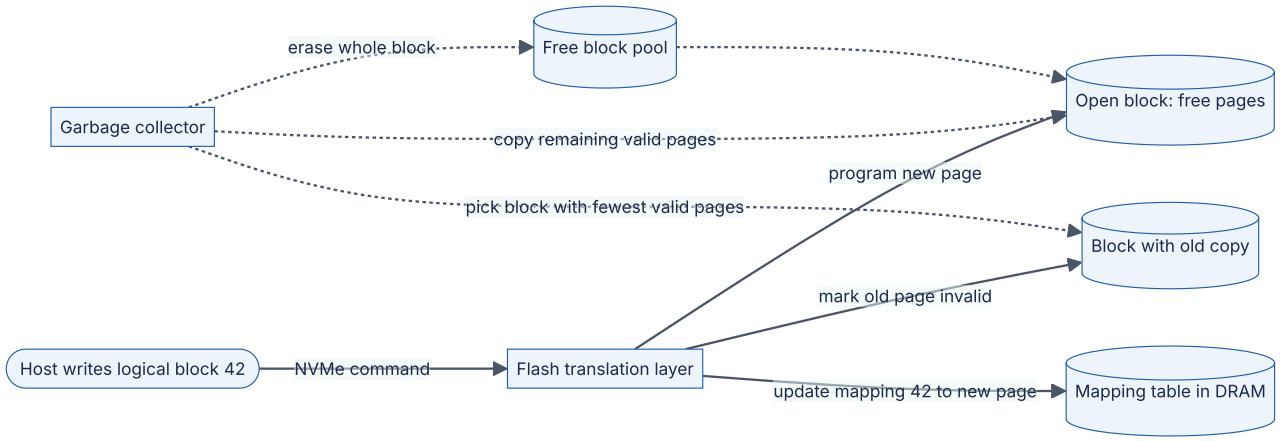
Flash is fast to read and has no seek time, but it has three peculiar rules that shape everything about SSD behavior [Agrawal et al. 2008]:

1. **Read and write in pages.** The smallest unit you can read or program (write) is a **page**, typically 4–16 KiB (as of 2024, approximate).
2. **Erase in blocks.** A page cannot be overwritten in place. It must first be erased, and erasure works only on a whole **erase block** of hundreds of pages (several MiB in modern chips).

3. **Cells wear out.** Each block survives a limited number of program/erase (P/E) cycles — on the order of 1,000–3,000 for TLC (three bits per cell) flash and fewer for QLC (four bits per cell) (as of 2024, approximate; vendors rarely publish exact figures).

The analogy is a notebook written in pen. You cannot rub out one line; to reuse a page you must tear out a whole chapter, and the binding can only take so many tear-outs. So when you "update" a line, you write the new version on a fresh page and cross out the old one. Periodically you copy the still-valid lines from a messy chapter to a fresh one and tear the old chapter out. That is exactly what an SSD controller does.

Figure 5.6 — How an SSD handles an overwrite and garbage collection.



Reading the diagram. The host addresses data by **logical block address** (LBA); the FTL translates LBAs to physical flash pages using a mapping table held in the SSD's own DRAM (backed up to flash). An overwrite from the host (solid arrows, synchronous with the write command) becomes "program a fresh page, then repoint the mapping", and the old page is merely marked invalid. In the background (dotted arrows, asynchronous), the **garbage collector** chooses a block with few valid pages, copies the survivors elsewhere and erases the block, returning it to the free pool. The failure point is garbage collection under sustained random writes: when free blocks run out, the host's writes wait behind GC, producing latency spikes. Drives mitigate this with **over-provisioning** (spare capacity invisible to the host) and the host helps with **TRIM**/deallocate commands that tell the drive which pages no longer hold useful data. The mapping table is also why SSDs need power-loss protection capacitors in enterprise models.

5.6.3 Write amplification and endurance

FORMULA

Write amplification factor and drive lifetime

$$WAF = \frac{\text{bytes written to flash}}{\text{bytes written by the host}}, \qquad \text{Lifetime (days)} \approx \frac{C \times PE}{W_{host} \times WAF}$$

Symbol	Meaning	Units
WAF	Write amplification factor (≥ 1 for a drive without compression)	dimensionless
C	Raw flash capacity	bytes
PE	Rated program/erase cycles per block	cycles
W_{host}	Host write volume per day	bytes/day

WORKED EXAMPLE

Worked example — How long will this SSD last?

A 1 TB TLC SSD, assumed rating $PE = 3000$ cycles, so total flash write budget $= 10^{12} \times 3000 = 3 \times 10^{15}$ bytes $= 3$ PB. A database writes $W_{host} = 500$ GB/day (0.5 drive writes per day).

1. With sequential, log-structured writes, $WAF \approx 2.5$: flash writes $= 500 \times 2.5 = 1250$ GB/day $= 1.25$ TB/day. Lifetime $= 3000$ TB/1.25 TB/day $= 2400$ days ≈ 6.6 years.
2. With small random in-place updates on a nearly full drive, $WAF \approx 5$: flash writes $= 2.5$ TB/day. Lifetime $= 3000/2.5 = 1200$ days ≈ 3.3 years.

Interpretation. The same host workload wears the drive out twice as fast purely because of the write *pattern*. **Engineering implication.** Write amplification compounds: an LSM tree's own compaction (§13.11) multiplies with the SSD's internal WAF. Prefer large, sequential, aligned writes; leave free space (or over-provisioning) on write-heavy drives; and monitor the drive's wear indicators (SMART / NVMe health log).

5.6.4 SATA versus NVMe

SSDs first plugged into the same **SATA** interface designed for hard disks. SATA III signals at 6 Gbit/s, and after its 8b/10b line encoding (10 bits on the wire per data byte) delivers at most 600 MB/s; real drives reach about 550 MB/s. Its command protocol, AHCI, offers

one command queue of 32 entries — ample for a disk that can do 100 operations per second, but a straitjacket for flash that can do hundreds of thousands.

NVMe (Non-Volatile Memory Express) is a protocol designed for flash that attaches drives directly to **PCIe** lanes. It supports up to about 65,535 I/O queues, each up to 65,536 commands deep [NVM Express Base Specification], so every CPU core can have its own submission and completion queue pair with no locking between cores. A PCIe 4.0 x4 link carries roughly 7.9 GB/s of payload after encoding (16 GT/s × 4 lanes × 128/130 ÷ 8 ≈ 7.9 GB/s), and fast drives deliver about 7 GB/s sequential and around a million random 4 KiB reads per second at high queue depth (as of 2024, approximate).

5.6.5 IOPS, throughput and queue depth

DEFINITION

Definition — IOPS. Input/output operations per second: the number of independent read or write requests a device completes per second, quoted for a stated request size (usually 4 KiB) and **queue depth** (number of requests outstanding at once).

FORMULA

Little’s Law applied to a storage device

$$IOPS = \frac{QD}{L}, \qquad \text{Throughput} = IOPS \times S$$

Symbol	Meaning	Units
QD	Average number of requests outstanding (queue depth)	requests
L	Average latency per request	seconds
S	Request size	bytes

WORKED EXAMPLE

Worked example — Why a single-threaded reader cannot exploit an NVMe SSD.

An NVMe SSD has a random-read latency of $L = 80$ µs.

1. One request at a time ($QD = 1$): $IOPS = 1/(80 \times 10^{-6}) = 12\,500$; throughput $= 12\,500 \times 4096 = 51.2$ MB/s.
2. To reach the drive's rated 10^6 IOPS: $QD = IOPS \times L = 10^6 \times 80 \times 10^{-6} = 80$ requests outstanding.

Interpretation. A program that issues one blocking read, waits, then issues the next will use about 1% of a fast SSD. **Engineering implication.** To use modern storage you need **concurrency in the I/O path**: many threads, asynchronous I/O (io_uring, §6.13), or batched requests. The same law governs memory (§5.9.2) and network connections (§7.15).

5.6.6 Persistent memory and newer tiers

Persistent memory (PMem) is byte-addressable like DRAM — the CPU reads it with ordinary load instructions — but keeps its contents without power. The best-known product, Intel Optane persistent memory, offered larger capacities than DRAM at read latencies of a few hundred nanoseconds (approximate); Intel announced in 2022 that it was winding the business down. The ideas survive in capacitor-backed DRAM inside storage controllers and in **CXL** (Compute Express Link), which attaches extra memory over the PCIe physical layer at somewhat higher latency than local DRAM. Programming persistent memory requires explicit cache-line flushes and fences, because data still in a volatile CPU cache is not durable.

Table 5.6 — Storage device comparison (as of 2024–2025, approximate).

	HDD	SATA SSD	NVMe SSD	Persistent memory / CXL memory
What it is	Spinning magnetic platters	Flash behind a disk-era interface	Flash on PCIe with a flash-native protocol	Byte-addressable memory on the memory bus or CXL
How it works	Mechanical seek + rotation	FTL, 1 queue × 32 commands	FTL, up to ~64K queues	CPU loads/stores
Advantages	Cheapest per TB; good sequential speed	Drop-in replacement for disks	Very high IOPS and bandwidth	Nanosecond-scale access, large capacity
Disadvantages	~100 random IOPS; mechanical failure	Interface caps at ~550 MB/s	Wear-out; GC latency spikes	Niche, costly; Optane discontinued
Performance	~80–200 IOPS; ~0.2 GB/s	~50–100K IOPS; 0.55 GB/s	~0.5–1.5M IOPS; 3–14 GB/s	~100s ns latency
Cost per GB	~$0.02	~$0.05–0.10	~$0.05–0.15	Above DRAM-adjacent tiers
Choose when	Cold, bulk, sequential data	Legacy servers, budget	Databases, logs, anything random-access	Very large in-memory datasets; specialized logging

Real-world industry applications

INDUSTRY EXAMPLE

Apache Kafka (append-only log on ordinary disks). Kafka's designers observed that sequential disk throughput is hundreds of times higher than random-access throughput and that the operating system's page cache already keeps recently written data in RAM. Kafka therefore stores each partition as an append-only file, reads and writes it sequentially, and relies on the page cache rather than an in-process cache, which lets brokers sustain high throughput even on hard disks. Trade-off: the design favors sequential consumers; random lookups by key are not what it is for. *Evidence: Primary* — [Apache Kafka Documentation, Design]

Failure scenarios

Table 5.7 — Storage failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
p99 write latency spikes on a busy SSD	Garbage collection when free blocks are exhausted	Latency spikes correlate with sustained writes	Throttle writes; free space	Over-provision; TRIM; sequential writes
SSD wears out early	High write amplification from small random writes	SMART "percentage used" climbs fast	Replace drive; rebuild replica	Log-structured writes; endurance-rated drives
Database slow after moving from SSD to cheaper HDD tier	Random-access workload on ~100 IOPS devices	Queue depth high, low throughput, high await	Move back; add cache	Match the device to the access pattern
Data lost after power failure despite successful write	Data was still in volatile cache (OS, drive)	Corruption on restart	Restore from replica/backup	`fsync` and drives with power-loss protection (§6.14)

COMMON MISTAKE

"SSDs make access patterns irrelevant." Sequential I/O on an SSD is still faster than random I/O, writes are amplified by small random updates, and a single blocking thread cannot exploit the device's parallelism. SSDs shrink the penalty for randomness from ~600× to a few times; they do not remove it.

5.7 I/O operations

DEFINITION

Definition — I/O (input/output). Any transfer of data between the CPU/memory and a device outside it: storage, network cards, GPUs, keyboards. A **device controller** on each device does the physical work; the CPU communicates with it through **device registers** and shared memory.

The central question of I/O design is: *what does the CPU do while a slow device works?* Back in the kitchen, ordering from the supplier can be handled four ways. You can stand at the phone repeating "is it ready yet?" (**polling**). You can do something else and let the supplier ring a bell when the delivery arrives (**interrupts**). You can have the supplier's driver carry the goods straight into the fridge without you lifting a box (**DMA**). Or, for the busiest restaurants, you can bypass the front office entirely and deal with the driver directly (**kernel bypass**).

5.7.1 Programmed I/O

In **programmed I/O** (PIO) the CPU itself moves every word between the device and memory, reading and writing device registers in a loop. It is simple and still used for tiny,

infrequent transfers (configuring a device), but for bulk data it wastes the most expensive resource in the machine — CPU cycles — on copying.

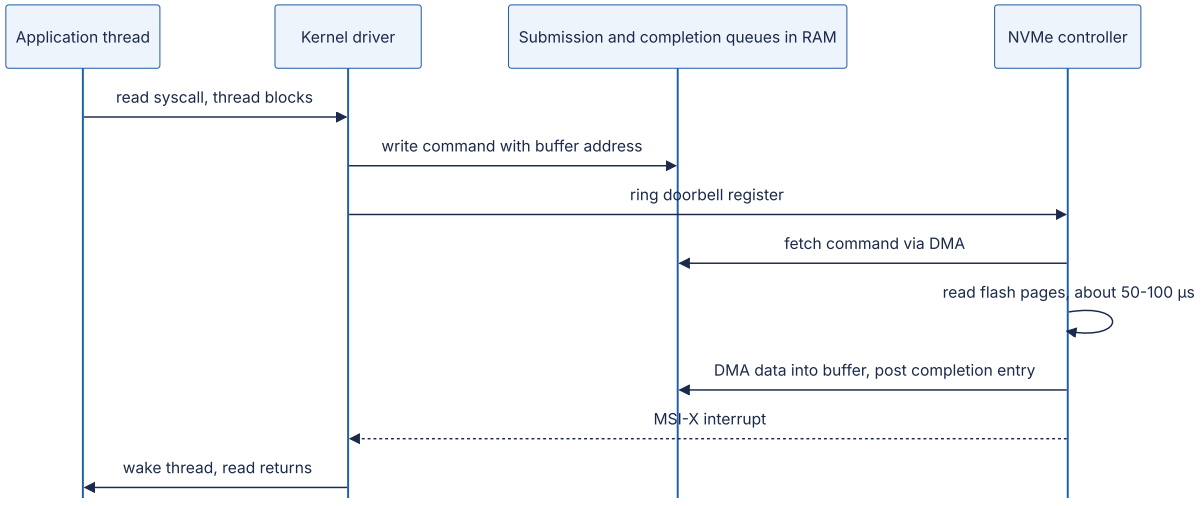
5.7.2 Interrupts

An **interrupt** is a hardware signal from a device that makes the CPU suspend its current work, run a short **interrupt handler** in the kernel, and then resume. The CPU starts an operation, goes off to run other threads, and is notified on completion. Modern PCIe devices raise **message-signaled interrupts** (MSI-X), which can be steered to a specific core. Interrupts are efficient when events are rare, but each one costs on the order of a microsecond or more of CPU time (handler entry, cache pollution, possible context switch; approximate). At millions of events per second — a single 10 Gbit/s link can deliver up to about 14.9 million minimum-size Ethernet frames per second (10^{10} bit/s ÷ (84 bytes × 8) on the wire, counting preamble and inter-frame gap) — one interrupt per packet would overwhelm the CPU.

5.7.3 Direct memory access (DMA)

> DEFINITION
>
> **Definition — Direct memory access (DMA).** A mechanism that lets a device controller read from or write to main memory directly, without the CPU copying each word; the CPU only sets up the transfer and is told when it finishes.

Figure 5.7 — Reading a block from an NVMe SSD with DMA and an interrupt.



Reading the diagram. Four participants: the application thread, the kernel's NVMe driver, the command queues living in ordinary RAM, and the SSD's controller. The application's `read` system call is synchronous *for the thread* — it blocks — but the CPU core is free to run other threads in the meantime. The kernel writes a command describing the request and the destination buffer into a submission queue in memory, then writes

to a **doorbell** register on the device over PCIe. From then on the device does the work: it fetches the command, reads flash, and **DMAs** the data straight into the buffer — no CPU copying. Finally it posts a completion entry and raises an interrupt (dashed arrow: asynchronous notification). The storage boundary is crossed only by the device. Failure points: the device may time out (the driver resets it and fails the I/O), and a buggy device with unrestricted DMA could overwrite arbitrary memory, which is why servers use an **IOMMU** to restrict which addresses each device may access. Scaling comes from many queue pairs (one per core) and many outstanding commands (§5.6.5).

5.7.4 Polling and interrupt coalescing

When events are very frequent, **polling** — a core repeatedly checking a completion queue — is cheaper than taking an interrupt per event, at the cost of burning a core even when idle. Practical systems mix the two. Network cards **coalesce** interrupts (one interrupt per batch of packets or per few microseconds), and Linux's NAPI network subsystem switches from interrupts to polling under load, then back again when traffic subsides. This is the batching principle of §5.12 appearing inside the kernel. How programs see all this — blocking calls versus non-blocking interfaces such as `epoll` and `io_uring` — is covered in §6.13; underneath, the device always works in parallel with the CPU, and software's job is to keep enough requests in flight.

5.7.5 Kernel bypass (introduction)

For each I/O, the conventional path crosses the user/kernel boundary, runs generic driver code, and often copies data between kernel and user buffers. At 10–100 Gbit/s or a million IOPS, those per-operation costs (each a few hundred nanoseconds to microseconds) become the bottleneck. **Kernel bypass** lets an application drive the device directly from user space:

- **DPDK** (Data Plane Development Kit) — user-space network drivers that poll NIC queues; used in software routers, load balancers and packet processors [DPDK Documentation].
- **SPDK** (Storage Performance Development Kit) — the same approach for NVMe storage [SPDK Documentation].
- **RDMA** (remote direct memory access) — network cards that read and write a *remote* machine's memory without involving the remote CPU, used in HPC and some databases and ML clusters (Ch 49, Ch 65).
- **io_uring** (Linux 5.1, 2019) — not a full bypass, but shared submission/completion rings between application and kernel that remove most per-operation system calls and can poll [Axboe 2019].

Bypass trades generality, security isolation and operational simplicity for raw speed: you dedicate cores to polling, give up the kernel's TCP stack or file system, and take on more

of the driver's responsibilities. Most services never need it; network appliances, exchanges and storage engines sometimes do.

Table 5.8 — I/O mechanisms compared.

Mechanism	CPU cost per transfer	Latency	Best for	Drawback
Programmed I/O	Very high (CPU copies every word)	Low for tiny transfers	Device configuration	Wastes CPU on bulk data
Interrupt-driven + DMA	Low per byte; ~µs per interrupt	Adds interrupt + wake-up time	General-purpose I/O	Interrupt storms at high event rates
Polling	A dedicated core, even when idle	Lowest	Very high event rates	Burns CPU and power
Coalescing / hybrid (NAPI)	Low	Slightly higher for single events	Network stacks under variable load	Tuning trade-off between latency and CPU
Kernel bypass (DPDK/SPDK/RDMA)	Lowest per operation	Lowest	Packet processing, storage engines, HPC	Complexity; loses kernel features

5.8 CPU-bound versus I/O-bound workloads

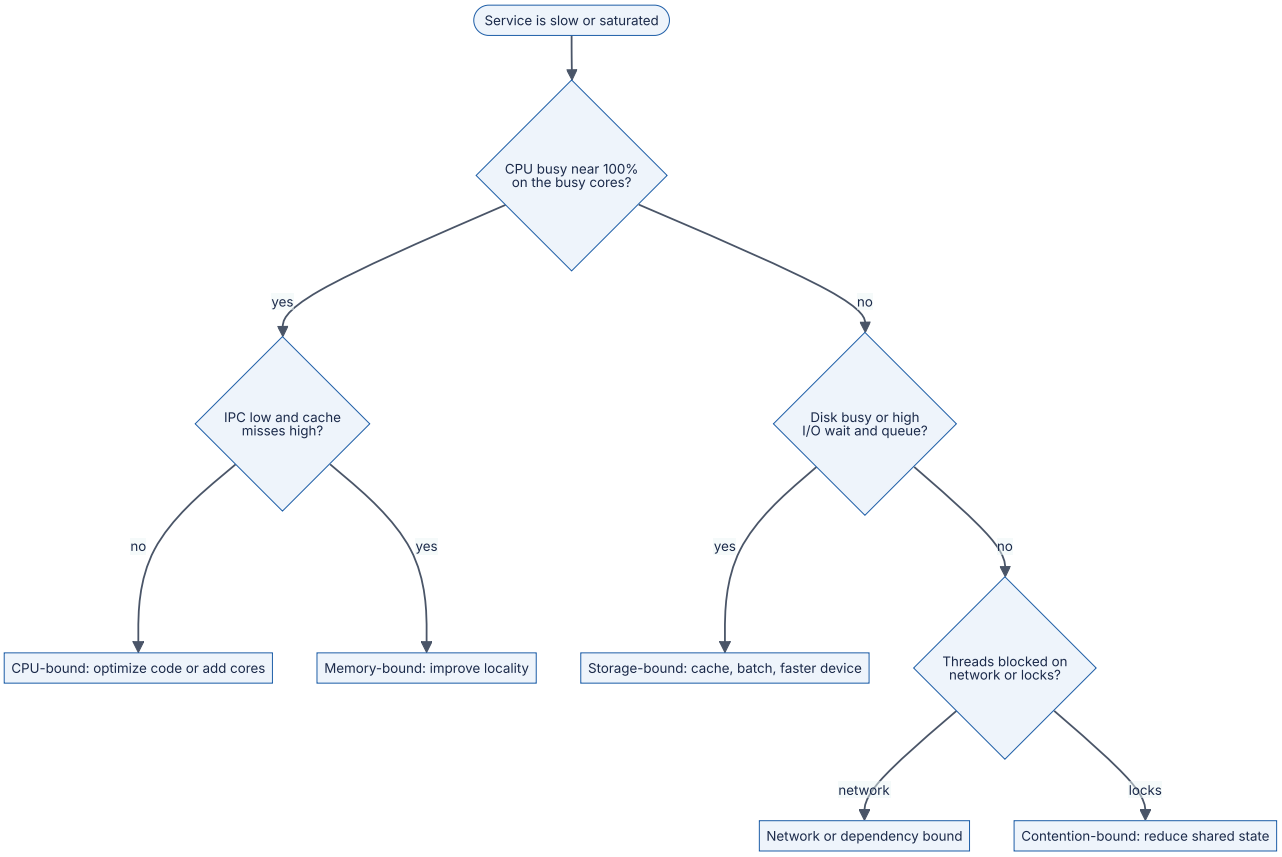
DEFINITION

Definition — CPU-bound and I/O-bound. A workload is **CPU-bound** when its speed is limited by how fast the processor can execute instructions; giving it a faster CPU or more cores speeds it up. It is **I/O-bound** when it spends most of its time waiting for storage or the network; a faster CPU barely helps, but more concurrency or faster devices do. A related category, **memory-bound**, is limited by memory latency or bandwidth (§5.9) — the CPU looks "busy" but is mostly stalled.

A cook who spends all day chopping is CPU-bound: hire more cooks. A cook who spends all day waiting for deliveries is I/O-bound: hiring more cooks only adds more people waiting — what helps is ordering many deliveries at once, or keeping stock closer to hand (caching).

5.8.1 How to tell

Figure 5.8 — Diagnosing what limits a workload.



Reading the diagram. Start at the top with a symptom and walk the decisions using measurements, not guesses. CPU utilization per core (not the machine average, which hides one saturated core) separates "computing" from "waiting". Among busy CPUs, instructions per cycle and cache-miss counters (from `perf stat` on Linux) separate genuine computation from stalls on memory. Among idle CPUs, disk utilization and queue length (`iostat -x`) reveal storage limits, and thread dumps or off-CPU profiles reveal whether threads wait on network calls to dependencies or on locks. Each leaf names a different remedy; applying the wrong one (more threads for a CPU-bound service, a faster CPU for an I/O-bound one) wastes money. This is the resource model of §2.6 applied to one machine; the systematic version is Brendan Gregg's USE method (§23.3) [Gregg 2020].

Table 5.9 — Signals that distinguish CPU-bound from I/O-bound workloads.

Signal	CPU-bound	I/O-bound
Per-core CPU utilization	Near 100% in user time	Low or moderate
`time` output for a command	user + sys ≈ real (× cores used)	real ≫ user + sys
Effect of a faster CPU	Proportional speed-up	Little effect
Effect of more threads	Helps up to the core count, then hurts	Helps until the device or dependency saturates
Typical examples	Compression, encryption, image resizing, JSON parsing at scale, model inference on CPU	Database queries over the network, file servers, API gateways, web crawlers

A caution about the Linux `%iowait` metric: it reports idle time during which some I/O was outstanding. It is a hint, not a measure of I/O capacity; a fully busy CPU can hide I/O waits, and on multi-core machines the number is easy to misread [Gregg 2020].

5.8.2 Why it matters for thread pools

FORMULA

Thread pool sizing heuristic [Goetz et al. 2006, §8.2]

$$N_{threads} = N_{cores} \times U_{target} \times (1 + \frac{W}{C})$$

Symbol	Meaning	Units
$N_{threads}$	Threads in the pool	threads
N_{cores}	Cores available to the pool	cores
U_{target}	Target CPU utilization (0–1)	dimensionless
W	Average time a task spends waiting (I/O, remote calls)	seconds
C	Average CPU time per task	seconds

WORKED EXAMPLE

Worked example — Sizing pools for two services on an 8-core machine.

1. *Image-thumbnail service* (CPU-bound): $W \approx 0$, so $N = 8 \times 1 \times (1 + 0) = 8$ threads. Goetz et al. suggest $N_{cores} + 1$ to cover the occasional page fault. Using 64 threads would add context switches and cache thrashing, not throughput.
2. *Order API* (I/O-bound): each request uses $C = 5$ ms of CPU and waits $W = 50$ ms on the database. At $U_{target} = 1$: $N = 8 \times (1 + 50/5) = 8 \times 11 = 88$ threads. At $U_{target} = 0.8$, leaving headroom: $8 \times 0.8 \times 11 = 70.4 \approx 70$ threads.
3. Maximum throughput of the order API is set by CPU: 8 cores$/5$ ms $= 1600$ requests/s at 100% CPU. Little's Law check: 1600 req/s $\times 55$ ms $= 88$ requests in flight ✓.

Interpretation. The I/O-bound service needs about 11× more threads than cores, because each thread spends 10/11 of its life waiting. **Engineering implication.** The formula assumes the dependency can absorb the load: 88 concurrent requests need about 88 database connections (§14.13). If the database saturates first, more threads only lengthen its queue. Event loops and async runtimes (§6.15) achieve the same concurrency with far fewer threads.

COMMON MISTAKE

“Python threads speed up CPU-bound work.” In CPython the global interpreter lock (GIL) lets only one thread execute Python bytecode at a time, so threads help I/O-bound Python code but not pure-Python CPU-bound code; use processes or native extensions (such as numpy) that release the lock. Free-threaded CPython builds exist experimentally since Python 3.13 (as of 2025), which may change this advice over time.

5.9 Memory latency and bandwidth

5.9.1 Two different numbers

DEFINITION

Definition — Latency and bandwidth (hardware). Latency is the time from issuing one request to receiving its first byte (for example, ~100 ns for a DRAM load). **Bandwidth** is the maximum rate at which data can be moved once transfers are flowing (for example, ~38 GB/s for one DDR5-4800 channel). Achieved bandwidth is **throughput**.

A motorway is the usual picture: latency is how long one car takes to drive from A to B; bandwidth is how many cars per hour the road can carry. Adding lanes raises bandwidth but does not make any single car arrive sooner. For hardware, latency improves slowly (DRAM latency has changed little in two decades), while bandwidth improves steadily with more channels and faster signaling [Hennessy & Patterson 2017, ch. 2]. Designs that need bandwidth can buy it; designs that need low latency must avoid the trip altogether — by caching, prefetching or co-locating data.

FORMULA

Peak DRAM bandwidth

$$BW_{peak} = R_{transfer} \times W_{bus} \times N_{channels}$$

Symbol	Meaning	Units
$R_{transfer}$	Data transfers per second per channel (the "4800" in DDR5-4800)	transfers/second (MT/s)
W_{bus}	Width of a channel's data path: 8 bytes (64 bits)	bytes/transfer
$N_{channels}$	Populated memory channels	channels

WORKED EXAMPLE

Worked example — How much bandwidth does a server socket have?

1. One DDR5-4800 channel: $4800 \times 10^6 \times 8 = 38.4 \times 10^9$ B/s $= 38.4$ GB/s.
2. A socket with 8 channels: $8 \times 38.4 = 307.2$ GB/s. With 12 channels (as on some 2023–2024 server CPUs): $12 \times 38.4 = 460.8$ GB/s.

Interpretation. These are theoretical peaks; sustained throughput on streaming benchmarks is typically 70–90% of peak (approximate). **Engineering implication.** Leaving channels unpopulated to save money (four DIMMs in an eight-channel server) halves memory bandwidth — a common, invisible misconfiguration for analytics and ML workloads.

5.9.2 Why one core cannot use all the bandwidth: Little's Law in memory

Bandwidth is only achieved if enough requests are in flight to cover the latency — the same law as for SSDs (§5.6.5).

WORKED EXAMPLE

Worked example — Memory-level parallelism.

Each core can track a limited number of outstanding L1 misses — on the order of 10–20 on recent x86 cores (as of 2024, approximate; hardware prefetchers into L2 add more). Assume 12 outstanding 64-byte misses and 100 ns latency.

1. Bytes in flight $= 12 \times 64 = 768$ B.
2. Throughput $= 768$ B/100 ns $= 7.68$ B/ns $= 7.68$ GB/s.
3. To saturate an 8-channel socket at 307.2 GB/s with a loaded latency of ~110 ns: bytes in flight $= 307.2 \times 10^9 \times 110 \times 10^{-9} = 33\,792$ B $= 528$ cache lines.

Interpretation. One thread doing demand loads tops out well below the socket's bandwidth; it takes many cores — or very effective prefetching — to keep 500+ lines in flight. **Engineering implication.** Memory-bound jobs (scans, aggregations, embedding lookups) scale with cores *until* the memory channels saturate, then stop, however many more cores you add. Pointer chasing is worst of all: with one outstanding miss, throughput is 64 B/100 ns = 0.64 GB/s.

5.9.3 Worked examples: scanning 1 GB

The single most useful exercise in this chapter is estimating how long it takes to read 1 GB (10^9 bytes) from each place it might live.

WORKED EXAMPLE

Worked example — Time to read 1 GB (as of 2024–2025, approximate rates).

Sequential reads: $T = 10^9$ B/throughput.

1. DRAM, one thread streaming at ~10 GB/s: $10^9/10^{10} = 0.1$ s $= 100$ ms. Whole socket at ~200 GB/s achieved: 5 ms.
2. NVMe SSD (PCIe 4.0) at ~7 GB/s: $10^9/(7 \times 10^9) \approx 0.143$ s $= 143$ ms.
3. SATA SSD at ~550 MB/s: $10^9/(5.5 \times 10^8) \approx 1.82$ s.
4. HDD at ~200 MB/s: $10^9/(2 \times 10^8) = 5$ s.
5. Network at 1 / 10 / 100 Gbit/s ($= 0.125$ / 1.25 / 12.5 GB/s): 8 s / 0.8 s / 0.08 s, before protocol overhead of a few percent.

Random reads: the same gigabyte read as many small, dependent requests.

6. DRAM, random 64-byte lines, one at a time: $10^9/64 = 15\,625\,000$ lines $\times$ 100 ns $= 1.5625$ s — about 16× slower than streaming the same memory.
7. NVMe, random 4 KiB reads at QD 1: $10^9/4096 \approx 244\,141$ reads $\times$ 80 µs ≈ 19.5 s. At QD 80 (~10^6 IOPS): $244\,141/10^6 \approx 0.24$ s.
8. HDD, random 4 KiB reads: $244\,141 \times 12.69$ ms ≈ 3098 s ≈ 51.6 minutes.

Interpretation. Between the best case (5 ms) and the worst (52 minutes) lies a factor of about 600,000 — for the *same* gigabyte. **Engineering implication.** The access pattern matters as much as the device: random HDD access is 620× slower than sequential HDD access, and random DRAM access is slower than sequential NVMe access. This is why databases build indexes that turn scans into a few targeted reads, why analytics systems store columns contiguously, and why caches exist at every level.

Table 5.10 — Time to read 1 GB, summary (as of 2024–2025, approximate).

Source and pattern	Rate or latency assumed	Time
DRAM, all cores streaming	~200 GB/s	~5 ms
DRAM, one thread streaming	~10 GB/s	~0.1 s
NVMe SSD, sequential	~7 GB/s	~0.14 s
10 Gbit/s network	1.25 GB/s	~0.8 s
DRAM, dependent random 64 B reads	100 ns each	~1.6 s
SATA SSD, sequential	0.55 GB/s	~1.8 s
HDD, sequential	0.2 GB/s	~5 s
NVMe SSD, random 4 KiB, QD 1	80 µs each	~20 s
HDD, random 4 KiB	12.7 ms each	~52 min

5.9.4 Latency numbers, then and now

Jeff Dean's list of "numbers everyone should know", presented in 2009 and building on a similar table by Peter Norvig, is the best-known summary of these facts [Dean 2009; Norvig 2001]. §4.17 discusses it in full; Table 5.11 shows how the hardware-specific entries compare with this chapter's figures.

Table 5.11 — Classic latency numbers versus approximate 2024–2025 values.

Operation	Dean 2009	Approx. 2024–2025 (this chapter)	What changed
L1 cache reference	0.5 ns	~1 ns	About the same in cycles; clocks stalled near 3–5 GHz
Branch mispredict	5 ns	~4–5 ns (15–20 cycles)	Little change
L2 cache reference	7 ns	~3–5 ns	Somewhat faster
Main memory reference	100 ns	~80–120 ns	Essentially unchanged
Read 1 MB sequentially from memory	250 µs	~50–100 µs per thread	Bandwidth grew ~3–5×
Disk seek	10 ms	~4–10 ms	Mechanics barely changed
Read 1 MB sequentially from disk	20 ms	~5 ms	Higher areal density
Random read from SSD	Not in 2009 list (150 µs in later versions)	~50–100 µs	SSDs became mainstream
Read 1 MB sequentially from NVMe SSD	Not in 2009 list (1 ms for SSD in later versions)	~0.15–0.3 ms	New tier

Versions of Dean's list differ slightly in individual entries; the durable lesson is the *shape*: memory latency stuck, bandwidth up, disks still mechanical, flash filling the gap between them.

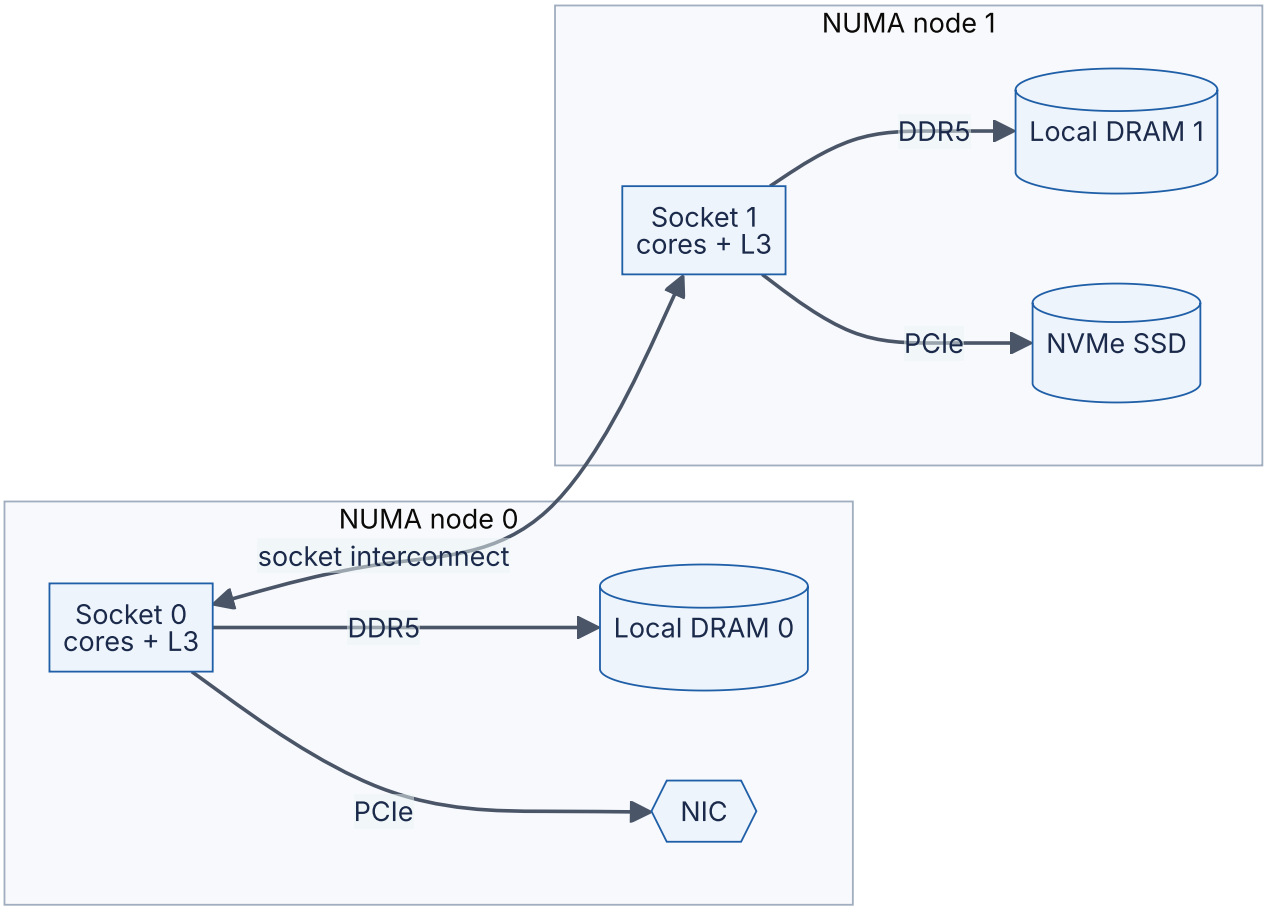
5.10 NUMA

DEFINITION

Definition — NUMA (non-uniform memory access). A memory architecture in which each processor socket (or each chiplet group within a socket) has its own directly attached memory. A core can access all memory in the machine, but accessing its **local** memory is faster than accessing **remote** memory attached to another socket.

Picture two kitchens joined by a corridor, each with its own fridge. A chef can fetch from either fridge, but the far one takes noticeably longer and the corridor can get crowded. NUMA exists because a single shared memory controller cannot scale to dozens of cores and hundreds of GB/s; attaching memory to each socket multiplies total bandwidth, at the price of uneven latency [Lameter 2013].

Figure 5.9 — A two-socket NUMA server.



Reading the diagram. Each socket, with its cores, its L3 cache, its memory channels and its PCIe devices, forms a **NUMA node**. A core on socket 0 reaches DRAM 0 directly; to reach DRAM 1 its request travels over the **socket-to-socket interconnect** (Intel UPI, AMD Infinity Fabric), adding latency — remote accesses commonly cost about 1.5–2× local ones (as of 2024, approximate; Linux reports relative distances via `numactl --hardware`, typically 10 for local and around 20 or more for remote). Devices are local to one node as well: packets arriving on a NIC attached to socket 0 are cheapest to process on socket 0's cores. The interconnect is shared and carries coherence traffic too, so it is both a latency penalty and a bandwidth bottleneck. Failure points are performance failures — a process whose threads run on node 1 while its memory sits on node 0. Scaling within the machine means keeping threads, their memory and their devices on the same node.

WORKED EXAMPLE

Worked example — The cost of ignoring NUMA.

Assume local DRAM latency 80 ns and remote 140 ns.

1. Two sockets, memory placed without regard to which node will use it: about half of accesses are remote. Average $= 0.5 \times 80 + 0.5 \times 140 = 40 + 70 = 110$ ns, 37.5% worse than all-local.
2. Four sockets, memory interleaved evenly: 75% remote. Average $= 0.25 \times 80 + 0.75 \times 140 = 20 + 105 = 125$ ns, 56% worse.

Interpretation. For memory-bound work, NUMA-unaware placement directly inflates latency and congests the interconnect. **Engineering implication.** On large servers, pin latency-sensitive processes to one node (`numactl --cpunodebind=0 --membind=0`), run one process per node rather than one huge process, or prefer smaller single-socket instances. Cloud VMs that span sockets expose NUMA topology too.

INDUSTRY EXAMPLE

MySQL “swap insanity” on two-socket servers. Jeremy Cole described MySQL servers with a buffer pool sized for the whole machine’s RAM that nevertheless swapped to disk. Linux’s default policy allocated memory from the local node of the allocating thread, so one NUMA node filled up while the other had free memory, and the kernel swapped instead of using the remote node. His recommended remedy was to start MySQL with memory interleaved across nodes (`numactl --interleave=all`), accepting uniformly higher latency in exchange for predictable behavior; later MySQL versions added an option to interleave the buffer pool. *Evidence: Primary* — [Cole 2010]

COMMON MISTAKE

“All RAM in a server is equally fast.” On multi-socket and many-chiplet servers it is not. Check `lscpu` and `numactl --hardware` before benchmarking, and keep the benchmark’s threads and memory on the same node or document that you did not.

5.11 SIMD and accelerators

5.11.1 SIMD

DEFINITION

Definition — SIMD (single instruction, multiple data). CPU instructions that apply the same operation to several data elements packed into one wide **vector register** at once — for example, adding eight pairs of 32-bit floats in a single instruction.

Instead of a cook slicing one carrot at a time, SIMD is a mandoline that slices eight at once with a single stroke. It pays off when the same operation runs over large arrays of uniform data: image and audio processing, compression, checksums, string search, database column scans and machine-learning arithmetic.

Table 5.12 — Common SIMD instruction sets (as of 2025).

Instruction set	Platform	Register width	32-bit floats per instruction
SSE family	x86	128 bits	4
AVX / AVX2	x86	256 bits	8
AVX-512	x86 (many server parts)	512 bits	16
NEON (Advanced SIMD)	ARM	128 bits	4
SVE / SVE2	ARM (some server parts)	128–2048 bits, implementation-defined	4–64

You rarely write SIMD instructions by hand. Compilers **auto-vectorize** simple loops, and libraries such as numpy, BLAS and database engines ship vectorized kernels. Your job is to give them data they can vectorize: contiguous arrays of one type, not lists of objects. The database research system MonetDB/X100 showed that processing data in cache-sized *vectors* of column values, rather than one row at a time, cut interpretation overhead and enabled SIMD, which shaped modern vectorized analytics engines [Boncz et al. 2005].

```
"""simd.py — interpreted loop vs vectorized (SIMD-backed) numpy."""
import time
import numpy as np

n = 10_000_000
a = np.random.rand(n).astype(np.float32)
b = np.random.rand(n).astype(np.float32)

t0 = time.perf_counter()
out = [0.0] * n
for i in range(n):                  # one element at a time, interpreted
    out[i] = a[i] * b[i] + 1.0
t1 = time.perf_counter()
c = a * b + 1.0                     # whole-array ops in compiled, SIMD loops
t2 = time.perf_counter()

print(f"python loop: {t1 - t0:.2f} s")
print(f"numpy:       {t2 - t1:.4f} s  ({(t1 - t0) / (t2 - t1):.0f}x faster)")
```

What to notice:

- Both versions compute the same 10 million results.
- The speed-up (about 20× on the test VM in 2026; often larger) comes from two sources: removing the interpreter's per-element overhead, and SIMD in numpy's compiled loops. Do not attribute it all to SIMD.
- `a * b + 1.0` makes two passes over memory and allocates a temporary array; at this size the vectorized version is limited by memory bandwidth (§5.9), not arithmetic.

5.11.2 Accelerators

When one kind of computation dominates a workload, it can pay to build or buy hardware specialized for it:

- **GPUs** — thousands of simple arithmetic lanes and very high-bandwidth memory (HBM), designed for massively parallel, regular computation. They dominate ML training and inference. Chapter 64 covers their architecture, the roofline model [Williams et al. 2009] and the compute-bound versus memory-bound distinction in depth.
- **TPUs and other ML ASICs** — chips built around large matrix-multiply units [Jouppi et al. 2017].
- **Fixed-function units inside the CPU** — AES and SHA instructions make TLS encryption cheap; compression and cryptography offload engines exist on some server CPUs and NICs.
- **SmartNICs / DPUs and FPGAs** — network cards with programmable processors that offload packet processing, storage virtualization or encryption from the host CPU.

The design question is always whether the workload is large and regular enough to justify specialized hardware, and whether data can reach it fast enough — an accelerator starved by PCIe or by CPU-side data preparation delivers a fraction of its rated speed.

5.12 Throughput versus latency at the hardware level

5.12.1 The pattern underneath everything

Every component in this chapter shows the same trade-off. A **pipeline** raises instruction throughput without shortening any instruction. **Out-of-order** cores and **memory-level parallelism** raise memory throughput by keeping many misses in flight. **NVMe queues** raise IOPS by keeping dozens of requests outstanding. **Interrupt coalescing** raises packet throughput by delaying notifications. In each case Little's Law ($L = \lambda W$, §4.11) holds: to get throughput λ from a resource with latency W, you need $L = \lambda W$ operations in flight. Latency is mostly fixed by physics; throughput is bought with parallelism and batching.

FORMULA

Throughput with batching (fixed plus per-item cost)

$$X(B) = \frac{B}{F + B \times v}, \qquad T_{batch}(B) = F + B \times v, \qquad X_{max} = \frac{1}{v}$$

Symbol	Meaning	Units
B	Items per batch	items
F	Fixed cost per operation (system call, device round trip, interrupt, network RTT)	seconds
v	Variable cost per item	seconds/item
$X(B)$	Throughput at batch size B	items/second
$T_{batch}(B)$	Time to complete one batch	seconds

WORKED EXAMPLE

Worked example — Batching small writes.

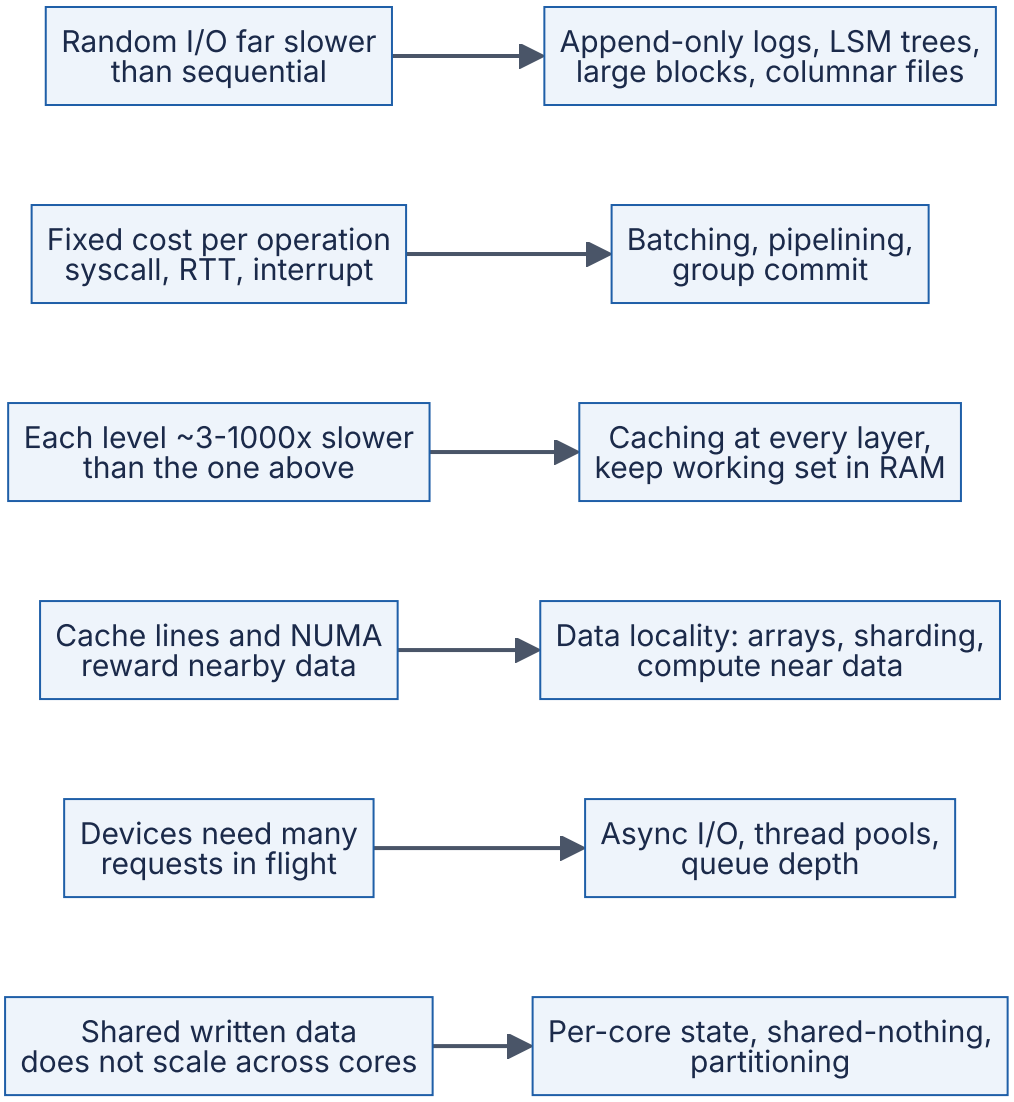
Writing 100-byte records to a log, each write call has fixed cost $F = 50$ µs and per-record cost $v = 0.1$ µs.

1. $B = 1$: $X = 1/50.1\ \mu s \approx 19\,960$ records/s; each write completes in 50.1 µs.
2. $B = 100$: $T = 50 + 100 \times 0.1 = 60$ µs; $X = 100/60\ \mu s \approx 1.67$ million records/s.
3. $B = 1000$: $T = 50 + 100 = 150$ µs; $X = 1000/150\ \mu s \approx 6.67$ million records/s.
4. Ceiling: $X_{max} = 1/0.1\ \mu s = 10$ million records/s.

Interpretation. Batching 100 records multiplies throughput by about 84× while raising per-batch latency only from 50 µs to 60 µs; going to 1000 gains another 4× in throughput but per-batch latency rises 2.5×, plus the time spent *waiting* for the batch to fill. **Engineering implication.** Batch until the fixed cost is amortized (a few times F/v items), then stop; bound the wait with a timer. Kafka producers (`linger.ms` , §31.6), group commit in databases (§13.5) and dynamic batching in model serving (Ch 66) all implement this curve.

5.12.2 How hardware facts drive system design decisions

Figure 5.10 — From hardware facts to design decisions.



Reading the diagram. Each row pairs a physical fact (left) with the design principle it forces (right); arrows mean “therefore”. None of these is a fashion — each follows from numbers you calculated in this chapter. The same principles reappear at datacenter scale: a cross-region network round trip is to a datacenter what a DRAM miss is to a core, so caching, batching, locality and parallelism return in Part IV (scalability, caching, CDNs) and Part V (distributed systems). When a design violates one of these pairs — chatty per-item network calls, random writes to disks, a global counter updated by every core — it usually fails at scale for precisely the reason on the left.

Table 5.13 — Hardware facts and the design decisions they drive.

Hardware fact (§)	Design decision	Examples in this book
Sequential ≫ random on HDD (~620×) and still better on SSD (§5.6)	Write sequentially; read in large chunks	Write-ahead logs (§13.5), LSM trees (§13.8), Kafka (§31.13)
Fixed cost per operation (§5.7, §5.12)	Batch and pipeline	Kafka batching (§31.6), HTTP/2 multiplexing (§7.9), dynamic batching (Ch 66)
Memory hierarchy steps of 3–1000× (§5.5)	Cache hot data close to its consumer	Buffer pools (§13.4), Redis (§20.6), CDNs (Ch 21)
Cache lines, prefetching, NUMA (§5.4, §5.10)	Keep related data together and near the compute	Columnar storage (§13.13), data locality in Spark (§29.7)
Devices need queue depth (§5.6.5)	Concurrency in the I/O path	io_uring and event loops (§6.13), connection pools (§7.16)
Coherence makes shared writes expensive (§5.4.6)	Avoid shared mutable state; partition it	Shard-per-core designs, partitioned databases (Ch 14)
DRAM is volatile (§5.5)	Durability needs persistent media or replicas	fsync (§6.14), replication (Ch 27)

INDUSTRY EXAMPLE

ScyllaDB and the Seastar framework (shard-per-core). ScyllaDB, a Cassandra-compatible database, is built on the Seastar framework, which runs one thread per core, partitions data so that each core owns its shard, and passes messages between cores instead of sharing locked data structures. The design avoids cache-line contention and lock overhead and keeps each core's data in its own caches and local NUMA memory. Trade-off: everything must be asynchronous, and skewed keys can overload a single core. *Evidence: Primary* — [Seastar Documentation]

RECOMMENDATION

Mechanical sympathy in practice. (1) Estimate before you build: write down the latency and bandwidth of each hop. (2) Prefer arrays and contiguous layouts for hot data. (3) Turn many small operations into fewer large ones. (4) Keep enough requests in flight to use your devices. (5) Do not share frequently written data across cores or machines. (6) Measure with hardware counters (`perf`) before and after; intuition about hardware is often wrong.

INTERVIEW TIP

Interview tip. When an interviewer asks "why is X fast?" (Kafka, Redis, a columnar database), the answer almost always maps onto one row of Table 5.13. Say the hardware fact and its number first, then the design choice.

5.13 Summary and revision notes

SUMMARY

- A CPU core repeatedly fetches, decodes and executes instructions. Execution time = instructions × CPI × cycle time; clock rates stalled near 3–5 GHz around 2005, so performance now comes from more work per cycle and more cores.
- Pipelining, superscalar issue and out-of-order execution raise throughput by overlapping instructions; branch prediction keeps the pipeline fed. Mispredictions (~15–20 cycles) and dependent memory accesses are what slow cores down.
- SMT (hyperthreading) shares one core between two hardware threads; a cloud vCPU is usually one such thread, not a full core.
- Caches (L1 ~1 ns, L2 ~4 ns, L3 ~15 ns, DRAM ~100 ns; as of 2024–2025, approximate) exploit temporal and spatial locality. Data moves in 64-byte cache lines; sequential access is the best case and pointer chasing the worst.
- AMAT = hit time + miss rate × miss penalty, applied level by level; layout alone can change it 10×.
- MESI keeps caches coherent per line; writes to one line from several cores cause ping-pong. False sharing is unrelated variables in one line; fix it with padding or per-thread data.
- The memory hierarchy spans ~1 ns to ~10 ms and about 1000× in cost per GB; DRAM and above are volatile.
- HDD access = seek + rotational latency + transfer; ~80–200 random IOPS versus ~200 MB/s sequential (~620× gap for 4 KiB reads).
- Flash writes pages, erases blocks and wears out; the FTL remaps writes, garbage-collects and causes write amplification. NVMe’s many deep queues unlock flash parallelism that SATA’s single 32-entry queue cannot.
- IOPS = queue depth / latency: fast devices need many requests in flight.
- I/O evolves from programmed I/O to interrupts + DMA to polling and kernel bypass as event rates rise.
- CPU-bound work needs ~one thread per core; I/O-bound work needs about N_cores × (1 + W/C) threads, limited by downstream capacity.
- Latency barely improves; bandwidth does. Peak DRAM bandwidth = transfer rate × 8 bytes × channels; achieving it needs hundreds of misses in flight.
- NUMA makes remote memory ~1.5–2× slower; keep threads, memory and devices on one node.
- SIMD and accelerators speed up regular, data-parallel work if data is contiguous and can be fed fast enough.

- Hardware facts drive design: sequential I/O, batching, caching, data locality, concurrency in the I/O path, and no shared mutable hot spots.

5.14 Knowledge checkpoint

1. Using the iron law, what happens to execution time if CPI rises from 0.5 to 0.75 at a fixed clock rate and instruction count?
2. Why does a deeper pipeline make branch mispredictions more expensive?
3. Why can an out-of-order core hide the latency of ten independent loads but not ten loads in a linked list?
4. What is the difference between temporal and spatial locality? Give one example of each.
5. In a 32 KiB, 8-way cache with 64-byte lines, how many sets are there, and why are addresses 4 KiB apart a problem?
6. Compute AMAT for t_{L1} = 1 ns, m_{L1} = 0.1, and a flat 50 ns penalty for every L1 miss.
7. Name the four MESI states and say which one allows a write without any coherence traffic.
8. Two threads increment separate counters and get slower when you add the second thread. What is the likely cause and the fix?
9. A 5400 RPM disk has an average seek of 10 ms. What is its average rotational latency and approximate random-read IOPS for small blocks?
10. Why can a flash SSD not overwrite a page in place, and what does the FTL do instead?
11. A device has 100 µs latency. What queue depth is needed for 400,000 IOPS?
12. What is DMA and what problem does it solve?
13. A service's `time` output shows real = 10 s, user + sys = 0.5 s. Is it CPU-bound or I/O-bound? What would you change first?
14. What is the peak bandwidth of six DDR5-5600 channels?
15. On a two-socket server, local latency is 90 ns and remote 150 ns. What is the average latency if 30% of accesses are remote?

Answers

1. Time rises by 50% (0.75 / 0.5 = 1.5), because time is proportional to CPI.
2. The branch outcome is known later in a deeper pipeline, so more stages hold wrongly fetched instructions that must be flushed; more cycles are lost per misprediction.
3. Independent loads can all be issued and outstanding at once, overlapping their latency. In a linked list each address is known only after the previous load returns, so the latencies add up serially.

4. Temporal: reusing the same data soon (a loop counter, a hot config value). Spatial: using nearby data soon (the next array element, adjacent struct fields).
5. $32\,768/(64 \times 8) = 64$ sets. Addresses $64 \times 64 = 4096$ bytes apart map to the same set, so a 4 KiB stride can use only 8 lines (one set) and suffers conflict misses.
6. $1 + 0.1 \times 50 = 6$ ns.
7. Modified, Exclusive, Shared, Invalid. Writes to an Exclusive line (moving it to Modified) need no bus/interconnect traffic; a line already in Modified also needs none.
8. False sharing: both counters are in one cache line, which ping-pongs between cores. Pad each counter to its own 64-byte line or keep per-thread counters and combine them at the end.
9. One revolution $= 60/5400 = 11.1$ ms; average rotational latency $= 5.56$ ms. Access $\approx 10 + 5.56 \approx 15.6$ ms, so $\approx 1/0.0156 \approx 64$ IOPS.
10. Flash must be erased before being reprogrammed, and erase works only on whole blocks of many pages. The FTL writes the new data to a free page, updates its logical-to-physical map, marks the old page invalid and later garbage-collects blocks.
11. $QD = 400\,000 \times 100 \times 10^{-6} = 40$ outstanding requests.
12. Direct memory access lets a device copy data to or from RAM itself; the CPU only sets up the transfer and handles the completion, so CPU cycles are not spent copying bytes.
13. I/O-bound (or waiting on something): the CPU was busy only 5% of the time. Find what it waits on — disk, network or locks — and add concurrency, caching or batching rather than a faster CPU.
14. $5600 \times 10^6 \times 8 \times 6 = 268.8 \times 10^9$ B/s $= 268.8$ GB/s.
15. $0.7 \times 90 + 0.3 \times 150 = 63 + 45 = 108$ ns.

5.15 Interview questions

Basic

Q1. Why is reading data sequentially faster than reading it randomly, on both disks and memory? Answer. On an HDD a random read pays a seek (~4–10 ms) and half a rotation (~4 ms at 7200 RPM) for every request, while a sequential read pays them once and then streams at ~200 MB/s — about 620× faster for 4 KiB requests. In memory, data arrives in 64-byte cache lines and hardware prefetchers detect sequential patterns and fetch ahead, so sequential reads hit in cache while random reads each pay ~100 ns of DRAM latency. SSDs narrow the gap but still favor large sequential I/O.

Q2. What is a cache line and why should a programmer care? Answer. The 64-byte (on most x86 and ARM servers) unit in which data moves between memory and caches. It means neighbors of anything you read are nearly free (so arrays and compact structs are

fast), and that coherence works per line, so threads writing different variables in the same line interfere (false sharing).

Intermediate

Q3. You moved a service from an 8-vCPU to a 32-vCPU instance and throughput rose only 30%. What could explain this, and how would you investigate? Answer. Candidates: (1) the service is limited by something other than CPU — a database, a lock, a single-threaded component (check per-thread CPU, thread dumps); (2) contention on shared cache lines (atomic counters, false sharing, a JVM internal structure) — check with `perf c2c` or cache-miss counters; (3) NUMA effects if the larger instance spans sockets; (4) vCPUs are hyperthreads, so 32 vCPUs are 16 cores. Measure per-core utilization and IPC before and after, then test hypotheses one by one. Netflix's published 2022 case was exactly this pattern, caused by cache-line sharing in the JVM.

Q4. How would you size a thread pool for a service that calls a database? Answer. Measure CPU time per request C and wait time W. Start with $N = N_{cores} \times U \times (1 + W/C)$; e.g., 8 cores, $C = 5$ ms, $W = 50$ ms gives ~88 threads at full utilization. Then cap it by the downstream: the database connection pool and the database's own capacity. Validate with a load test, watching p99 latency and CPU; if latency rises without throughput gain, the pool is too large. For very high concurrency, consider async I/O instead.

Advanced

Q5. Explain why Kafka can sustain high throughput even on hard disks. Answer. Each partition is an append-only log, so writes are sequential (no seeks). Reads by consumers are also mostly sequential and usually served from the OS page cache because recently written data is still in RAM. Producers and brokers batch many messages per request, amortizing per-request fixed costs (Table 5.13). Data is sent from page cache to socket without copying through user space (zero-copy, §31.13). Each design choice maps to a hardware fact: sequential ≫ random, fixed per-operation costs, and DRAM ≫ disk.

Q6. Design the counters for a metrics library that must record 50 million increments per second across 64 cores. Answer. A single shared atomic counter would ping-pong one cache line between 64 cores and cap at a few tens of millions of updates per second or less, with heavy cross-core traffic. Instead, give each core (or thread) its own counter, each padded to its own cache line (or grouped per core in a per-core region), and increment it with plain or relaxed atomic operations. A reader sums all slots when scraping — reads are rare, so their cost is irrelevant. This trades a little memory (64 lines × 64 B = 4 KiB per counter) and slightly stale reads for near-linear scaling. Keep each core's slots on its own NUMA node. This is the same "partition, don't share" principle used by shard-per-core databases.

5.16 Practical exercises

1. **Cache-line stride benchmark (Python + numpy).** Run the program below. Plot nanoseconds per element against stride. Explain why the cost per element rises until the stride reaches about 64–128 bytes and then levels off, and why total time stays roughly constant for strides up to 64 bytes.

```
"""stride.py — how access stride affects time per element touched.

Run: python3 stride.py   (needs numpy)
"""
import time
import numpy as np

N_BYTES = 256 * 1024 * 1024            # 256 MiB buffer, far larger than any L3
data = np.ones(N_BYTES // 8, dtype=np.int64)   # 8-byte elements

def ns_per_element(stride_elems: int, repeats: int = 3) -> float:
    view = data[::stride_elems]          # strided view, no copy
    best = float("inf")
    for _ in range(repeats):
        t0 = time.perf_counter()
        view.sum()                       # touches every element of the view
        best = min(best, time.perf_counter() - t0)
    return best / view.size * 1e9

print(f"{'stride (B)':>10} {'elements':>12} {'ns/element':>11}")
for stride in [1, 2, 4, 8, 16, 32, 64, 128, 512]:
    n = data[::stride].size
    print(f"{stride * 8:>10} {n:>12,} {ns_per_element(stride):>11.2f}")
```

What to notice: up to a 64-byte stride every cache line is still fetched, so total time is dominated by moving 256 MiB from DRAM and the time *per element* grows as fewer elements share each line; beyond 64 bytes each element costs one line fetch (plus adjacent-line prefetch effects up to ~128 bytes). On the test VM the cost rose from ~0.7 ns/element at an 8-byte stride to ~7 ns/element at 256 bytes and above.

2. **False sharing.** Compile and run `false_sharing.c` from §5.4.7. Then change `CACHE_LINE` to 32 and 128 and explain the results. Finally, run the packed version with both threads pinned to the same core (`taskset -c 0 ./fs`) and explain why the penalty disappears.
3. **Disk and SSD.** Using `fio`, measure random 4 KiB read IOPS at queue depths 1, 4, 16 and 64 on a scratch file on your SSD. Check that IOPS ≈ QD / latency until the device saturates.
4. **CPU-bound or I/O-bound?** Run a compression job (`gzip` on a large file) and a script that downloads 100 URLs sequentially, each under `time`. Compare real versus user + sys and watch `vmstat 1` during each.

5. **Topology tour.** On a Linux machine, record the output of `lscpu`, `lscpu -C` (cache sizes and line size) and `numactl --hardware`. Draw your own version of Figure 5.1 with real numbers.

5.17 Design challenges

1. **Log-structured key-value store on HDDs.** You must store 20 TB of 1 KB values on HDDs with 50,000 writes/s and 5,000 random reads/s. Estimate how many disks a random-write design would need versus an append-only log with an in-memory index, and what the memory cost of the index would be.
2. **Analytics scan budget.** Analysts want to scan a 2 TB table in under 10 seconds. Using Table 5.10, decide whether this is feasible from NVMe on one machine, from RAM on one machine, or only across a cluster, and how many nodes and what storage format (row or column) you would choose.
3. **Low-latency order gateway.** A trading gateway must handle 2 million messages/s with p99 under 20 µs on one server. Choose between interrupts, polling and kernel bypass for the NIC; decide thread-to-core and NUMA placement; and explain how you would avoid false sharing between the receive and send threads.

5.19 Open verification items

- Cost per GB in Table 5.5 and Table 5.6 reflects approximate 2024 street prices; DRAM and NAND prices moved sharply in 2025–2026. Re-check before publication.
- Exact URLs for [Dean 2009] (LADIS keynote slides), [Cole 2010] and [Filanovsky & Sane 2022] are omitted pending verification; confirm the specific entries of Dean’s

list (versions differ, e.g. 20 ms vs 30 ms for 1 MB from disk).
- Confirm the “up to ~30%” Hyper-Threading gain against [Marr et al. 2002] and the MySQL release that added buffer-pool NUMA interleaving.
- Cite a primary source (Intel investor communication, 2022) for the Optane wind-down.
- Microarchitectural ranges (branch-mispredict penalty 15–20 cycles; 10–20 outstanding L1 misses per core; reorder buffer “several hundred” entries) should be checked against current Intel/AMD/Arm optimization manuals.
- TLC endurance of 1,000–3,000 P/E cycles is a commonly quoted range, not a vendor specification.
- Status of free-threaded CPython (experimental from 3.13) may have changed.

Chapter 6 — Operating Systems

> **Level:** 1–2 · **Track:** Shared · **Estimated reading time:** 3 h

Every service you will design in this book, whether a URL shortener, a Kafka broker or an LLM inference server, is in the end a set of processes running on an operating system. The operating system decides which of them runs, how much memory each one sees, how its bytes reach the network card and the disk, and what happens when two of them touch the same data at once. When a service is "slow for no reason", the reason is often here: a context-switch storm, a page-fault spike, a thread pool sized for 200 that is serving 20,000 connections, or an `fsync` that took 400 ms. This chapter gives you the vocabulary and the mental models to see those problems, estimate them with numbers, and choose designs that avoid them.

6.1 Learning objectives

After this chapter you should be able to:

- Explain what a process and a thread are, draw the process state diagram, and list what the kernel stores in a process control block.
- Describe the steps of a context switch and estimate both its direct cost and its indirect cache cost.
- Compare FCFS, round robin, priority, MLFQ and Linux's CFS/EEVDF schedulers, and calculate turnaround and response times for a small workload.
- Trace a memory access through the TLB, page table and page-fault handler, and calculate effective access time and TLB reach.
- Explain what a system call is, why it costs more than a function call, and how batching and vDSO reduce that cost.
- Distinguish concurrency from parallelism and identify a race condition and its critical section in code.
- Choose between a mutex, semaphore, condition variable, atomic/CAS operation, read-write lock and lock-free structure, and explain the ABA problem.
- State the four Coffman conditions, apply prevention, avoidance and detection to deadlock, and explain priority inversion using the Mars Pathfinder incident.
- Compare blocking, non-blocking, multiplexed (`select` / `poll` / `epoll` / `kqueue`) and completion-based (`io_uring`) I/O, and explain the C10K problem.
- Write a crash-safe file update using `fsync` correctly and name the common durability pitfalls.

- Compare thread-per-request, event loop, actor, goroutine and async/await concurrency models and size a server's memory for a target number of concurrent connections.

6.2 Prerequisites

- CPU cores, registers and caches — §5.3–§5.4 (context-switch cost is mostly a cache story).
- RAM and the memory hierarchy — §5.5 and §5.9 (virtual memory sits on top of it).
- Storage devices and I/O with DMA and interrupts — §5.6–§5.7 (I/O models and `fsync` depend on them).
- Little's Law — §4.11 (used to size thread pools and connection counts).
- Amdahl's Law — §4.12 (limits on parallel speed-up).
- Powers of two and binary prefixes — §4.3 and §4.5 (page sizes and address spaces are powers of two). In this chapter, **KiB/MiB/GiB** (powers of two) are used for page sizes, stacks and address spaces; **KB/MB/GB** (powers of ten) for rough capacity estimates.

6.3 Processes and threads

6.3.1 What an operating system is for

> DEFINITION
>
> **Definition — Operating system (OS).** The software layer that manages a computer's hardware (CPU, memory, storage, network) and provides running programs with safe, shared, abstract access to it. The privileged core of the OS that runs with full hardware access is the **kernel**.

First-principles explanation

Think of a busy shared kitchen. Many cooks (programs) want the same stoves (CPU cores), counter space (memory) and fridge (disk). The kitchen manager (the kernel) gives each cook a private-looking workstation, rotates stove time fairly, and is the only person allowed to touch the gas valves (the hardware).

The OS provides three big illusions, which is how *Operating Systems: Three Easy Pieces* organizes the subject [Arpaci-Dusseau 2018]:

1. **Virtualization** — each program believes it has its own CPU and its own large, private memory.
2. **Concurrency** — many things appear to happen at once, safely.

3. **Persistence** — data survives power loss, through file systems.

Why does this exist?

Running several programs at once (**multiprogramming**) keeps the CPU busy while one program waits for I/O, but creates three problems: programs could overwrite each other's memory, one could hog the CPU forever, and each would have to drive the hardware itself. The kernel solves all three by being the single trusted intermediary. The CPU enforces this with **privilege levels**: user code runs in **user mode** and cannot execute privileged instructions or touch kernel memory; the kernel runs in **kernel mode** (on x86-64, ring 0 versus ring 3).

6.3.2 The process and its address space

DEFINITION

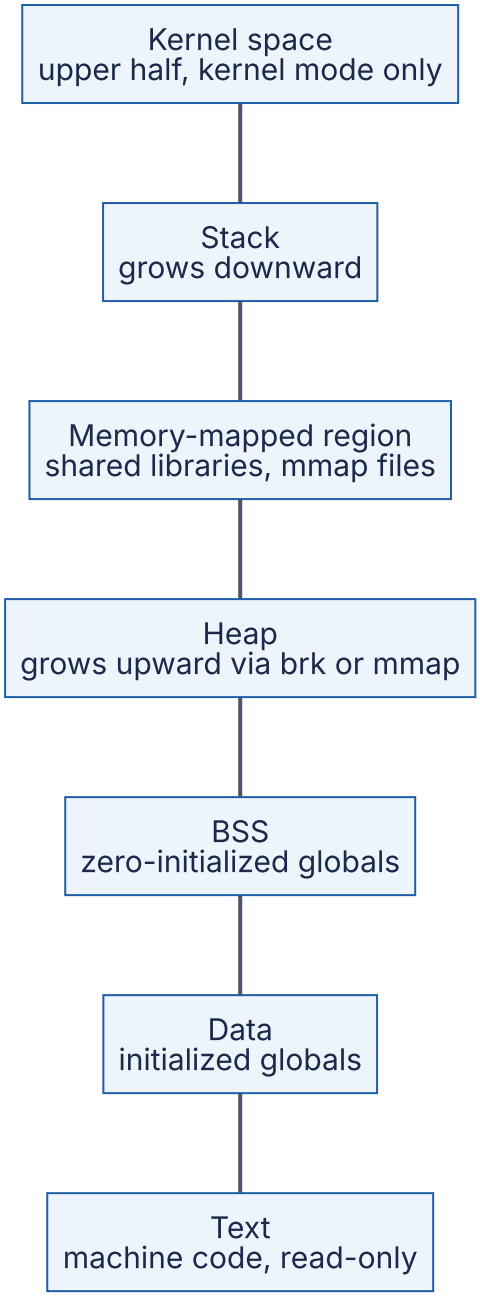
Definition — Process. A running instance of a program: its code, its private **virtual address space**, one or more threads of execution, and the OS resources it holds (open files, sockets, signal handlers, credentials).

DEFINITION

Definition — Address space. The range of memory addresses a process can use. On Linux x86-64 with 4-level page tables, user space spans 2^{47} bytes = 128 TiB of *virtual* addresses; the kernel occupies the upper half and is not accessible from user mode.

A program is a recipe on disk; a process is a cook following it, with their own bench and progress marker. Every process sees the same layout of its private memory (Figure 6.1).

Figure 6.1 — Layout of a process's virtual address space on Linux x86-64.



Reading the diagram. High addresses are at the top. **Text** holds the program's instructions, mapped read-only so a stray write crashes rather than corrupts. **Data** and **BSS** hold global variables. The **heap** (`malloc` / `new`) grows upward; the **stack** (call frames, locals; one per thread) grows downward. The **memory-mapped region** holds shared libraries and `mmap`ed files (§6.6.6). The gap between heap and stack is *unbacked*: no physical memory is used until a page is touched. The **kernel** region is mapped into every process but protected by the CPU's privilege check. Failure points: a stack overflowing into its guard page (a crash) and a heap growing until memory runs out (§6.6.4). There are no network edges or storage boundaries: this is one process's view of memory.

6.3.3 The process control block

DEFINITION

Definition — Process control block (PCB). The kernel data structure that records everything needed to stop a process and later resume it exactly where it left off. In Linux it is `struct task_struct`.

The PCB is the cook's clipboard. It typically contains [Silberschatz et al. 2018]:

- **Identity:** process ID (PID), parent PID, user and group IDs.
- **State:** new, ready, running, blocked, terminated (§6.3.4).
- **CPU context:** saved program counter, stack pointer and general-purpose registers (on Linux these are saved on the task's kernel stack and in `thread_struct`).
- **Scheduling information:** priority, nice value, accumulated CPU time, which run queue it is on.
- **Memory-management information:** a pointer to the page tables and the list of mapped regions (Linux `mm_struct`).
- **I/O and file information:** the table of open file descriptors, current directory.
- **Signal information:** pending signals and installed handlers.
- **Accounting:** CPU time used, start time, resource limits.

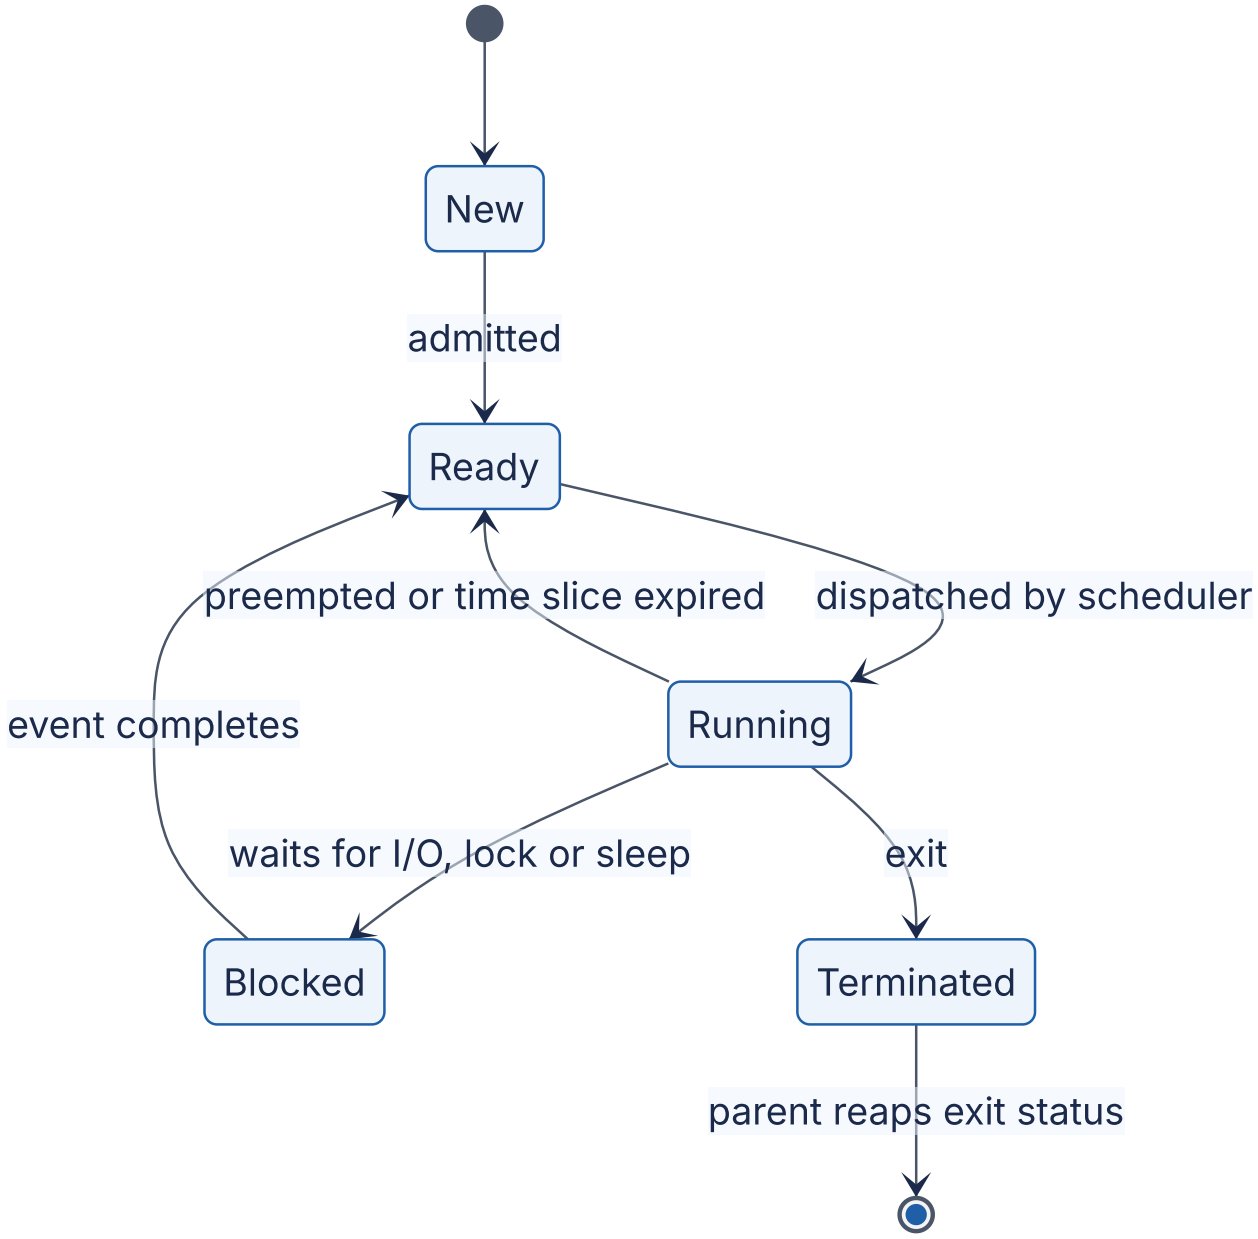
On Linux, each thread is also a `task_struct`; threads of one process point at the same `mm_struct` and file table. A `task_struct` is several kilobytes, and each task also has a 16 KiB kernel stack on x86-64 (as of Linux 6.x), so 10,000 threads cost roughly 200 MB of kernel memory before their user-space stacks are counted.

6.3.4 Process states

DEFINITION

Definition — Process state. The scheduling status of a process (or thread): whether it is running on a CPU, ready and waiting for a CPU, or blocked waiting for an event.

Figure 6.2 — Process state diagram.



Reading the diagram. A process is **New** while the kernel builds its PCB and address space, then **Ready**: runnable but waiting for a CPU. The scheduler (§6.5) **dispatches** one ready task per core to **Running**. A running process leaves the CPU in three ways: it is **preempted** (slice expired or a higher-priority task woke) and returns to Ready; it waits for something not yet available (disk, network packet, lock, timer) and becomes **Blocked**; or it **exits**. When the awaited event occurs, usually signaled by a hardware interrupt (§5.7), the process returns to Ready, *not* straight to Running. A **Terminated** process whose parent has not collected its exit status is a **zombie**. Every transition is made by the kernel.

Linux reports these states in `ps` and `top` with single letters: **R** (running *or* ready, Linux does not distinguish them), **S** (interruptible sleep, the normal blocked state), **D** (uninterruptible sleep, usually waiting on disk or network file system I/O, cannot be killed until

the I/O completes), **T** (stopped by a signal or debugger) and **Z** (zombie). On Linux, tasks in **D** count toward the **load average** along with R tasks, which is why a server with a hung NFS mount can show a load average of 200 while its CPUs are idle [Gregg 2020].

6.3.5 Threads

> DEFINITION
>
> **Definition — Thread.** An independent sequence of execution within a process, with its own program counter, registers and stack, sharing the process's address space, heap, globals and open files with the process's other threads.

If a process is a cook with a private workstation, threads are several cooks *sharing one workstation*: they pass ingredients instantly (shared memory) but can reach for the same knife at once (a race condition, §6.9).

How it works internally

1. A process starts with one thread (the **main thread**).
2. Creating a thread (`pthread_create`, `new Thread()`, `threading.Thread`) asks the kernel, on Linux via the `clone()` system call, to create a new schedulable task that *shares* the address space and file table instead of copying them.
3. The runtime allocates a new **user-space stack** for the thread (by default 8 MiB of *virtual* address space for glibc threads on Linux, taken from `ulimit -s`; 1 MiB for Java platform threads on 64-bit Linux, as of JDK 21) plus a **guard page** below it to catch overflow.
4. The kernel scheduler sees each thread as an independent task. Two threads of one process can run truly simultaneously on two cores.

Linux uses a **1:1 threading model**: every user thread is one kernel task. Go goroutines, Erlang processes and Java virtual threads multiplex many lightweight user-space threads onto a few kernel threads (an **M:N model**, §6.15). New processes are created with `fork()`, a near-copy of the caller made cheap by copy-on-write (§6.6.5), usually followed by `exec()` to load a new program.

Table 6.1 — Processes versus threads.

Aspect	Process	Thread
Address space	Private	Shared with sibling threads
Creation cost (Linux, order of magnitude)	Tens to hundreds of µs (`fork` + `exec` more)	~10 µs or less
Communication	IPC: pipes, sockets, shared memory (§6.12)	Direct reads/writes to shared memory
Isolation	Strong: a crash or wild pointer affects only itself	Weak: one bad thread can crash all
Context-switch cost	Higher: may change page tables	Lower: same page tables
Memory overhead	Full set of page tables and mappings	Stack + kernel task (~16 KiB kernel stack)
Typical use	Isolation between services, browser tabs, worker pools (e.g. PostgreSQL backends)	Parallelism inside one service (e.g. Java/Go servers)
Choose when	Faults must be contained, or code is not thread-safe	Tasks share large data and need low-latency communication

The creation-cost figures are orders of magnitude, not benchmarks; measure on your own hardware.

Real-world industry applications

INDUSTRY EXAMPLE

PostgreSQL versus MySQL. PostgreSQL forks one backend *process* per client connection, containing faults at the cost of per-connection memory, which is why large deployments put a pooler such as PgBouncer in front (§14.13). MySQL uses one *thread* per connection inside a single process: cheaper connections, shared fate. *Evidence: Primary* — [PostgreSQL Docs: Architectural Fundamentals]; [MySQL Docs: Connection Interfaces]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Zombie processes accumulate until no PIDs are left	Parent never calls `wait()` ; in containers, the app runs as PID 1 and does not reap orphans	`ps` shows many `Z` entries; `fork` fails with `EAGAIN`	Restart the parent	Reap children; run a minimal init (e.g. `tini`) as PID 1 in containers
Load average 200 but CPU idle	Many tasks in **D** state on hung storage or NFS	`ps -eo stat` shows `D` ; `/proc/<pid>/stack`	Fix storage; reboot if stuck	Timeouts on network file systems; monitor I/O latency

Common misconceptions

COMMON MISTAKE

“Threads are free.” Each costs a kernel task, kernel stack, user stack and scheduling work. Ten thousand threads is feasible; a million kernel threads on one machine is not (§6.15.6).

6.4 Context switching and its cost

DEFINITION

Definition — Context switch. The kernel operation that stops one thread running on a CPU core, saves its CPU state into its PCB, and loads the saved state of another thread so that it resumes where it left off.

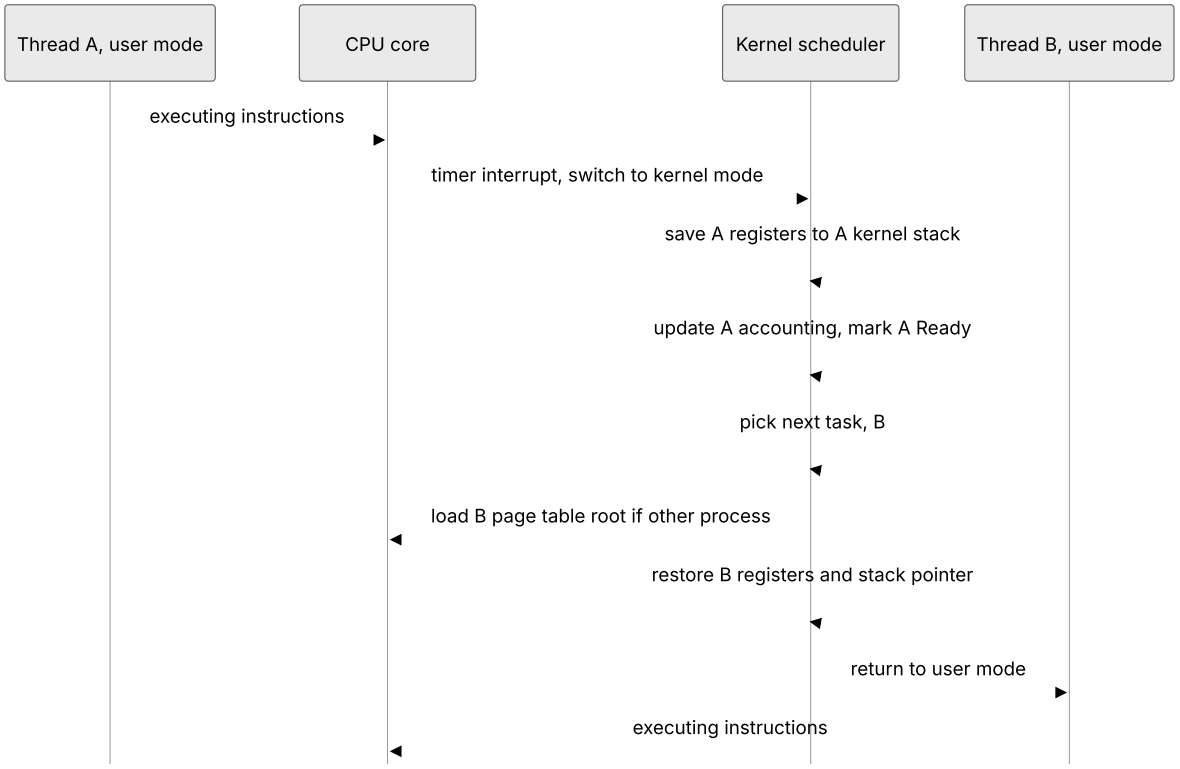
First-principles explanation

Switching between two books, noting your page is quick; reloading the plot into your head is what costs. Likewise, saving and loading registers is quick; the expensive part is that the new thread finds the CPU’s caches full of the *old* thread’s data. Switching exists because a core runs one thread at a time: pausing a thread that waits for a 10 ms disk read lets the core do useful work meanwhile.

How it works internally

A switch is triggered in one of two ways. A **voluntary** switch happens when the running thread blocks (reads from an empty socket, waits for a lock, sleeps). An **involuntary** switch happens when the kernel preempts the thread, usually because a periodic **timer interrupt** found its time slice used up or a higher-priority thread became ready.

Figure 6.3 — A context switch between two threads triggered by a timer interrupt.



Reading the diagram. The dotted arrow is asynchronous: the timer interrupt arrives regardless of what A is doing and forces the CPU into kernel mode, saving A's instruction pointer and stack pointer. Solid arrows are synchronous steps on the same core. The kernel saves A's remaining registers, returns A to the Ready queue and asks the scheduling policy (§6.5) for the next task. If B belongs to a *different process*, the kernel loads B's page-table root (on x86-64, the `CR3` register); **process-context identifiers (PCIDs)** let TLB entries of different processes coexist, avoiding a full TLB flush. B's registers are restored and the CPU returns to user mode. No storage or network is involved; the failure point is performance: too-frequent switches leave the core in the kernel and refilling caches.

Mathematical foundations

There are two costs.

- **Direct cost** — the kernel instructions above: entering the kernel, saving and restoring registers, running the scheduler, switching page tables. On modern x86-64 Linux this is roughly **1–5 µs** per switch (as of the 2020s; it varies with CPU, kernel version and security mitigations such as those for Spectre and Meltdown).
- **Indirect cost** — after the switch the incoming thread's data and instructions are no longer in the L1/L2 caches (§5.4) and its address translations are no longer in the TLB (§6.6.3), so it runs slowly until they are reloaded. This can exceed the direct cost by one or two orders of magnitude for threads with large working sets [Li et al. 2007].

FORMULA

Context-switch overhead fraction

$$f = \frac{C}{Q + C}$$

Symbol	Meaning	Units
f	Fraction of CPU time lost to switching	dimensionless (0–1)
C	Effective cost of one switch, direct + indirect	µs
Q	Average time a thread runs between switches	µs

FORMULA

Cache refill estimate (indirect cost)

$$C_{\text{refill}} \approx \frac{W}{L} \times \frac{t_{\text{miss}}}{M}$$

Symbol	Meaning	Units
C_{refill}	Time spent reloading the working set after a switch	ns
W	Working set that was evicted	bytes
L	Cache line size (64 on x86-64 and most ARM servers)	bytes/line
t_{miss}	Latency of one miss to the next memory level	ns
M	Memory-level parallelism: misses overlapped in flight	dimensionless (≥ 1)

WORKED EXAMPLE

Worked example — When does switching hurt?

Case 1: CPU-bound batch job. A thread runs a full 4 ms slice ($Q = 4000$ µs) and the direct switch cost is $C = 3$ µs. $f = 3/(4000 + 3) = 0.00075$, i.e. **0.075 %** of CPU time. Negligible.

Case 2: the same switch, but the thread's 1 MiB working set was evicted to DRAM. $W = 1,048,576$ bytes, $L = 64$ bytes, so $W/L = 16,384$ lines. Take $t_{\text{miss}} = 90$ ns to DRAM and $M = 8$ overlapping misses: $C_{\text{refill}} = 16,384 \times 90/8 = 184,320$ ns $\approx$ **184 µs**, about 60× the direct cost.

Case 3: a chatty server. Threads handle tiny requests and block on the network every 20 µs ($Q = 20$ µs). With a modest 10 µs effective switch cost (direct plus a small refill), $f = 10/(20 + 10) = 0.33$: **a third of the CPU goes to switching**.

Interpretation. Context switches are cheap when threads run for milliseconds and expensive when they run for microseconds. **Engineering implication:** for high-rate, short-request workloads, prefer designs that do many small units of work per switch: event loops (§6.13), batching (§23.8), fewer threads than cores-times-a-small-factor for CPU-bound pools, and pinning hot threads to cores.

How to observe it

- `vmstat 1` — the `cs` column is context switches per second for the whole machine. Tens of thousands per second per core is normal for a busy server; hundreds of thousands per core deserves investigation.
- `pidstat -w 1` or `/proc/<pid>/status` — per-task voluntary switches (blocking: lock contention, small I/Os) versus involuntary ones (preemption: CPU contention). If thread migrations between NUMA sockets are frequent, pin threads (§5.10).
- `perf sched` and `perf stat -e context-switches,cpu-migrations` for detailed analysis [Gregg 2020].

COMMON MISTAKE

"A context switch costs a few microseconds, so it never matters." The few microseconds is only the direct cost. The cache and TLB refill afterwards can cost far more, and it appears in your profile as "slow application code", not as kernel time.

6.5 CPU scheduling

DEFINITION

Definition — CPU scheduler. The part of the kernel that decides which ready thread runs next on each core and for how long. The rule it follows is the **scheduling policy**; the mechanism that performs the switch is the dispatcher (§6.4).

First-principles explanation

A doctor with a waiting room is a scheduler. Strict arrival order leaves a 2-minute renewal stuck behind a 60-minute consultation; quickest-first minimizes average waiting but may leave the long case waiting all day; 10 minutes each in rotation means nobody waits long to be *seen*, but long cases finish later. Every CPU scheduling policy is one of these trade-offs. It optimizes some mix of:

- **Turnaround time** — arrival to completion; matters for batch work.
- **Response time** — arrival to first run; matters for interactive work and request handlers.
- **Throughput**, **fairness** (each thread, user or container gets its share) and **utilization**.

These conflict: shortest-job-first minimizes turnaround but is unfair to long jobs; rapid rotation minimizes response time but adds switching overhead.

6.5.1 First-come, first-served (FCFS)

Run jobs to completion in arrival order. Simple, but suffers the **convoy effect**: short jobs queue behind a long one. **Shortest job first (SJF)** and its preemptive form **STCF** are optimal for average turnaround but need job lengths in advance, which a general-purpose OS does not have [Arpaci-Dusseau 2018].

6.5.2 Round robin (RR)

Run each ready thread for a fixed **time slice** (**quantum**), then move it to the back of the queue. RR gives good response time and cannot starve anyone, but too short a slice wastes time switching (§6.4) and too long a slice degenerates into FCFS. General-purpose systems use roughly 1–10 ms.

FORMULA

Average turnaround and response time

$$\bar{T}_{\text{turn}} = \frac{1}{n}\sum_{i=1}^{n}\left(T^{i}_{\text{completion}} - T^{i}_{\text{arrival}}\right) \qquad \bar{T}_{\text{resp}} = \frac{1}{n}\sum_{i=1}^{n}\left(T^{i}_{\text{first run}} - T^{i}_{\text{arrival}}\right)$$

Symbol	Meaning	Units
n	Number of jobs	jobs
T^{i}_{arrival}	Time job i became ready	ms
$T^{i}_{\text{first run}}$	Time job i first got a CPU	ms
$T^{i}_{\text{completion}}$	Time job i finished	ms

WORKED EXAMPLE

Worked example — FCFS vs SJF vs RR on one core. Three jobs arrive at $t = 0$: A needs 100 ms of CPU, B needs 10 ms, C needs 10 ms. Ignore switching cost.

FCFS (order A, B, C). Completions: A = 100, B = 110, C = 120. Average turnaround = (100 + 110 + 120)/3 = **110 ms**. First runs: A = 0, B = 100, C = 110; average response = **70 ms**.

SJF (order B, C, A). Completions: B = 10, C = 20, A = 120. Average turnaround = (10 + 20 + 120)/3 = **50 ms**. Average response = (0 + 10 + 20)/3 = **10 ms**.

RR, 10 ms slice. A runs 0–10, B 10–20 (done), C 20–30 (done), then A alone 30–120. Average turnaround = (120 + 20 + 30)/3 ≈ **56.7 ms**. Average response = (0 + 10 + 20)/3 = **10 ms**.

Interpretation. RR matches SJF's response time and comes close to its turnaround *without knowing job lengths*. FCFS is more than twice as bad on turnaround because two short jobs waited behind a long one. **Engineering implication:** the same convoy effect appears in application queues: one slow request type in a shared FIFO worker pool inflates latency for every fast request. Separate queues or pools per request class (bulkheads, §22.14) apply this lesson at the service level.

6.5.3 Priority scheduling

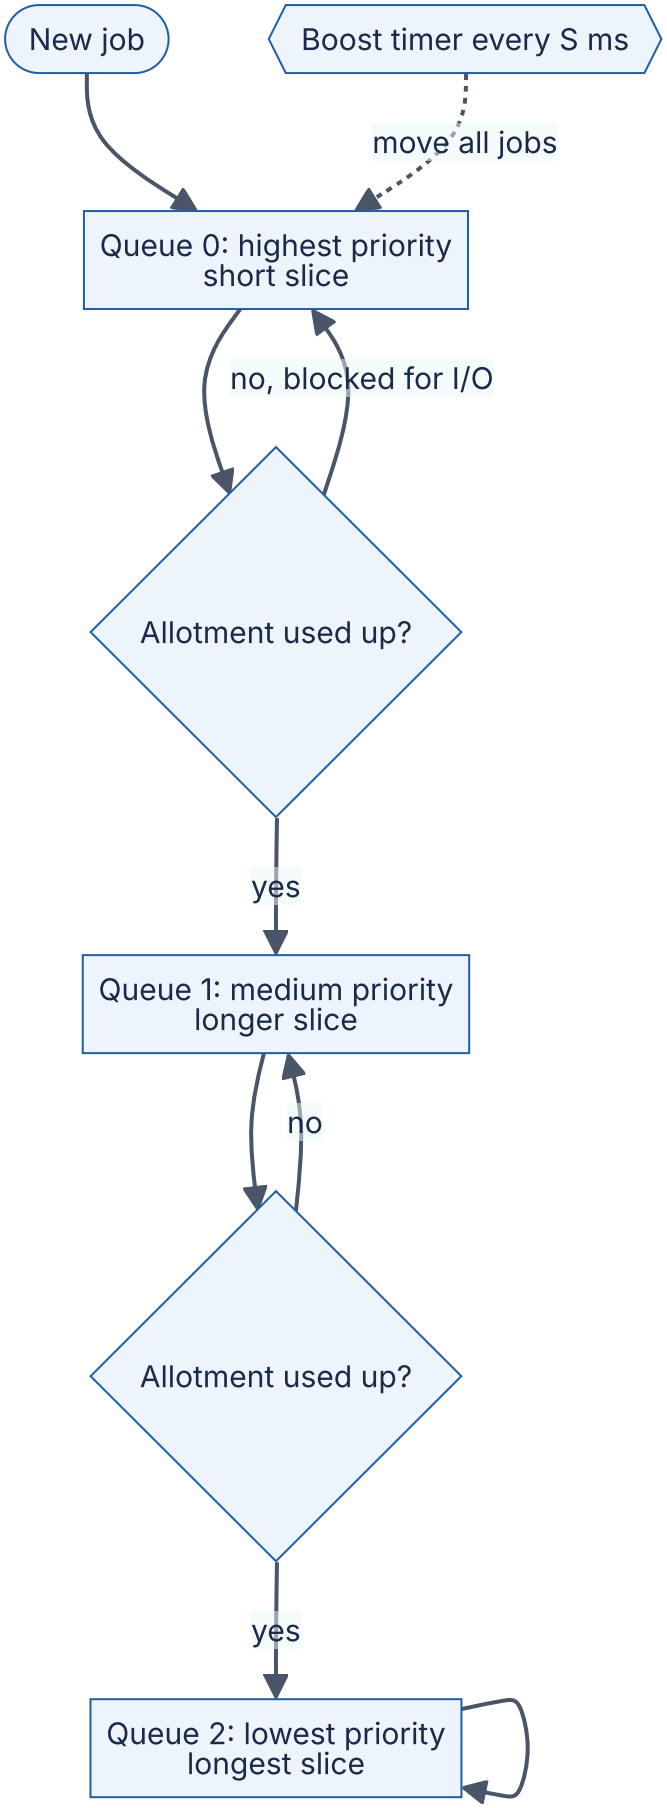
Each thread has a priority; the highest-priority ready thread runs. This lets important work (an audio driver, a heartbeat thread) preempt bulk work, but low-priority threads can **starve**: wait forever because higher-priority work keeps arriving. The classic remedy is **aging**: gradually raise the priority of threads that have waited a long time. Priorities also create **priority inversion** with locks (§6.11.5).

6.5.4 Multi-level feedback queue (MLFQ)

MLFQ, first described for the CTSS time-sharing system in 1962 by Corbató and colleagues, learns a thread’s behavior instead of requiring it to be declared. It keeps several RR queues at different priority levels and applies five rules, as formulated in OSTEP [Arpaci-Dusseau 2018]:

1. If priority(A) > priority(B), A runs.
2. If priority(A) = priority(B), A and B run round robin.
3. A new job starts at the highest priority.
4. Once a job uses up its time allotment at a level, however many times it gave up the CPU, its priority drops one level.
5. After some period S, move every job back to the top queue (a **priority boost**).

Figure 6.4 — Multi-level feedback queue decisions.



New job
Boost timer every S ms
move all jobs
Queue 0: highest priority short slice
no, blocked for I/O
Allotment used up?
yes
Queue 1: medium priority longer slice
no
Allotment used up?
yes
Queue 2: lowest priority longest slice

Reading the diagram. Rectangles are run queues; the highest non-empty queue is served (rule 1), round robin within it (rule 2). New jobs enter Queue 0 (rule 3). Interactive jobs block for I/O before exhausting their allotment and stay high, so they respond fast; CPU-bound jobs sink to lower queues with longer slices (rule 4). The dotted arrow is the asynchronous priority boost (rule 5), which prevents starvation of the bottom queue. Counting *total* allotment used stops a program gaming the scheduler by yielding just before its slice expires. Variants of MLFQ underlie the schedulers of BSD derivatives, Solaris and Windows [Arpaci-Dusseau 2018].

6.5.5 Linux: CFS and EEVDF

Linux's normal scheduling class (`SCHED_NORMAL`, also called `SCHED_OTHER`) aims at **proportional-share fairness**: each runnable thread should get a share of CPU proportional to its **weight**, which is derived from its **nice value** (−20 = highest weight, +19 = lowest).

CFS (Completely Fair Scheduler) was the default from Linux 2.6.23 (2007) until Linux 6.6 (2023). It tracks for each thread a **virtual runtime** (`vruntime`): actual CPU time scaled inversely by weight. It keeps runnable threads in a red-black tree ordered by `vruntime` and always runs the thread that has had the least weighted CPU, so picking the next thread costs $O(\log n)$ [Linux Docs: CFS].

EEVDF (Earliest Eligible Virtual Deadline First) replaced CFS's selection logic in Linux 6.6 (October 2023), based on an algorithm by Stoica and Abdel-Wahab [Stoica & Abdel-Wahab 1995]. Each thread has a **lag**: CPU time owed minus time received. Threads with non-negative lag are **eligible**; among them EEVDF runs the one with the earliest **virtual deadline** (roughly eligible time plus requested slice divided by weight). Fairness is kept, and latency-sensitive threads that request shorter slices get a principled advantage instead of hand-tuned heuristics [Linux Docs: EEVDF; Corbet 2023]. The default base slice is about 0.75 ms (as of Linux 6.6–6.x, scaled up on many-CPU machines).

Linux also has **real-time** classes (`SCHED_FIFO`, `SCHED_RR`, priorities 1–99) that always preempt normal threads, `SCHED_DEADLINE` for tasks with explicit runtime and period guarantees, and, from Linux 6.12 (2024), **sched_ext**, which lets a scheduling policy be loaded as a BPF program [Linux man-pages: sched(7)].

FORMULA

Proportional CPU share

$$s_i = \frac{w_i}{\sum_{j \in R} w_j}$$

Symbol	Meaning	Units
s_i	Fraction of one core's time thread i receives when all threads in R compete	dimensionless (0–1)
w_i	Weight of thread i, from its nice value (nice 0 = 1024; each nice step changes weight by about 1.25×)	dimensionless
R	Set of runnable threads competing on that core	—

WORKED EXAMPLE

Worked example — Nice values. Two CPU-bound threads share one core. Thread X has nice 0 (weight 1024); thread Y has nice 5 (weight 335, from the kernel's weight table). $s_X = 1024/(1024 + 335) = 1024/1359 \approx 0.753$; $s_Y \approx 0.247$. **Interpretation.** Five nice levels give roughly a 3:1 split, consistent with the rule of thumb that each nice step shifts about 10 % of CPU between two competing threads. **Engineering implication:** to keep a log-compaction or backup job from hurting request latency on the same machine, running it at nice 10–19 is a cheap first step; cgroup CPU weights do the same for whole containers.

Table 6.2 — CPU scheduling policies compared.

Policy	How it works	Advantages	Disadvantages	Choose when
FCFS	Run in arrival order to completion	Simple, no switching	Convoy effect; poor response time	Batch queues of similar-sized jobs
SJF / STCF	Shortest (remaining) job first	Optimal average turnaround	Needs job lengths; starves long jobs	Job sizes known (some batch systems)
Round robin	Fixed slice, rotate	Good response time; no starvation	Switching overhead; poor turnaround for equal jobs	Time-sharing with similar priorities
Priority	Highest priority runs	Important work goes first	Starvation; priority inversion	Real-time and control systems
MLFQ	Priority queues; demote CPU hogs; periodic boost	Learns behavior; good interactivity	Many tuning knobs	General-purpose desktops and servers
CFS / EEVDF (Linux)	Weighted fair share by virtual runtime; EEVDF adds lag and virtual deadlines	Fair, scalable, tunable by nice and cgroups	Fairness is not latency; complex	Default on Linux servers (as of 2026)

Real-world industry applications

INDUSTRY EXAMPLE

CPU limits in containers cause throttling. Kubernetes CPU limits use CFS **bandwidth control**: a cgroup gets a CPU-time quota per period (default 100 ms, `cpu.max` in cgroup v2). A service limited to 1 CPU with 4 busy threads uses its quota in 25 ms and is **throttled** for the remaining 75 ms, delaying in-flight requests even on an idle node. `nr_throttled` in `cpu.stat` reveals it. Mitigations: raise or remove limits for latency-critical services, or size thread pools to the limit rather than the host's cores (§42.13). *Evidence: Primary* — [Linux Docs: CFS Bandwidth Control]

Common misconceptions

COMMON MISTAKE

"Nice -20 makes my latency-sensitive service fast." Nice changes the *share* of CPU under contention; on a machine that is not CPU-saturated it has almost no effect. For latency, keep runnable threads below core count and avoid CPU throttling.

6.6 Virtual memory, paging and the page cache

6.6.1 The idea of virtual memory

DEFINITION

Definition — Virtual memory. A mechanism in which every address a program uses is a **virtual address** that the hardware's **memory-management unit (MMU)** translates, using tables maintained by the kernel, into a **physical address** in RAM, or into a fault if no valid mapping exists.

First-principles explanation

A hotel guest is told "you are in room 12"; the front desk's private sheet for that guest says room 12 is physically room 407. Two guests can both have "room 12", luggage can be moved without telling the guest, and a guest asking for a room not on their sheet is stopped at the desk. Virtual memory gives each process exactly this, and so delivers **isolation** (separate tables), **convenience** (the same layout for everyone, Figure 6.1) and **flexibility** (memory allocated lazily, shared, mapped to files or moved to disk).

6.6.2 Paging and page tables

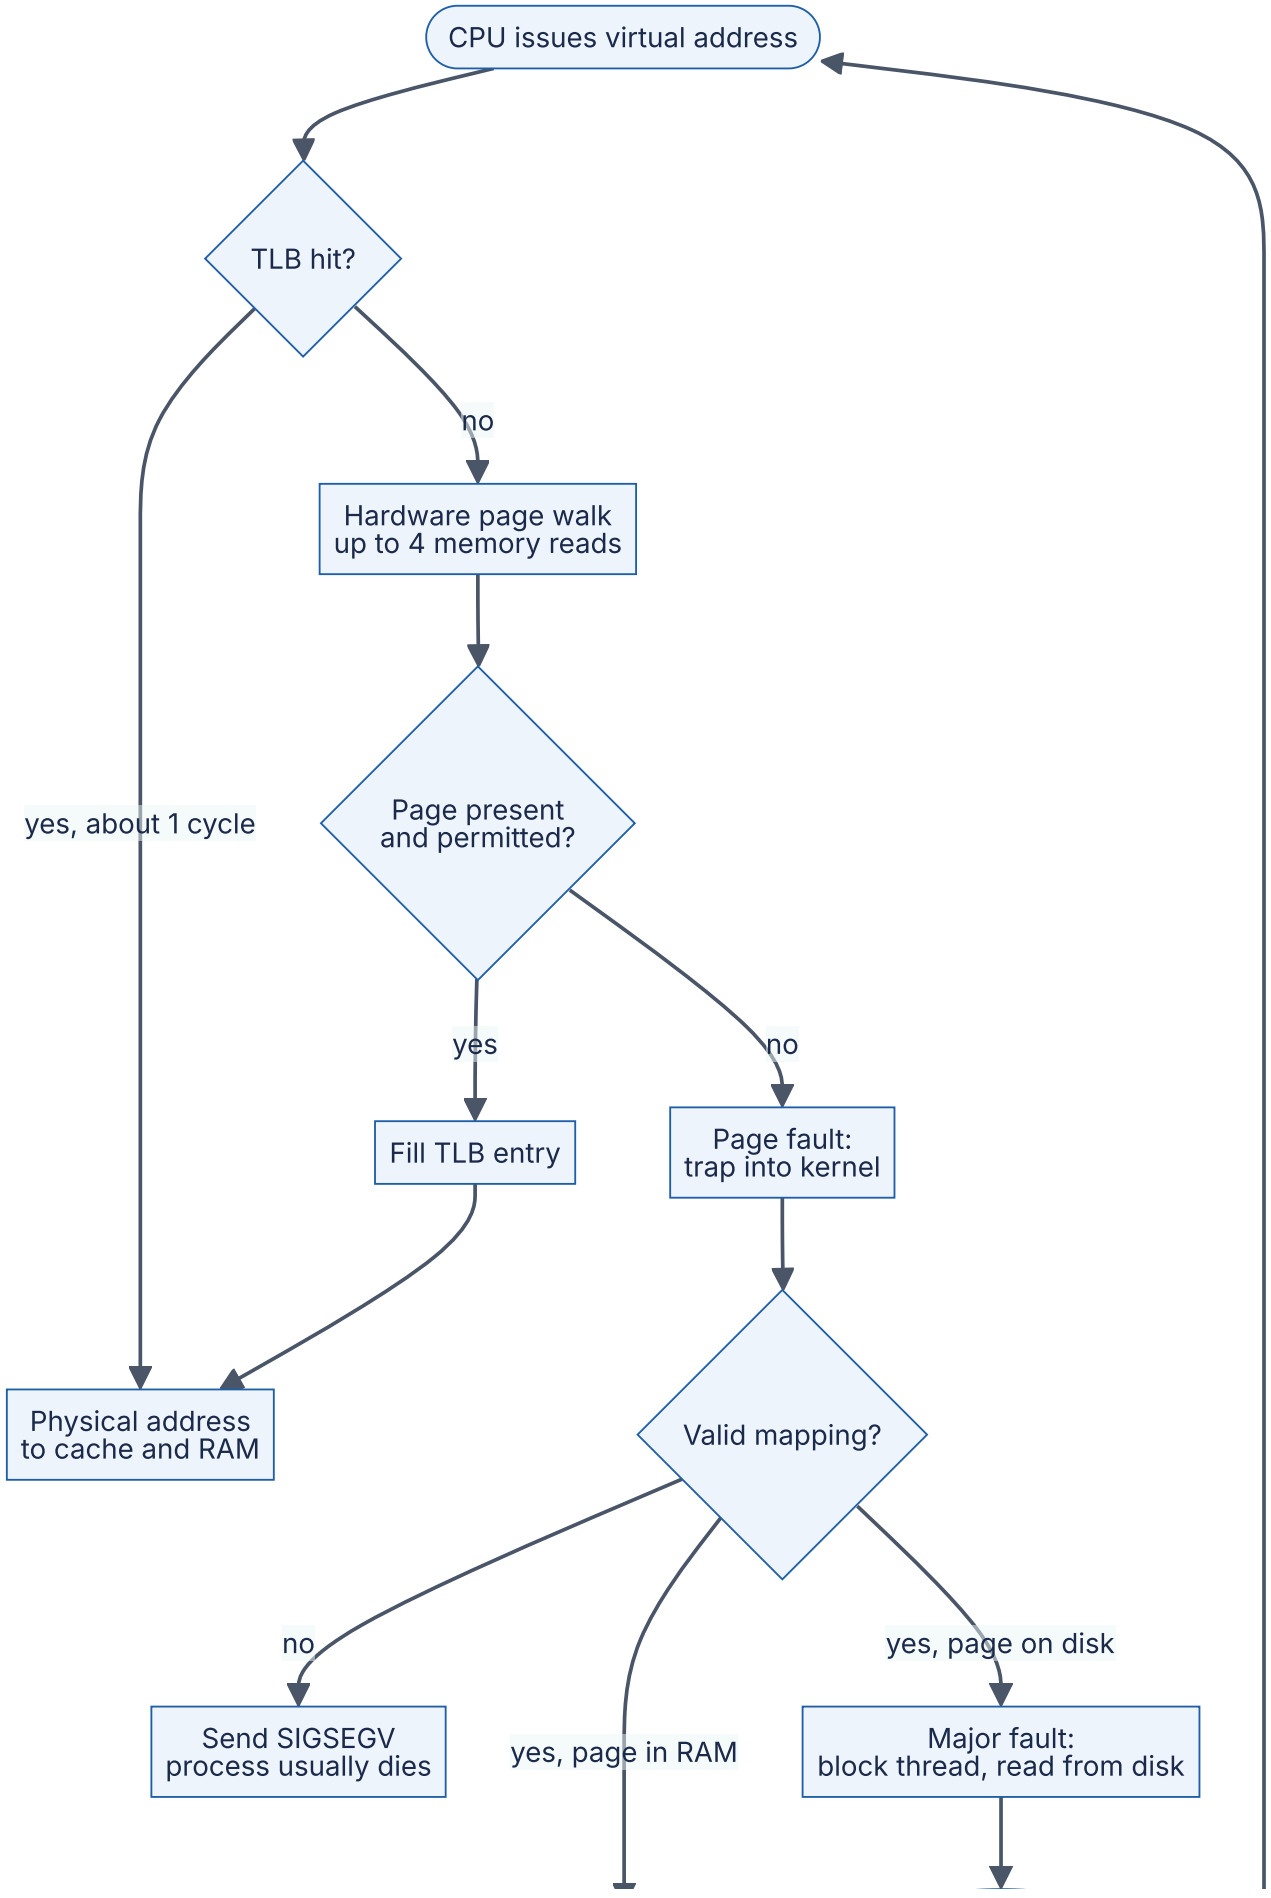
Memory is divided into fixed-size blocks: **pages** in virtual memory and **frames** in physical memory, typically **4 KiB** on x86-64 and most ARM servers. A virtual address is split into a **virtual page number** and an **offset** within the page. The kernel keeps a **page table** per process that maps virtual page numbers to physical frame numbers, plus permission bits: *present*, *writable*, *user-accessible*, *no-execute*, and *accessed*/*dirty* flags that the hardware sets so the kernel knows which pages were used or modified.

A flat table for 128 TiB of virtual space would need 2^{35} entries, far too large. So the table is a **multi-level tree**: on x86-64 with 4-level paging, the 48-bit address is split into four 9-bit indices (one per level) and a 12-bit offset (9 + 9 + 9 + 9 + 12 = 48). Only the branches actually used are allocated. Newer CPUs support 5-level paging (57-bit addresses) for very large-memory machines.

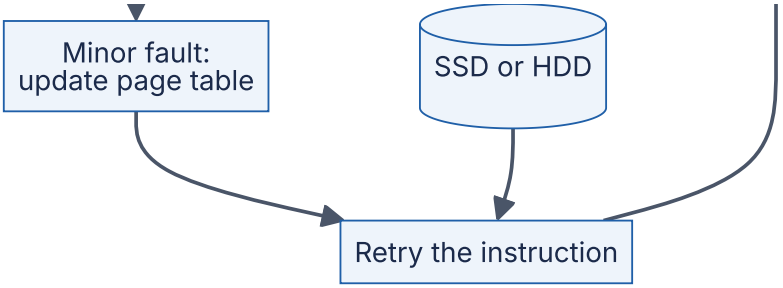
6.6.3 The TLB

Walking a four-level tree means up to four extra memory reads for every load or store, which would make every memory access several times slower. The **translation lookaside buffer (TLB)** is a small cache inside the CPU core that holds recent virtual-to-physical translations. Typical server cores have tens of entries in the first-level TLB and roughly 1,000–3,000 entries in a second-level TLB (as of 2020s x86-64 and ARM designs; consult your CPU's documentation).

Figure 6.5 — Translating a virtual address: TLB, page walk and page fault.



CPU issues virtual address
TLB hit?
yes, about 1 cycle
no
Hardware page walk
up to 4 memory reads
Page present
and permitted?
yes
no
Fill TLB entry
Page fault:
trap into kernel
Physical address
to cache and RAM
Valid mapping?
no
Send SIGSEGV
process usually dies
yes, page in RAM
yes, page on disk
Major fault:
block thread, read from disk



Reading the diagram. Every load, store and instruction fetch starts at the top. A **TLB hit** makes translation essentially free. On a **miss**, the MMU hardware walks the page table; if the entry is present and permitted, the TLB is filled. Otherwise the CPU raises a **page fault**, a synchronous trap into the kernel. An invalid address (null pointer, write to read-only code) gets **SIGSEGV**. A valid page already in RAM (a shared library page, a fresh zero page on first touch) is a cheap **minor fault**: the kernel just fills in the entry. A page that must come from storage (a file page or a swapped-out page) is a **major fault**: the thread blocks while the disk is read, the storage boundary in this figure. Then the instruction is retried. The failure point that matters is the major-fault path, which turns a 100 ns access into a 100 µs (SSD) to 10 ms (HDD) wait.

FORMULA

TLB reach

$$R_{\text{TLB}} = E \times P$$

Symbol	Meaning	Units
R_{TLB}	Amount of memory addressable without a TLB miss	bytes
E	Number of TLB entries	entries
P	Page size per entry	bytes

FORMULA

Effective memory access time with page faults

$$\mathrm{EAT} = (1 - p) \times t_{\mathrm{mem}} + p \times t_{\mathrm{fault}}$$

Symbol	Meaning	Units
EAT	Average time per memory access	ns
p	Probability that an access causes a major page fault	dimensionless (0–1)
t_{mem}	Time for an access with no fault	ns
t_{fault}	Time to service a major fault, including the disk read	ns

WORKED EXAMPLE

Worked example — Why huge pages and why swapping hurts.

TLB reach. A core with $E = 1,536$ second-level entries and 4 KiB pages has $R = 1,536 \times 4 = 6,144$ KiB **= 6 MiB**. A database with a 64 GiB in-memory buffer pool touching memory randomly will miss in the TLB on most accesses. With 2 MiB **huge pages**, the same entries cover $1,536 \times 2$ MiB **= 3 GiB**, 512× more. This is why databases and JVMs often use explicit huge pages.

Page faults. Let $t_{\mathrm{mem}} = 100$ ns and a major fault from an NVMe SSD take $t_{\mathrm{fault}} = 100$ µs = 100,000 ns. If one access in 10,000 faults ($p = 10^{-4}$): EAT $= 0.9999 \times 100 + 0.0001 \times 100,000 = 99.99 + 10 \approx$ **110 ns**, a 10 % slowdown. To keep the slowdown under 10 % with a 10 ms HDD ($t_{\mathrm{fault}} = 10^{7}$ ns), we need $p \times 10^{7} < 10$, i.e. $p < 10^{-6}$: **fewer than one fault per million accesses**.

Interpretation. Even rare major faults dominate the average. **Engineering implication:** a latency-sensitive service must keep its working set in RAM. When the working set exceeds RAM and the system swaps heavily (**thrashing**), throughput collapses by orders of magnitude rather than degrading gracefully.

6.6.4 Demand paging and overcommit

Linux allocates physical memory lazily: `malloc(1 GiB)` reserves only virtual addresses, and frames are assigned on first touch. It also **overcommits** by default, promising more virtual memory than exists. When the bet fails, the **OOM killer** kills a process, typically the largest, with SIGKILL; a container exceeding its cgroup limit (`memory.max`) is killed the same way (§42.3). Watch **resident set size** (RSS, physical pages in use), not virtual size.

6.6.5 Copy-on-write

When `fork()` creates a child, the kernel shares all the parent's pages with the child and marks them read-only in both. The first write by either side triggers a fault, and only then is that one page copied. This makes `fork` fast and allows a process to take a consistent **snapshot** of its memory cheaply.

INDUSTRY EXAMPLE

Redis background snapshots. Redis calls `fork()` to snapshot; the child writes its frozen copy-on-write view to disk while the parent keeps serving writes. Overhead is proportional to pages modified meanwhile, up to twice the dataset for write-heavy instances. Redis recommends disabling **Transparent Huge Pages**, because then one small write copies a 2 MiB page instead of 4 KiB, causing latency spikes. *Evidence: Primary* — [Redis Docs: Persistence]; [Redis Docs: Latency diagnosis]

6.6.6 The page cache and mmap

DEFINITION

Definition — Page cache. The kernel's in-RAM cache of file contents, organized in pages. Reads are served from it when possible; writes normally modify pages in it (marking them **dirty**) and return immediately, with the kernel writing them back to storage later.

Linux uses almost all otherwise-free RAM as page cache, so `free` reports little "free" memory on a healthy server; watch "available" instead. By default dirty pages are written back by kernel threads after they have been dirty for about 30 s, checked every 5 s (`vm.dirty_expire_centisecs = 3000`, `vm.dirty_writeback_centisecs = 500`, as of Linux 6.x) or sooner under memory pressure. The consequence for durability is in §6.14.

`mmap` maps a file directly into a process's address space: reading the memory reads the file through the page cache, with no `read()` system call and no copy into a user buffer. It is elegant for read-mostly data (shared libraries are loaded this way), but it hides I/O inside ordinary memory accesses: any pointer dereference may block on a major fault, I/O errors arrive as a `SIGBUS` signal instead of an error code, and the kernel, not the application, decides what to evict. Crotty, Leis and Pavlo argue that for these reasons database systems should usually manage their own buffer pool instead of relying on `mmap` [Crotty et al. 2022] (see §13.4).

INDUSTRY EXAMPLE

Apache Kafka relies on the page cache. Kafka brokers append to log files and let the OS page cache hold recent data instead of caching messages in the JVM, avoiding double caching, surviving process restarts and keeping heaps small. Consumers of recent data are served from the page cache via `sendfile`, without copying through user space (§31.13). *Evidence: Primary* — [Apache Kafka Docs: Design, Persistence]

6.6.7 Swapping

Swapping moves rarely used **anonymous** pages (heap and stack, with no file behind them) to disk so their frames can be reused; clean file-backed pages are simply dropped and re-read later. Modest swap moves idle memory out of the way; swapping a working set is thrashing. Many latency-sensitive deployments disable swap or set `vm.swappiness` low.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Process killed with exit code 137, no error log	OOM killer or cgroup limit sent SIGKILL	`dmesg` "Out of memory: Killed process"; container `OOMKilled` status	Restart with more memory	Set memory limits above peak RSS; bound caches and queues
Latency rises 100× under load	Working set exceeds RAM; major faults or swap thrashing	`vmstat` `si` / `so` columns; major-fault counters (`sar -B`)	Add RAM or shed load	Capacity plan working set; avoid swap for latency tiers
"Free memory is 1 %" alert fires constantly	Page cache is counted as used	Compare with "available"	None needed	Alert on available memory and major faults instead

6.7 System calls and the kernel/user boundary

DEFINITION

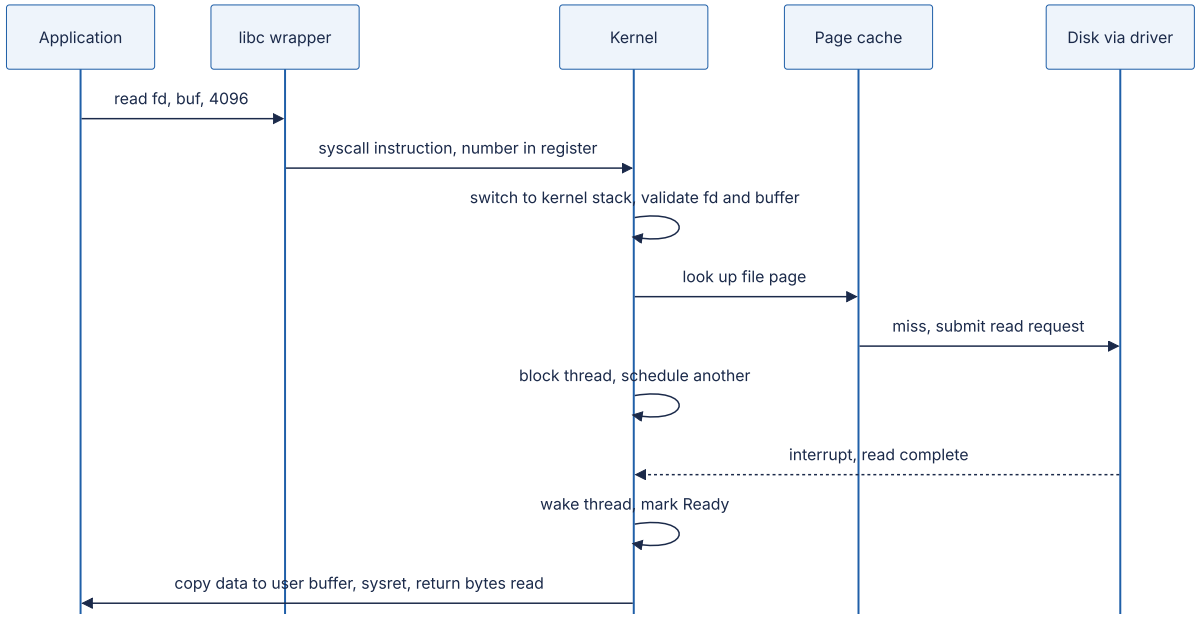
Definition — System call (syscall). A controlled entry from user mode into the kernel to request a privileged service, such as reading a file, sending on a socket, allocating memory or creating a process. Linux x86-64 has a few hundred system calls, each identified by a number [Linux man-pages: syscalls(2)].

First-principles explanation

A bank customer cannot walk into the vault; they hand a slip through one narrow window where every request is checked. A system call is that window, and library functions such as `printf` or Python's `open()` are wrappers that fill in the slip.

How it works internally

Figure 6.6 — A `read()` system call that must wait for the disk.



Reading the diagram. The library wrapper puts the system-call number and arguments in registers and executes the `syscall` instruction, entering the kernel at a fixed entry point, the only way in. The kernel *validates* everything, since user code can pass any value: is the descriptor open, does the buffer lie in the caller's memory? On a page-cache hit (§6.6.6) it copies the data and returns within about a microsecond. On a miss it submits a request across the storage boundary and the thread **blocks** (a voluntary context switch). The dotted arrow is the device's asynchronous completion interrupt; the thread becomes Ready, runs again, and the kernel copies the data out and returns. Failure points: bad arguments return `EBADF` or `EFAULT`, device errors `EIO`, and a signal can interrupt a slow call with `EINTR`, which callers must retry.

What it costs

A trivial system call costs on the order of **100 ns to a few hundred ns** on modern x86-64 Linux, against about 1–5 ns for a function call (as of the 2020s). The cost rose in 2018 when **kernel page-table isolation (KPTI)**, the Meltdown mitigation, began switching page tables on every kernel entry on affected CPUs. A rough Python measurement on this

chapter's test VM found `os.getppid()` at about 190 ns per call against about 50 ns for a built-in function call.

Three techniques reduce syscall cost:

1. **Batching** — do more per call: `readv`/`writev` for scatter/gather I/O, `sendmmsg` for many UDP datagrams, larger buffers.
2. **vDSO (virtual dynamic shared object)** — the kernel maps a small read-only library into every process so that some calls, notably `clock_gettime` and `gettimeofday`, run entirely in user mode by reading kernel-maintained data.
3. **Shared-memory rings** — `io_uring` (§6.13.5) lets the application queue many I/O requests in memory shared with the kernel, submitting them with one system call or, in polled mode, none.

To observe system calls, `strace -c -p <pid>` counts and times them (with heavy overhead); `perf trace` and eBPF tools such as `syscount` are cheaper [Gregg 2020].

> COMMON MISTAKE
>
> **"Calling `write()` means my data is on disk."** `write()` returns when the data is in the page cache. It is durable only after a successful `fsync()` (§6.14.3).

6.8 Concurrency versus parallelism

> DEFINITION
>
> **Definition — Concurrency and parallelism. Concurrency** is the *structuring* of a program as multiple tasks whose lifetimes overlap, so that progress on one does not wait for the others to finish. **Parallelism** is the *simultaneous execution* of multiple computations on multiple hardware units (cores, CPUs, GPUs).

One cook juggling three dishes, stirring one while another simmers, is concurrent but not parallel. Three cooks each making one dish are parallel. Rob Pike's summary: concurrency is about *dealing with* many things at once; parallelism is about *doing* many things at once [Pike 2012].

I/O-bound work (a web server waiting on databases) needs concurrency: thousands of requests in flight, mostly waiting, which one core can serve with an event loop (§6.13). **CPU-bound** work (image encoding) needs parallelism, with speed-up limited by the serial fraction (Amdahl's Law, §4.12). Concurrency alone gives no CPU speed-up.

CPython's **global interpreter lock (GIL)** is the standard illustration: Python threads are concurrent, and overlap well while waiting on I/O, but only one executes Python bytecode

at a time, so CPU-bound Python code gains nothing from threads. Use processes (`multiprocessing`), native extensions that release the GIL, or the optional free-threaded build of CPython (experimental in 3.13, officially supported but not the default in 3.14, as of 2026) for CPU parallelism.

6.9 Race conditions and critical sections

DEFINITION

Definition — Race condition. A bug in which the result of a program depends on the relative timing or interleaving of concurrent operations on shared state. A **data race** is the specific case where two threads access the same memory location concurrently, at least one access is a write, and nothing orders them.

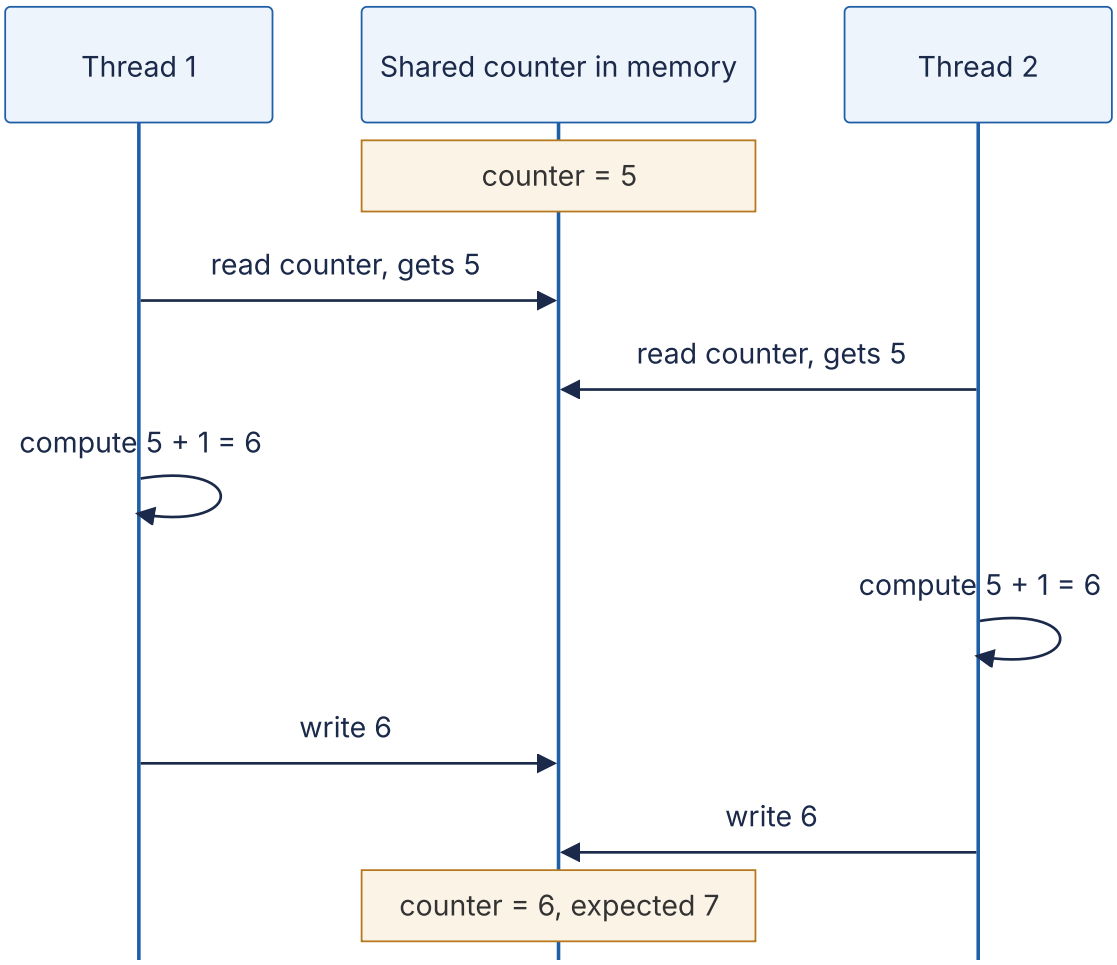
DEFINITION

Definition — Critical section. A region of code that accesses shared state and must not be executed by more than one thread at a time. Guaranteeing this is **mutual exclusion**.

First-principles explanation

Two people deposit $50 at the same moment into a shared account holding $100, at different cash machines. Each machine reads $100, adds $50 and writes $150; the correct balance is $200. Neither machine erred alone: the bug is the *interleaving* of read, modify and write, the **lost update**.

Figure 6.7 — Two threads lose an update to a shared counter.



Reading the diagram. Each arrow is a synchronous step, but the two threads' steps interleave in an order chosen by the scheduler and hardware. Both read before either writes, so one increment is lost. The critical section is *read, compute, write*; making it indivisible, with a lock or one atomic instruction, removes the bug. The same failure occurs across machines when two service instances read-modify-write a database row (§11.13, §26.13).

Code example

The Python program below makes the race visible. `counter += 1` in CPython is not atomic, but the GIL makes the bad interleaving rare, so `time.sleep(0)` deliberately yields the CPU between the read and the write, exactly where a preemption could occur.

```
        """Lost updates: a read-modify-write race, then the fix with a mutex."""
        import threading
        import time

        N_THREADS = 4
        N_INCREMENTS = 10_000

        counter = 0
        lock = threading.Lock()

        def unsafe_increment() -> None:
            global counter
            for _ in range(N_INCREMENTS):
                current = counter      # 1. read
                time.sleep(0)          # widen the window: yield the CPU (see note)
                counter = current + 1  # 2. modify + 3. write

        def safe_increment() -> None:
            global counter
            for _ in range(N_INCREMENTS):
                with lock:             # critical section starts
                    current = counter
                    time.sleep(0)
                    counter = current + 1
                                       # critical section ends (lock released)

        def run(worker) -> int:
            global counter
            counter = 0
            threads = [threading.Thread(target=worker) for _ in range(N_THREADS)]
            for t in threads:
                t.start()
            for t in threads:
                t.join()
            return counter

        if __name__ == "__main__":
            expected = N_THREADS * N_INCREMENTS
            print(f"expected       = {expected}")
            print(f"without a lock = {run(unsafe_increment)}")
            print(f"with a lock    = {run(safe_increment)}")
```

A run on CPython 3.13 printed `expected = 40000`, `without a lock = 10000` and `with a lock = 40000`; the unsafe count varies between runs.

What to notice:

- The unsafe version loses about three quarters of the increments: writes overwrite each other.

- `with lock:` makes read-compute-write a critical section: correct, but threads now take turns.
- Removing `time.sleep(0)` makes the race *rarer*, not absent. Tests that pass “most of the time” are the hallmark of races.

The Go version needs no artificial delay, because goroutines run in parallel on multiple cores:

```go
// Three counters incremented by many goroutines: racy, mutex, atomic.
package main

import (
    "fmt"
    "sync"
    "sync/atomic"
)

const goroutines = 8
const increments = 100_000

func main() {
    var wg sync.WaitGroup

    // 1. Racy: counter++ is a read-modify-write, not one indivisible step.
    racy := 0
    for g := 0; g < goroutines; g++ {
        wg.Add(1)
        go func() {
            defer wg.Done()
            for i := 0; i < increments; i++ {
                racy++
            }
        }()
    }
    wg.Wait()

    // 2. Mutex: only one goroutine at a time inside the critical section.
    var mu sync.Mutex
    locked := 0
    for g := 0; g < goroutines; g++ {
        wg.Add(1)
        go func() {
            defer wg.Done()
            for i := 0; i < increments; i++ {
                mu.Lock()
                locked++
                mu.Unlock()
            }
        }()
    }
    wg.Wait()

    // 3. Atomic: the hardware performs the increment indivisibly.
    var atomicCount atomic.Int64
    for g := 0; g < goroutines; g++ {
        wg.Add(1)
        go func() {
            defer wg.Done()
            for i := 0; i < increments; i++ {
                atomicCount.Add(1)
            }
        }()
    }
    wg.Wait()
```

```
        fmt.Println("expected:", goroutines*increments)
        fmt.Println("racy:    ", racy)
        fmt.Println("mutex:   ", locked)
        fmt.Println("atomic:  ", atomicCount.Load())
    }
```

On a 4-core VM with Go 1.24, `go run .` printed `racy: 493557` against `expected: 800000`; the mutex and atomic counters were exact.

What to notice:

- `go run -race .` runs Go's **race detector**, which reports `WARNING: DATA RACE` with both stack traces; use `-race` in CI [Go Docs: Data Race Detector].
- `atomic.Int64` (Go 1.19+) is one locked hardware instruction, usually faster than a mutex for a single counter; for two or more variables, use a mutex.
- In Go, Java and C/C++, racy programs have weak or undefined semantics: compilers and CPUs may reorder or cache values [Go Docs: Memory Model].

COMMON MISTAKE

"It is only a counter; a small error is fine." The same pattern guards bank balances, inventory counts, rate-limit tokens and "is this seat booked?" flags. Treat every read-modify-write of shared state as a critical section, or replace it with a single atomic operation.

6.10 Synchronization primitives

Each primitive below answers a specific coordination problem. Table 6.3 at the end of the section compares them.

6.10.1 Mutexes and spinlocks

DEFINITION

Definition — Mutex (mutual-exclusion lock). An object with two operations, `lock` and `unlock`, guaranteeing that at most one thread holds it at a time. A thread that calls `lock` while another holds it waits.

A mutex is the key to a single-occupancy bathroom. A **spinlock** waits by looping, burning CPU but reacting within nanoseconds; it suits tiny kernel critical sections. A **blocking mutex** puts the waiter to sleep (§6.4) and wakes it on unlock. Linux builds mutexes on **futexes**: an uncontended lock is one atomic instruction in user space; only under contention does the thread call `futex()` to sleep in the kernel [Franke et al. 2002]. Most mutexes

spin briefly, then sleep. Uncontended locks cost tens of nanoseconds; contended ones cost microseconds of context switching.

6.10.2 Semaphores

DEFINITION

Definition — Semaphore. An integer counter with two atomic operations introduced by Dijkstra: **wait** (P, or *acquire*) decrements it and blocks if the result would be negative; **signal** (V, or *release*) increments it and wakes a waiter [Dijkstra 1965].

A semaphore initialized to N is a car park with N spaces: the natural tool for **limiting concurrency**, such as at most 20 database connections or 4 concurrent inferences on one GPU. Unlike a mutex, any thread may signal it, so it has no owner and cannot support priority inheritance (§6.11.5).

6.10.3 Condition variables

DEFINITION

Definition — Condition variable. A queue of threads waiting for some condition on shared state to become true, always used together with a mutex. `wait` atomically releases the mutex and sleeps; `notify` (`signal`) wakes one waiter and `notify_all` (`broadcast`) wakes all.

A mutex answers “only one at a time”; a condition variable answers “wait until something is true”, such as “the queue is not empty”. The bounded buffer below is the canonical example: producers wait while the buffer is full, consumers while it is empty.

```
        """A bounded buffer (producer/consumer) built from one mutex and two condition
variables."""
        import threading
        from collections import deque

        class BoundedBuffer:
            def __init__(self, capacity: int) -> None:
                self.capacity = capacity
                self.items = deque()
                self.lock = threading.Lock()
                self.not_full = threading.Condition(self.lock)   # producers wait here
                self.not_empty = threading.Condition(self.lock)  # consumers wait here

            def put(self, item) -> None:
                with self.lock:
                    while len(self.items) == self.capacity:      # while, not if
                        self.not_full.wait()                     # releases lock while
asleep
                    self.items.append(item)
                    self.not_empty.notify()                      # wake one consumer

            def get(self):
                with self.lock:
                    while not self.items:
                        self.not_empty.wait()
                    item = self.items.popleft()
                    self.not_full.notify()                       # wake one producer
                    return item

        if __name__ == "__main__":
            buf = BoundedBuffer(capacity=8)
            N_PRODUCERS, PER_PRODUCER = 3, 10_000
            results = []

            def producer(pid: int) -> None:
                for i in range(PER_PRODUCER):
                    buf.put((pid, i))

            def consumer() -> None:
                for _ in range(N_PRODUCERS * PER_PRODUCER):
                    results.append(buf.get())

            threads = [threading.Thread(target=producer, args=(p,)) for p in
range(N_PRODUCERS)]
            threads.append(threading.Thread(target=consumer))
            for t in threads:
                t.start()
            for t in threads:
                t.join()
            print("consumed:", len(results), "unique:", len(set(results)))
```

Output: `consumed: 30000 unique: 30000`.

What to notice:

- The condition is re-checked in a `while` **loop**: under **Mesa semantics**, used by almost every real system, a woken thread only becomes runnable, and another thread may take the item first; **spurious wake-ups** are also allowed [Lampson & Redell 1980].
- `wait()` releases the lock while sleeping and reacquires it before returning.
- The bounded capacity is **backpressure** (§22.10): producers slow to the consumer's pace instead of exhausting memory. Python's `queue.Queue` works this way.

6.10.4 Atomics and compare-and-swap

DEFINITION

Definition — Compare-and-swap (CAS). An atomic CPU instruction that, in one indivisible step, compares a memory location with an expected value and, only if they are equal, replaces it with a new value, reporting whether it succeeded. On x86-64 it is `LOCK CMPXCHG`; ARMv8.1 and later provide `CAS`, and earlier ARM uses load-linked/store-conditional pairs.

Atomic instructions (atomic add, exchange, CAS) make a single read-modify-write indivisible in hardware, with no lock and no sleeping. CAS is the building block for everything else: to apply any update, read the current value, compute the new one, and CAS it in; if another thread changed the value meanwhile, the CAS fails and you retry.

```
        import java.util.concurrent.atomic.AtomicLong;

        /** A lock-free "max seen so far" tracker built from a compare-and-swap retry
loop. */
        public class CasCounter {
            private final AtomicLong max = new AtomicLong(Long.MIN_VALUE);
            private final AtomicLong retries = new AtomicLong();

            void offer(long candidate) {
                while (true) {
                    long current = max.get();                       // 1. read
                    if (candidate <= current) return;               // nothing to do
                    if (max.compareAndSet(current, candidate)) {    // 2. swap only if
unchanged
                        return;
                    }
                    retries.incrementAndGet();                      // 3. someone beat
us: retry
                }
            }

            public static void main(String[] args) throws InterruptedException {
                CasCounter tracker = new CasCounter();
                Thread[] workers = new Thread[4];
                for (int t = 0; t < workers.length; t++) {
                    final int id = t;
                    workers[t] = new Thread(() -> {
                        for (long i = 0; i < 1_000_000; i++) {
                            tracker.offer(i * workers.length + id);
                        }
                    });
                    workers[t].start();
                }
                for (Thread w : workers) w.join();
                System.out.println("max     = " + tracker.max.get());   // 3999999
                System.out.println("retries = " + tracker.retries.get());
            }
        }
```

On JDK 21 with 4 threads this printed `max = 3999999` and several hundred thousand retries.

What to notice:

- No thread blocks; a failed CAS means another thread made progress. This is **lock-free** progress.
- Each retry bounced a cache line between cores (§5.4); under heavy contention a CAS loop can be slower than a mutex.
- Atomics also impose **memory ordering**: writes before an atomic store become visible to threads that observe it. Plain variables have no such guarantee.

6.10.5 Read-write locks

A **read-write lock** allows many concurrent readers or one writer. It helps when reads dominate *and* critical sections are long, such as a routing table. Caveats: every reader updates the lock's shared counter, so for very short reads on many cores it can be slower than a mutex; and readers can starve writers unless the lock is **writer-preferring**. For read-mostly data, **copy-on-write snapshots** (readers load an atomic pointer to an immutable version; writers swap in a new one) and Linux's **read-copy-update (RCU)** avoid reader locking entirely.

6.10.6 Lock-free data structures and the ABA problem

A **lock-free** data structure guarantees that some thread always makes progress, even if others are paused mid-operation; a **wait-free** one guarantees that *every* thread finishes in a bounded number of steps [Herlihy & Shavit 2012]. The classic example is the **Treiber stack** [Treiber 1986]: `push` reads the current top, sets the new node's `next` to it, and CASes the top from old to new.

The **ABA problem** breaks naive CAS designs. CAS checks only that the value *looks* the same, not that it *is* unchanged:

1. Thread 1 reads top = A (with A.next = B) and is preempted before its CAS(top, A → B).
2. Thread 2 pops A, pops B, frees B, then pushes A back (or a new node reusing A's memory). Top is A again, but A.next is now something else.
3. Thread 1 resumes; CAS(top, A → B) *succeeds*, because top equals A, and installs the freed node B as the top. The stack is corrupted.

Remedies: pair the pointer with a **version counter** and CAS both together (a tagged pointer); use **hazard pointers** [Michael 2004] or **epoch-based reclamation** so memory is not reused while any thread may hold a reference; or rely on garbage collection, which prevents node reuse while referenced. In practice, use tested concurrent collections (`java.util.concurrent`, Go channels, Rust's `crossbeam`) rather than writing your own.

Table 6.3 — Synchronization primitives compared.

Primitive	Problem it solves	Waiting behavior	Typical cost (uncontended)	Pitfalls	Choose when
Spinlock	Mutual exclusion for tiny sections	Busy-waits	~10–20 ns	Wastes CPU; terrible if holder is preempted	Kernel code, sections of a few instructions
Mutex	Mutual exclusion	Spin briefly, then sleep	~20–50 ns	Deadlock, contention, priority inversion	Default for protecting shared state
Semaphore	Limit concurrency to N	Sleeps	Similar to mutex	No ownership; easy to miscount	Connection or resource pools
Condition variable	Wait until a predicate holds	Sleeps, releases mutex	Similar to mutex	Must loop on predicate; lost wake-ups	Queues, producer/consumer
Atomic / CAS	Single-variable read-modify-write	Never sleeps; may retry	~5–20 ns; more when contended	Only one variable; ABA; ordering subtleties	Counters, flags, pointers
Read-write lock	Many readers, rare writers	Sleeps	Higher than mutex	Writer starvation; reader-counter contention	Long read-mostly sections
Lock-free structure	Progress without locks	Never sleeps	Varies	ABA; memory reclamation; very hard to verify	Proven library implementations only

Costs are orders of magnitude on current x86-64 servers (as of the 2020s) and grow sharply under contention, when cache lines move between cores.

6.11 Deadlock, livelock, starvation and priority inversion

6.11.1 Deadlock and the Coffman conditions

DEFINITION

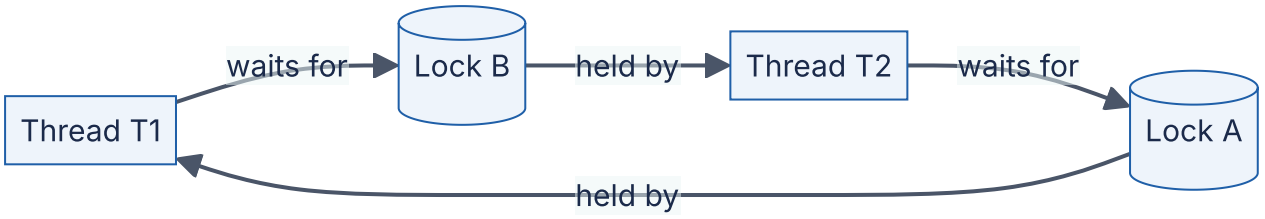
Definition — Deadlock. A state in which each thread in a set is waiting for a resource held by another thread in the same set, so none can ever proceed.

Four cars at a four-way junction, each waiting for the car on its right, will never move. Deadlock requires all four of these conditions at once [Coffman et al. 1971; Tanenbaum & Bos 2014]:

1. **Mutual exclusion** — a resource can be held by only one thread at a time.
2. **Hold and wait** — a thread holds at least one resource while waiting for another.

3. **No preemption** — a resource cannot be forcibly taken away; it is released only voluntarily.
4. **Circular wait** — there is a cycle of threads, each waiting for a resource held by the next.

Figure 6.8 — Resource-allocation graph with a deadlock cycle.



Reading the diagram. Rectangles are threads, cylinders are locks. Thread → lock means "waits for"; lock → thread means "is held by". Following the arrows from T1 returns to T1: a **cycle**. With single-instance resources such as locks, a cycle is necessary and sufficient for deadlock, which is how deadlock detectors, including those in databases (§11.15), work. Every edge is a synchronous blocking wait; breaking any one edge removes the deadlock.

The code below produces exactly this cycle. Because a real deadlock would hang forever, it uses `acquire(timeout=...)` to detect the situation:

```
        """Two threads take two locks in opposite order -> deadlock (detected via time-
out)."""
        import threading
        import time

        lock_a = threading.Lock()
        lock_b = threading.Lock()

        def worker(name: str, first: threading.Lock, second: threading.Lock) -> None:
            with first:
                time.sleep(0.1)                      # make the bad interleaving very
likely
                if second.acquire(timeout=1.0):      # a real program would block for-
ever
                    second.release()
                    print(f"{name}: finished")
                else:
                    print(f"{name}: gave up after 1 s -- probable deadlock")

        t1 = threading.Thread(target=worker, args=("T1", lock_a, lock_b))
        t2 = threading.Thread(target=worker, args=("T2", lock_b, lock_a))  # opposite
order!
        t1.start(); t2.start(); t1.join(); t2.join()

        # Fix: impose a global lock order (always A before B) and the cycle cannot form.
        t1 = threading.Thread(target=worker, args=("T1", lock_a, lock_b))
        t2 = threading.Thread(target=worker, args=("T2", lock_a, lock_b))
        t1.start(); t2.start(); t1.join(); t2.join()
```

Typical output: `T1: gave up after 1 s -- probable deadlock`, `T2: finished`, `T1: finished`, `T2: finished`.

What to notice:

- In the first run each thread holds one lock and wants the other. When T1 gives up and releases A, T2 can finish: the timeout broke **hold and wait**, which is how databases resolve deadlocks by aborting a victim transaction.
- In the second run both threads take A before B. No cycle can form, so no timeout is needed.

6.11.2 Handling deadlock: prevention, avoidance, detection

Prevention makes one Coffman condition impossible by design:

- *Circular wait:* define a global **lock ordering** (by address, by ID, by level) and always acquire locks in that order. This is the most practical technique.
- *Hold and wait:* acquire all needed locks at once, or use `tryLock` and release everything on failure.

- *No preemption:* use timeouts so a waiting thread gives up what it holds.
- *Mutual exclusion:* avoid locks entirely: immutable data, lock-free structures, or one owner thread per piece of state (actors, §6.15.3).

Avoidance refuses requests that *could* lead to deadlock. Dijkstra's **banker's algorithm** grants a resource only if some order still exists in which every thread can obtain its declared maximum and finish (a **safe state**) [Dijkstra 1965]; needing maximum demands in advance makes it rare in practice.

Detection and recovery lets deadlocks happen, finds cycles in the wait-for graph and aborts a victim, as databases do. For applications, a **thread dump** (`jstack`, Go's `SIGQUIT` dump) shows each thread's held and awaited locks.

6.11.3 Livelock

In a **livelock**, threads keep reacting to each other without progress, like two people in a corridor stepping aside the same way again and again; threads that `tryLock`, fail, release and retry in lock-step do the same. The fix is **randomized backoff**, as with retry jitter (§22.12).

6.11.4 Starvation

In **starvation**, a thread waits indefinitely because others are always preferred: low priority under strict priority scheduling, writers under a reader-preferring lock, a thread that always loses an unfair lock. Remedies are fairness policies: FIFO locks (Java's `new ReentrantLock(true)`), aging, priority boosts. Fair locks cost throughput, since each handoff to a sleeping thread is a context switch, so most locks default to unfair.

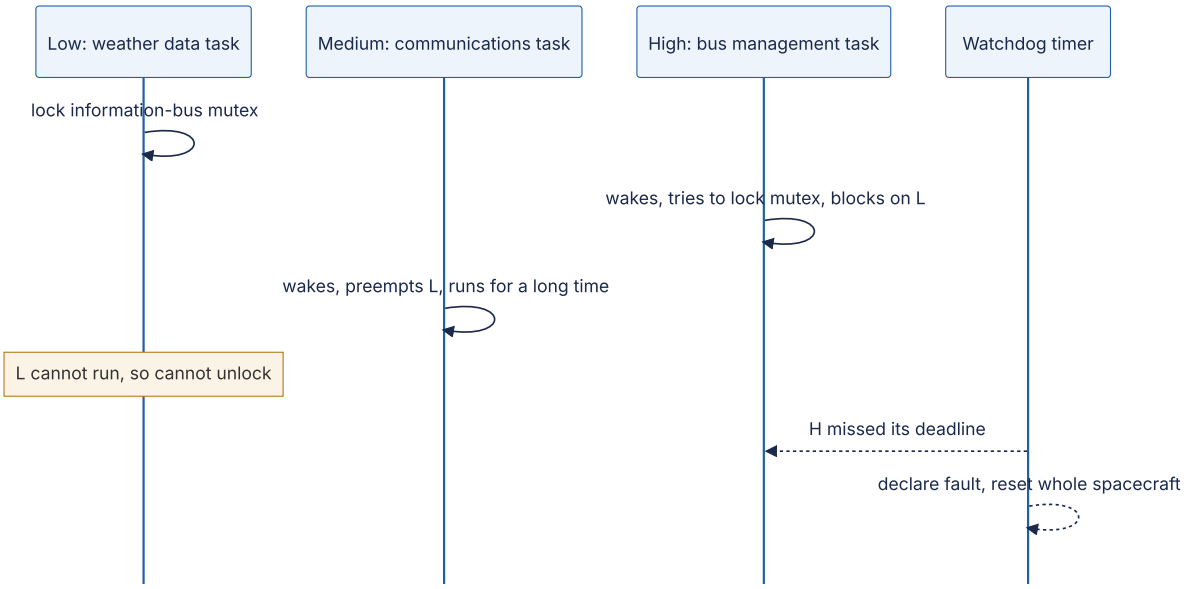
6.11.5 Priority inversion

DEFINITION

Definition — Priority inversion. A situation in which a high-priority thread is blocked waiting for a lock held by a low-priority thread, while a medium-priority thread, which needs no lock, preempts the low-priority one, so the high-priority thread effectively runs at the lowest priority.

6.11.6 Case study: Mars Pathfinder, 1997

Figure 6.9 — Priority inversion on Mars Pathfinder.



Reading the diagram. Three tasks share one CPU under strict priorities, and one mutex guards a shared memory area, the information bus. The low-priority weather task takes the mutex; the high-priority bus task blocks on it, normally briefly. The medium-priority communications task, which needs no mutex, preempts the low task, so the mutex is never released and the high task waits as long as the medium task runs. The dotted arrows are asynchronous: a watchdog saw that the high-priority work had not completed in time and reset the computer. Failure point: the mutex. Fix: priority inheritance.

INDUSTRY EXAMPLE

Mars Pathfinder, July 1997. Days after landing on 4 July 1997, the Pathfinder lander began suffering total system resets, losing data each time. JPL engineers reproduced the problem on an identical ground system and traced it to priority inversion on a mutex in the VxWorks real-time operating system. The mutex had been created with **priority inheritance** disabled. Priority inheritance temporarily raises a lock holder to the priority of the highest thread waiting for it, so the low task would have run at high priority, released the lock quickly, and not been preempted by the medium task [Sha et al. 1990]. Because the team had left debugging facilities enabled in the flight software, they could change the mutex's initialization parameter remotely; after the patch was uploaded the resets stopped. The lessons: real-time systems need priority-inheritance (or priority-ceiling) locks, and the ability to diagnose and patch in production is a design requirement, not a luxury. *Evidence: Primary* — account by Glenn Reeves, JPL software team lead [Reeves 1997], as summarized by Mike Jones [Jones 1997]

Priority inversion also appears in servers, when a background job holds a lock, pool slot or database row lock that user-facing requests need.

Table 6.4 — Liveness failures compared.

Failure	What it looks like	Threads are	Root cause	Detection	Fix
Deadlock	Requests hang forever; CPU idle	Blocked	Cycle of waits (all four Coffman conditions)	Thread dump shows lock cycle	Lock ordering, timeouts, victim abort
Livelock	CPU busy, no progress	Running	Symmetric retry reactions	High CPU with zero throughput	Randomized backoff
Starvation	Some requests never finish; others are fine	Ready or blocked	Unfair scheduling or locking	Per-class latency; wait-time histograms	Fair locks, aging, quotas
Priority inversion	High-priority work delayed by low-priority work	High blocked; medium running	Lock held by low-priority thread	Latency spikes correlated with background jobs	Priority inheritance or ceiling; avoid sharing locks across priorities

6.12 Inter-process communication

Processes have private address spaces (§6.3.2), so they cooperate through kernel-provided channels, trading speed, structure and reach.

- **Pipes** — a one-way byte stream through a kernel buffer (64 KiB by default on Linux), as in `grep error log | wc -l`; *named pipes* (FIFOs) let unrelated processes connect. A writer to a full pipe blocks: built-in backpressure.
- **Unix domain sockets** — the socket API on one machine, addressed by a file path; bidirectional, and able to pass file descriptors. Docker's API and local database connections use them; they skip the TCP/IP stack.
- **TCP/UDP sockets** — slower locally, but the same code works across machines (§7.7).
- **Shared memory** — processes map the same physical pages (`shm_open` + `mmap`). Fastest, with no system calls after setup, but the processes must synchronize themselves. PostgreSQL's shared buffer pool uses it.
- **Message queues** — POSIX `mq_open` keeps discrete, prioritized messages in the kernel, locally; distributed brokers (Chapter 30) generalize the idea.
- **Signals** — asynchronous notifications carrying only a number: `SIGTERM` (please exit), `SIGKILL` (exit now, uncatchable), `SIGINT` (Ctrl-C), `SIGHUP` (often "reload"), `SIGCHLD` (child exited). Handlers interrupt the program anywhere, so they may call only **async-signal-safe** functions; set a flag and act in the main loop [Linux manpages: signal(7)]. Kubernetes sends `SIGTERM`, waits a grace period (30 s by default), then `SIGKILL`, so services must handle `SIGTERM` to drain gracefully (§42.7.4).

Table 6.5 — IPC mechanisms compared.

Mechanism	Direction	Data model	Speed (local)	Scope	Synchronization	Choose when
Pipe / FIFO	One-way	Byte stream	Fast	Same machine (pipe: related processes)	Built in (blocking)	Streaming between parent and child, shell pipelines
Unix domain socket	Two-way	Stream or datagram	Fast	Same machine	Built in	Local client–server, sidecars, passing file descriptors
TCP socket	Two-way	Stream	Moderate	Network	Built in	Anything that may later run on another machine
Shared memory	Any	Raw bytes	Fastest	Same machine	Do it yourself	Very high throughput, low latency, large shared data
POSIX message queue	One-way	Discrete messages	Fast	Same machine	Built in	Small prioritized messages between local processes
Signal	One-way	A number	Fast	Same machine	Asynchronous	Lifecycle control: stop, reload, child exit

6.13 I/O models: from blocking to io_uring

A network server spends most of its life waiting. The **I/O model** decides what a thread does while it waits, and so how many connections one machine can hold.

6.13.1 Blocking and non-blocking I/O

With **blocking I/O**, `read()` on a socket with no data puts the thread to sleep until data arrives: simple code, but one thread per waiting connection. With **non-blocking I/O** (`O_NONBLOCK`), `read()` returns `EAGAIN` immediately when there is no data, so one thread can juggle many sockets, but it needs a way to sleep until *any* of them is ready rather than spinning.

6.13.2 I/O multiplexing: select, poll, epoll, kqueue

I/O multiplexing lets one thread ask the kernel: “here are my sockets; sleep until at least one can be read or written without blocking, and tell me which.” These are **readiness** notifications.

- `select` (4.2BSD) passes descriptor bitmaps on every call, is limited to descriptors below `FD_SETSIZE` (1,024 on Linux/glibc), and scans all of them: $O(n)$ work per wake-up.
- `poll` uses an array, removing the limit, but still scans all n.
- `epoll` (Linux 2.6) registers interest once (`epoll_ctl`); the kernel maintains a ready list, and `epoll_wait` returns only ready descriptors, so cost scales with *ready*, not watched, descriptors [Linux man-pages: epoll(7)].
- `kqueue` (FreeBSD 4.1, 2000; also macOS) scales the same way and also covers files, signals, timers and processes [Lemon 2001].

Level-triggered notification keeps reporting a socket while data remains; **edge-triggered** reports only new arrivals, so the program must read until `EAGAIN`. Readiness has a blind spot: regular files are always “ready” yet reads can block on disk, which is why Node.js’s libuv runs file operations on a thread pool (4 threads by default) [Node.js Docs: Don’t Block the Event Loop].

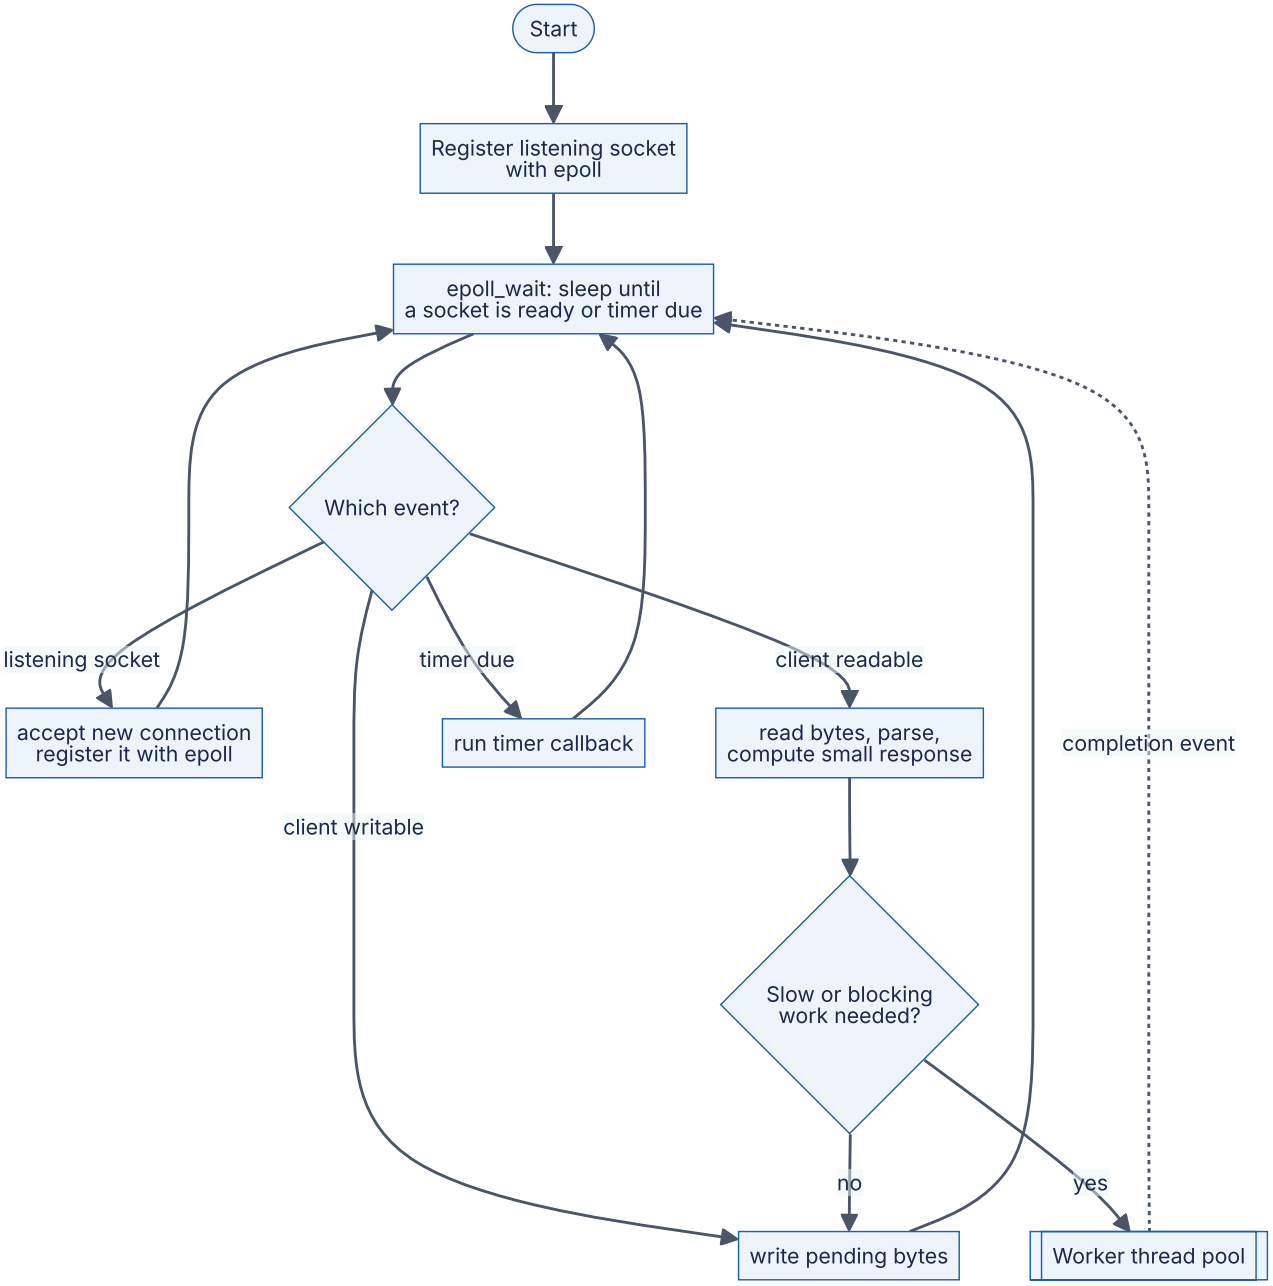
6.13.3 The C10K problem

In 1999 Dan Kegel’s web page *The C10K problem* asked how one server could handle ten thousand simultaneous clients, when the hardware clearly could but the software could not [Kegel 1999]. Thread-per-connection hit memory and scheduling limits, and `select` / `poll` spent their time rescanning idle sockets. Kegel surveyed the strategies (thread per client, readiness notification, asynchronous completion); the eventual answer was event-driven servers on `epoll` / `kqueue`, the architecture of nginx, HAProxy, Node.js and Redis. Today a tuned server holds millions of mostly idle connections (see §9.9).

6.13.4 The event loop

> DEFINITION
>
> **Definition — Event loop.** A single thread that repeatedly waits for events (ready sockets, expired timers, completed tasks) using an I/O multiplexing call, and dispatches each event to a short, non-blocking handler.

Figure 6.10 — An event loop on epoll.



Reading the diagram. One thread sleeps in `epoll_wait`, the only place it may block, and dispatches each ready event: accept a connection, read and parse a request, flush output, run a timer. Handlers must be short. Blocking or CPU-heavy work (disk reads, password hashing, a synchronous database driver) goes to a **worker pool**, whose completion returns asynchronously as a new event (dotted arrow). The failure point is a slow handler: while one callback runs for 200 ms, *every* connection on the loop waits 200 ms. To use more cores, run one loop per core (nginx workers, `SO_REUSEPORT`, Node.js cluster).

The Python program below is a complete event-loop echo server. On Linux, `selectors.DefaultSelector` uses `epoll`; on macOS, `kqueue`.

```
        """A single-threaded echo server: one event loop, many connections.

        On Linux, selectors.DefaultSelector is backed by epoll; on macOS/BSD by kqueue.
        """
        import selectors
        import socket

        sel = selectors.DefaultSelector()

        def accept(server: socket.socket) -> None:
            conn, _addr = server.accept()              # ready, so this will not block
            conn.setblocking(False)
            sel.register(conn, selectors.EVENT_READ, handle)

        def handle(conn: socket.socket) -> None:
            data = conn.recv(4096)                     # ready, so this will not block
            if data:
                conn.sendall(data)                     # simplification: assumes the
send buffer has room
            else:                                      # empty read = peer closed
                sel.unregister(conn)
                conn.close()

        def serve(host: str = "127.0.0.1", port: int = 9000) -> None:
            server = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
            server.setsockopt(socket.SOL_SOCKET, socket.SO_REUSEADDR, 1)
            server.bind((host, port))
            server.listen(1024)
            server.setblocking(False)
            sel.register(server, selectors.EVENT_READ, accept)
            print(f"selector = {type(sel).__name__}; listening on {host}:{port}")
            while True:                                # THE event loop
                for key, _mask in sel.select():        # block until >= 1 socket is
ready
                    callback = key.data
                    callback(key.fileobj)              # run the handler; it must not
block

        if __name__ == "__main__":
            serve()
```

Connect with `nc 127.0.0.1 9000` from several terminals; in testing it printed `selector = EpollSelector` and served 200 concurrent clients correctly.

What to notice:

- There is exactly one blocking call, `sel.select()`. Everything else runs only when the kernel has said it will not block.

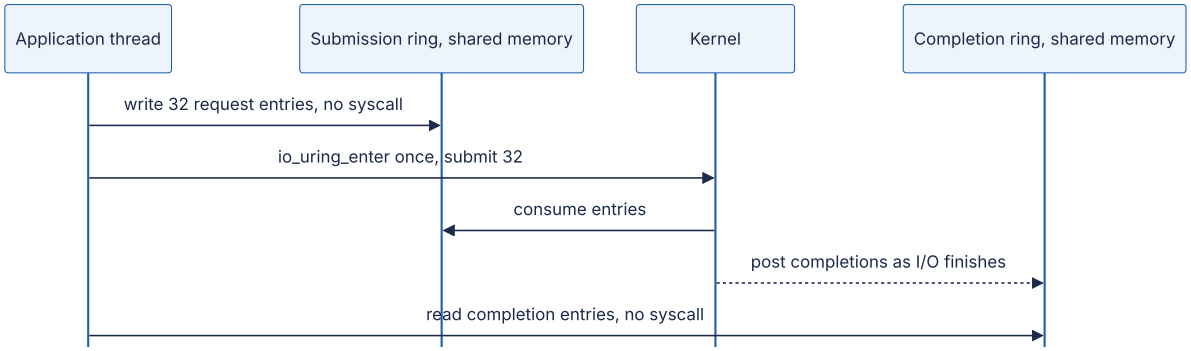
- `sendall` on a non-blocking socket can still fail if the client is slow to read; a production server keeps a per-connection output buffer and registers for `EVENT_WRITE`. Frameworks handle this for you.

6.13.5 Completion-based I/O and io_uring

Readiness APIs need one system call to learn a socket is ready and another to read it. **Completion-based** APIs instead let the application *submit* an operation and later be told it is *complete* (Windows I/O completion ports; Linux's older AIO worked well only for `O_DIRECT` files).

io_uring, added in Linux 5.1 (2019) by Jens Axboe, provides two ring buffers in memory shared between application and kernel: a **submission queue (SQ)** and a **completion queue (CQ)** [Axboe 2019].

Figure 6.11 — io_uring submission and completion rings.



Reading the diagram. The application writes request entries (opcode, descriptor, buffer, user tag) into the shared submission ring with plain memory writes, then submits any number with *one* `io_uring_enter` call. The kernel performs them, files and sockets alike, and posts results asynchronously to the completion ring (dotted arrow), possibly out of order; the tag matches results to requests. Reaping completions needs no system call, and in **SQPOLL** mode a kernel thread polls the submission ring so submission needs none either. Costs: a more complex programming model and a large new kernel attack surface. Google reported in 2023 that most kernel exploits submitted to its bug-bounty program involved io_uring and that it had restricted io_uring on ChromeOS, Android apps and its production servers [Google Security Blog 2023]; some container runtimes block it by default.

Table 6.6 — I/O models compared.

Model	How it works	Advantages	Disadvantages	Scales to	Choose when
Blocking, thread per connection	Each thread blocks in `read` / `write`	Simplest code; natural stack traces	Memory and switching per connection	Thousands of connections	Moderate concurrency; blocking libraries
Non-blocking + busy polling	Loop calling `read` until not `EAGAIN`	Lowest latency on a dedicated core	Burns a full core	Few connections	Kernel-bypass and trading systems
`select` / `poll`	Readiness for a set passed each call	Portable	$O(n)$ per call; `select` limited to 1,024	Hundreds	Small tools, portability
`epoll` / `kqueue`	Register once; wait for ready list	$O(\text{ready})$; mature	Readiness only; files still block	Millions of sockets	Network servers on Linux/BSD
`io_uring`	Shared submission/completion rings	Batching; async files and sockets; few syscalls	Newer; security restrictions; complex	Very high IOPS	Storage engines, proxies on modern Linux

6.14 File systems, journaling and fsync

6.14.1 What a file system does

A **file system** turns an array of numbered disk blocks into named, hierarchical files. Each file has an **inode** holding metadata (size, owner, permissions, timestamps) and the locations of its data blocks; a **directory** maps names to inode numbers. Creating `/data/log.txt` touches several structures: a new inode, the free-block bitmap, data blocks and the parent directory.

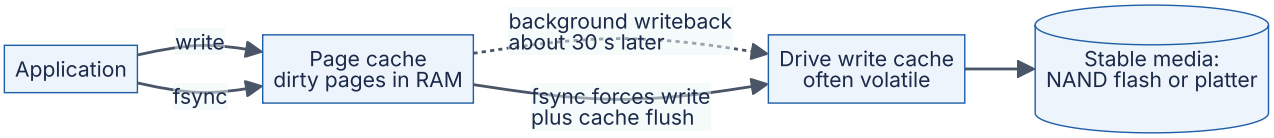
6.14.2 Crash consistency and journaling

A crash midway through those updates can leave a directory entry pointing at an uninitialized inode; older file systems needed a full-disk `fsck`, taking hours on large disks. A **journaling** file system uses a **write-ahead log** (§13.5): record the intended changes in a journal, commit, then apply them in place; after a crash, replay committed entries in seconds. ext4 offers three modes: **`data=journal`** (data and metadata both journaled: safest, slowest), **`data=ordered`** (the default: only metadata journaled, but data blocks are written before the metadata that points at them) and **`data=writeback`** (metadata only, no ordering: a crash can expose stale data). XFS journals metadata. **Copy-on-write** file systems such as ZFS and Btrfs never overwrite in place: they write new blocks and atomically switch a root pointer.

Journaling protects the file system's *own* structures. It does **not** make your application's data durable at any particular moment.

6.14.3 fsync and durability

Figure 6.12 — The write path from application to stable storage.



Reading the diagram. `write()` copies data into the page cache and returns; nothing is on disk yet. The dotted arrow is asynchronous background writeback (§6.6.6), roughly 30 s later by default. `fsync(fd)` is the synchronous path: it writes the file's dirty pages and metadata, waits for the device, and issues a **cache flush** so the drive's volatile write cache reaches stable media, the storage boundary that matters. Enterprise SSDs with **power-loss protection** capacitors can treat their cache as stable. Failure points: a crash loses dirty pages, a drive that ignores flushes loses its cache, and a writeback I/O error can lose data silently.

Durability pitfalls, each of which has caused real data loss:

1. **`write()` is not durable.** Without `fsync` (or `fdatasync`, which skips non-essential metadata), a crash loses acknowledged writes.
2. **The directory needs `fsync` too.** Creating or renaming a file changes the *directory*, which must also be synced [Linux man-pages: fsync(2); Pillai et al. 2014].
3. **"Write temp, then rename" needs `fsync` before the rename**, or a crash can leave the new name pointing at an empty file.
4. **`fsync` errors are not retryable.** On Linux a failed writeback may mark pages clean, so a second `fsync` can succeed although the data was lost. After the 2018 "fsyncgate" investigation, PostgreSQL crashes and recovers from its write-ahead log on any `fsync` failure [PostgreSQL Wiki: Fsync Errors; Rebello et al. 2020].
5. **macOS `fsync` does not flush the drive cache**; use `fcntl(fd, F_FULLFSYNC)` [Apple: fsync(2) man page].
6. **`O_DIRECT` is not `O_SYNC`**: bypassing the page cache does not make writes durable.
7. **Torn writes**: a crash mid-write can leave half-old, half-new sectors; databases detect this with checksums (§13.12).

The program below replaces a file atomically and durably on POSIX systems:

```
        """Atomically and durably replace a file on a POSIX system (Linux, macOS)."""
        import os

        def durable_replace(path: str, data: bytes) -> None:
            directory = os.path.dirname(os.path.abspath(path))
            tmp_path = path + ".tmp"

            fd = os.open(tmp_path, os.O_WRONLY | os.O_CREAT | os.O_TRUNC, 0o644)
            try:
                view = memoryview(data)
                while view:                           # write() may write fewer bytes
than asked
                    written = os.write(fd, view)
                    view = view[written:]
                os.fsync(fd)                          # 1. file contents reach stable
storage
            finally:
                os.close(fd)

            os.replace(tmp_path, path)                # 2. atomic rename over the old
file

            dir_fd = os.open(directory, os.O_RDONLY)
            try:
                os.fsync(dir_fd)                      # 3. the rename itself (a directory
entry) is durable
            finally:
                os.close(dir_fd)

        if __name__ == "__main__":
            durable_replace("config.json", b'{"version": 2}\n')
            with open("config.json", "rb") as f:
                print(f.read())
```

What to notice:

- Readers see the complete old or complete new file, never a mixture: `os.replace` is an atomic rename within one file system.
- Skipping step 1 risks an empty file under the new name; skipping step 3 risks the old file reappearing after a crash.
- If `os.fsync` raises, the function propagates the exception rather than retrying (pitfall 4). On macOS, add `fcntl.fcntl(fd, fcntl.F_FULLFSYNC)` for power-loss durability.

FORMULA

Group-commit throughput

$$X = \frac{B}{t_{\text{fsync}}}$$

Symbol	Meaning	Units
X	Maximum durable commits per second on one log	commits/s
B	Commits made durable by one `fsync` (batch size)	commits
t_{fsync}	Latency of one `fsync`	s

WORKED EXAMPLE

Worked example — Why databases batch fsyncs. An SSD without power-loss protection takes $t_{\text{fsync}} = 2$ ms (0.002 s) per `fsync`. One commit per `fsync`: $X = 1/0.002 =$ **500 commits/s**, no matter how fast the CPU is. **Group commit** waits briefly to collect concurrent commits into one `fsync`. With $B = 50$: $X = 50/0.002 =$ **25,000 commits/s**, at the price of up to a couple of milliseconds of extra latency per commit. **Interpretation.** Durable write throughput is set by fsync latency, not bandwidth. **Engineering implication:** databases batch commits into one log flush, and drives with power-loss protection raise the ceiling further. When a vendor quotes “100,000 writes per second”, ask how many `fsync`s that included.

Table 6.7 — Durability options for a write.

Option	What is guaranteed at return	Relative cost	Choose when
`write()` only	Data in page cache; lost on power failure or kernel crash	Lowest	Caches, temporary data, data you can regenerate
`write()` + `fdatasync()`	Data and size metadata on stable storage	High (one device flush)	Write-ahead logs and append-only files
`write()` + `fsync()`	Data and all metadata on stable storage	High	General durable files
+ `fsync()` on directory	The file’s name and existence are durable	Additional flush	Newly created or renamed files
`O_DSYNC` / `O_SYNC` on open	Every `write` behaves as if followed by `fdatasync` / `fsync`	Highest per write	Small, critical, infrequent writes
Replication instead of local fsync	Data in RAM on several machines	Network round trip	Distributed logs that accept correlated-failure risk (§27.3)

6.15 Concurrency models in practice

The five models below answer one question differently: *what represents a waiting request, and what does it cost?*

6.15.1 Thread per request

Each request gets an OS thread (usually from a pool) running blocking code start to finish: classic Tomcat servlets, Apache httpd's worker model, threaded Python WSGI servers. **Strengths:** sequential code, readable stack traces, parallelism across cores. **Weaknesses:** each waiting request costs a whole thread, capping concurrency by memory and switching overhead, and a slow dependency can tie up every pool thread.

6.15.2 Event loop (Node.js, nginx, Redis)

One thread runs an event loop (§6.13.4); a waiting request costs a small state object and a callback. Node.js runs JavaScript on one libuv loop; nginx runs one loop per worker process; Redis executes commands on one main thread, making each command trivially atomic. **Strengths:** tiny per-connection cost, no locks for loop-owned state. **Weaknesses:** one core per loop, and any blocking callback stalls every connection [Node.js Docs: Don't Block the Event Loop].

6.15.3 Actors (Erlang/OTP, Akka)

An **actor** is an isolated unit of state with a **mailbox**; actors share no memory, communicate only by asynchronous messages and process one message at a time, so their state has no data races [Hewitt et al. 1973]. Erlang processes, scheduled by the BEAM virtual machine with one scheduler thread per core, take a few hundred machine words each at creation [Erlang Docs: Efficiency Guide]. Erlang/OTP adds **supervision trees** that restart crashed actors ("let it crash") [Armstrong 2003]; Akka brings the model to the JVM. **Weaknesses:** unbounded mailboxes, extra plumbing for request/response, and hard reasoning about ordering across actors.

> INDUSTRY EXAMPLE
>
> **WhatsApp on Erlang.** WhatsApp built its messaging servers on Erlang/FreeBSD and reported in a 2012 engineering blog post more than two million simultaneous TCP connections on a single server, attributing it to lightweight Erlang processes and kernel tuning. *Evidence: Primary* — [WhatsApp Blog 2012]

6.15.4 Goroutines (Go)

Go multiplexes **goroutines** onto `GOMAXPROCS` OS threads (by default the number of usable CPUs). A goroutine starts with a 2 KiB stack that grows on demand. On network I/O the runtime parks the goroutine and registers the socket with its **netpoller** (built on `epoll` / `kqueue`), so blocking-style code gets event-loop efficiency; since Go 1.14 long-running goroutines can also be preempted. **Weaknesses:** shared memory still allows races and deadlocks (§6.9), and leaked goroutines accumulate silently. Java's **virtual threads** (JDK 21, 2023) apply the same idea to the JVM [OpenJDK JEP 444].

6.15.5 async/await (Python asyncio, JavaScript, C#, Rust)

async/await is syntax for event-loop code that reads sequentially. An `async` function is a **coroutine**; each `await` is a point where it may suspend and return control to the loop. Scheduling is **cooperative**: coroutines yield only at `await`.

```
        """10,000 concurrent 'requests', one thread, about one second."""
        import asyncio
        import time

        async def handle_request(i: int) -> int:
            await asyncio.sleep(1.0)        # stands in for a 1 s network call; yields
to the loop
            return i

        async def main() -> None:
            start = time.perf_counter()
            results = await asyncio.gather(*(handle_request(i) for i in range(10_000)))
            elapsed = time.perf_counter() - start
            print(f"{len(results)} requests finished in {elapsed:.2f} s on one thread")

        asyncio.run(main())
```

Output in testing: `10000 requests finished in 1.09 s on one thread`.

What to notice:

- 10,000 one-second waits overlap on one thread: this is concurrency without parallelism (§6.8).
- Replace `await asyncio.sleep(1.0)` with `time.sleep(1.0)` and the program takes about 10,000 seconds: one blocking call inside a coroutine blocks the whole loop.
- async is "contagious": a function that awaits must itself be `async`, so libraries split into synchronous and asynchronous versions (the "function color" problem).

6.15.6 Comparison and capacity

Table 6.8 — Concurrency models compared.

Aspect	Thread per request	Event loop	Actors	Goroutines / virtual threads	async/await
Unit of concurrency	OS thread	Callback + state	Actor with mailbox	Runtime-managed thread	Coroutine
Memory per waiting request (order of magnitude)	64 KiB–1 MiB touched stack + kernel task	~1 KiB or less	~1–3 KB	~2–8 KiB	~1–2 KiB
Scheduling	Preemptive, kernel	Cooperative, one thread	Runtime, per message	Runtime, mostly preemptive	Cooperative at `await`
Uses multiple cores	Yes	No (run one loop per core)	Yes	Yes	Only with multiple loops or executors
Shared-state safety	Locks needed	Safe within the loop	Safe by isolation	Locks or channels needed	Safe within one loop
Main failure mode	Thread exhaustion; context switching	Blocking the loop	Mailbox overflow	Goroutine leaks; races	Accidental blocking call
Code style	Sequential, blocking	Callbacks or promises	Message handlers	Sequential, blocking	Sequential with `await`
Examples	Tomcat, Apache httpd, Django with threads	nginx, Node.js, Redis	Erlang/OTP, Akka	Go servers, Java 21 virtual threads	FastAPI, aiohttp, Rust Tokio
Choose when	Moderate concurrency, blocking libraries	Many connections, light per-request CPU	Fault isolation, many stateful entities	High concurrency with simple code	High I/O concurrency in Python/JS/Rust

Memory figures are orders of magnitude for planning (as of 2026 runtimes), not measurements; measure your own service’s resident memory per connection.

FORMULA

Memory for concurrent connections

$$M_{\text{total}} = N \times (m_{\text{unit}} + m_{\text{conn}})$$

Symbol	Meaning	Units
M_{total}	Memory needed for concurrency overhead	bytes
N	Concurrent connections (or in-flight requests)	connections
m_{unit}	Resident memory per concurrency unit (thread stack + kernel task, or coroutine)	bytes
m_{conn}	Per-connection buffers (socket buffers, TLS state, request object)	bytes

WORKED EXAMPLE

Worked example — 10,000 and 100,000 connections. A chat gateway must hold $N = 10,000$ mostly idle WebSocket connections. Assume $m_{\text{conn}} = 20$ KB of socket buffers and TLS state per connection in every model.

Thread per connection (Java platform threads). Each thread reserves 1 MiB of virtual stack, but only touched pages are resident; assume 64 KiB touched + 16 KiB kernel stack + ~8 KiB other kernel state ≈ 88 KB. $M = 10,000 \times (88 + 20)$ KB **= 1.08 GB**. Workable, though with 10,000 schedulable threads. *Goroutines.* Assume 8 KiB per goroutine (≈ 8 KB). $M = 10,000 \times (8 + 20)$ KB **= 280 MB**.

Now scale to $N = 100,000$: threads need **10.8 GB** plus 100,000 kernel tasks (beyond typical `pids.max` and thread limits, and every wake-up is a context switch); goroutines need **2.8 GB**; an event loop with ~1 KB per connection needs about **2.1 GB**, dominated by socket buffers.

Interpretation. Thread-per-connection works at thousands of connections and becomes the bottleneck at hundreds of thousands, where per-connection buffers also start to dominate. **Engineering implication:** for connection-heavy services (gateways, push, chat; §9.9) choose event loops, goroutines or virtual threads; for CPU-heavy work, core count matters more than the model.

FORMULA

Thread-pool sizing

$$N_{\text{threads}} = \lambda \times W \qquad \text{and, for mixed CPU/I/O work,} \qquad N_{\text{threads}} \approx N_{\text{cpu}} \times U \times \left(1 + \frac{T_{\text{wait}}}{T_{\text{cpu}}}\right)$$

Symbol	Meaning	Units
N_{threads}	Threads needed to sustain the load	threads
λ	Request arrival rate	requests/s
W	Time a request occupies a thread	s
N_{cpu}	Available cores	cores
U	Target CPU utilization	dimensionless (0–1)
T_{wait}, T_{cpu}	Per-request time spent waiting and computing	ms

WORKED EXAMPLE

Worked example — Sizing a blocking service. A service receives $\lambda = 2,000$ requests/s; each request spends 10 ms on CPU and 90 ms waiting for a database ($W = 0.1$ s). Little's Law (§4.11): $N_{\text{threads}} = 2,000 \times 0.1 =$ **200 threads** in use on average. CPU check: $2,000 \times 0.010$ s = 20 core-seconds per second, so at least **20 cores**. With $N_{\text{cpu}} = 32$, $U = 0.7$: $N_{\text{threads}} \approx 32 \times 0.7 \times (1 + 90/10) = 224$, consistent with 200 [Goetz et al. 2006]. **Interpretation.** 200–250 threads is reasonable here. If the database slows to 900 ms, the same load needs $2,000 \times 0.91 \approx 1,820$ threads: a fixed pool of 250 saturates and requests queue. **Engineering implication:** bound the pool and the queue, set timeouts on downstream calls (§22.11), and shed load rather than letting a slow dependency consume every thread.

COMMON MISTAKE

"Async is faster." async/await and event loops do not make individual operations faster; they make *waiting* cheaper, so more requests can wait at once. For CPU-bound work they are no better than threads, and a single misplaced blocking call makes them much worse.

6.16 Summary and revision notes

SUMMARY

- A **process** is a running program with a private address space; a **thread** is an execution context sharing its process's memory. The PCB (`task_struct`) stores everything needed to resume. States: New → Ready ⇄ Running → Blocked → Ready → … → Terminated.
- A **context switch** costs ~1–5 µs directly, but cache and TLB refill can cost 10–100× more. Overhead fraction $f = C/(Q + C)$: it matters when threads run only microseconds between switches.
- **Scheduling** trades turnaround, response time and fairness. RR fixes FCFS's convoy effect; MLFQ learns interactivity; Linux uses weighted fair sharing (CFS from 2.6.23, EEVDF from 6.6). CPU quotas in containers can throttle a service even when the host is idle.
- **Virtual memory** translates addresses through page tables cached in the TLB. TLB reach = entries × page size; huge pages extend it. Major page faults cost 100 µs–10 ms, so even rare faults dominate average access time. The **page cache** holds file data; `mmap` maps it into memory; copy-on-write makes `fork` cheap.
- A **system call** costs ~100 ns or more versus ~1 ns for a function call; batch, use vDSO, or use shared rings (`io_uring`).
- **Concurrency** is about structure and overlapping waits; **parallelism** is simultaneous execution. Neither implies the other.
- A **race condition** is a timing-dependent bug; protect every read-modify-write of shared state as a **critical section**, and run race detectors in CI.
- Mutex for exclusion; semaphore to limit concurrency; condition variable (in a `while` loop) to wait for a predicate; atomics/CAS for single-word updates; read-write locks for long read-mostly sections; lock-free structures only from proven libraries, minding ABA.
- **Deadlock** needs all four Coffman conditions; break circular wait with lock ordering. Livelock → randomized backoff; starvation → fairness; priority inversion → priority inheritance (Mars Pathfinder, 1997).
- IPC: pipes, sockets, shared memory (fastest), message queues, signals (handle `SIGTERM`).
- I/O: blocking needs a thread per connection; `epoll` / `kqueue` readiness notification solved C10K; `io_uring` adds batched completion-based I/O. An event loop must never block.
- `write()` is not durable. Use `fsync` on the file *and* its directory, treat `fsync` errors as fatal, and batch commits (group commit $X = B/t_{\text{fsync}}$).
- Thread-per-request is simple but costs ~100 KB per connection; event loops, goroutines, virtual threads and async/await make waiting cheap. Size pools

> with Little’s Law and bound them.

6.17 Knowledge checkpoint

1. What is the difference between a program, a process and a thread?
2. Name five pieces of information stored in a PCB.
3. Why does a process go from Blocked to Ready rather than directly to Running?
4. Distinguish the direct and indirect costs of a context switch.
5. Three jobs of 100, 10 and 10 ms arrive together. What is the average turnaround time under FCFS (in that order) and under SJF?
6. How does a CPU limit in a container cause latency spikes on an idle host?
7. Calculate the TLB reach of 2,048 entries with 4 KiB pages and with 2 MiB pages.
8. What is the difference between a minor and a major page fault?
9. Why must a condition-variable wait be inside a `while` loop?
10. Describe the ABA problem in one or two sentences and give one remedy.
11. List the four Coffman conditions and the most practical way to break one.
12. Why does `epoll` not help with reading regular files?
13. List the three steps to durably replace a file and the consequence of skipping each.
14. A service handles 1,000 requests/s, each holding a thread for 250 ms. How many threads are busy on average?

Answers

1. A program is an executable file; a process is a running instance with its own address space and resources; a thread is one execution context (registers, stack) inside a process, sharing its memory.
2. Any five of: PID and parent PID, state, saved registers and program counter, scheduling priority and accounting, page-table pointer and memory map, open file table, signal handlers, credentials, resource limits.
3. The event that unblocked it does not mean a CPU is free; it must be chosen by the scheduler like any other ready task.
4. Direct: kernel work to save and restore state and choose the next task (~1–5 µs). Indirect: slower execution afterwards because caches and TLB hold the previous thread’s state.
5. FCFS: completions 100, 110, 120 → average 110 ms. SJF: 10, 20, 120 → average 50 ms.
6. CFS bandwidth control gives the cgroup a quota per period (default 100 ms). Several threads exhaust it early and the cgroup is throttled for the rest of the period, delaying requests regardless of host load.
7. 2,048 × 4 KiB = 8 MiB; 2,048 × 2 MiB = 4 GiB.

8. A minor fault needs no I/O (page already in RAM, or a fresh zero page); a major fault reads from storage and blocks the thread for 100 µs–10 ms.
9. Under Mesa semantics another thread may change the state before the woken waiter reacquires the lock, and spurious wake-ups are allowed.
10. A CAS succeeds because a location again holds value A, although it changed to B and back in between, so the CAS acts on stale assumptions. Remedies: version-tagged pointers, hazard pointers, epoch-based reclamation.
11. Mutual exclusion, hold and wait, no preemption, circular wait. Break circular wait with a global lock order.
12. Regular files are always reported ready, yet reads can block on disk. Use a thread pool or `io_uring`.
13. `fsync` the temporary file (else the new name may point at empty data), rename atomically (else readers may see a partial file), `fsync` the directory (else the old file may reappear after a crash).
14. Little's Law: 1,000 × 0.25 = 250 threads.

6.18 Interview questions

Basic

Q1. What is the difference between a process and a thread, and when would you choose processes? Answer. A process has its own address space; threads share their process's memory and file descriptors but have their own stacks and registers. Threads communicate cheaply and switch faster; processes isolate faults. Choose processes for isolation (untrusted code, non-thread-safe libraries, PostgreSQL backends) or to bypass a GIL; threads for low-latency sharing of large in-memory state.

Q2. What is a race condition? Give an example and two fixes. Answer. A bug whose outcome depends on the interleaving of concurrent operations; e.g. two threads both read 5 and both write 6. Fixes: a mutex around the read-modify-write, or one atomic operation (atomic add, CAS loop); across services, transactions or conditional writes. Tests rarely reveal races, so use race detectors.

Q3. What is a deadlock and how do you prevent it in application code? Answer. A cycle of threads each waiting for a resource held by the next, requiring all four Coffman conditions. Acquire locks in one global order, never hold locks across I/O or unknown call-backs, use `tryLock` with timeouts, and prefer single-owner state or message passing. Detect with thread dumps.

Intermediate

Q4. Your service's p99 latency doubled after you increased the worker pool from 64 to 2,000 threads on a 16-core machine. Why might that be? Answer. If the work is CPU-bound, 2,000 runnable threads on 16 cores each wait behind ~125 others; involuntary switches multiply and evict caches, so throughput falls while queueing grows, and lock contention rises. Check `vmstat` (cs, run queue), voluntary versus involuntary switches and lock profiles. Size the pool with Little's Law and the CPU/wait ratio, with a bounded queue and load shedding. If the work is I/O-bound, async or virtual threads are cheaper than a huge pool.

Q5. Explain how an event loop serves 10,000 connections on one thread, and what breaks it. Answer. Non-blocking sockets are registered with `epoll` / `kqueue`; the loop sleeps in one wait call and runs short handlers for the ready sockets, so a waiting connection costs a small state object, not a thread. It breaks when a handler blocks or burns CPU (synchronous DB driver, large JSON parse, file I/O), stalling every connection. Mitigations: worker pools, one loop per core, event-loop-lag monitoring.

Q6. A database acknowledges writes after `write()` but before `fsync()`. What can go wrong, and how do real databases make commits durable but fast? Answer. A crash loses data still in the page cache, so acknowledged commits vanish. Durable systems append to a write-ahead log and `fdatasync` before acknowledging, using group commit to amortize flushes ($X = B/t_{\text{fsync}}$); they `fsync` directories after creating files, treat `fsync` errors as fatal, and use drives with power-loss protection. Alternatively, replicate to other machines before acknowledging, trading flush latency for a network round trip and correlated-failure risk.

Advanced

Q7. Explain priority inversion with a real example and how to prevent it, including outside real-time systems. Answer. A high-priority task blocks on a lock held by a low-priority task, which a medium-priority task preempts, so the high task waits indefinitely. Mars Pathfinder (1997) reset repeatedly because a VxWorks mutex shared by a low-priority weather task and a high-priority bus task lacked priority inheritance; JPL enabled it remotely. Prevention: priority inheritance or ceiling locks, no locks shared across priority levels, short critical sections. In servers, isolate pools and resources so background jobs cannot hold what user traffic needs.

Q8. Compare epoll and io_uring. When would you adopt io_uring? Answer. `epoll` is readiness-based: it says a socket can be read, then a separate call reads it, and file reads can still block. `io_uring` is completion-based, with shared submission and completion rings, giving batching, asynchronous file I/O and, with SQPOLL, near-zero system calls. Adopt it for high-IOPS storage engines or proxies where syscall overhead is a mea-

sured bottleneck, accepting complexity, kernel-version dependence and security restrictions. For typical web services, `epoll` via a mature runtime is enough.

Q9. Design the concurrency model for a WebSocket gateway holding 1 million mostly idle connections across a fleet. Justify it with numbers. Answer. Thread-per-connection at ~100 KB each needs ~100 GB and a million kernel tasks: impractical. An event loop or goroutines at ~1–8 KB plus ~20 KB of socket and TLS buffers needs ~25–30 GB in total; spread it over, say, 10 nodes × 100,000 connections so one node loss affects 10 %. Run one loop per core (or Go with GOMAXPROCS = cores), raise file-descriptor limits, size socket buffers deliberately, push heavy work to other services via queues, and drain connections gradually on `SIGTERM` to avoid reconnect storms (§9.9).

6.19 Practical exercises

1. **Watch process states.** Run `sleep 100 &`, a CPU loop (`yes > /dev/null &`) and `cat` reading from a terminal. Use `ps -o pid,stat,wchan:20,cmd` to identify R and S states. Kill the parent of a child that has exited without being reaped and observe the zombie.
2. **Measure a context switch.** Run the following ping-pong program, once normally and once pinned to one core with `taskset -c 0`. Explain the difference. On one test VM for this chapter, it gave about 24 µs per round trip unpinned and about 4 µs pinned, because cross-core wake-ups add inter-processor interrupts and idle-state exits.

```
    """Two processes bounce one byte over a pair of pipes (POSIX only: uses fork).

    Each round trip forces at least two blocking reads and wake-ups, so the
    time per round trip upper-bounds the cost of two context switches plus
    four system calls and Python interpreter overhead.
    """
    import os
    import time

    ROUNDS = 100_000

    parent_to_child_r, parent_to_child_w = os.pipe()
    child_to_parent_r, child_to_parent_w = os.pipe()

    pid = os.fork()
    if pid == 0:                                    # child process
        for _ in range(ROUNDS):
            os.read(parent_to_child_r, 1)           # block until parent writes
            os.write(child_to_parent_w, b"x")       # wake the parent
        os._exit(0)

    start = time.perf_counter()
    for _ in range(ROUNDS):
        os.write(parent_to_child_w, b"x")           # wake the child
        os.read(child_to_parent_r, 1)               # block until child answers
    elapsed = time.perf_counter() - start
    os.waitpid(pid, 0)
    print(f"{elapsed / ROUNDS * 1e6:.1f} us per round trip")
```

3. **Find the race.** Run the Go program in §6.9 with `go run -race .`. Then write a version that uses a channel owned by one goroutine instead of a mutex, and confirm the race detector is silent.
4. **Break the event loop.** Add `time.sleep(2)` inside `handle()` in the echo server of §6.13.4, connect three clients, and measure how long the third waits. Fix it by moving the slow work to a `concurrent.futures.ThreadPoolExecutor`.
5. **Count system calls.** Run `strace -c python3 -c "open('/etc/hostname').read()"` and then the same for a program that copies a 100 MB file using 1-byte reads versus 64 KiB reads. Relate the time difference to §6.7.
6. **Durability check.** Write a program that appends 10,000 small records with and without `fsync` after each, and with one `fsync` per 100 records. Compute the commits per second and compare with the group-commit formula in §6.14.3.

6.20 Design challenges

1. **Log-ingestion agent.** Design a host agent that tails 500 log files, batches lines, and ships them to a remote collector at 50 MB/s, surviving agent restarts without losing or duplicating more than one batch. Decide: threads versus event loop versus `io_uring`; how offsets are made durable (`fsync` strategy and cost); how backpres-

sure works when the collector is slow; how the agent behaves when the disk fills. Justify each choice with numbers from this chapter.

2. **Multi-tenant job runner.** Design a single-machine runner for untrusted user jobs that guarantees each tenant a fair CPU share and a memory cap, and kills runaway jobs without affecting others. Discuss processes versus threads, cgroup CPU weights versus quotas (and throttling), OOM behavior, signals for graceful termination, and how to prevent a tenant from starving others through a shared lock or file system. Relate to §47.
3. **In-memory rate limiter.** Design a per-API-key rate limiter inside a service handling 200,000 requests/s on 32 cores. Compare a global mutex-protected map, a sharded map with per-shard locks, per-core counters merged periodically, and atomic CAS on token buckets. Estimate contention, explain where false sharing appears (§5.4), and state which you would ship and why (see §22.4).

6.22 Open verification items

- Exact LWN article URL and date for [Corbet 2023] (lwn.net was unreachable from the authoring environment). EEVDF merge in 6.6 and the 0.75 ms × (1 + log2 ncpus) base slice were confirmed against the v6.6 scheduler pull request and commit e4ec3318; whether later 6.x releases changed the default is not verified.
- Magnitude of indirect context-switch cost reported by [Li et al. 2007]; direct-cost range 1–5 µs on current hardware.
- Mars Pathfinder details (task names, watchdog mechanism, remote patch via onboard interpreter) against Reeves’s original text; Cornell mirror URL.
- Google Security Blog 2023 io_uring statistics and the exact scope of the restriction; full article URL.
- WhatsApp 2012 “2 million connections” blog post URL and wording.
- Erlang process initial size (“a few hundred words”) for the current OTP release; Python 3.14 free-threading status.
- Whether Dijkstra’s banker’s algorithm should be cited to EWD 123 or EWD 108.
- MySQL “Connection Interfaces” page title for thread-per-connection.
- TLB entry counts (1,000–3,000 second-level entries) for current server CPUs.

Chapter 7 — Networking Fundamentals

> **Level:** 1–2 · **Track:** Shared · **Estimated reading time:** 5 h

Every system in this book is a set of computers that talk to each other. A database replica talks to its primary, a browser talks to a load balancer, and a model server streams tokens to a phone. Whenever two computers talk, the network sets hard limits on how fast they can do it, how often it fails, and what it costs. Those limits come from physics (the speed of light), from economics (the cost of bandwidth), and from decades-old protocol decisions that you cannot change. You can design around them only if you understand them.

This chapter builds the network up from nothing. We start with the layered model that lets thousands of independently built protocols cooperate, then follow a single request down through addressing, routing, name resolution, transport, security and application protocols. We finish by tracing everything that happens when you type a URL into a browser. Throughout, the goal is quantitative intuition: by the end you should be able to estimate, with arithmetic, how long a request will take and why.

7.1 Learning objectives

After this chapter you should be able to:

- Explain the OSI and TCP/IP layer models and describe how **encapsulation** wraps application data in transport, network and link headers.
- Read and compute IPv4 and IPv6 CIDR blocks: network address, broadcast address, usable host count and whether an address falls in a subnet.
- Describe how packets are routed inside a network and between autonomous systems with BGP, and explain how anycast steers users to a nearby server.
- Draw the DNS resolution sequence (stub, recursive resolver, root, TLD, authoritative), name the common record types, and reason about TTLs and the limits of DNS-based load balancing.
- Explain TCP’s three-way handshake, four-way close, TIME_WAIT, sequence numbers, retransmission, flow control and congestion control (slow start, AIMD, CUBIC, BBR), and identify head-of-line blocking.
- Decide when UDP is the right transport and what you must rebuild on top of it.
- Compare HTTP/1.1, HTTP/2 and HTTP/3 (over QUIC) and justify a choice for a given workload.

- Sequence the TLS 1.3 handshake, explain certificate validation, and state the security caveats of 0-RTT.
- Distinguish forward proxies from reverse proxies, and explain NAT, firewalls and cloud security groups.
- Decompose latency into propagation, transmission, queuing and processing delay; compute the bandwidth-delay product; and apply the Mathis formula to estimate TCP throughput under loss.
- Quantify the cost of connection setup and size a connection pool.
- Describe leaf–spine (Clos) datacenter fabrics and why east–west traffic dominates modern datacenters.

7.2 Prerequisites

- Units: bits vs bytes, SI prefixes, rates — §4.5 (every calculation here converts between bits per second and bytes).
- Percentiles and tail latency — §4.8 (network latency is heavy-tailed; averages mislead).
- Little's Law — §4.11 (used to size connection pools in §7.16).
- Latency numbers every engineer should know — §4.17 (this chapter derives several of them).
- Processes, sockets as file descriptors, and I/O models (blocking, epoll) — §6.7 and §6.13 (a TCP connection is a kernel object your process reads and writes).

No prior networking knowledge is assumed.

7.3 OSI and TCP/IP models

7.3.1 The postal analogy

Imagine you want to send a letter to a friend in another country. You write the letter (the content). You put it in an envelope and write your friend's name on it. The post office puts your envelope into a mail sack addressed to a sorting center in the destination city. The mail sack goes into a truck, then a plane, then another truck. At each sorting center, a worker reads only the sack label, not your letter, and decides where it goes next. At the far end, the sack is opened, the envelope is delivered to the right house, and your friend opens it and reads the letter.

Three ideas in this story are the foundation of all computer networking:

1. **Layering.** Each participant does one job and trusts the others to do theirs. The letter writer does not care whether the mail flies or sails. The truck driver does not read letters.

2. **Encapsulation.** Each layer wraps the thing it was given in its own envelope with its own address, and the matching layer at the far end unwraps it.
3. **Hop-by-hop forwarding.** Intermediate sorting centers look only at the outer address and forward toward the destination. They do not need the whole route in advance.

Computer networks work the same way. Your application writes bytes. The operating system wraps them in a **segment** with port numbers (which program on the machine), then in a **packet** with IP addresses (which machine on the planet), then in a **frame** with hardware addresses (which device on this particular wire). Routers along the way read the packet header and forward it, and the receiving machine unwraps each layer in reverse.

DEFINITION

Definition — Protocol. A set of rules two parties agree on for exchanging messages: message formats, the meaning of each field, and the actions each side takes on sending, receiving or timing out. A **protocol stack** is a set of protocols layered so that each uses the service provided by the layer below and offers a service to the layer above.

DEFINITION

Definition — Encapsulation. The process by which each layer of the stack prepends its own header (and sometimes appends a trailer) to the data unit handed down by the layer above, treating that data unit as an opaque payload. **Decapsulation** is the reverse at the receiver.

Why does this exist?

In the 1970s, every computer vendor had its own networking scheme, and machines from different vendors could not talk. Layering solved two problems. First, it made **interoperability** possible: if two vendors implement the same protocol at a layer, their machines can communicate regardless of what is above or below. Second, it made **independent evolution** possible: Wi-Fi replaced Ethernet cables at the bottom and HTTP/3 replaced HTTP/1.1 at the top, while IP in the middle stayed the same. This “narrow waist” design, with many link technologies below and many applications above one common Internet Protocol, is the main reason the Internet scaled from a few dozen hosts in 1970 to billions of devices.

7.3.2 The two models

There are two reference models you will hear about. The **OSI model** (Open Systems Interconnection), standardized by ISO in the early 1980s, has seven layers. It is a teach-

ing vocabulary; the OSI protocol suite itself lost to TCP/IP in the market. The **TCP/IP model** (also called the Internet model) has four or five layers and describes the protocols the Internet actually runs. Engineers mix the vocabularies freely: “an L4 load balancer” uses the OSI number for the transport layer, and “an L7 proxy” uses the OSI number for the application layer.

Table 7.1 — OSI and TCP/IP layers compared.

OSI layer	TCP/IP layer	Job	Example protocols	Data unit (PDU)	Address used
7 Application	Application	Meaning of messages for a specific application	HTTP, DNS, SMTP, gRPC	Message	URL, hostname
6 Presentation	(folded into application)	Encoding, compression, encryption	TLS*, JSON, Protobuf	—	—
5 Session	(folded into application)	Dialogue management, resumption	TLS sessions*, RPC sessions	—	—
4 Transport	Transport	Process-to-process delivery; reliability; flow and congestion control	TCP, UDP, QUIC**	Segment (TCP), datagram (UDP)	Port number
3 Network	Internet	Host-to-host delivery across many networks	IPv4, IPv6, ICMP	Packet	IP address
2 Data link	Link	Delivery across one physical network segment	Ethernet, Wi-Fi (802.11)	Frame	MAC address
1 Physical	Link (or separate physical layer)	Bits as voltages, light or radio	Copper, fiber, radio	Bit/symbol	—

*TLS does not fit cleanly: it runs on top of TCP but below HTTP, so people place it at 5, 6 or “4.5”. **QUIC runs on top of UDP yet provides transport services (reliability, streams, congestion control), so it is a transport protocol implemented in user space.

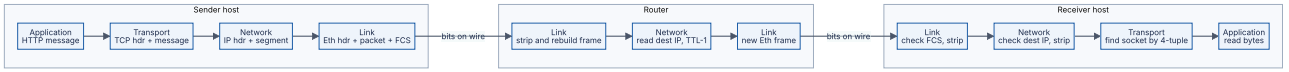
Do not memorize the OSI layers 5 and 6 as separate things that exist in real stacks; they do not. What matters in practice is the five-layer view: physical, link, network, transport, application. This is the organizing structure of the standard textbook treatment [Kurose and Ross 2021], which is the recommended companion for this chapter.

7.3.3 How encapsulation works internally

Follow one HTTP request from a browser to a web server.

1. **Application.** The browser produces the bytes `GET /index.html HTTP/1.1\r\nHost: example.com\r\n\r\n` (about 40 bytes) and calls `write()` on a socket.
2. **Transport.** The kernel's TCP implementation copies the bytes into the socket's send buffer, splits them into segments no larger than the **maximum segment size (MSS)**, and prepends a 20-byte TCP header (up to 60 bytes with options) containing source port (say 52,814), destination port 443, a sequence number, an acknowledgment number, flags and a window size.
3. **Network.** IP prepends a 20-byte IPv4 header (or a 40-byte IPv6 header) containing source and destination IP addresses, a time-to-live (TTL, renamed "hop limit" in IPv6) counter, and the protocol number of the payload (6 for TCP, 17 for UDP).
4. **Link.** The network interface driver looks up the MAC address of the next hop (the local router) using ARP (IPv4) or Neighbor Discovery (IPv6), and prepends a 14-byte Ethernet header (destination MAC, source MAC, EtherType) and appends a 4-byte frame check sequence (a CRC for error detection).
5. **Physical.** The network card serializes the frame onto the wire as electrical or optical symbols.
6. **Each router** receives the frame, checks the CRC, strips the Ethernet header, reads the IP destination, decrements the TTL, looks up the next hop, and wraps the packet in a *new* link-layer frame for the next link. The IP packet travels end to end; link-layer frames live for one hop only.
7. **The server** decapsulates in reverse: the NIC checks the frame, IP checks the destination address, TCP uses the (source IP, source port, destination IP, destination port) **4-tuple** to find the right socket, and the application reads the original bytes.

Figure 7.1 — Encapsulation down the sender's stack and decapsulation up the receiver's.



Reading the diagram. The left group is the sending host; data flows down its stack, gaining one header per layer. The middle group is a single router: it operates only up to the network layer, stripping the incoming Ethernet frame, reading and modifying the IP header (decrementing TTL), and building a fresh frame for the outgoing link. The right group is the receiving host, where data flows up and each layer removes its own header. All arrows are synchronous hand-offs within the same packet's journey; nothing here is queued asynchronously except inside each device's transmit buffer, which is a failure point (buffers overflow and drop packets, see §7.15). Storage boundaries are absent: the network stores nothing durably. To scale, you add links and routers; the layered design means hosts need not change.

Mathematical foundations: header overhead

FORMULA

Protocol efficiency (goodput fraction)

$$\eta = \frac{P}{P + H}$$

Symbol	Meaning	Units
η	Fraction of transmitted bytes that are application payload	dimensionless (0–1)
P	Application payload bytes per frame	bytes
H	Total per-frame overhead from all layers (headers, trailers, and on Ethernet the preamble and inter-frame gap)	bytes

WORKED EXAMPLE

Worked example — How much of a gigabit link carries your data?

A standard Ethernet **maximum transmission unit (MTU)** is 1,500 bytes: the largest IP packet a frame can carry. Inside that, IPv4 uses 20 bytes and TCP 20 bytes, plus 12 bytes for the commonly enabled TCP timestamp option.

1. TCP payload per packet: $1500 - 20 - 20 - 12 = 1448$ bytes.
2. On-the-wire cost per frame: 1,500 (packet) + 14 (Ethernet header) + 4 (FCS) + 8 (preamble) + 12 (inter-frame gap) = 1,538 bytes.
3. Efficiency: $\eta = 1448/1538 \approx 0.941$.
4. Maximum TCP goodput on 1 Gbps Ethernet: $0.941 \times 1000 \approx 941$ Mbps.

Interpretation: about 6% of a full-size frame is overhead. Now consider a tiny 40-byte request carried in one packet: the wire cost is $40 + 20 + 32 + 38 = 130$ bytes, so efficiency is $40/130 \approx 31\%$.

Engineering implication: small messages are dominated by header cost (and, more importantly, by per-packet processing cost in CPUs and switches). This is one reason systems **batch** small writes (§23.8) and why the 941 Mbps "real" ceiling of gigabit Ethernet is a well-known measurement in `iperf` tests.

Common misconceptions

COMMON MISTAKE

“Layer 7 means HTTP and Layer 4 means TCP, so a Layer 4 device cannot see anything about HTTP.” Roughly right, but the numbers are labels for *what a device inspects*, not for physical boxes. A “Layer 4 load balancer” makes decisions using IP addresses and ports; a “Layer 7 load balancer” parses HTTP and can route on path or header. Both receive the full packet (§19.3).

7.4 IP addressing, IPv4/IPv6, subnets and CIDR

7.4.1 What an IP address is

DEFINITION

Definition — IP address. A numeric identifier assigned to a network interface that the Internet Protocol uses to deliver packets. An **IPv4** address is 32 bits, written as four decimal octets (`203.0.113.25`) [RFC 791]. An **IPv6** address is 128 bits, written as eight groups of four hexadecimal digits separated by colons (`2001:db8:0:1::25`) [RFC 8200].

First-principles explanation

A postal address is hierarchical: country, city, street, house number. A sorting center in another country only needs to read the country to forward the letter; only the local post office reads the house number. IP addresses are hierarchical in the same way, but the split point is flexible. The leading bits form the **network prefix** (which network), and the trailing bits identify the **host** within that network. Routers far away only need the prefix.

Why does this exist?

Routers must decide where to send every packet in nanoseconds. If they had to store a route for every one of billions of devices, their tables would not fit in fast memory. Grouping addresses into prefixes lets a router store one entry for millions of hosts. The original 1981 scheme fixed the split at 8, 16 or 24 bits (“classes A, B, C”), which wasted addresses: an organization needing 300 addresses had to take a class B with 65,536. **Classless Inter-Domain Routing (CIDR)**, introduced in 1993 and specified today in RFC 4632, allows the split at any bit.

7.4.2 CIDR notation and subnet arithmetic

DEFINITION

Definition — CIDR block. An address range written as `address/prefix-length`, for example `192.168.10.64/26`. The prefix length n says that the first n bits identify the network; the remaining $32 - n$ bits (IPv4) or $128 - n$ bits (IPv6) identify hosts. The **subnet mask** is the same information as a dotted number with n one-bits followed by zeros (`/26` = `255.255.255.192`).

FORMULA

Addresses in a CIDR block

$$N_{\text{addr}} = 2^{W-n} \qquad N_{\text{hosts,IPv4}} = 2^{32-n} - 2$$

Symbol	Meaning	Units
N_{addr}	Total addresses in the block	addresses
W	Address width: 32 for IPv4, 128 for IPv6	bits
n	Prefix length	bits
$N_{\text{hosts,IPv4}}$	Assignable IPv4 hosts on a traditional subnet: subtract the **network address** (all host bits 0) and the **broadcast address** (all host bits 1)	addresses

The "−2" applies to ordinary IPv4 LAN subnets. Point-to-point `/31` links (RFC 3021) and single-host `/32` routes are exceptions, and cloud providers reserve more: AWS reserves five addresses in every VPC subnet (network, VPC router, DNS, one reserved for future use, broadcast), as of 2025 [AWS Docs: VPC subnets].

WORKED EXAMPLE

Worked example 1 — Which subnet is 192.168.10.77/26 in?

1. A `/26` leaves $32 - 26 = 6$ host bits, so each subnet holds $2^6 = 64$ addresses.
2. The mask is 26 one-bits: `11111111.11111111.11111111.11000000` = `255.255.255.192`.
3. Only the last octet is split. Subnets start at multiples of 64 in that octet: .0, .64, .128, .192.
4. 77 lies between 64 and 127, so the network address is **192.168.10.64**.
5. Broadcast address: last address of the block = 64 + 64 − 1 = **192.168.10.127**.
6. Usable hosts: **192.168.10.65 – 192.168.10.126**, which is $64 - 2 = 62$ hosts.

Bitwise check: 77 = `01001101`; AND with mask `11000000` gives `01000000` = 64. Correct.

WORKED EXAMPLE

Worked example 2 — Carving a cloud VPC into subnets.

You are given the VPC range `10.0.0.0/16` and want equal subnets across three availability zones, each with public and private tiers (six subnets), leaving room to grow.

1. The VPC has $2^{32-16} = 65,536$ addresses.
2. Choose `/20` subnets: $2^{20-16} = 16$ subnets of $2^{12} = 4,096$ addresses each. Six are used now; ten remain for growth.
3. With `/20`, the third octet advances in steps of $4096/256 = 16$: `10.0.0.0/20`, `10.0.16.0/20`, `10.0.32.0/20`, … , `10.0.240.0/20`.
4. Usable per subnet on AWS: $4096 - 5 = 4,091$.
5. Membership test: is `10.0.37.200` in `10.0.32.0/20`? The block covers third-octet values 32–47 (32 + 16 − 1). 37 is in that range, so **yes**; its range is `10.0.32.0` – `10.0.47.255`.

Interpretation: a `/20` per subnet sounds generous, but container platforms that give every pod its own VPC address (for example, the AWS VPC CNI for Kubernetes) can consume thousands of addresses per subnet. Running out of IPs in a subnet is a common production incident; size for pods, not for nodes (Ch 42).

WORKED EXAMPLE

Worked example 3 — Do two networks overlap?

Team A uses `10.0.0.0/16` (10.0.0.0–10.0.255.255). Team B uses `10.0.128.0/17` (10.0.128.0–10.0.255.255). B's range lies entirely inside A's, so the two VPCs **overlap** and cannot be peered or connected with simple routing: a packet to 10.0.200.1 would be ambiguous. Engineering implication: allocate non-overlapping RFC 1918 ranges centrally (an IP address management plan) *before* teams create networks; renumbering later is painful.

Table 7.2 — CIDR quick reference (IPv4).

Prefix	Mask	Addresses	Typical use
/8	255.0.0.0	16,777,216	Large private network (10.0.0.0/8)
/16	255.255.0.0	65,536	A cloud VPC
/20	255.255.240.0	4,096	A large subnet per availability zone
/24	255.255.255.0	256	Classic LAN; smallest prefix widely accepted in global BGP
/26	255.255.255.192	64	Small subnet
/30	255.255.255.252	4	Legacy point-to-point link (2 usable)
/31	255.255.255.254	2	Point-to-point link (RFC 3021, both usable)
/32	255.255.255.255	1	A single host route

7.4.3 Private and special-purpose ranges

Some ranges are reserved and never routed on the public Internet. The most important are the **private** ranges of RFC 1918, which any organization may reuse internally; they reach the Internet only through NAT (§7.13).

Table 7.3 — Special-purpose address ranges.

Range	Size	Purpose
10.0.0.0/8	16,777,216	Private (RFC 1918)
172.16.0.0/12	1,048,576	Private (RFC 1918): 172.16.0.0–172.31.255.255
192.168.0.0/16	65,536	Private (RFC 1918), common in homes
100.64.0.0/10	4,194,304	Shared address space for carrier-grade NAT (RFC 6598)
127.0.0.0/8	16,777,216	Loopback (`127.0.0.1` = this machine)
169.254.0.0/16	65,536	Link-local; cloud instance metadata services commonly live at `169.254.169.254`
192.0.2.0/24, 198.51.100.0/24, 203.0.113.0/24	256 each	Documentation examples (RFC 5737); used in this book
`::1/128`	1	IPv6 loopback
`fe80::/10`	—	IPv6 link-local
`fc00::/7`	—	IPv6 unique local addresses (RFC 4193), the IPv6 analog of private space
`2000::/3`	—	IPv6 global unicast
`2001:db8::/32`	—	IPv6 documentation (RFC 3849)

7.4.4 IPv4 exhaustion and IPv6

IPv4 offers $2^{32} \approx 4.29$ billion addresses, fewer than the number of connected devices. The regional Internet registries ran out of freely allocatable IPv4 space during the 2010s, and IPv4 addresses are now bought and sold. Two responses coexist: NAT (§7.13), which lets many devices share one public address, and IPv6, which offers $2^{128} \approx 3.4 \times 10^{38}$ addresses.

IPv6 makes several other changes [RFC 8200]:

- **Fixed 40-byte header** with optional extension headers, simpler for hardware to parse.
- **No fragmentation by routers.** Only the sender fragments; routers send an ICMPv6 “Packet Too Big” message instead, so path MTU discovery is mandatory.
- **No header checksum** (the link and transport layers already check).
- **Standard /64 subnets.** A single LAN gets 2^{64} addresses, enough for hosts to self-assign addresses (SLAAC). A typical site receives a `/48`, which holds $2^{64-48} = 65,536$ `/64` subnets.
- **Notation shortcuts.** Leading zeros in a group may be dropped, and one run of all-zero groups may be replaced by `::`. So `2001:0db8:0000:0000:0000:0000:0000:0025` is

`2001:db8::25`.

Clients with both IPv4 and IPv6 use **Happy Eyeballs** (RFC 8305): they start connecting over IPv6 and, if that has not succeeded within a short delay (around 250 ms is recommended), race an IPv4 attempt, using whichever connects first. This prevents broken IPv6 paths from adding seconds of delay.

> COMMON MISTAKE
>
> **"Private addresses are a security feature."** RFC 1918 ranges are not routed on the Internet, which incidentally makes hosts unreachable from outside without NAT rules. But reachability is not access control: a compromised host inside the network reaches them freely. Use firewalls and authentication (§7.14, §10.10), not address choice, for security.

7.5 Routing basics, BGP and anycast

7.5.1 Forwarding and longest-prefix match

> DEFINITION
>
> **Definition — Routing and forwarding. Forwarding** is the per-packet act of choosing an outgoing interface for a packet based on its destination address and the **forwarding table**. **Routing** is the control-plane process of building those tables by exchanging reachability information with other routers.

Each router holds a table of prefixes and next hops. When a packet arrives, the router selects the **most specific** (longest) prefix that contains the destination. This rule is called **longest-prefix match**.

WORKED EXAMPLE

Worked example — Longest-prefix match.

A router has these entries:

Prefix	Next hop
0.0.0.0/0 (default route)	ISP uplink
10.0.0.0/8	Core router A
10.1.0.0/16	Core router B
10.1.2.0/24	Access switch C

- Destination `10.1.2.3` matches /0, /8, /16 and /24. Longest is /24, so it goes to **C**.
- `10.1.9.9` matches /0, /8, /16: goes to **B**.
- `10.200.0.1` matches /0 and /8: goes to **A**.
- `8.8.8.8` matches only /0: goes to the **ISP uplink**.

Engineering implication: longest-prefix match lets operators override broad routes with specific ones. It also lets an attacker or a misconfiguration hijack traffic by announcing a *more specific* prefix than the legitimate owner, as the industry example below shows.

When several equally good next hops exist, routers use **equal-cost multi-path (ECMP)** routing: they hash each packet's flow identifiers (the 5-tuple of protocol, source and destination address and port) to pick one path. All packets of one flow take the same path, which avoids reordering, while different flows spread across paths. ECMP is the foundation of datacenter fabrics (§7.17) and of horizontally scaled load balancers (§19.8).

7.5.2 Interior and exterior routing

The Internet is a network of networks. Each independently operated network, such as an ISP, a cloud provider or a large enterprise, is an **autonomous system (AS)** identified by an AS number (ASN). Routing happens at two levels:

- **Interior gateway protocols** (OSPF, IS-IS) run *inside* an AS. They compute shortest paths using link costs, converge in seconds or less, and assume everyone is cooperative.
- **The Border Gateway Protocol (BGP)**, version 4 (RFC 4271), runs *between* ASes. It is the protocol that holds the Internet together.

DEFINITION

Definition — BGP. A **path-vector** routing protocol in which neighboring routers (peers) exchange, over a TCP session on port 179, announcements of the form "prefix P is reachable via AS path [X, Y, Z]". Each AS chooses among the paths it hears according to its own **policy**, then re-announces its chosen path (with its own ASN prepended) to the peers its policy allows.

How BGP works internally

1. Two routers in different ASes open a TCP connection on port 179 and exchange OPEN messages.
2. Each sends UPDATE messages announcing prefixes it can reach, with attributes including the **AS path** (the list of ASes traversed), the next hop, and preference hints.
3. Each router stores all received paths, then chooses one best path per prefix. The decision is policy-first: a network prefers routes learned from paying customers over routes from peers, and peers over upstream providers it pays. Only after policy does it prefer the shortest AS path, and then a series of tie-breakers.
4. The router installs the best path in its forwarding table and announces it onward, prepending its own ASN. Loops are prevented because a router rejects any path that already contains its own ASN.
5. When a route disappears, a WITHDRAW propagates. Convergence across the Internet can take seconds to minutes.

Two consequences matter for system designers. First, **BGP picks paths by business policy, not latency**: traffic between two cities may detour through a third. Second, **BGP trusts announcements by default**. The Resource Public Key Infrastructure (RPKI) lets prefix owners publish cryptographically signed statements of which ASN may originate their prefixes, and route-origin validation is increasingly deployed, but it is not universal.

7.5.3 Anycast

DEFINITION

Definition — Anycast. An addressing scheme in which the same IP prefix is announced via BGP from many locations at once. Each client's packets are routed to whichever announcing location is "closest" according to BGP path selection.

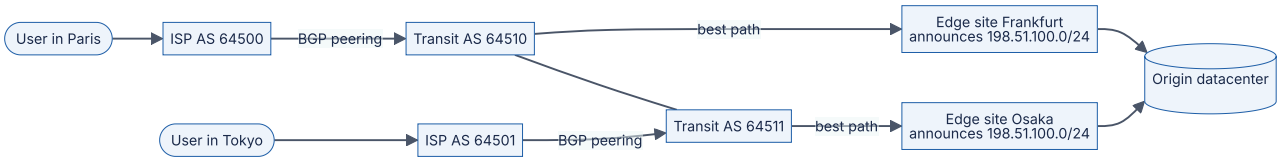
Analogy: a national emergency phone number connects you to your nearest dispatch center, not to a single central office. You dial the same number everywhere.

Anycast is how the DNS root servers, public resolvers such as `8.8.8.8` and `1.1.1.1`, and most CDNs (§21.3) put one address in front of hundreds of sites. Its strengths are auto-

matic proximity, natural absorption of distributed denial-of-service (DDoS) traffic across many sites (§10.11), and failover by **withdrawal**: if a site fails, it stops announcing the prefix, and BGP reroutes clients to the next-nearest site.

Its weaknesses follow from BGP. “Closest” means best by BGP policy, which usually but not always correlates with lowest latency. And because routing can change mid-connection, a long-lived TCP connection can suddenly have its packets delivered to a different site that has no state for it. For this reason anycast was first popular for short UDP exchanges such as DNS; operators that use it for TCP rely on route stability in practice and design for the occasional reset.

Figure 7.2 — BGP routing between autonomous systems, with an anycast prefix announced from two sites.



Reading the diagram. Two users (stadiums) reach their ISPs, which are separate autonomous systems connected to transit providers by BGP sessions. Two edge sites announce the *same* prefix, `198.51.100.0/24`. The Paris user’s ISP hears the shortest policy-preferred path via Frankfurt, and the Tokyo user’s ISP hears a path via Osaka, so the same destination address is served from different continents. Traffic flows synchronously left to right for requests (responses return along a path that may differ, because Internet routing is asymmetric). The origin datacenter is the storage boundary; the edges may cache (§21.4). Failure points: if Frankfurt withdraws its announcement, Paris traffic reconverges toward Osaka (or another site) within seconds to minutes, and in-flight TCP connections break. Scaling: add more announcing sites.

Real-world industry applications

INDUSTRY EXAMPLE

Facebook, 4 October 2021. During routine maintenance, a command intended to assess backbone capacity unintentionally disconnected Facebook’s backbone, and a bug in an audit tool failed to stop it. Facebook’s DNS servers are designed to withdraw their BGP anycast announcements when they cannot reach the datacenters, as a health safeguard. With the backbone gone, every DNS site withdrew at once, so `facebook.com` and related names could not be resolved anywhere. The outage lasted roughly six hours, and recovery was slowed because internal tools depended on the same network. Lesson: a health-driven withdrawal that is correct for one site can become a global outage when all sites share a failure; build in “never withdraw the last route” guards and out-of-band access. *Evidence: Primary* — [Janardhan 2021]

INDUSTRY EXAMPLE

YouTube prefix hijack, February 2008. Pakistan Telecom, intending to block YouTube domestically, announced a more-specific `/24` covering YouTube's address space. Its upstream provider propagated the announcement globally, and by longest-prefix match much of the Internet sent YouTube traffic to Pakistan for about two hours. The incident is a standard case study for BGP's trust model and motivates prefix filtering and RPKI. *Evidence: Secondary* — [RIPE NCC 2008]

Failure scenarios

Table 7.4 — Routing failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Route leak or hijack	A network announces prefixes it does not own, or re-announces routes against policy	External BGP monitors; sudden traffic shifts; latency jumps	Contact upstreams; announce more-specific prefixes	RPKI origin validation, prefix filters, max-prefix limits
Self-inflicted withdrawal	Health checks or automation withdraw all announcements simultaneously	Global reachability probes fail	Out-of-band access to re-announce	Guard rails preventing withdrawal of the last route; staged changes
Slow convergence	BGP path exploration after a failure	Elevated loss for seconds to minutes	Wait; fail over at a higher layer (DNS, client retry)	Multiple upstreams; BFD for fast failure detection
Anycast connection resets	Route change moves an in-flight TCP flow to another site	Spikes in TCP resets during route changes	Client retries	Short-lived connections; stable announcements

7.6 DNS: the Internet's directory

7.6.1 What DNS is and why it exists

DEFINITION

Definition — Domain Name System (DNS). A hierarchical, distributed database that maps human-readable **domain names** (such as `www.example.com`) to data, most often IP addresses, and the protocol used to query it [RFC 1034; RFC 1035].

First-principles explanation

People remember names; routers need numbers. In the early ARPANET, every host downloaded a single file, `HOSTS.TXT`, listing every name and address. As the network grew, that file became too large, changed too often, and depended on one central maintainer. DNS replaced it with a **delegated hierarchy**, much like a library catalog split across buildings: the front desk (the **root**) does not know where every book is, but it knows which building holds each subject (the **top-level domains** such as `.com`), and each building knows which room holds each shelf (the **authoritative servers** for `example.com`). Responsibility for each zone is delegated to whoever owns it, so no one party maintains everything.

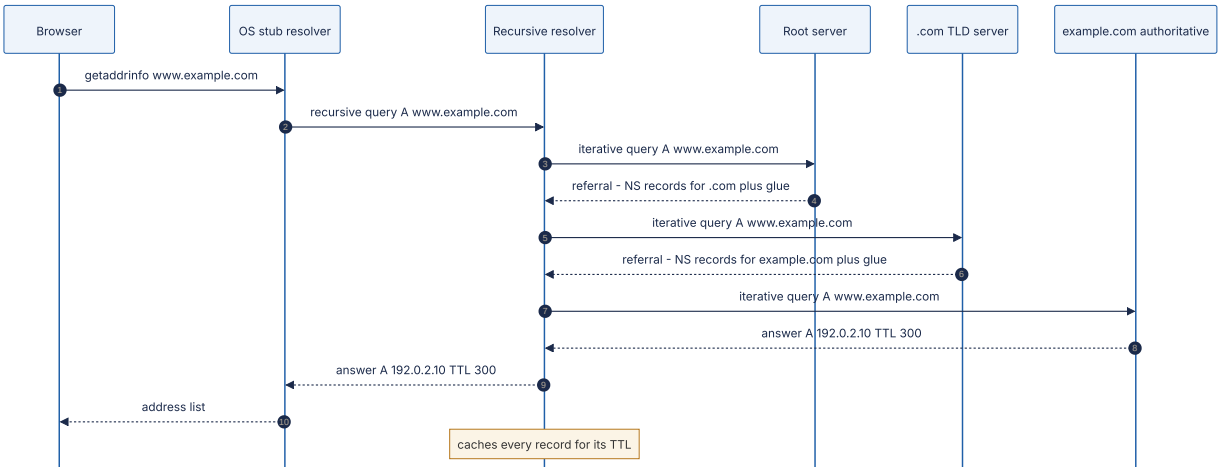
The cast of characters

- **Stub resolver.** A small library in your operating system. It does not do the work itself; it asks a recursive resolver and waits.
- **Recursive resolver** (also called a caching or full-service resolver). Run by your ISP, your company, or a public service such as `8.8.8.8` or `1.1.1.1`. It chases the answer through the hierarchy on your behalf and caches the results.
- **Root name servers.** Thirteen named server identities (`a.root-servers.net` through `m.root-servers.net`), each replicated via anycast (§7.5.3) to many physical instances worldwide. They know where each top-level domain's servers are.
- **TLD name servers.** Authoritative for a top-level domain such as `.com` or `.uk`. They know the name servers for each second-level domain.
- **Authoritative name servers.** Hold the actual records for a zone such as `example.com`. Managed DNS providers and cloud DNS services operate these for most companies.

7.6.2 Recursive versus iterative resolution

There are two query styles. In a **recursive query**, the client asks "give me the final answer", and the server must either return it or an error. Your stub resolver sends recursive queries to the recursive resolver. In an **iterative query**, the server returns the best information it has, often a **referral** ("I don't know, but ask these servers"), and the asker continues. Recursive resolvers send iterative queries to root, TLD and authoritative servers.

Figure 7.3 — DNS resolution of www.example.com with an empty cache.



Reading the diagram. Six participants appear from left to right: the application, the operating system's stub resolver, the recursive resolver, and three levels of authoritative servers. Steps 1–2 are the recursive part: the stub asks once and waits. Steps 3–8 are iterative: the resolver walks down the hierarchy, receiving referrals (dashed return arrows) from the root and the TLD, each containing the name-server (NS) records for the next level and **glue** records giving those servers' IP addresses. Step 8 is the final answer, here an A record with a 300-second TTL. All exchanges are synchronous request/response, normally over UDP port 53. The resolver's cache is the storage boundary: once populated, steps 3–8 are skipped for every client of that resolver until the TTL expires, and the root and TLD referrals are cached for much longer (typically days). Failure points: any server not responding forces a timeout and retry against another listed server (each zone must have at least two). Scaling comes from caching and from anycast replication of the root and TLD servers. (The address 192.0.2.10 is a documentation address used for illustration.)

Mathematical foundations: what a cold lookup costs

WORKED EXAMPLE

Worked example — Cold versus warm DNS lookup.

Assume the client is 5 ms from its recursive resolver, and the resolver is 20 ms from the root instance, 30 ms from the TLD server and 40 ms from the authoritative server (all round-trip times).

1. Cold cache: $5 + 20 + 30 + 40 = 95$ ms before the browser can even open a connection.
2. Root and TLD referrals cached (typical, since they have long TTLs) but the name itself expired: $5 + 40 = 45$ ms.
3. Fully warm at the resolver: 5 ms.
4. Cached in the operating system or browser: effectively 0 ms.

Interpretation: almost all real lookups hit case 3 or 4, which is why DNS feels free. The cold path matters for rarely visited domains, for very low TTLs, and for every new third-party domain a page references. Engineering implication: minimize the number of distinct hostnames on a critical path, and use `<link rel="dns-prefetch">` or `preconnect` hints for domains you know you will need.

7.6.3 Record types

Table 7.5 — Common DNS record types.

Type	Maps a name to	Example	Typical use
A	An IPv4 address	`www.example.com. 300 IN A 192.0.2.10`	Host address
AAAA	An IPv6 address	`www.example.com. 300 IN AAAA 2001:db8::10`	Host address over IPv6
CNAME	Another name (an alias)	`shop.example.com. 3600 IN CNAME shops.saas-provider.example.`	Point your name at a provider's hostname
MX	A mail server name, with priority	`example.com. 3600 IN MX 10 mail1.example.com.`	Email delivery (lower number = preferred)
NS	The authoritative name servers of a zone	`example.com. 86400 IN NS ns1.dnsprovider.example.`	Delegation
TXT	Arbitrary text	`example.com. 300 IN TXT "v=spf1 include:_spf.mailer.example -all"`	Domain ownership proofs, SPF, DKIM, DMARC
SRV	Host and port for a service, with priority and weight	`_sip._tcp.example.com. 300 IN SRV 10 60 5060 sip1.example.com.`	Service discovery (RFC 2782); used by SIP, XMPP, some service meshes
SOA	Zone metadata: primary server, serial, timers, negative-caching TTL	—	Zone administration
PTR	A name, for reverse lookup of an address	`10.2.0.192.in-addr.arpa. PTR www.example.com.`	Logs, mail server checks
CAA	Which certificate authorities may issue for the domain	`example.com. CAA 0 issue "letsencrypt.org"`	Restricting certificate issuance (§7.10)
HTTPS / SVCB	Connection parameters: ALPN protocols, ports, address hints	`example.com. HTTPS 1 . alpn="h3,h2"`	Advertising HTTP/3 before the first connection (RFC 9460)

Three rules trip people up. First, a **CNAME cannot coexist with other records at the same name**, so you cannot put a CNAME at the zone apex (`example.com` itself, which must hold SOA and NS records). DNS providers offer non-standard "ALIAS" or "CNAME flattening" features to work around this. Second, every record in a response carries its own TTL. Third, MX and SRV records point to *names*, never directly to addresses.

7.6.4 TTL and caching

DEFINITION

Definition — DNS time to live (TTL). A per-record value, in seconds, that tells any cache how long it may reuse the record before asking again. **Negative caching** stores "this name does not exist" (NXDOMAIN) answers for a duration derived from the zone's SOA record [RFC 2308].

Caches exist at several levels: the browser, the operating system, the recursive resolver, and sometimes in application runtimes. (Some runtimes have historically cached DNS answers far longer than the TTL, or forever, by default; the Java Virtual Machine's behavior depends on configuration and security manager settings, so check your runtime.)

TTL is a trade-off between **agility** (how quickly a change takes effect) and **load and latency** (how often resolvers must re-query). Short TTLs (30–60 s) let you fail over quickly but raise query volume and the fraction of slow cold lookups. Long TTLs (hours to a day) are efficient but make changes slow.

WORKED EXAMPLE

Worked example — How long does a DNS failover really take?

Your record has TTL 300 s, and your health checker takes 30 s (three failed probes, 10 s apart) to declare the primary site dead and update DNS.

1. Detection: 30 s.
2. Worst-case cache staleness: a resolver that refreshed one second before the update keeps serving the old answer for up to 300 s.
3. Worst-case total for well-behaved resolvers: $30 + 300 = 330$ s, about 5.5 minutes. The average client re-queries halfway through the TTL, so the mean is about $30 + 150 = 180$ s.
4. Clients holding open connections are not affected by DNS at all: they keep sending to the dead address until their connections fail and they reconnect.
5. Misbehaving caches that enforce a minimum TTL or ignore it extend the tail indefinitely.

Engineering implication: DNS failover is a *minutes-scale* mechanism. If you need seconds, put a stable address in front (an anycast virtual IP or a load balancer, §19.8) and fail over behind it.

Before a planned migration, lower the TTL well in advance. If the old TTL is 86,400 s (one day), you must lower it at least one day before the cut-over, because resolvers that cached the record just before you changed it will not re-query for a day.

7.6.5 DNS-based load balancing and its limits

Because a DNS answer can differ per query, DNS is the coarsest and cheapest load balancer:

- **Round-robin DNS.** Return several A records, rotating their order. Clients typically try the first.
- **Weighted answers.** Return each address in proportion to configured weights.
- **Geo-DNS / latency-based DNS.** Answer based on the resolver's (or, with the EDNS Client Subnet extension, the client's) location, pointing users to a nearby region (Ch 44, §19.9).
- **Health-checked DNS.** Remove addresses whose health checks fail.

The limits are fundamental, not implementation details:

1. **Caching defeats fine control.** A large resolver (an ISP serving millions of users) caches one answer and hands it to all its clients for the TTL, so "1/N of queries" is not "1/N of users".
2. **Resolver location is not client location.** Geo-DNS sees the recursive resolver's address. A user in Singapore using a resolver in the US may be sent to the US region, unless EDNS Client Subnet is supported.
3. **Failover speed is bounded by TTL** and by stale clients, as computed above.
4. **No load awareness.** DNS does not see connection counts or server latency; it picks before the connection exists.
5. **Clients behave inconsistently.** Some try only the first address; some try all; some pin forever.

DNS is therefore used to pick a **region or site**, and real load balancers distribute connections *within* the site (Chapter 19).

Transport details

DNS normally uses UDP port 53 because a query and a response each fit in one datagram, avoiding a handshake. Classic DNS limited UDP responses to 512 bytes; the EDNS(0) extension (RFC 6891) lets clients advertise larger buffers, and current operational guidance favors about 1,232 bytes to avoid IP fragmentation. If a response is too large, the server sets the truncation (TC) bit and the client retries over TCP. Zone transfers between servers use TCP. Encrypted variants exist: DNS over TLS (port 853, RFC 7858) and DNS over HTTPS (RFC 8484), which hide queries from on-path observers.

Failure scenarios

Table 7.6 — DNS failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Authoritative provider outage	DDoS or provider failure; all NS records at one provider	Resolution failures from external probes	Wait, or change NS at the registrar (slow: TLD TTLs are long)	Two independent DNS providers serving the same zone
Stale records after migration	TTL was long when you changed the record	Traffic still reaching old addresses	Keep old endpoint alive until TTL × 2 has passed	Lower TTL in advance of planned changes
Resolver overload / latency	Too many lookups per request; no local caching	High p99 on connection setup; resolver timeouts	Add local caching resolver	Cache in-process with TTL respect; reuse connections
Negative-cache trap	Name queried before it was created; NXDOMAIN cached	"Works for me, not for them"	Wait out SOA negative TTL	Create records before announcing names
Split-horizon mismatch	Internal and external views of a zone differ	Errors only inside or only outside the network	Fix the view	Test both views in deployment checks

COMMON MISTAKE

"Changing a DNS record takes 24–48 hours to propagate." DNS does not propagate; caches *expire*. A change is visible to a given resolver as soon as its cached copy's TTL runs out. The folklore "48 hours" comes from long TTLs, especially on NS records at the TLD.

7.7 TCP: reliable byte streams over an unreliable network

7.7.1 What TCP provides

IP is a **best-effort** service: packets may be lost, duplicated, delayed or delivered out of order, and IP will not tell you. Most applications want the opposite: a reliable, ordered pipe of bytes. The **Transmission Control Protocol** builds that pipe on top of IP [RFC 9293].

DEFINITION

Definition — TCP. A connection-oriented transport protocol that provides a reliable, ordered, full-duplex **byte stream** between two endpoints identified by (IP address, port) pairs. It achieves reliability with sequence numbers, acknowledgments and retransmission; it protects a slow receiver with **flow control**; and it protects the network with **congestion control**.

First-principles explanation

Imagine mailing a 300-page manuscript one page per envelope through an unreliable postal service. To make sure your editor gets every page in order, you would number each page, ask the editor to send back postcards saying “I have everything up to page 57”, and resend any page not acknowledged within a reasonable time. You would also avoid sending all 300 pages at once if the editor’s desk is small (flow control) or if the post office is visibly overwhelmed (congestion control). That is TCP. The one twist is that TCP numbers **bytes**, not pages: the stream has no message boundaries, so an application that writes “hello” and then “world” may receive “hellowor” and “ld”. Application protocols must add their own framing (a length prefix or a delimiter).

7.7.2 The segment

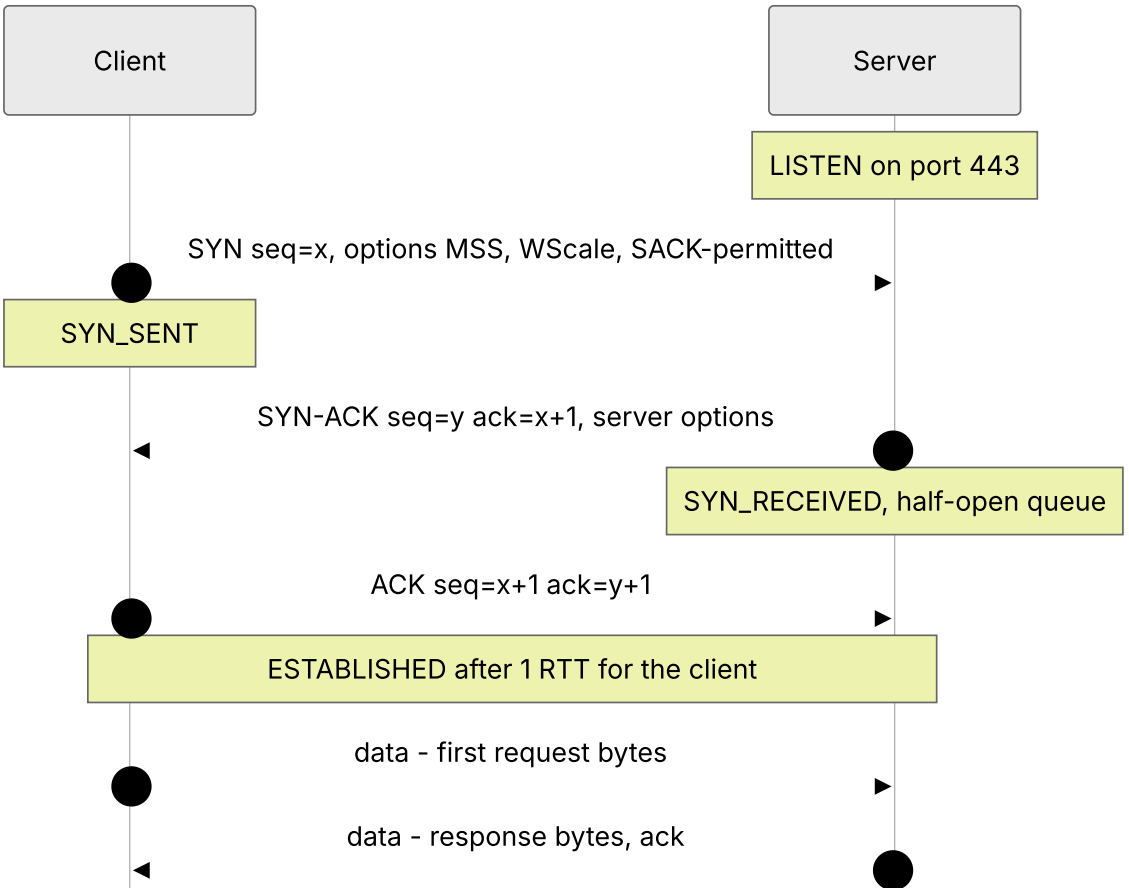
Every TCP segment carries a header of 20 bytes plus up to 40 bytes of options. The fields you will reason about most are:

- **Source and destination ports** (16 bits each). Together with the IP addresses they form the connection’s 4-tuple.
- **Sequence number** (32 bits). The stream offset of the first payload byte in this segment, relative to a random **initial sequence number (ISN)**.
- **Acknowledgment number** (32 bits). The next byte the sender of this segment expects to receive: “I have everything before this”.
- **Flags.** SYN (synchronize, opens a connection), ACK (acknowledgment field valid), FIN (no more data from me), RST (abort), PSH, URG, plus ECE/CWR for explicit congestion notification.
- **Window** (16 bits). How many more bytes the sender of this segment is willing to receive (flow control, §7.7.6).
- **Options.** MSS, window scale, selective acknowledgments (SACK) and timestamps, mostly negotiated in the handshake.

7.7.3 The three-way handshake

Before data flows, both sides must agree that the connection exists and learn each other’s initial sequence numbers. Each ISN is chosen randomly so that stray segments from an old connection, or an off-path attacker, are unlikely to fall into the valid window.

Figure 7.4 — TCP three-way handshake followed by the first request.



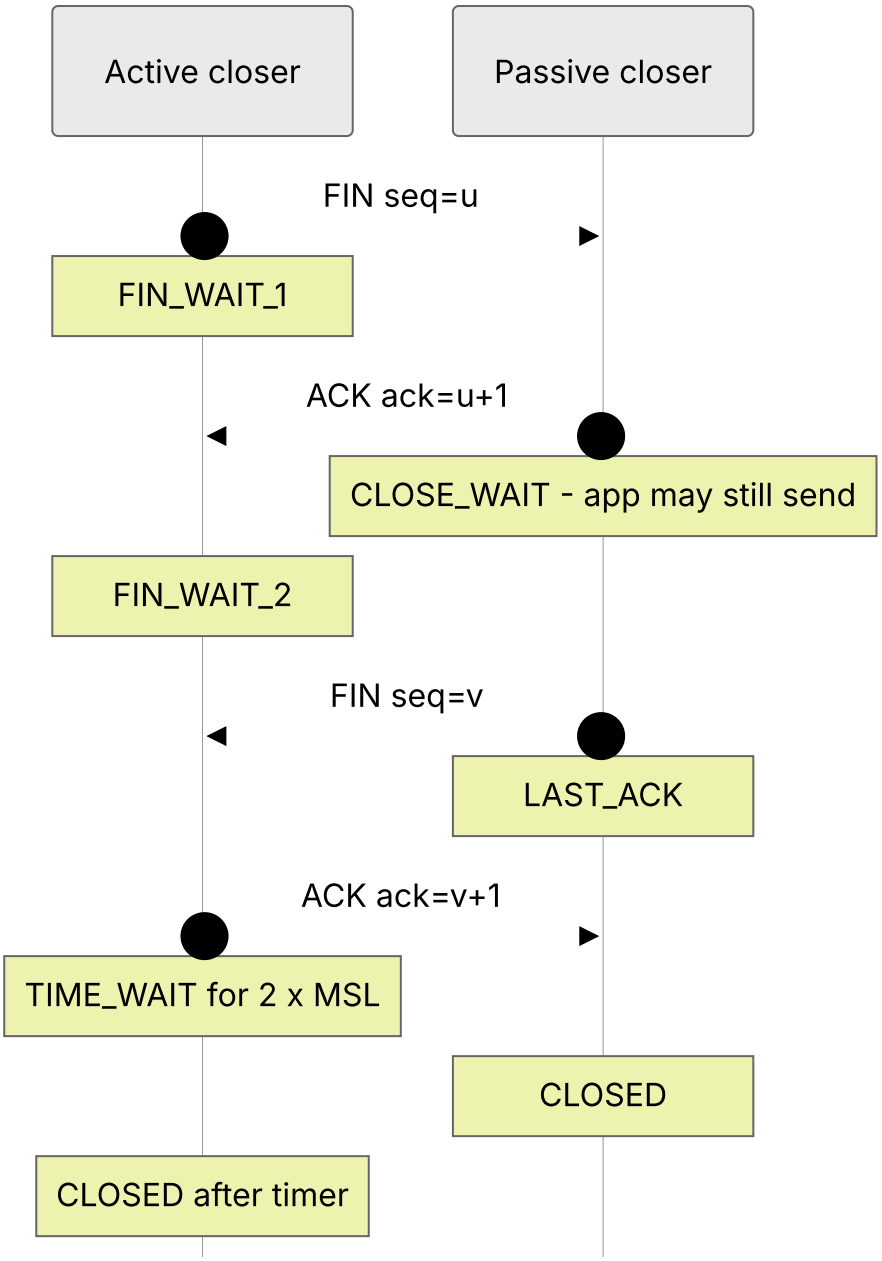
Reading the diagram. Two participants: the client, which actively opens, and the server, which is listening. Step 1 is the SYN, carrying the client's random ISN x and its option offers. Step 2, the SYN-ACK, acknowledges $x + 1$ (a SYN consumes one sequence number) and carries the server's own ISN y. Step 3 completes the handshake. The client may send data immediately after step 3, so the handshake costs the client **one round-trip time (RTT)** before its request can leave; the server sees the request 1.5 RTTs after the client began. All exchanges are synchronous. The server's half-open queue (connections between steps 2 and 3) is a failure point: a **SYN flood** attack fills it with spoofed SYNs, which servers counter with **SYN cookies**, encoding the connection state in the ISN instead of storing it. Scaling: the server's accept queue (`listen` backlog) must be sized for connection bursts.

TCP Fast Open (RFC 7413) lets a returning client put data in the SYN using a cookie from a previous connection, saving one RTT, but middlebox interference and replay concerns have limited its deployment. QUIC (§7.9.4) achieves the same goal more robustly.

7.7.4 The four-way close and TIME_WAIT

TCP is full-duplex, so each direction closes independently. Each side sends a FIN when it has no more data, and the other acknowledges it.

Figure 7.5 — TCP four-way close and the TIME_WAIT state.



Reading the diagram. The **active closer** is whichever side calls `close()` first; the other is the **passive closer**. Steps 1–2 close the active side's direction; the passive side enters CLOSE_WAIT and may keep sending until its application also closes (a pile-up of CLOSE_WAIT sockets is the classic symptom of an application that forgets to close connections). Steps 3–4 close the other direction. Steps 2 and 3 are often combined into one segment, making the close effectively three segments. The active closer then waits in **TIME_WAIT** for twice the **maximum segment lifetime (MSL)**. All steps are synchronous; RST is the abrupt alternative that skips all of this and discards unsent data.

TIME_WAIT exists for two reasons. First, if the final ACK (step 4) is lost, the passive side will retransmit its FIN, and the active side must still be around to re-acknowledge it. Second, it ensures that delayed segments from this connection have died out before a

new connection with the same 4-tuple can be created and misinterpret them. RFC 793 set MSL to two minutes; Linux hard-codes TIME_WAIT at 60 seconds.

WORKED EXAMPLE

Worked example — Ephemeral port exhaustion from TIME_WAIT.

A service opens a new TCP connection for every request to one backend (one destination IP and port) and closes it afterward, so the service is the active closer.

1. Each connection needs a unique source port. Linux's default ephemeral port range is 32,768–60,999: $60,999 - 32,768 + 1 = 28,232$ ports.
2. Each closed connection holds its port in TIME_WAIT for 60 s.
3. Sustainable new-connection rate to that single destination: $28,232/60 \approx 470$ connections per second.
4. At 1,000 requests per second with one connection per request, ports run out after about $28,232/1,000 \approx 28$ s, and `connect()` starts failing with `EADDRNOTAVAIL`.

Interpretation: TIME_WAIT is not a bug, but opening a connection per request is. Fixes, in order of preference: reuse connections with keep-alive and pooling (§7.16); add destination IPs or ports (each distinct 4-tuple has its own port space); widen the ephemeral range; enable `net.ipv4.tcp_tw_reuse` for outgoing connections. Never use the long-removed `tcp_tw_recycle`, which broke clients behind NAT.

7.7.5 Sequence numbers, acknowledgments and retransmission

TCP uses **cumulative acknowledgments**: ACK number *N* means "I have all bytes before *N*". The sender keeps every unacknowledged byte in its send buffer and retransmits on one of two signals:

1. **Retransmission timeout (RTO).** If no ACK arrives within a timeout computed from measured RTTs, the sender retransmits the oldest unacknowledged segment, doubles the timeout (**exponential backoff**), and treats the event as severe congestion.
2. **Fast retransmit.** If the receiver gets a segment out of order, it immediately resends its last ACK. Three **duplicate ACKs** strongly suggest a single lost segment with later ones still arriving, so the sender retransmits at once without waiting for the timer [RFC 5681].

Selective acknowledgments (SACK) let the receiver report exactly which blocks beyond the gap it holds, so the sender retransmits only what is missing.

FORMULA

Retransmission timeout (RFC 6298)

On each new RTT sample R (after the first):

$$\text{RTTVAR} \leftarrow (1-\beta)\,\text{RTTVAR} + \beta\,|\text{SRTT} - R|$$

$$\text{SRTT} \leftarrow (1-\alpha)\,\text{SRTT} + \alpha R$$

$$\text{RTO} = \text{SRTT} + \max(G,\ 4\,\text{RTTVAR})$$

Symbol	Meaning	Units
R	Latest measured round-trip time	ms
SRTT	Smoothed (exponentially averaged) RTT	ms
RTTVAR	Smoothed RTT variation	ms
α, β	Smoothing gains, $1/8$ and $1/4$	dimensionless
G	Clock granularity	ms
RTO	Retransmission timeout; RFC 6298 says round up to at least 1 s	ms

WORKED EXAMPLE

Worked example — Computing an RTO.

Current state: SRTT = 100 ms, RTTVAR = 10 ms. A new sample arrives: $R = 140$ ms. Assume G is negligible.

1. RTTVAR $= 0.75 \times 10 + 0.25 \times |100 - 140| = 7.5 + 10 = 17.5$ ms (computed with the *old* SRTT, as the RFC requires).
2. SRTT $= 0.875 \times 100 + 0.125 \times 140 = 87.5 + 17.5 = 105$ ms.
3. RTO $= 105 + 4 \times 17.5 = 175$ ms.
4. RFC 6298 rounds this up to its 1 s minimum; Linux uses a 200 ms minimum, so Linux would wait 200 ms.

Interpretation: inside a datacenter, where RTTs are around 0.1–0.5 ms, a single timeout-driven retransmission costs 200 ms, hundreds of times the normal latency. This is why one lost packet can dominate p99 latency for small RPCs (§23.6), and why datacenter operators tune minimum RTOs down and work hard to avoid drops.

7.7.6 Flow control and the receive window

Flow control prevents a fast sender from overflowing a slow receiver. Each ACK advertises the **receive window** (`rwnd`): the free space in the receiver's socket buffer. The sender never has more than `rwnd` unacknowledged bytes outstanding. If the application stops reading, the buffer fills, the advertised window drops to zero, and the sender pauses, probing periodically until the window reopens. Flow control is how TCP provides **backpressure** end to end (§22.10).

The header's window field is 16 bits, so it can express at most 65,535 bytes. That is far too small for fast long-distance links (see the bandwidth-delay product in §7.15), so the **window scale** option (RFC 7323), negotiated in the SYN, multiplies the window by 2^s for $s \le 14$, allowing windows up to about 1 GiB ($65,535 \times 2^{14} = 1,073,725,440$ bytes).

7.7.7 Congestion control

Flow control protects the receiver. **Congestion control** protects the network. In October 1986, the early Internet suffered **congestion collapse**: throughput between Lawrence Berkeley Laboratory and UC Berkeley fell from 32 kbps to 40 bps [Jacobson 1988] because senders retransmitted aggressively into already-full queues, so most bandwidth carried duplicate packets that were then dropped. Van Jacobson's 1988 algorithms, refined into today's RFC 5681, made each sender infer congestion and back off.

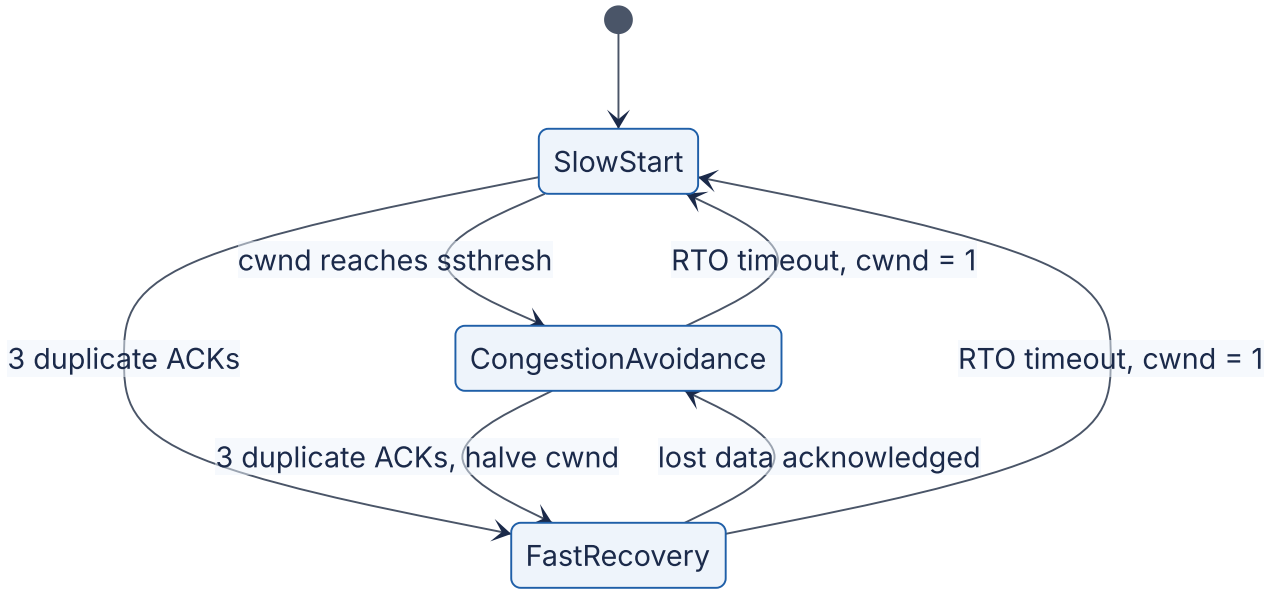
> DEFINITION
>
> **Definition — Congestion window (cwnd).** A sender-side limit, in bytes or segments, on unacknowledged data in flight, based on the sender's estimate of what the network path can absorb. The sender may have at most $\min(\text{cwnd}, \text{rwnd})$ bytes outstanding.

How classic congestion control works

1. **Slow start.** A new connection starts with a small initial window (10 segments, about 14.6 KB, per RFC 6928) and increases cwnd by one segment for every segment acknowledged. That **doubles cwnd every RTT**: "slow" only in comparison with sending everything at once.
2. When cwnd reaches the **slow-start threshold** (`ssthresh`), the sender switches to **congestion avoidance**: it adds about one segment per RTT (**additive increase**).
3. On a loss detected by three duplicate ACKs, the sender halves cwnd (**multiplicative decrease**), sets ssthresh to the new value, retransmits, and continues in congestion avoidance via **fast recovery**.
4. On a retransmission timeout, the sender assumes something severe happened, sets ssthresh to half the flight size, resets cwnd to one segment, and re-enters slow start.

Steps 2 and 3 together are **AIMD (additive increase, multiplicative decrease)**. It produces the familiar sawtooth of cwnd over time, and it has a beautiful property: multiple AIMD flows sharing a bottleneck converge toward an equal share.

Figure 7.6 — Loss-based TCP congestion control states (Reno-style).



Reading the diagram. Each box is a sender state. A connection begins in slow start, where cwnd doubles each RTT. Reaching ssthresh moves it to congestion avoidance (linear growth). Three duplicate ACKs, a mild loss signal, move it to fast recovery with cwnd halved; once the lost data is acknowledged, it returns to congestion avoidance. A timeout, the severe signal, sends it all the way back to slow start with cwnd of one segment. All transitions are driven by asynchronous events (ACK arrivals and timers) on the sender. Failure point: repeated timeouts on a lossy path keep the connection in slow start with exponentially growing RTOs, which users experience as a “hung” transfer.

WORKED EXAMPLE

Worked example — How many RTTs does slow start need for 1 MB?

Assume MSS = 1,460 bytes, initial cwnd = 10 segments, no loss, a large receive window, and ignore delayed ACKs.

1. Segments needed: $1,000,000/1,460 \approx 685$.
2. Segments sent per round (RTT): 10, 20, 40, 80, 160, 320, 640.
3. Cumulative: 10, 30, 70, 150, 310, 630, 1,270.
4. After 6 rounds, 630 < 685; the 7th round finishes the transfer. So **7 RTTs** of data transfer.
5. At an 80 ms RTT that is $7 \times 80 = 560$ ms, plus 1 RTT of TCP handshake and 1 RTT of TLS 1.3 handshake (§7.10): $9 \times 80 = 720$ ms in total, regardless of whether the link is 100 Mbps or 10 Gbps.

Interpretation: for small and medium transfers on long paths, **latency, not bandwidth, determines download time**. A 10× faster link barely helps; reducing RTT (a CDN edge close to the user, §21.3) or reusing a connection whose cwnd is already large (§7.16) helps enormously.

CUBIC

On fast long-distance paths, Reno's "add one segment per RTT" is painfully slow to regain a large window after a loss: after a loss halves a 10,000-segment window, regaining the missing 5,000 segments at one segment per 100 ms RTT takes $5,000 \times 0.1 = 500$ s. **CUBIC** [Ha et al. 2008; RFC 9438] replaces linear growth with a cubic function of *time since the last loss*, independent of RTT. It has been Linux's default since 2006 and is the default in most operating systems today.

FORMULA

CUBIC window growth

$$W(t) = C\,(t - K)^3 + W_{\max}, \qquad K = \sqrt[3]{\frac{W_{\max}\,(1-\beta)}{C}}$$

Symbol	Meaning	Units
$W(t)$	Congestion window t seconds after the last loss	segments
$W_{\max}$	Window just before the last loss	segments
β	Multiplicative decrease factor; window becomes $\beta W_{\max}$ after loss (0.7)	dimensionless
C	Scaling constant (0.4)	segments/s³
K	Time to climb back to $W_{\max}$	s

WORKED EXAMPLE

Worked example — CUBIC recovery time.

Suppose $W_{\max} = 100$ segments when a loss occurs.

1. After the loss: $W(0) = 0.7 \times 100 = 70$ segments. Check with the formula: $K^3 = 100 \times 0.3/0.4 = 75$, so $K = \sqrt[3]{75} \approx 4.22$ s, and $W(0) = 0.4 \times (-4.22)^3 + 100 = 0.4 \times (-75) + 100 = 70$. Consistent.
2. Growth is fast at first, flattens as $t \to K$ (the curve is cautious near the window where loss last occurred), and reaches 100 segments at $t \approx 4.22$ s.
3. Beyond K the window accelerates again, probing for newly available bandwidth.

Interpretation: recovery time depends on $W_{\max}$ and constants, not on RTT, so long-RTT flows are not penalized as much as under Reno. The plateau around $W_{\max}$ keeps CUBIC near the last known-good operating point.

BBR

Loss-based algorithms (Reno, CUBIC) treat packet loss as *the* congestion signal. That has two problems. On paths with large buffers, they keep filling the queue until it overflows, adding hundreds of milliseconds of queuing delay (**bufferbloat**, §7.15). On paths with random loss unrelated to congestion (wireless, long-haul links), they back off when they should not.

BBR (Bottleneck Bandwidth and Round-trip propagation time) [Cardwell et al. 2016] instead builds an explicit model of the path. It continuously estimates the **bottleneck bandwidth** (the maximum recent delivery rate) and the **minimum RTT** (the propagation delay with empty queues). It then paces packets at the estimated bandwidth and keeps roughly one bandwidth-delay product in flight, periodically probing slightly above that rate to discover more bandwidth and periodically draining the queue to re-measure minimum RTT.

Table 7.7 — Congestion control algorithms compared.

Aspect	Reno (AIMD)	CUBIC	BBR (v1)
Congestion signal	Packet loss	Packet loss	Measured bandwidth and RTT model
Growth function	+1 MSS per RTT	Cubic in time since last loss	Pacing at estimated bottleneck rate, with probing
Response to loss	Halve cwnd	Multiply by 0.7	Largely ignores isolated loss
Queue occupancy	Fills buffers until loss	Fills buffers until loss	Aims for little standing queue
Strength	Simple, fair among equals	Good on high-BDP paths; default almost everywhere	Low latency; high throughput with random loss
Weakness	Slow on high-BDP paths	Bufferbloat; collapses with random loss	Fairness issues versus loss-based flows; retransmissions with shallow buffers
Where used	Teaching baseline	Linux, Windows, macOS defaults	Google services, available in Linux since 4.9

INDUSTRY EXAMPLE

BBR at Google. Google reported deploying BBR on its B4 inter-datacenter backbone, where it delivered 2–25× higher throughput than CUBIC, and on YouTube and google.com traffic, where it reduced median RTT (by reducing queuing) while improving throughput. Later work (BBRv2/v3) addresses fairness and loss-sensitivity issues found in BBRv1. *Evidence: Primary* — [Cardwell et al. 2016]

7.7.8 Nagle's algorithm and delayed ACKs

In 1984, John Nagle observed that interactive programs sending one keystroke per write produced 41-byte packets (40 bytes of headers, 1 byte of data), wasting bandwidth. **Nagle's algorithm** (RFC 896) says: if there is unacknowledged data in flight, buffer small writes until either the ACK arrives or a full segment accumulates.

Separately, receivers use **delayed ACKs**: they wait briefly (up to 500 ms by RFC 1122; Linux uses about 40 ms or more) hoping to piggyback the ACK on response data or to acknowledge two segments at once.

Each idea is reasonable; together they cause a notorious stall. A client writes a request header (small write 1), then the body (small write 2), then waits for a response. Write 1 is sent. Nagle holds write 2 until write 1 is acknowledged. The server cannot respond before it has the whole request, so it has nothing to piggyback on and delays its ACK. The pair sit idle for the delayed-ACK timer, adding tens of milliseconds to every request. The fixes are to assemble the full message and write it once, or to set the `TCP_NODELAY` socket option, which disables Nagle. Almost every RPC framework and database driver sets `TCP_NODELAY` by default.

7.7.9 Head-of-line blocking

Head-of-line (HOL) blocking occurs when an item at the front of a queue holds up everything behind it. TCP guarantees in-order delivery of one byte stream, so if segment 5 is lost and segments 6–20 arrive, the receiving kernel holds 6–20 in its buffer and the application can read nothing until segment 5's retransmission arrives, at least one RTT later. If the application multiplexed several independent requests over that connection (HTTP/2, §7.9.3), all of them stall because of one packet that belonged to only one of them. This is the central motivation for QUIC (§7.9.4), which provides independent streams with no cross-stream HOL blocking.

7.7.10 Code example: a TCP echo server and client

```
        # echo_server.py — a minimal, runnable TCP echo server (Python 3.8+).
        import socket

        HOST, PORT = "127.0.0.1", 9000

        with socket.socket(socket.AF_INET, socket.SOCK_STREAM) as srv:
            srv.setsockopt(socket.SOL_SOCKET, socket.SO_REUSEADDR, 1)  # rebind despite
TIME_WAIT
            srv.bind((HOST, PORT))
            srv.listen(128)                          # backlog of completed handshakes
            print(f"listening on {HOST}:{PORT}")
            while True:
                conn, addr = srv.accept()            # handshake already done by the ker-
nel
                with conn:
                    conn.setsockopt(socket.IPPROTO_TCP, socket.TCP_NODELAY, 1)
                    while True:
                        data = conn.recv(4096)       # may return fewer bytes than were
sent
                        if not data:                 # empty read: peer sent FIN
                            break
                        conn.sendall(data)           # loops until every byte is queued
```

```
        # echo_client.py — measures connect time and one request/response round trip.
        import socket, time

        t0 = time.perf_counter()
        s = socket.create_connection(("127.0.0.1", 9000))   # SYN, SYN-ACK, ACK
        t1 = time.perf_counter()
        s.sendall(b"hello")
        reply = s.recv(4096)
        t2 = time.perf_counter()
        s.close()                                            # client is active closer:
TIME_WAIT here
        print(reply, f"connect={1e3*(t1-t0):.3f} ms  rtt={1e3*(t2-t1):.3f} ms")
```

What to notice:

- `accept()` returns only after the kernel has completed the three-way handshake; your application never sees SYNs.
- `recv(4096)` returns *up to* 4,096 bytes. TCP is a byte stream, so a real protocol must loop until a complete message has arrived, using a length prefix or delimiter.
- `recv` returning `b""` is how the application learns that the peer sent FIN.
- `SO_REUSEADDR` lets a restarted server bind its port while old connections linger in TIME_WAIT.
- The server handles one client at a time; production servers use threads, an event loop (§6.13) or `asyncio`.

- Over loopback, both timings will be tens of microseconds; the same client against a server 80 ms away would show about 80 ms for each.

Failure scenarios

Table 7.8 — TCP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Ephemeral port exhaustion	Connection per request; TIME_WAIT holds ports	`EADDRNOTAVAIL`; many TIME_WAIT sockets in `ss -s`	Reuse connections; `tcp_tw_reuse`	Pooling and keep-alive (§7.16)
CLOSE_WAIT leak	Application never closes sockets after peer FIN	Growing CLOSE_WAIT count; file-descriptor exhaustion	Restart process; fix code	Close in `finally` /context managers; timeouts
Half-open connection	Peer crashed or a NAT/firewall dropped state; no FIN sent	Writes hang or eventually reset; reads block forever	Application-level timeouts; reconnect	TCP keep-alive or application heartbeats; read deadlines
Retransmission-driven tail latency	Packet loss; minimum RTO of 200 ms+	p99 spikes; `nstat` retransmission counters	—	Avoid drops; hedged requests (§23.7)
Nagle/delayed-ACK stall	Multiple small writes per request	Latency floor of about 40 ms on small requests	Set `TCP_NODELAY`	Write whole messages; framework defaults
SYN flood	Spoofed SYNs fill the half-open queue	Many SYN_RECV sockets	SYN cookies	SYN cookies on by default; DDoS protection

COMMON MISTAKE

"TCP guarantees my message was processed." An ACK means the peer's *kernel* received the bytes into a buffer, not that the application read them, let alone acted on them or wrote them durably. If the server crashes after ACKing, the data is gone. End-to-end confirmation must come from the application (§24.14, the end-to-end argument).

COMMON MISTAKE

"A TCP connection notices immediately when the other side dies." If the peer vanishes without sending FIN or RST (power loss, cable cut, a firewall silently dropping state), an idle connection looks healthy indefinitely. TCP keep-alive probes default to starting after two hours of idleness on Linux. Always set application-level timeouts.

7.8 UDP and when to use it

DEFINITION

Definition — UDP. The User Datagram Protocol [RFC 768] is a connectionless transport protocol that adds only port numbers, a length and a checksum to IP. Its 8-byte header provides process-to-process delivery of individual **datagrams** with no handshake, no acknowledgments, no retransmission, no ordering, and no flow or congestion control.

If TCP is registered mail with numbered pages and receipts, UDP is a postcard: cheap, immediate, and with no guarantee it arrives or that two postcards arrive in order. UDP does preserve message boundaries: one `sendto()` produces one datagram, and the receiver gets exactly that datagram or nothing.

Why does this exist?

Some applications are hurt more by TCP's guarantees than helped:

- **Request/response with tiny messages.** A DNS query fits in one packet. A TCP handshake would triple the latency; if the reply is lost, the client simply asks again.
- **Real-time media and games.** A voice packet that arrives 300 ms late is useless; it is better to skip it than to stall the stream waiting for a retransmission (TCP's head-of-line blocking).
- **Custom transports.** QUIC (§7.9.4) implements its own reliability, streams and congestion control *on top of* UDP, because UDP passes through existing firewalls and NATs and can be implemented in user space without kernel changes.
- **Multicast and broadcast**, such as DHCP address assignment and market-data feeds, which TCP's one-to-one connections cannot express.
- **High-volume, loss-tolerant telemetry**, such as StatsD metrics, where an occasional lost sample does not matter.

Table 7.9 — TCP versus UDP.

Aspect	TCP	UDP
What it is	Reliable, ordered byte stream	Unreliable datagrams
Connection setup	3-way handshake (1 RTT)	None
Header	20–60 bytes	8 bytes
Reliability and ordering	Yes, via sequence numbers and retransmission	No
Message boundaries	No (byte stream)	Yes (one datagram = one message)
Flow and congestion control	Yes	No; application's responsibility
Head-of-line blocking	Yes, within the stream	No
State on server	Per connection	None required
Typical uses	HTTP/1.1, HTTP/2, databases, RPC	DNS, VoIP, games, QUIC/HTTP/3, DHCP, telemetry
Choose when	You need every byte, in order, and can tolerate setup cost	Timeliness beats completeness, or you are building your own transport

What you must rebuild on UDP

Choosing UDP moves responsibilities into your application: detecting loss (sequence numbers), deciding whether to retransmit, reordering, splitting messages to fit the path MTU (a UDP datagram larger than the MTU gets fragmented by IP, and losing any fragment loses the whole datagram), and above all **congestion control**. A UDP application that sends at a fixed high rate regardless of loss harms every other flow on the path; RFC 8085 gives guidelines for responsible UDP use.

> WARNING / TRADE-OFF
>
> **UDP amplification attacks.** Because UDP has no handshake, an attacker can forge the source address of a small request so that a server sends a much larger response to the victim. Open DNS resolvers, NTP and memcached servers exposed over UDP have been abused for very large DDoS attacks. Never expose UDP services that send responses much larger than requests to the Internet without rate limiting and source validation (§10.11).

7.9 HTTP/1.1, HTTP/2, HTTP/3 and QUIC

7.9.1 HTTP semantics

The **Hypertext Transfer Protocol** is a request/response application protocol. A client sends a request with a **method** (GET, POST, PUT, DELETE, …), a **target** (path), **header**

fields (metadata such as `Host`, `Content-Type`, `Cache-Control`) and an optional body. The server answers with a **status code** (200 OK, 301 redirect, 404 not found, 503 unavailable, …), headers and an optional body. RFC 9110 defines these **semantics** separately from how they are encoded on the wire, and three wire versions coexist: HTTP/1.1 [RFC 9112], HTTP/2 [RFC 9113] and HTTP/3 [RFC 9114]. Your application code sees the same methods, headers and status codes whichever version carries them. API design on top of HTTP is covered in §8.6. For a performance-oriented treatment of everything in this section, see [Grigorik 2013].

7.9.2 HTTP/1.1: text, keep-alive and pipelining

HTTP/1.1 messages are human-readable text:

```
GET /index.html HTTP/1.1
Host: www.example.com
User-Agent: curl/8.5.0
Accept: */*
```

The response begins `HTTP/1.1 200 OK`, followed by headers, a blank line and the body. The body's end is marked by `Content-Length` or by **chunked transfer encoding**.

HTTP/1.0 opened a new TCP connection per request. HTTP/1.1 made **persistent connections** (keep-alive) the default: after a response, the connection stays open for the next request, saving a TCP (and TLS) handshake and keeping the warmed-up congestion window.

The remaining problem is that one connection carries **one request at a time**. HTTP/1.1 defined **pipelining**, sending several requests without waiting, but responses must return in request order, so one slow response blocks all those behind it (application-level head-of-line blocking). Buggy intermediaries and that HOL problem meant browsers never enabled pipelining by default. Browsers instead open **multiple parallel connections**, typically six per host, and sites used to "shard" assets across hostnames to get more. Each extra connection costs handshakes, server memory and separate slow starts, and connections compete with each other for bandwidth.

7.9.3 HTTP/2: binary framing and multiplexing

HTTP/2 (originally RFC 7540 in 2015, now RFC 9113) keeps HTTP semantics but changes the wire format.

How it works internally

1. **Binary framing.** Each message is split into **frames** with a 9-byte header giving length, type (HEADERS, DATA, SETTINGS, WINDOW_UPDATE, RST_STREAM,

GOAWAY, PING, …), flags and a **stream identifier**.

2. **Streams and multiplexing.** Each request/response pair is a **stream** with its own ID (odd numbers for client-initiated streams). Frames from many streams interleave on one TCP connection, so a slow response no longer blocks others at the HTTP layer. One connection per origin replaces six.
3. **Header compression with HPACK** [RFC 7541]. Requests repeat nearly identical headers (cookies, user agent). HPACK keeps a **static table** of 61 common header fields and a **dynamic table** of recently sent ones on both ends, so repeated headers are sent as small integer indexes; new values may be Huffman-coded. HPACK avoids the compression side-channel attacks (CRIME) that made general-purpose compression of headers unsafe.
4. **Per-stream and connection flow control** with WINDOW_UPDATE frames, so one large download cannot starve other streams of buffer space.
5. **Stream cancellation** with RST_STREAM, without closing the connection.

Two features have faded. The original priority tree was complex and inconsistently implemented, and RFC 9113 deprecates it in favor of the simpler scheme in RFC 9218. **Server push**, which let servers send resources before they were requested, proved hard to use well; major browsers have removed support.

The TCP head-of-line problem remains

HTTP/2 removed head-of-line blocking at the HTTP layer, but all streams still share one TCP byte stream. A single lost packet stalls *every* stream until it is retransmitted (§7.7.9). On a clean network HTTP/2's single connection beats six HTTP/1.1 connections; at loss rates of a few percent, typical of poor mobile networks, it can do worse, because six independent connections each suffer only their own losses.

7.9.4 QUIC and HTTP/3

QUIC [RFC 9000] is a general-purpose transport protocol, developed first at Google and standardized by the IETF in 2021, that runs over UDP. **HTTP/3** [RFC 9114] is HTTP mapped onto QUIC.

Why does this exist?

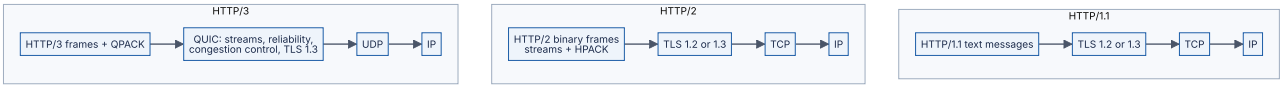
Three problems could not be fixed inside TCP. First, TCP's head-of-line blocking is inherent in its single ordered stream. Second, a secure connection costs two sequential handshakes (TCP, then TLS). Third, TCP lives in operating-system kernels and is inspected and sometimes rewritten by **middleboxes** (firewalls, NATs, load balancers), so new TCP features take a decade to deploy, a problem called **ossification**. Building on UDP, implementing the transport in user space, and encrypting nearly all transport headers solves all three.

How it works internally

1. **Integrated handshake.** QUIC carries the TLS 1.3 handshake inside its own packets [RFC 9001]. Transport and cryptographic setup happen together in **1 RTT**; a resumed connection can send application data in its first flight (**0-RTT**, with the caveats in §7.10.4).
2. **Independent streams.** Reliability and ordering are per stream. A lost packet delays only the streams whose data it carried.
3. **Connection IDs.** A QUIC connection is identified by connection IDs chosen by the endpoints, not by the IP/port 4-tuple. When a phone moves from Wi-Fi to cellular and its IP address changes, the connection **migrates** without a new handshake.
4. **Encrypted headers.** Packet numbers and most transport metadata are encrypted, so middleboxes cannot depend on (and ossify) them.
5. **Better loss recovery.** Packet numbers are never reused (a retransmission gets a new number), which removes TCP's ambiguity about whether an ACK refers to the original or the retransmission [RFC 9002].
6. **QPACK** [RFC 9204] replaces HPACK, because HPACK assumes in-order delivery of headers, which independent streams no longer guarantee.

Clients learn that a server supports HTTP/3 from an `Alt-Svc` response header on an earlier HTTP/2 connection, or from a DNS HTTPS record (§7.6.3), and fall back to HTTP/2 over TCP when UDP is blocked, as it is on some enterprise networks.

Figure 7.7 — Protocol stacks for the three HTTP versions.



Reading the diagram. Each column is one protocol stack, top (application) to bottom (network). In HTTP/1.1 and HTTP/2, the security layer (TLS) sits between HTTP and TCP, and reliability lives in the kernel's TCP. HTTP/2 changes only the top box: binary framing and multiplexed streams over a single TCP connection. In HTTP/3, QUIC absorbs the jobs of both TCP and TLS and runs over UDP, so the stream abstraction moves into the transport and loss on one stream no longer blocks others. Arrows represent encapsulation (synchronous hand-off of each message down the stack). Failure point specific to HTTP/3: networks that block or throttle UDP, handled by falling back to HTTP/2. Scaling consideration: QUIC runs in user space and encrypts every packet individually, so it has historically cost more server CPU per byte than kernel TCP with TLS; implementations close the gap with UDP segmentation offload and batching.

Table 7.10 — HTTP/1.1, HTTP/2 and HTTP/3 compared.

Aspect	HTTP/1.1	HTTP/2	HTTP/3
Specification	RFC 9112	RFC 9113	RFC 9114 (over QUIC, RFC 9000)
Encoding	Text	Binary frames	Binary frames
Transport	TCP	TCP	QUIC over UDP
Concurrency per connection	One request at a time	Many multiplexed streams	Many independent streams
Head-of-line blocking	HTTP layer and TCP	TCP layer only	None across streams
Header compression	None	HPACK	QPACK
Encryption	Optional (TLS)	Effectively required by browsers	Always (TLS 1.3 built in)
New-connection setup with TLS 1.3	2 RTT (TCP + TLS)	2 RTT	1 RTT; 0 RTT on resumption
Connection migration	No	No	Yes, via connection IDs
Debuggability	Plain text with telnet or curl	Needs tools	Needs tools and decrypting keys
Choose when	Simple clients, internal tooling, legacy	Default for APIs and gRPC; most traffic	Mobile and lossy networks, latency-sensitive web traffic

RECOMMENDATION

Choosing an HTTP version. Terminate HTTP/2 (and HTTP/3 where your load balancer or CDN supports it) at the edge for browsers and mobile clients. Inside a datacenter, HTTP/2 over long-lived connections (for example, gRPC, §8.8) is the common default: loss is rare, so TCP HOL blocking matters little, while kernel TCP is cheap and mature. Do not hand-roll HTTP/3 between internal services without a measured reason.

COMMON MISTAKE

“HTTP/2 is always faster than HTTP/1.1.” HTTP/2 wins in most browser workloads because it removes connection limits and compresses headers. But one connection means one congestion window and one point of HOL blocking: under heavy loss, or when a single connection’s cwnd is the bottleneck for bulk transfer, several HTTP/1.1 connections can outperform it. Measure on your traffic.

7.10 TLS 1.3 and HTTPS

7.10.1 What TLS provides

DEFINITION

Definition — Transport Layer Security (TLS). A protocol that gives two communicating applications **confidentiality** (eavesdroppers cannot read the data), **integrity** (tampering is detected) and **authentication** (at least the server proves its identity, usually with an X.509 certificate). **HTTPS** is HTTP carried over TLS, on TCP port 443 by default. TLS 1.3 is specified in RFC 8446 (2018).

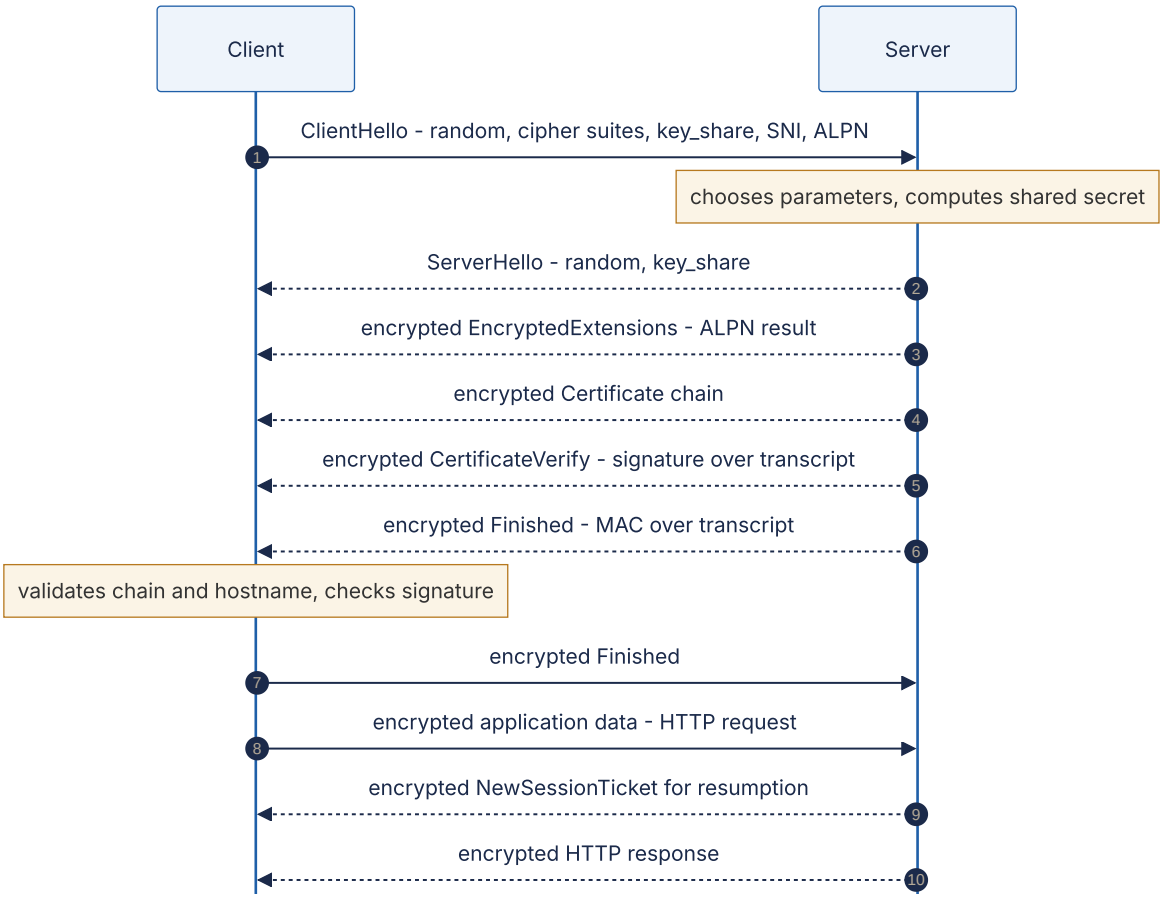
Analogy: before discussing secrets with a stranger on the phone, you check their government-issued ID (the certificate, vouched for by a trusted issuer), then the two of you agree on a code that only you two know, without ever saying it aloud on the line (a **key exchange**), and from then on you speak only in that code and seal every sentence so changes would be noticed (authenticated encryption).

The cryptography itself (Diffie–Hellman, signatures, AEAD ciphers) is covered in §10.4. Here we focus on the round trips and their operational consequences.

7.10.2 The TLS 1.3 handshake

TLS 1.2 needed **two** round trips before application data could flow. TLS 1.3 needs **one**, because the client guesses the key-exchange group the server will accept and sends its key share in the very first message.

Figure 7.8 — TLS 1.3 full handshake (after the TCP handshake).



Reading the diagram. Step 1, the **ClientHello**, carries a random nonce, the cipher suites the client supports, its ephemeral Diffie–Hellman **key share**, the **Server Name Indication (SNI)** naming the host it wants (so one IP address can serve many sites), and the **ALPN** list of application protocols it speaks (`h2`, `http/1.1`). Steps 2–6 are the server's single flight. From the ServerHello onward, both sides can derive handshake keys, so everything after it, including the certificate, is encrypted (in TLS 1.2 the certificate traveled in clear text). CertificateVerify proves the server holds the private key for the certificate; Finished proves nobody tampered with the handshake. In step 7 the client sends its Finished and, in step 8, its first request, all after **one RTT**. Steps 9–10 arrive later: a session ticket for faster resumption, and the response. Everything is synchronous request/response over the already-established TCP connection. Failure points: certificate validation (expired, wrong name, untrusted issuer) aborts the handshake; mismatched protocol versions or cipher suites fail at step 2. Scaling consideration: the server's signature in step 5 is the main CPU cost of a handshake, which is a reason to reuse connections (§7.16) and resume sessions.

7.10.3 Certificates and the chain of trust

A **certificate** binds a public key to one or more names (in the Subject Alternative Name field), with a validity period, signed by a **certificate authority (CA)**. Browsers and operating systems ship a **root store** of trusted root CAs. Servers send their own (**leaf**) certifi-

cate plus **intermediate** certificates; the client builds a chain from leaf to a trusted root and checks:

1. each signature in the chain verifies with the issuer's public key;
2. the current time is within every certificate's validity period;
3. the requested hostname matches a name in the leaf;
4. the certificate has not been revoked (via OCSP or CRLs, imperfectly in practice); and
5. publicly trusted certificates appear in Certificate Transparency logs, as major browsers require.

Operationally, the most common TLS outage is mundane: **an expired certificate**. Publicly trusted certificates have a maximum lifetime of 398 days as of 2025, and the CA/Browser Forum has adopted a schedule to shorten it further over the coming years; ACME-based automation (as popularized by Let's Encrypt) is the only sane response. Monitor expiry dates of every certificate, including internal ones.

Mutual TLS (mTLS), in which the client also presents a certificate, is the standard way to authenticate services to each other inside a zero-trust network (§10.10). PKI design — issuance, revocation and private CAs — is covered in §10.5.

Table 7.11 — TLS 1.2 versus TLS 1.3.

Aspect	TLS 1.2 (RFC 5246)	TLS 1.3 (RFC 8446)
Full handshake	2 RTT	1 RTT
Resumption	1 RTT	1 RTT, or 0-RTT with early data
Key exchange	RSA key transport or (EC)DHE	(EC)DHE only, so forward secrecy is mandatory
Cipher suites	Many, including weak legacy options	Five AEAD suites
Certificate visibility	Sent in clear text	Encrypted
Removed features	—	RSA key transport, static DH, CBC-mode ciphers, compression, renegotiation

Forward secrecy means that stealing a server's long-term private key later does not let an attacker decrypt previously recorded sessions, because each session's keys came from ephemeral Diffie–Hellman values that were discarded.

7.10.4 0-RTT and its caveats

With a session ticket from a previous connection, a TLS 1.3 client can send **early data** in its first flight, encrypted under a key derived from the resumption pre-shared key.

Combined with QUIC, a returning client can deliver a request with zero round trips of setup. Two caveats make 0-RTT dangerous if used carelessly [RFC 8446 §8]:

1. **Replay.** An attacker who records the first flight can resend it, and the server may process the early data twice. TLS cannot fully prevent this across a distributed server fleet.
2. **Weaker forward secrecy for early data**, which is protected only by the resumption key, not by fresh ephemeral key exchange.

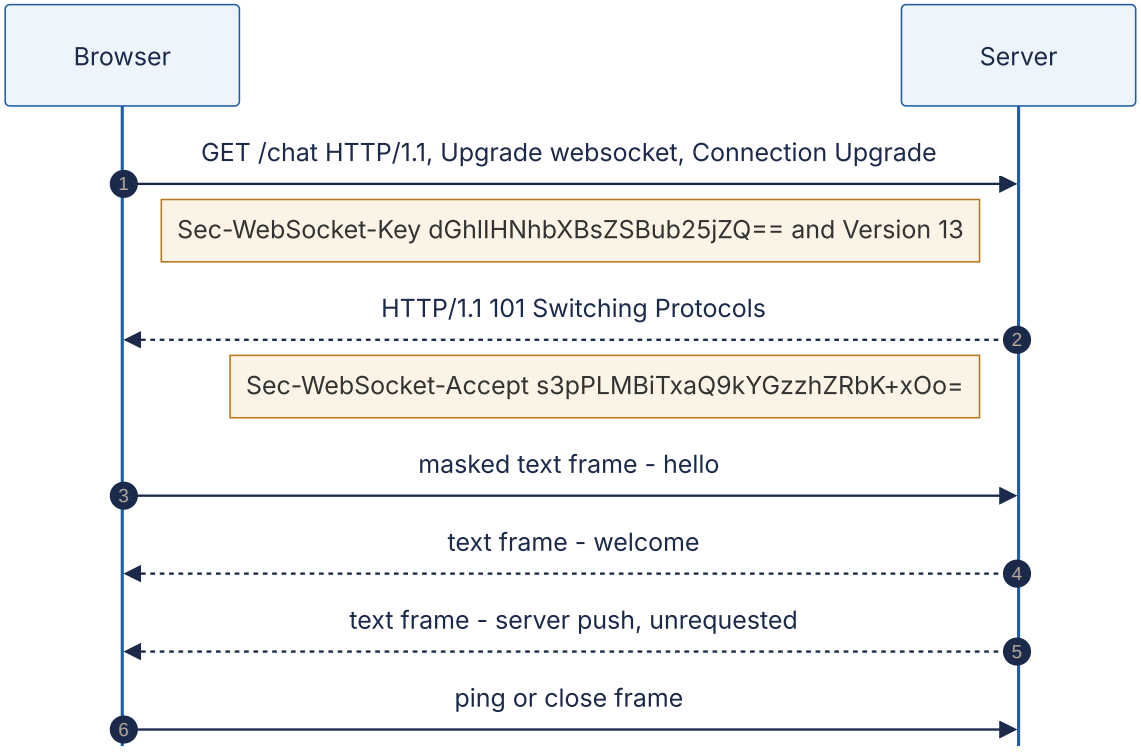
The rule: accept 0-RTT only for **idempotent, safe requests** (GET without side effects). Servers and CDNs that support it typically restrict it to such methods, and HTTP defines the `Early-Data` header and the 425 (Too Early) status code (RFC 8470) so origins can reject replay-unsafe early requests. Never let a payment or any non-idempotent POST ride in 0-RTT (see idempotency keys, §22.15).

> COMMON MISTAKE
>
> **"TLS is too slow to use internally."** With TLS 1.3, a handshake costs one RTT (sub-millisecond inside a datacenter) and some CPU, and modern CPUs encrypt with AES-GCM at several GB/s per core using hardware instructions. With connection reuse, the steady-state cost is small. The exceptions are extreme-throughput paths, where kernel TLS and NIC offload exist for exactly this reason.

7.11 WebSockets (introduction)

HTTP is client-initiated: the server cannot speak until asked. Chat, live dashboards, collaborative editors and multiplayer games need the server to push data whenever it has some. **WebSocket** [RFC 6455] provides a persistent, full-duplex, message-oriented channel between browser and server, created by **upgrading** an HTTP/1.1 connection.

Figure 7.9 — WebSocket opening handshake and framing.



Reading the diagram. Steps 1–2 are an ordinary HTTP/1.1 exchange over an existing TCP (usually TLS) connection. The client sends a random base64 key; the server proves it understood the WebSocket protocol by returning `Sec-WebSocket-Accept`, the base64-encoded SHA-1 hash of the key concatenated with the fixed GUID `258EAFA5-E914-47DA-95CA-C5AB0DC85B11` (the values shown are the example from RFC 6455). After the `101` response the same TCP connection carries WebSocket **frames** in both directions, at any time (steps 3–6): either side may send without being asked, so the arrows are asynchronous in the application sense. Frames from client to server are **masked** with a random 4-byte key to stop malicious pages from crafting bytes that confuse caching proxies. Control frames (ping, pong, close) keep the connection alive and close it cleanly. Failure points: intermediaries with idle timeouts (load balancers commonly default to around 60 s) silently kill quiet connections, so applications send periodic pings; and every connection pins state to one server, which complicates deploys and load balancing.

The full design space (long polling, Server-Sent Events, WebSockets at scale, sticky routing, presence) is Chapter 9. WebSockets can also run over HTTP/2 (RFC 8441) and HTTP/3 (RFC 9220) using an extended CONNECT method.

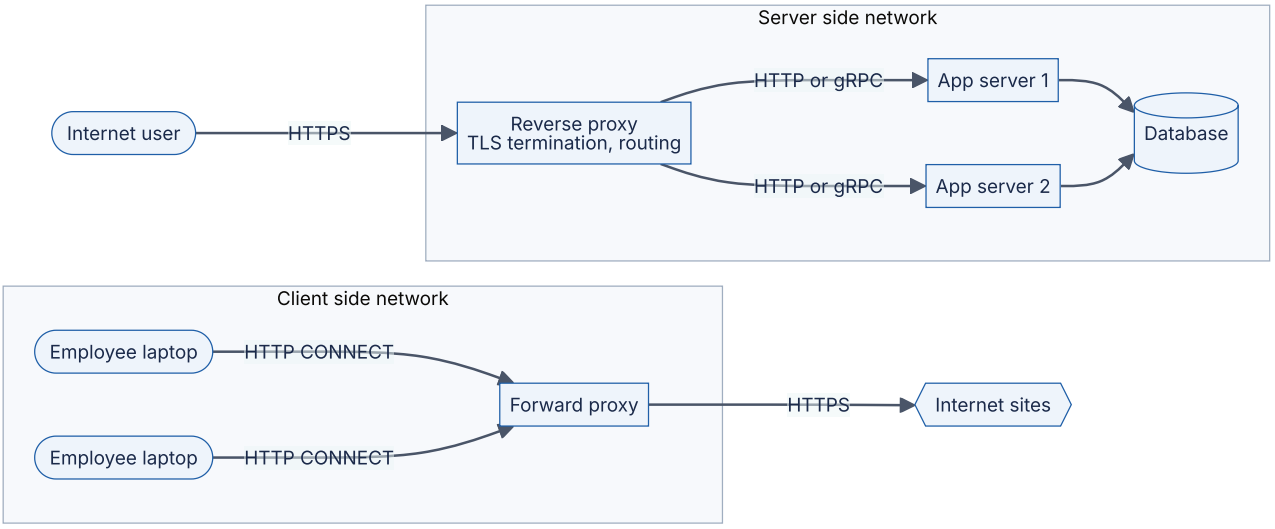
7.12 Forward proxies and reverse proxies

DEFINITION

Definition — Proxy. An intermediary that terminates a client's connection and opens its own connection onward, relaying requests and responses. A **forward proxy** acts on behalf of **clients** and is chosen by them (or their network administrator). A **reverse proxy** acts on behalf of **servers** and is chosen by the site operator; clients usually do not know it exists.

Analogy: a forward proxy is your personal assistant who places all your calls, so callees see the assistant's number. A reverse proxy is a company switchboard: callers dial one number and the receptionist routes them to the right employee, who never has to expose a direct line.

Figure 7.10 — Forward proxy versus reverse proxy.



Reading the diagram. On the left, client machines inside an organization send all outbound traffic through a forward proxy, using the HTTP `CONNECT` method to tunnel TLS connections; destination sites see the proxy's address. On the right, Internet users connect to a reverse proxy, which terminates TLS, inspects HTTP and forwards each request to one of several application servers over internal HTTP or gRPC; users see only the proxy. Both paths are synchronous request/response. The database behind the app servers is the storage boundary. Failure points: each proxy is a single point of failure unless replicated behind anycast, ECMP or DNS (§19.8). Scaling: reverse proxies scale horizontally and absorb connection-handling work (TLS, slow clients) so app servers do not have to.

Table 7.12 — Forward and reverse proxies compared.

Aspect	Forward proxy	Reverse proxy
Acts for	Clients	Servers
Configured by	Client or client's network	Service operator
Hides	Client identity from servers	Server topology from clients
Typical functions	Egress filtering, caching, auditing, access control, anonymity	TLS termination, load balancing, routing by path or host, caching, compression, rate limiting, WAF, request buffering
Examples	Squid, corporate secure web gateways, egress proxies in VPCs	NGINX, HAProxy, Envoy, cloud load balancers, CDNs, API gateways
System-design relevance	Controlled egress from private networks	Nearly every web architecture's front door

A reverse proxy that distributes load is a **load balancer** (Chapter 19); one that adds authentication, quotas and API management is an **API gateway** (§34.6); one deployed beside every service instance is a **sidecar** in a **service mesh**. Proxies that terminate TCP also shield back-ends from slow clients: the proxy buffers a slowly uploaded request and hands the application a complete one, so the application's limited workers are not tied up for seconds.

WARNING / TRADE-OFF

The client IP problem. Behind a reverse proxy, the application sees the proxy's IP as the source. Proxies pass the original address in the `X-Forwarded-For` or standard `Forwarded` header (RFC 7239), or at L4 via the PROXY protocol. Trust these headers only when they were set by your own proxy; otherwise clients can forge them to evade rate limits or IP allow-lists.

7.13 NAT

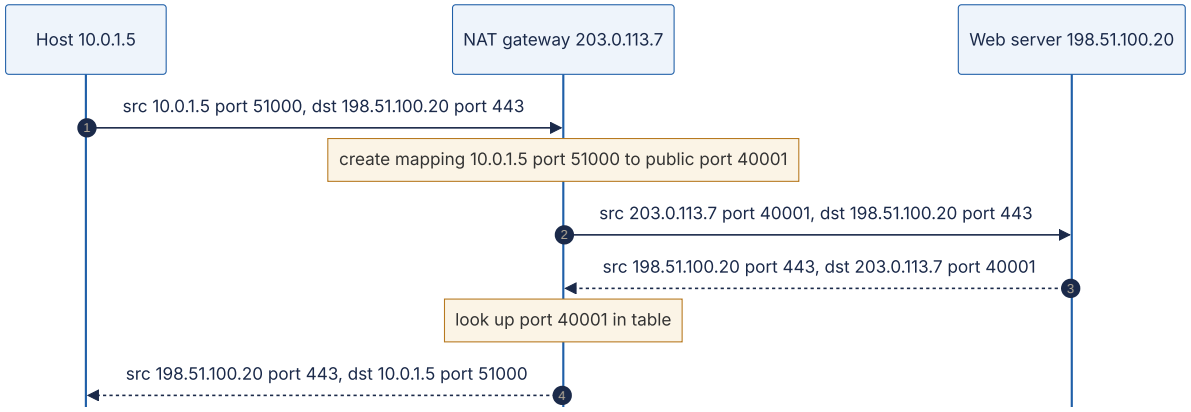
DEFINITION

Definition — Network Address Translation (NAT). A function, usually in a router or gateway, that rewrites the source and/or destination IP addresses (and usually ports) of packets as they pass, keeping a **translation table** so that replies can be rewritten back. The most common form, **source NAT with port translation** (NAPT, often just "NAT"), lets many hosts with private addresses share one public address [RFC 3022].

Analogy: an office building with one street address and a mailroom. Outgoing letters carry the building's return address with an internal "room code" written on them; when

replies come back with that code, the mailroom forwards them to the right room. A letter that arrives with no room code the mailroom has issued has nowhere to go.

Figure 7.11 — Source NAT for an outbound connection.



Reading the diagram. A private host (left) opens a connection to a public server (right) through a NAT gateway (middle). In step 1 the packet carries the host's private address. The NAT rewrites the source to its own public address and a free public port, recording the mapping (steps 2–3). The server replies to the public address (step 4), and the NAT reverses the translation using the table (steps 5–6). All traffic is synchronous and flows through the same NAT in both directions: the NAT is **stateful**, which makes it a failure point (if it restarts or the mapping times out, existing connections die) and a scaling limit (ports per destination).

Consequences for system design

- **Inbound connections are impossible by default**, because no mapping exists until the inside host sends first. Peer-to-peer systems (WebRTC, §9.7) use STUN to discover their public mapping and fall back to TURN relays when NAT behavior prevents direct connections.
- **Mappings time out.** Idle UDP mappings may expire in tens of seconds and TCP mappings in minutes to hours, depending on the device. Long-lived idle connections need keep-alives shorter than the NAT timeout, or they become half-open (§7.7).
- **Port exhaustion.** A single public IP has about 64,000 usable ports per destination (IP, port, protocol). AWS documents a NAT gateway limit of 55,000 simultaneous connections per assigned IP address to each unique destination, raisable by assigning more IPs (as of 2025) [AWS Docs: NAT gateways]. A fleet of services calling one external API through one NAT IP can exhaust this; connection pooling and more NAT IPs fix it.
- **Carrier-grade NAT (CGNAT)**: mobile and some fixed ISPs place many subscribers behind shared addresses from `100.64.0.0/10`. Thousands of users can share one public IP, so **IP-based rate limiting and blocking punish innocent users**.

- **Cost.** Managed cloud NAT gateways usually charge per gigabyte processed; routing bulk traffic to cloud storage through them instead of private endpoints is a common surprise on the bill.

7.14 Firewalls and security groups

DEFINITION

Definition — Firewall. A device or software function that permits or denies traffic according to rules. A **stateless** (packet-filter) firewall evaluates each packet independently against rules on addresses, ports and protocol. A **stateful** firewall tracks connections, so a reply to an allowed outbound connection is automatically permitted. **Application-layer firewalls**, including web application firewalls (WAFs), parse protocols such as HTTP to block malicious requests.

Cloud providers expose two common forms. A **security group** (AWS, similar constructs elsewhere) is a stateful, allow-only rule set attached to a network interface or instance. A **network ACL** is a stateless, ordered allow-and-deny rule list attached to a subnet. Because NACLs are stateless, you must explicitly allow return traffic, typically to the client's ephemeral port range, which is a frequent source of "connection hangs" misconfigurations.

Table 7.13 — Firewall mechanisms compared.

Aspect	Stateless ACL	Stateful firewall / security group	Web application firewall
Inspects	Packet headers	Headers plus connection state	HTTP requests (L7)
Return traffic	Must be explicitly allowed	Allowed automatically	N/A (proxy)
Rule style	Ordered allow/deny	Usually allow-only	Signatures, rate rules, custom logic
Cost of state	None	Connection table (can be exhausted)	Full proxying
Typical placement	Subnet boundary	Each instance or interface	In front of web apps, often at the CDN
Choose when	Coarse subnet guardrails	Default micro-segmentation between tiers	Blocking injection, bots, abusive patterns

Practical rules

1. **Default deny.** Allow only the ports and sources each tier needs: the load balancer may reach the app tier on port 8080; only the app tier may reach the database on

5432.

2. **Reference groups, not addresses.** Security groups can name other groups as sources (“allow from sg-app”), which keeps rules correct as instances scale in and out.
3. **Firewalls are one layer of defense in depth.** Combine them with authentication and encryption (mTLS, §10.10); a network position is not an identity.
4. **Watch the state table.** Stateful devices track every connection; a flood of connections (legitimate or attack) can exhaust their tables and drop everything. Linux’s `conntrack` table is a common culprit on busy proxies.
5. **Silent drops cause timeouts, rejections cause fast failure.** A firewall that drops packets makes clients wait for a timeout; one that sends RST or ICMP unreachable fails fast. Choose deliberately.

7.15 Latency, bandwidth, the bandwidth-delay product and packet loss

7.15.1 The four components of latency

Think of a highway. **Bandwidth** is the number of lanes: how many cars per second can pass a point. **Latency** is how long one car takes to travel from entrance to exit. Adding lanes does not make the drive shorter. A packet’s one-way delay through each hop is the sum of four parts.

> DEFINITION
>
> **Definition — Components of network delay. Propagation delay**: time for a signal to travel the physical distance. **Transmission (serialization) delay**: time to push all of a packet’s bits onto the link. **Queuing delay**: time spent waiting in buffers behind other packets. **Processing delay**: time for a device to examine headers, look up routes and copy the packet.

FORMULA

One-hop delay

$$d_{\text{hop}} = \underbrace{\frac{D}{v}}_{\text{propagation}} + \underbrace{\frac{L}{R}}_{\text{transmission}} + d_{\text{queue}} + d_{\text{proc}}$$

Symbol	Meaning	Units
D	Physical length of the link	m (or km)
v	Signal speed in the medium: about 2×10^8 m/s in optical fiber (roughly two-thirds of c)	m/s
L	Packet size	bits
R	Link rate (bandwidth)	bits/s
d_{queue}	Queuing delay: bytes waiting ahead ÷ link rate	s
d_{proc}	Processing delay: microseconds in software, sub-microsecond in switch hardware	s

Table 7.14 — Delay components at a glance.

Component	Depends on	Typical magnitude	How to reduce it
Propagation	Distance, medium	~5 µs per km of fiber; tens of ms across oceans	Move closer: CDNs, edge, regional replicas
Transmission	Packet size, link rate	12 µs for 1,500 B at 1 Gbps; 1.2 µs at 10 Gbps	Faster links, smaller packets
Queuing	Load, buffer size	0 to hundreds of ms	Lower utilization, AQM, BBR
Processing	Device and software path	~µs (hardware) to tens of µs (software)	Kernel bypass, offloads, fewer hops

WORKED EXAMPLE

Worked example 1 — The speed-of-light floor from New York to London.

The great-circle distance between New York and London is about 5,570 km.

1. One-way propagation in fiber: $5,570 \text{ km} / 200,000 \text{ km/s} = 0.02785 \text{ s} = 27.85 \text{ ms}$.
2. Round-trip time: $2 \times 27.85 = 55.7 \text{ ms}$.
3. Even in a vacuum at $c \approx 299,792$ km/s, the RTT would be $2 \times 5,570 / 299,792 \approx 37.2 \text{ ms}$.
4. Real cables do not follow the great circle, and routers, transmission and queuing add more, so measured RTTs are noticeably higher than 55.7 ms (often in the 70 ms range).

Interpretation: no engineering can make a New York–London round trip faster than about 56 ms over fiber. A user in London calling a single-region service in New York pays at least that on every round trip, and a page needing five sequential round trips pays at least 280 ms. Engineering implication: for global users, reduce round trips (connection reuse, TLS 1.3, QUIC) and move content and computation closer (CDNs, Ch 21; multi-region, Ch 44).

WORKED EXAMPLE

Worked example 2 — Transmission versus propagation.

Send one 1,500-byte packet ($L = 12,000$ bits).

- On a 10 Mbps link: $12,000 / 10^7 = 1.2$ ms.
- On a 1 Gbps link: $12,000 / 10^9 = 12$ µs.
- On a 100 Gbps link: $12,000 / 10^{11} = 120$ ns.

Compare with propagation across a 100 m datacenter cable: $100 / (2 \times 10^8) = 0.5$ µs. Interpretation: on slow access links, serialization dominates; on fast datacenter links, serialization becomes negligible and per-hop processing and software stacks dominate.

WORKED EXAMPLE

Worked example 3 — Bufferbloat.

A home router has a 10 MB buffer in front of a 1 Gbps uplink. When a large upload fills that buffer, a newly arriving packet waits behind $10 \times 10^6 \times 8 = 8 \times 10^7$ bits, so its queuing delay is $8 \times 10^7 / 10^9 = 0.08$ s = 80 ms. On a 20 Mbps uplink the same buffer would add $8 \times 10^7 / (2 \times 10^7) = 4$ s. Loss-based congestion control (CUBIC) keeps such buffers full, so a video call alongside a big upload suffers seconds of lag. Fixes: active queue management (CoDel, FQ-CoDel) on the bottleneck, and delay-aware congestion control such as BBR.

7.15.2 Throughput and the bandwidth-delay product

A reliable sender can only have a window's worth of unacknowledged data in flight; it then waits for ACKs, which take one RTT. So:

FORMULA

Window-limited throughput and the bandwidth-delay product (BDP)

$$\text{Throughput} \le \frac{W}{\text{RTT}} \qquad \text{BDP} = R \times \text{RTT}$$

Symbol	Meaning	Units
W	Effective window, $\min(\text{cwnd}, \text{rwnd})$	bytes
RTT	Round-trip time	s
R	Bottleneck link rate	bits/s (divide by 8 for bytes/s)
BDP	Data that must be in flight to keep the link full	bits or bytes

WORKED EXAMPLE

Worked example — BDP for a 10 Gbps, 80 ms path.

1. BDP $= 10 \times 10^9$ bits/s $\times\ 0.080$ s $= 8 \times 10^8$ bits.
2. In bytes: $8 \times 10^8 / 8 = 10^8$ bytes $=$ **100 MB**.
3. Without window scaling, W is at most 65,535 bytes, giving throughput $\le 65,535 \times 8 / 0.08 \approx 6.55$ Mbps, about 0.07% of the link.
4. To fill the link, the receiver must advertise (and the sender buffer) about 100 MB per connection: window scaling must be on and kernel buffer limits (`net.ipv4.tcp_rmem` and `tcp_wmem` maximums on Linux) must be at least that large.

Interpretation: on “long fat networks”, a single TCP connection is limited by buffers and window, not by the link. Engineering implication: bulk cross-region transfers (backups, replication, dataset copies) need tuned buffers, parallel streams, or both.

7.15.3 Packet loss and the Mathis formula

Loss hurts TCP twice: each lost packet must be retransmitted, and each loss signal halves (Reno) or cuts (CUBIC) the congestion window. For loss-based congestion avoidance with random loss probability p, Mathis, Semke, Mahdavi and Ott derived a simple upper bound on steady-state throughput [Mathis et al. 1997].

FORMULA

Mathis throughput formula

$$\text{Throughput} \le \frac{\text{MSS}}{\text{RTT}} \times \frac{C}{\sqrt{p}}$$

Symbol	Meaning	Units
MSS	Maximum segment size	bits (or bytes, for bytes/s)
RTT	Round-trip time	s
p	Packet loss probability	dimensionless
C	Constant, $\sqrt{3/2} \approx 1.22$ for periodic loss with every packet ACKed	dimensionless

WORKED EXAMPLE

Worked example — Loss caps a long-distance connection.

MSS = 1,460 bytes = 11,680 bits; RTT = 80 ms.

1. MSS/RTT $= 11,680/0.08 = 146,000$ bits/s.
2. With $p = 10^{-4}$ (0.01% loss): $C/\sqrt{p} = 1.22/0.01 = 122$, so throughput $\leq 146,000 \times 122 \approx 17.8$ Mbps.
3. With $p = 10^{-6}$: $C/\sqrt{p} = 1,220$, so throughput ≤ 178 Mbps.
4. To reach 10 Gbps: $\sqrt{p} = 1.22 \times 146,000/10^{10} \approx 1.79 \times 10^{-5}$, so $p \approx 3.2 \times 10^{-10}$, about one loss in three billion packets.

Interpretation: throughput falls with 1/RTT and $1/\sqrt{p}$, independent of link speed. A tiny 0.01% loss caps a single transcontinental CUBIC- or Reno-style flow at under 20 Mbps on a 10 Gbps link. Engineering implications: (a) find and fix lossy links, which are often a dirty optic or a bad cable; (b) reduce RTT; (c) for bulk transfers, use parallel connections or a model-based algorithm such as BBR that does not treat random loss as congestion. The formula is an approximation for loss-based algorithms in congestion avoidance; it does not describe BBR, short flows still in slow start, or timeout-dominated regimes.

7.16 Connection pooling and keep-alive

7.16.1 The cost of a new connection

Before the first byte of a response can arrive over a new HTTPS connection, the client pays for DNS, the TCP handshake, the TLS handshake, and the request itself.

Table 7.15 — Round trips before the first response byte (DNS cached).

Stack	Setup RTTs	Request RTT	Total	At RTT 80 ms	At RTT 0.5 ms (same datacenter)
HTTP over TCP, no TLS	1	1	2	160 ms	1.0 ms
HTTPS, TCP + TLS 1.2	1 + 2	1	4	320 ms	2.0 ms
HTTPS, TCP + TLS 1.3	1 + 1	1	3	240 ms	1.5 ms
HTTP/3, QUIC first connection	1	1	2	160 ms	1.0 ms
HTTP/3, QUIC 0-RTT resumption	0	1	1	80 ms	0.5 ms
Any stack, reused connection	0	1	1	80 ms	0.5 ms

Round trips are only part of the cost. Each new connection also burns CPU (the TLS asymmetric cryptography is the expensive part), allocates kernel and proxy memory, starts in slow start with a small congestion window (§7.7.7), and leaves a TIME_WAIT entry when closed (§7.7.4).

WORKED EXAMPLE

Worked example — Reusing connections to a cross-region dependency.

Service A in Virginia calls service B in Oregon (RTT about 70 ms) 200 times per second. Each call takes 10 ms of server time.

1. New TCP + TLS 1.3 connection per call: latency $\approx 3 \times 70 + 10 = 220$ ms per call.
2. Reused connection: $1 \times 70 + 10 = 80$ ms per call, a 2.75× reduction.
3. Handshake work avoided: 200 TLS handshakes per second, each involving a signature on B and verification on A.
4. Ports: with per-call connections and A as active closer, $200 \times 60 = 12,000$ sockets sit in TIME_WAIT at any time, about 43% of the 28,232 default ephemeral ports.

Interpretation: connection reuse is not a micro-optimization; it changes latency by a factor of nearly three and removes a scaling cliff.

7.16.2 Sizing a pool with Little's Law

A **connection pool** keeps a set of open connections that callers borrow and return. For protocols that carry one request at a time per connection (HTTP/1.1, most database protocols), the number of connections in use equals the number of requests in flight, which Little's Law gives directly (§4.11).

FORMULA

Connections needed for a one-request-per-connection protocol

$$N = \lambda \times W$$

Symbol	Meaning	Units
N	Average connections busy	connections
λ	Request rate	requests/s
W	Time a request holds a connection (network RTT plus server time)	s

WORKED EXAMPLE

Worked example — Database pool sizing.

An application server issues 2,000 queries per second; each holds a connection for 5 ms on average (0.5 ms RTT plus 4.5 ms of query execution).

1. $N = 2,000 \times 0.005 = 10$ busy connections on average.
2. Add headroom for bursts and tail latency: if p99 hold time is 25 ms, bursts can need $2,000 \times 0.025 = 50$. A pool of 20–50 is reasonable.
3. With 40 application servers each holding a pool of 50, the database must accept 2,000 connections. Many databases degrade with thousands of connections (PostgreSQL uses a process per connection), which is why connection proxies such as PgBouncer sit in between (Chapter 14).

Interpretation: size pools from rate × hold time, not by guessing; and remember pools multiply across instances.

7.16.3 Keep-alive pitfalls

- **Idle-timeout races.** If the server (or a load balancer) closes idle connections after 60 s and the client's pool keeps them for 90 s, the client will occasionally send a request on a connection the server has just closed, getting a reset. Set client idle

timeouts **shorter** than every server-side timeout along the path, and retry idempotent requests on this specific failure.

- **Stale connections after failover.** Long-lived connections keep talking to an old backend after DNS changes, so set a maximum connection lifetime.
- **Load imbalance with multiplexed protocols.** An HTTP/2 or gRPC client may send all its traffic over one long-lived connection to one backend; an L4 load balancer balances connections, not requests, so new backends receive nothing. Use L7 (request-level) load balancing or client-side balancing, and cap connection age so connections periodically redistribute (§19.10).
- **TCP keep-alive is not HTTP keep-alive.** HTTP keep-alive means "reuse this connection for more requests". TCP keep-alive sends empty probes on an idle connection to detect dead peers and refresh NAT and firewall state.

7.17 Datacenter networking

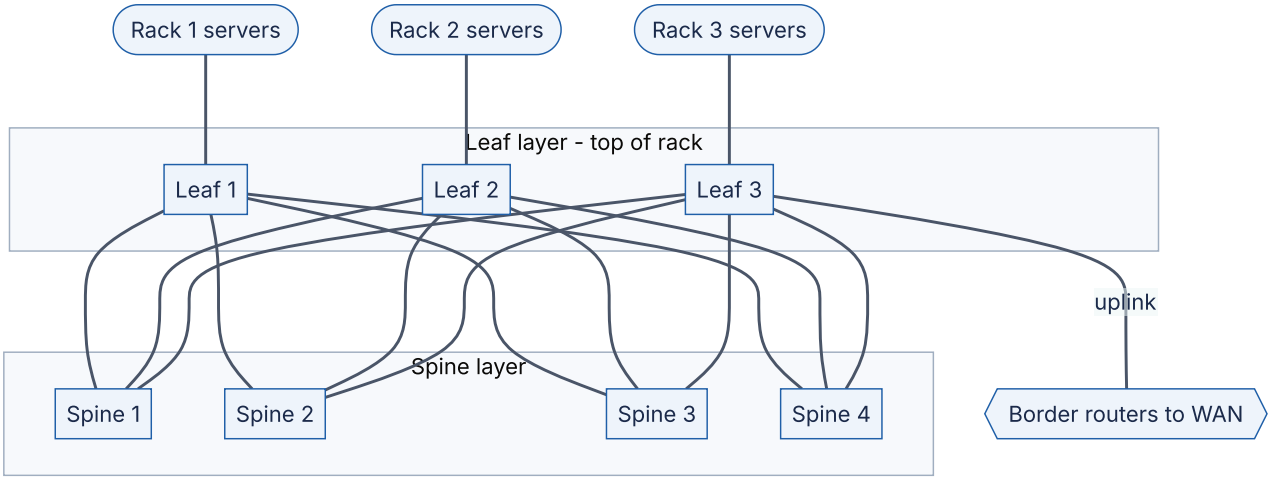
7.17.1 From trees to leaf–spine

Traditional enterprise networks were **trees**: servers connect to access switches, which connect to aggregation switches, which connect to a pair of large core routers. Trees suit **north–south** traffic (between users outside and servers inside). Modern applications are different: a single user request fans out to dozens of internal services, caches and databases, and batch jobs shuffle terabytes between servers. Most bytes now flow **east–west**, server to server inside the datacenter. In a tree, east–west traffic converges on the few links near the top, which become the bottleneck, and the expensive core routers become both a cost and a failure concentration.

DEFINITION

Definition — Leaf-spine (folded Clos) network. A two-tier topology in which every **leaf** (top-of-rack) switch connects to every **spine** switch, and servers attach only to leaves. Any two servers on different leaves are exactly two switch hops apart (leaf → spine → leaf), and traffic is spread across all spines with ECMP. It is a form of the multistage **Clos network**, first described by Charles Clos in 1953 for telephone switching. Larger fabrics add a third tier.

Figure 7.12 — A leaf-spine fabric with ECMP.



Reading the diagram. Servers in each rack connect to their leaf switch. Every leaf has one uplink to every spine (a full bipartite mesh), so a flow from rack 1 to rack 3 has four equal-cost two-hop paths, and leaves pick among them by hashing each flow's 5-tuple (ECMP). Spines never connect to each other or to servers. One leaf (or a dedicated pair) connects to border routers for north–south traffic. Links are undirected because traffic flows both ways; all forwarding is synchronous hardware switching. Failure points: losing a spine removes one quarter of cross-rack capacity rather than isolating anything; losing a leaf isolates its rack, which is why critical services spread replicas across racks. Scaling: add spines for more bandwidth, add leaves (up to the spine port count) for more racks.

FORMULA

Oversubscription ratio at a leaf

$$\text{Oversubscription} = \frac{\text{total server-facing bandwidth}}{\text{total uplink bandwidth}}$$

Symbol	Meaning	Units
Server-facing bandwidth	Sum of the leaf's downlink port speeds	Gbps
Uplink bandwidth	Sum of the leaf's spine-facing port speeds	Gbps

WORKED EXAMPLE

Worked example — Sizing a leaf-spine fabric.

Each leaf has 48 × 25 Gbps server ports and 6 × 100 Gbps uplinks; each spine has 64 × 100 Gbps ports.

1. Downlink: $48 \times 25 = 1,200$ Gbps. Uplink: $6 \times 100 = 600$ Gbps.
2. Oversubscription: $1,200/600 = 2{:}1$. If every server sends cross-rack at full rate, each gets at most 12.5 Gbps.
3. Each leaf uses one port on each of 6 spines, so there are 6 spines. Each spine has 64 ports, so at most 64 leaves.
4. Maximum servers: $64 \times 48 = 3,072$.
5. Total leaf-to-spine capacity: $64 \text{ leaves} \times 600 \text{ Gbps} = 38.4$ Tbps. The **bisection bandwidth** (capacity between any half of the leaves and the other half) is $32 \times 600 = 19.2$ Tbps.

Interpretation: oversubscription is a cost lever. 1:1 (“non-blocking”) fabrics cost more uplinks and spines; 3:1 is acceptable for workloads that are mostly rack-local. Larger fabrics add a third tier of switches to go beyond the port count of one spine.

INDUSTRY EXAMPLE

Google Jupiter. Google’s SIGCOMM 2015 paper describes a decade of five datacenter network generations, culminating in Jupiter. Instead of buying ever-larger proprietary routers, Google built multistage Clos topologies from many small switches using commodity merchant silicon, managed them with centralized, software-defined control rather than traditional distributed routing protocols, and scaled capacity about 100× over ten years to more than 1 Pbps of bisection bandwidth. The paper’s argument (that bandwidth demand from east–west traffic grows faster than any single box can, so the network must scale out like the servers) is now standard practice across large datacenter operators. *Evidence: Primary* — [Singh et al. 2015]

7.17.2 Datacenter-specific problems

- **Incast.** When a client fans a request out to 100 servers that all reply at the same instant, the replies converge on one leaf port, overflow its shallow buffer, and drop packets. The dropped flows wait for a 200 ms minimum RTO in a network whose RTT is about 100 µs, producing extreme tail latency (§23.6). Mitigations: limit fan-out concurrency, jittered responses, smaller minimum RTOs, and ECN-based congestion control such as DCTCP.
- **ECMP hash collisions.** Two elephant flows hashed onto the same spine link share it while other links sit idle. Flowlet switching, packet spraying and adaptive routing

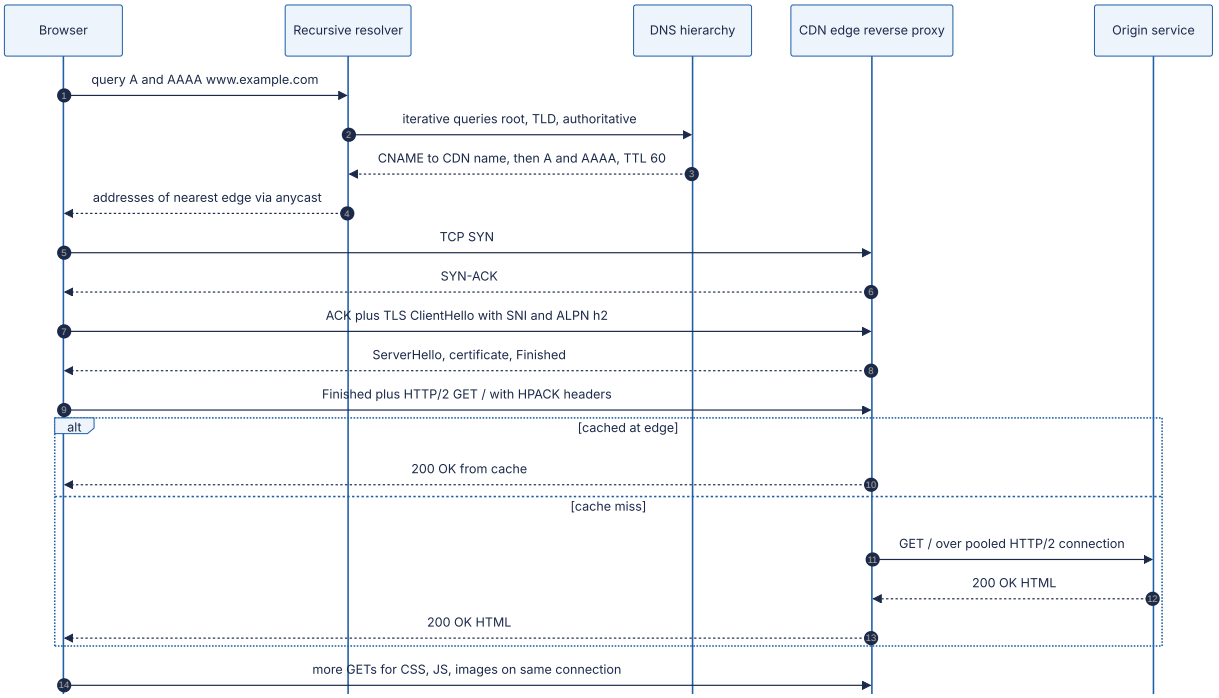
reduce this.

- **Gray failures.** A link that drops 1% of packets is worse than a dead one, because routing still uses it while TCP throughput collapses (recall the Mathis formula). Operators monitor per-link error counters and drain suspect links automatically.

7.18 What happens when you type a URL

Everything in this chapter appears in the life of one request. Suppose you type `https://www.example.com/` into a browser on a laptop connected by Wi-Fi at home, with a cold DNS cache, and the site is served by a CDN edge 20 ms away (RTT) with HTTP/2.

Figure 7.13 — Loading https://www.example.com/ end to end.



Reading the diagram. Steps 1–4: the browser (via the operating system stub) asks a recursive resolver, which walks the DNS hierarchy (§7.6); the authoritative server returns a CNAME pointing into the CDN, whose own authoritative servers answer with an anycast address (§7.5.3). Steps 5–7: the TCP handshake (§7.7.3), with the TLS ClientHello piggybacked on the final ACK. Step 8: the server's TLS 1.3 flight (§7.10.2), including the certificate the browser validates. Step 9: the client's Finished and the first HTTP/2 request, with ALPN having selected `h2` (§7.9.3). Steps 10–13: the edge serves from cache or fetches from the origin over a pre-warmed, pooled connection (§7.16), so the user does not pay the origin's handshakes. Step 14: subresources reuse the same multiplexed connection. All steps are synchronous; the edge cache and origin are the storage boundaries. Failure points include DNS (every step depends on it), certificate validity, and the origin path on cache misses.

7.18.1 Steps the diagram leaves out

Figure 7.13 shows the protocol messages. Several steps happen around them:

1. **Before any network traffic**, the browser parses the URL into scheme (`https`, so port 443), host and path, applies its HSTS list (which may force HTTPS), and checks its HTTP cache and any existing connection to the origin. A reused connection skips steps 1–9 of the figure entirely.
2. **Choosing an address (§7.4).** With both AAAA and A answers, Happy Eyeballs tries IPv6 first and races IPv4 if needed.
3. **The first hop (§7.3).** The destination is off-subnet, so the laptop frames the packet for its default gateway, learning the gateway's MAC address with ARP or Neighbor Discovery.
4. **NAT (§7.13).** For IPv4, the home router rewrites the private source address (for example `192.168.1.23`) to its public address and records the mapping; the ISP may add carrier-grade NAT.
5. **Routing (§7.5).** ISP routers forward by longest-prefix match, and BGP delivers the anycast destination to a nearby edge site.
6. **Edge admission (§7.14, Chapter 19).** DDoS filtering and an L4 load balancer (ECMP plus consistent hashing) pick the server running the reverse proxy.
7. **Behind the edge (§8.5, Chapter 21).** On a cache miss, the origin's reverse proxy routes the request to an application server, which may call caches and databases across a leaf–spine fabric (§7.17).
8. **After the response.** The browser discovers CSS, JavaScript and images and fetches them as concurrent streams on the same connection, ramping up under slow start (§7.7.7). An `Alt-Svc` header may advertise HTTP/3 for later connections.

WORKED EXAMPLE

Worked example — Time to first byte budget.

Assume: 5 ms RTT to the resolver; resolver needs root, TLD and authoritative lookups costing 15, 20 and 30 ms, plus 25 ms for the CDN’s authoritative servers; 20 ms RTT to the edge; 2 ms edge processing on a cache hit.

1. DNS: $5 + 15 + 20 + 30 + 25 = 95$ ms (cold); 5 ms warm.
2. TCP handshake: 20 ms.
3. TLS 1.3 handshake: 20 ms.
4. Request and first response byte: $20 + 2 = 22$ ms.
5. Total cold: $95 + 20 + 20 + 22 = 157$ ms. Warm DNS: $5 + 62 = 67$ ms. Reused connection: 22 ms.
6. On a cache miss with the origin 70 ms from the edge over a pooled connection, add $70 + $ origin processing (say 30 ms) = 100 ms.

Interpretation: on a cold visit, connection setup (DNS, TCP, TLS) is most of the time to first byte, and the server’s own work is a small slice. This is why the biggest wins for global latency are fewer round trips and shorter round trips, not faster servers.

7.19 Summary and revision notes

SUMMARY

- **Layering and encapsulation.** Each layer adds its own header: application message → TCP segment or UDP datagram (ports) → IP packet (addresses) → link frame (MAC). Routers rewrite link frames at every hop; IP packets travel end to end.
- **Addressing.** IPv4 is 32 bits, IPv6 is 128. CIDR `/n` leaves 2^{32-n} IPv4 addresses (minus 2 on ordinary subnets; minus 5 on AWS). Private ranges: 10/8, 172.16/12, 192.168/16. Plan non-overlapping ranges before networks need to connect.
- **Routing.** Forwarding uses longest-prefix match. BGP connects autonomous systems by policy, not latency, and trusts announcements by default. Anycast announces one prefix from many sites to steer users to a nearby one.
- **DNS.** Stub → recursive resolver (recursive query) → root → TLD → authoritative (iterative queries). Caches expire by TTL; nothing "propagates". DNS load balancing picks sites, not servers, and fails over in minutes.
- **TCP.** 1-RTT handshake; four-way close; the active closer holds TIME_WAIT (60 s on Linux), which can exhaust ephemeral ports. Reliability via sequence numbers, cumulative ACKs, fast retransmit and RTO (200 ms minimum on Linux). Flow control uses the receive window; congestion control uses cwnd: slow start doubles per RTT, AIMD halves on loss, CUBIC grows by a cubic of time, BBR paces at measured bandwidth. One lost segment blocks the whole stream (head-of-line blocking). Set `TCP_NODELAY` for RPC.
- **UDP.** 8-byte header, no setup, no reliability. Use it when timeliness beats completeness or to build your own transport; you then own congestion control.
- **HTTP.** 1.1: one request at a time per connection, about six connections per host. 2: binary frames, multiplexed streams, HPACK, but TCP HOL blocking. 3: QUIC over UDP with independent streams, built-in TLS 1.3, 1-RTT (0-RTT on resumption) setup and connection migration.
- **TLS 1.3.** 1-RTT handshake, encrypted certificates, mandatory forward secrecy. 0-RTT early data is replayable: use only for idempotent requests. Expired certificates are the most common TLS outage; automate renewal.
- **Middle of the network.** Forward proxies act for clients; reverse proxies act for servers (TLS termination, routing, load balancing). NAT shares public IPs, blocks unsolicited inbound traffic, and has finite ports per destination. Security groups are stateful; network ACLs are stateless.
- **Numbers.** Fiber propagation is about 5 µs/km; NY–London RTT is at least 56 ms. BDP $= R \times \text{RTT}$: 10 Gbps × 80 ms = 100 MB in flight. Mathis: throughput $\leq (\text{MSS}/\text{RTT}) \times 1.22/\sqrt{p}$, so 0.01% loss caps an 80 ms flow near 18 Mbps.

- **Connections.** A new HTTPS connection with TLS 1.3 costs 3 RTTs to first byte, versus 1 on a reused connection. Pool connections; size pools with $N = \lambda W$; set client idle timeouts shorter than server timeouts.
- **Datacenters.** East–west traffic dominates; leaf–spine Clos fabrics with ECMP give every rack equal-cost two-hop paths and scale out with commodity switches (Google Jupiter: over 1 Pbps of bisection bandwidth).

7.20 Knowledge checkpoint

1. Which headers does a router remove and rebuild at each hop, and which header fields does it modify?
2. What are the network address, broadcast address and usable host range of `172.20.14.200/22`?
3. A router has routes for `10.0.0.0/8`, `10.4.0.0/14` and `10.4.4.0/24`. Which is used for `10.5.1.1`?
4. Why can anycast break long-lived TCP connections, and why is it nevertheless ideal for DNS?
5. Distinguish recursive and iterative DNS queries, and say which participants send each kind.
6. Why can’t you place a CNAME at the zone apex?
7. You need to move a service to new IP addresses; the A record’s TTL is 86,400 s. What must you do and when?
8. What does an acknowledgment number of 5,001 mean?
9. Why does the active closer of a TCP connection enter TIME_WAIT, and for how long on Linux?
10. Explain the difference between flow control and congestion control, naming the window each uses.
11. Starting from an initial window of 10 segments, how many RTTs of slow start are needed to send 300 segments with no loss?
12. Explain how Nagle’s algorithm and delayed ACKs together add latency, and give the standard fix.
13. HTTP/2 multiplexes streams over one connection. Why does it still suffer head-of-line blocking, and how does HTTP/3 avoid it?
14. Why must 0-RTT early data be limited to idempotent requests?
15. Compute the BDP of a 1 Gbps link with a 40 ms RTT, in megabytes.
16. Using the Mathis formula, what is the maximum throughput with MSS 1,460 bytes, RTT 20 ms and 1% loss?
17. Why are network ACLs a frequent cause of “connection hangs” while security groups are not?

18. What is the oversubscription ratio of a leaf with 32 × 100 Gbps server ports and 8 × 400 Gbps uplinks?

Answers

1. The router strips the incoming link-layer (Ethernet) header and trailer and builds a new frame with new source and destination MACs for the next link. In the IP header it decrements TTL (hop limit) and, for IPv4, recomputes the header checksum. NAT devices also rewrite addresses and ports.
2. A `/22` has $2^{10} = 1,024$ addresses; the third octet advances in steps of 4. 14 lies in 12–15, so network `172.20.12.0`, broadcast `172.20.15.255`, usable `172.20.12.1` – `172.20.15.254` (1,022 hosts).
3. `10.4.0.0/14` covers 10.4.0.0–10.7.255.255, which includes 10.5.1.1; the /24 does not. Longest match is the /14.
4. A BGP route change can deliver a flow's later packets to a different site that has no state for the connection, which resets it. DNS queries are typically single UDP request/response exchanges with no connection state, so a route change between queries is harmless.
5. A recursive query asks the server for a final answer; the stub resolver sends it to the recursive resolver. An iterative query accepts referrals; the recursive resolver sends these to root, TLD and authoritative servers.
6. A CNAME may not coexist with any other record at the same name, and the apex must hold SOA and NS records.
7. Lower the TTL (for example to 60 s) at least 86,400 s before the change, so all caches have refreshed with the short TTL; make the change; keep the old addresses serving until at least the short TTL (plus margin for misbehaving caches) has passed; then raise the TTL again.
8. The receiver has received every byte up to and including byte 5,000 (relative to the ISN) and expects byte 5,001 next.
9. To retransmit the final ACK if the peer resends its FIN, and to let delayed segments of the old connection expire before the same 4-tuple can be reused. Linux uses 60 s (2 × MSL).
10. Flow control protects the receiver's buffer using the advertised receive window (rwnd). Congestion control protects the network using the sender's congestion window (cwnd). The sender is limited by $\min(\text{cwnd}, \text{rwnd})$.
11. Cumulative segments: 10, 30, 70, 150, 310. 300 segments complete in the 5th RTT.
12. With unacknowledged data in flight, Nagle holds a second small write; the receiver delays its ACK because it has no response ready until the full request arrives; both wait for the delayed-ACK timer. Fix: write whole messages at once and set `TCP_NODELAY`.
13. All streams share one ordered TCP byte stream, so a lost segment blocks delivery of later bytes for every stream. QUIC orders data per stream, so loss stalls only the affected stream.

14. An attacker can capture and replay the first flight, causing the server to process the early request again; idempotent requests are safe to repeat.
15. $10^9 \times 0.04 = 4 \times 10^7$ bits $= 5 \times 10^6$ bytes $= 5$ MB.
16. MSS/RTT $= 11,680/0.02 = 584,000$ bits/s; $1.22/\sqrt{0.01} = 12.2$; throughput ≤ about 7.1 Mbps.
17. NACLs are stateless, so return traffic to the client's ephemeral ports must be explicitly allowed; if it is not, SYN-ACKs or responses are silently dropped and clients wait for timeouts. Security groups are stateful and allow return traffic automatically.
18. Downlink $32 \times 100 = 3,200$ Gbps; uplink $8 \times 400 = 3,200$ Gbps; ratio 1:1 (non-blocking).

7.21 Interview questions

Basic

Q1. What is the difference between TCP and UDP, and when would you choose UDP?

Answer. TCP provides a connection-oriented, reliable, ordered byte stream with flow and congestion control, at the cost of a 1-RTT handshake, head-of-line blocking and per-connection state. UDP provides unreliable, unordered datagrams with an 8-byte header and no setup. Choose UDP when timeliness matters more than completeness (voice, video, games), when exchanges are a single small request and response (DNS), or when you need a custom transport (QUIC). Mention the cost: the application must handle loss, ordering, message sizing to the MTU and, critically, congestion control.

Q2. Walk me through what happens during a DNS lookup.

Answer. The application calls the OS stub resolver, which checks local caches and then sends a recursive query to a recursive resolver. If the resolver's cache is cold, it queries a root server, which refers it to the TLD servers; the TLD server refers it to the domain's authoritative servers; the authoritative server returns the record with a TTL. The resolver caches every record for its TTL and returns the answer. Mention UDP port 53 with TCP fallback, TTL trade-offs, and that DNS changes do not "propagate"; caches expire.

Q3. What happens during a TCP three-way handshake, and why three messages?

Answer. The client sends SYN with its random ISN; the server replies SYN-ACK with its own ISN and acknowledges the client's; the client ACKs the server's ISN. Three messages are the minimum for each side to announce its ISN and confirm the other's has been received, in both directions. It costs the client one RTT before sending data. Strong answers mention option negotiation (MSS, window scaling, SACK), SYN floods and SYN cookies.

Intermediate

Q4. Your service's p99 latency to a dependency in another region is far higher than its p50. What network causes would you investigate?

Answer. First, connection setup: if connections are not reused, some requests pay DNS plus TCP plus TLS handshakes (3+ RTTs instead of 1); check pool hit rates and idle-timeout races that produce resets and retries. Second, packet loss: a single retransmission timeout costs at least 200 ms on Linux, and loss also shrinks cwnd; check retransmission counters (`nstat`, `ss -ti`). Third, slow start after idle: large responses on cold or idle connections need several RTTs to ramp. Fourth, queuing (bufferbloat) on congested links, Nagle/delayed-ACK stalls on small writes, DNS resolution timeouts, and NAT port exhaustion. Measure with connection-phase timings (e.g., `curl -w`) and distributed traces before changing anything.

Q5. Compare HTTP/1.1, HTTP/2 and HTTP/3 for a mobile application.

Answer. HTTP/1.1 serializes requests per connection, so clients open several connections, each paying handshakes and slow start. HTTP/2 multiplexes streams on one connection with HPACK header compression, a big improvement, but a lost TCP segment stalls all streams, which hurts on lossy mobile links. HTTP/3 over QUIC gives per-stream reliability (no cross-stream HOL blocking), a 1-RTT combined transport and TLS handshake with 0-RTT resumption, and connection migration when the device switches networks. Costs: UDP may be blocked (keep HTTP/2 fallback), and QUIC uses more server CPU. For a mobile app, enable HTTP/3 at the CDN or edge with HTTP/2 fallback, and use 0-RTT only for idempotent requests.

Q6. How would you use DNS for global traffic distribution, and what are its limitations?

Answer. Use latency-based or geo-DNS with health checks to return the nearest healthy region's address, typically pointing at a regional load balancer or anycast address. Limitations: resolvers cache answers for the TTL, so control is coarse and failover takes the detection time plus up to one TTL (and longer for misbehaving caches); geo decisions see the resolver, not the client, unless EDNS Client Subnet is used; DNS has no knowledge of load; clients with open connections ignore DNS changes. So use DNS for region selection with moderate TTLs (30–300 s), anycast or load balancers for fast failover within and across sites, and client retries across regions for resilience.

Advanced

Q7. A nightly replication job copies data between regions 80 ms apart over a 10 Gbps link but achieves only about 200 Mbps. Diagnose and fix.

Answer. Compute the BDP: $10\ \text{Gbps} \times 80\ \text{ms} = 100$ MB must be in flight. Check whether the window is the limit: 200 Mbps × 0.08 s = 2 MB, so the effective window is about 2 MB, possibly because of `tcp_rmem` / `tcp_wmem` maximums or application socket buffer settings. Check loss: by Mathis, 200 Mbps at 80 ms RTT corresponds to $p \approx (1.22 \times 146{,}000/2 \times 10^8)^2 \approx 8 \times 10^{-7}$, so even tiny loss could explain it with CUBIC. Fixes: raise buffer limits and ensure window scaling; use several parallel streams (each has its own cwnd); consider BBR for the bulk sender, since it does not treat random loss as congestion; fix lossy links; compress data. Verify with `ss -ti` (cwnd, rtt, retransmits) and `iperf3`.

Q8. Design the network path for a global API with low latency, high availability and DDoS resilience.

Answer. Publish the API hostname with DNS from two independent providers, pointing at an anycast address announced from many edge sites, so users reach a nearby edge and attacks spread across sites. At each edge, L4 load balancers using ECMP and consistent hashing feed L7 reverse proxies that terminate TLS 1.3 and HTTP/2/HTTP/3, apply WAF rules and rate limits, and cache what they can. Edges forward to the nearest healthy regional origin over pre-warmed, pooled, long-lived connections (mTLS), avoiding per-request handshakes on long paths. Regions are active–active behind health-checked routing, with DNS TTLs of about 60 s as a slower backstop. Inside regions, leaf–spine fabrics and security groups segment tiers. Discuss trade-offs: anycast and TCP stability, 0-RTT replay restrictions, certificate automation, and cost of egress.

Q9. Explain BBR to someone who knows CUBIC, including when you would and would not deploy it.

Answer. CUBIC infers congestion from loss: it grows cwnd as a cubic function of time since the last loss and multiplies cwnd by 0.7 on loss, so it fills buffers until they overflow and reacts badly to random loss. BBR builds a model: it measures the bottleneck bandwidth (maximum delivery rate) and the minimum RTT, paces at the bandwidth estimate, and keeps about one BDP in flight, cycling its pacing gain to probe for more bandwidth and periodically draining queues to re-measure min RTT. Benefits: much higher throughput on lossy long paths (Google reported 2–25× on its B4 backbone) and lower queuing delay. Concerns: BBRv1 can be unfair to loss-based flows sharing a bottleneck and can cause high retransmission rates with shallow buffers; later versions address this. Deploy it on senders serving users over the WAN or doing bulk transfers on lossy paths; be cautious in shared, shallow-buffer datacenter fabrics, and A/B test.

7.22 Practical exercises

1. **Trace DNS by hand.** Run `dig +trace www.wikipedia.org` and identify the root, TLD and authoritative steps. Then run `dig www.wikipedia.org` twice against your resolver

and compare the TTL values in the two answers; explain the difference. Query `dig example.com MX`, `dig example.com TXT`, and `dig _xmpp-server._tcp.jabber.org SRV`, and read each record using Table 7.5.

2. **Time a request phase by phase.** Run:

```
        curl -o /dev/null -s -w 'dns=%{time_namelookup} tcp=%{time_connect} tls=%
{time_appconnect} ttfb=%{time_starttransfer} total=%{time_total}\n'
https://www.example.com/
```

   All values are cumulative seconds from the start. Compute the TCP handshake (`tcp − dns`), TLS handshake (`tls − tcp`) and server time (`ttfb − tls`). Repeat with `--http1.1`, `--http2` and (if your curl supports it) `--http3`, and against a nearby and a distant site. Estimate RTT from the TCP phase and check it against `ping`.

3. **Watch a handshake.** Start the echo server from §7.7.10, then in another terminal run `sudo tcpdump -i lo -nn 'tcp port 9000'` and run the client. Identify the SYN, SYN-ACK, ACK, data segments, FIN/ACK exchanges and their sequence and acknowledgment numbers. Run `ss -tan state time-wait` afterward and find the TIME_WAIT socket on the client side. Repeat the capture in Wireshark and use "Follow TCP Stream".

4. **Exhaust and fix.** Write a client that opens and closes a new connection to the echo server in a tight loop, and count TIME_WAIT sockets with `ss -s`. Then rewrite it to reuse one connection, and compare throughput.

5. **Feel the Mathis formula.** On a Linux test machine, add delay and loss to loopback with `sudo tc qdisc add dev lo root netem delay 40ms loss 0.1%` (giving roughly an 80 ms RTT), measure throughput with `iperf3`, then remove it with `sudo tc qdisc del dev lo root`. Compare your result with the formula, and repeat with `-C bbr` if the BBR module is available.

6. **Subnet calculator.** Verify the worked examples in §7.4 with Python's standard library:

```
        import ipaddress
        n = ipaddress.ip_network("192.168.10.77/26", strict=False)
        print(n, n.netmask, n.broadcast_address, n.num_addresses - 2)   #
192.168.10.64/26 255.255.255.192 192.168.10.127 62
        print(ipaddress.ip_address("10.0.37.200") in
ipaddress.ip_network("10.0.32.0/20"))  # True
        print(list(ipaddress.ip_network("10.0.0.0/16").subnets(new_prefix=20))
[:3])
        print(ipaddress.ip_network("10.0.0.0/16").overlaps(ipaddress.ip_network("1
0.0.128.0/17")))  # True
```

7. **Inspect a certificate.** Run `openssl s_client -connect www.example.com:443 -servername www.example.com -tls1_3 </dev/null` and identify the chain, the negotiated protocol and cipher, and the leaf's validity period.

7.23 Design challenges

1. **Global login service.** Users on five continents must log in with p95 under 300 ms. The credential database must live in one region. Design the network path (DNS, anycast or regional endpoints, TLS termination location, connection reuse between edge and origin) and compute the round-trip budget for a user in Sydney with the database in Virginia (great-circle distance about 15,700 km). Which steps can 0-RTT safely accelerate, and which cannot?
2. **Egress at scale.** 3,000 containers in private subnets call a single third-party payments API through cloud NAT. Calls take 300 ms, peak load is 20,000 requests per second, and each call currently opens a new TLS connection. Estimate concurrent connections with Little's Law, identify the NAT and TIME_WAIT limits you will hit, and redesign (pooling, egress proxies, multiple NAT IPs, keep-alive settings).
3. **Datacenter fabric for an analytics cluster.** 2,000 servers with 25 Gbps NICs run shuffle-heavy batch jobs. Choose leaf and spine port counts and an oversubscription ratio, compute the bisection bandwidth, and explain how you would detect and mitigate incast and ECMP hot spots.

7.25 Open verification items

- [RIPE NCC 2008]: confirm the exact title and URL of the YouTube hijacking case study and the “about two hours” duration.
- [AWS Docs: VPC subnets]: confirm the URL and that five addresses per subnet are still reserved (stated “as of 2025”).
- The current CA/Browser Forum schedule for reducing maximum public certificate lifetime below 398 days (deliberately not quantified in §7.10.3).
- “Measured NY–London RTTs are often in the 70 ms range” (§7.15.1) is an order-of-magnitude statement; replace with a dated measurement if one is wanted.
- Jacobson’s 1986 collapse figure (32 kbps to 40 bps) and Google’s BBR results (2–25× on B4) should be checked against the primary texts.
- Linux defaults quoted (TIME_WAIT 60 s, minimum RTO 200 ms, delayed-ACK minimum about 40 ms, ephemeral range 32,768–60,999, keep-alive after two hours) are version- and distribution-dependent.
- Runnable code is inline only; per style guide §8 it should also be copied to `code/ch07/` (not done, since this task was limited to the chapter file).

Chapter 8 — Web Application Fundamentals

> **Level:** 1–2 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

8.1 Learning objectives

After this chapter you should be able to:

- Explain the client–server model and why stateless application servers are the basis of horizontal scaling.
- Compare server-side rendering, single-page applications, static generation and native mobile clients, and say which constraints each puts on the backend.
- Trace one HTTPS request from a browser through DNS, the load balancer, the web server, the application and the database and back, and estimate its latency hop by hop.
- Design a resource-oriented REST API: choose URIs, methods, status codes, a pagination scheme (offset or cursor, with the SQL behind each), filtering, sorting and an RFC 9457 error format.
- Explain how GraphQL executes a query, why it suffers from the N+1 problem and how DataLoader fixes it.
- Define a gRPC service in Protocol Buffers, choose among its four streaming modes and propagate deadlines.
- Encode a Protocol Buffers message by hand, explain varints, and state the schema-evolution rules for Protobuf, Avro, Thrift and JSON.
- Configure cookies safely (`Secure`, `HttpOnly`, `SameSite`) and choose between server-side sessions and signed cookies.
- Distinguish authentication from authorization; compare RBAC, ABAC and ReBAC, and describe Google’s Zanzibar.
- Build and validate a JWT, explain HS256 versus RS256, and describe the revocation problem and its mitigations.
- Draw the OAuth 2.0 authorization code flow with PKCE, and say what OpenID Connect adds.
- Version and deprecate an API without breaking clients, and describe it in OpenAPI.

8.2 Prerequisites

- DNS resolution and TTLs — §7.6 (the first hop of every web request is a DNS lookup).
- TCP handshake and connection reuse — §7.7, §7.16 (connection setup dominates the latency of short requests).
- HTTP/1.1, HTTP/2 and HTTP/3 — §7.9 (REST and gRPC are built on HTTP semantics and HTTP/2 framing).
- TLS 1.3 — §7.10 (cookies marked `Secure`, bearer tokens and OAuth all assume an encrypted channel).
- Reverse proxies — §7.12 (load balancers and web servers in front of the application are reverse proxies).
- Basic SQL `SELECT … WHERE … ORDER BY … LIMIT` — §11.6 (needed for the pagination queries; you can read this chapter first and come back).
- Hashes, MACs and digital signatures at the level of "a MAC proves a shared-key holder made this; a signature proves a private-key holder made this" — §10.4 (needed for signed cookies, JWTs and OAuth).

8.3 Client–server architecture

8.3.1 The client–server model

> DEFINITION
>
> **Definition — Client-server architecture.** A way of dividing a system into two roles: a **client**, which initiates requests on behalf of a user or another program, and a **server**, which waits for requests, performs work on shared resources (data, computation) and returns responses. The two communicate over a network using an agreed **protocol**.

First-principles explanation

Think of a restaurant. You, the diner, are the **client**. You do not walk into the kitchen; you tell a waiter what you want, in a format the kitchen understands (the menu is the **protocol**). The kitchen is the **server**: it holds the shared, expensive resources (stoves, ingredients, the chef's skill), serves many diners at once, and sends back a plate (the **response**). Three properties of this arrangement carry directly into software:

1. **The client initiates.** The kitchen never comes to your table unasked. In classic HTTP the server cannot send anything until the client asks; Chapter 9 covers the techniques that work around this.

2. **The server is shared and centralized.** One kitchen serves hundreds of tables, so the restaurant can keep its ingredients (data) consistent in one place.
3. **The menu decouples the two.** You can change tables, or the kitchen can hire a new chef, without either side noticing, as long as the menu stays the same. In software, that contract is the **API (application programming interface)**.

Why does this exist?

Before networks, a program and its data lived on one computer. Once many people needed the *same* data — a bank's balances, an airline's seat map — something had to own the single authoritative copy and arbitrate concurrent changes. Putting that copy on a server, and letting many thin clients talk to it, solves three problems at once: **shared state** (one source of truth), **security** (clients never touch the database directly, so they cannot bypass business rules) and **independent evolution** (you can ship a new server without reinstalling every client, and vice versa, provided the contract holds).

How it works internally

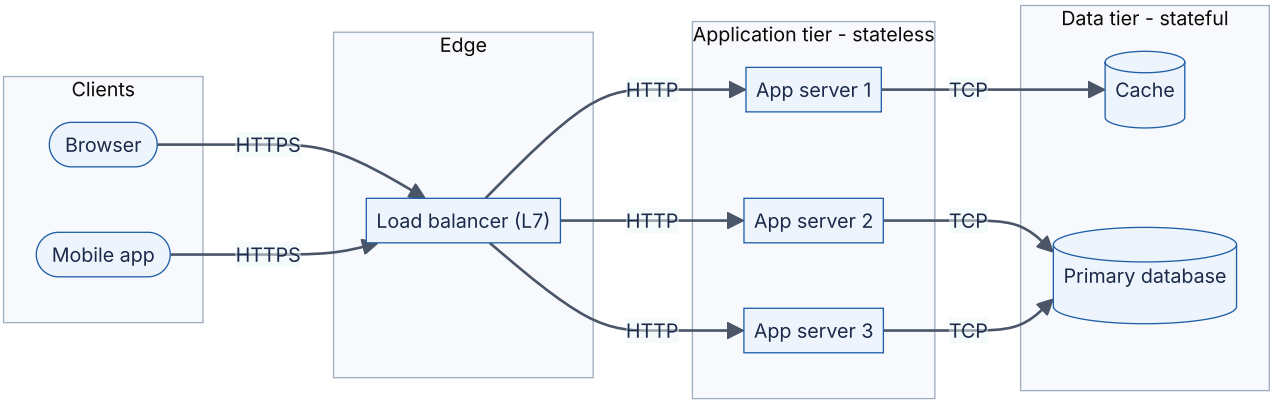
A modern web system usually has three **tiers**:

1. **Presentation tier** — the client: a browser running HTML/JavaScript, or a native mobile app.
2. **Application tier** — one or more **services** that implement business logic. They are normally **stateless**: they keep nothing about a user between requests in their own memory.
3. **Data tier** — databases, caches and object stores that hold durable state.

Each request flows inwards (client → application → data) and the response flows back out. Because the application tier is stateless, any copy of it can handle any request, which is what makes the tier easy to scale horizontally behind a load balancer (see §18.5 and Chapter 19).

Architecture diagram

Figure 8.1 — Three-tier client-server architecture.



Reading the diagram. Two kinds of client (stadium shapes) send HTTPS requests to a layer-7 load balancer, which terminates TLS and forwards plain HTTP (or re-encrypted HTTPS) inside the private network to one of three identical application servers. All arrows are synchronous request/response calls. The application servers are stateless, so the only storage boundary is the data-tier subgraph: the cache and the primary database. Failure points: the load balancer (mitigated by running a redundant pair, §19.8), any single app server (the load balancer's health checks remove it, §19.5) and the database (the hardest to make redundant; Chapter 14). Scaling: add app servers freely; the data tier scales with caching (Chapter 20), replicas and partitioning (Chapter 14).

8.3.2 Statelessness

DEFINITION

Definition — Stateless service. A service that keeps no client-specific data in its own memory between requests. Every request carries, or lets the service look up from a shared store, everything needed to process it.

A waiter who memorizes your order is **stateful**: if he goes home sick, your order is lost and only he can serve your table. A waiter who writes every order on a ticket and pins it to a shared board is **stateless**: any waiter can pick up any table. Stateless servers can be added, removed, restarted and replaced without losing anything, which is why every scaling, deployment and fault-tolerance technique later in this book assumes them.

State does not disappear; it moves. Login status moves into a cookie or token the client sends on every request (§8.10, §8.13), or into a shared session store (§8.10.2). Shopping carts move into a database. The price is an extra lookup per request (typically ~0.5–1 ms to an in-datacenter cache), which is almost always worth paying.

Failure scenarios

Table 8.1 — Client-server failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Users logged out after a deploy	Sessions stored in app-server memory	Spike in 401s and login traffic after each rollout	Users log in again	Move sessions to a shared store or signed cookie
One server overloaded, others idle	Sticky sessions pin heavy users to one server	Uneven per-server CPU and p99	Drain and rebalance	Make servers stateless; avoid affinity (§19.6)
Old mobile clients break	Server changed the API contract	Error rate segmented by app version	Hotfix server to accept old format	Compatibility rules and versioning (§8.15)
Database saturated	Every tier's requests ultimately land on one primary	DB CPU, connection count, lock waits	Shed load, add read replicas	Caching, connection pooling, partitioning

Common misconceptions

COMMON MISTAKE

"Stateless means the system has no state." It means the *compute* tier holds no per-client state between requests. The state lives in databases, caches and the client. Designing a stateless tier is really deciding *where* state should live.

COMMON MISTAKE

"Client-server is the opposite of peer-to-peer, so it is obsolete." Almost every web, mobile and inter-service interaction today is client–server; even "peer" microservices act as client in one call and server in the next. Peer-to-peer appears in specific niches (WebRTC media, §9.7; BitTorrent-style distribution).

8.4 Frontend and backend; SPA, SSR and mobile clients

8.4.1 Frontend and backend

The **frontend** is the code that runs on the user's device and draws the interface: HTML, CSS and JavaScript in a browser, or Swift/Kotlin in a mobile app. The **backend** is the code that runs on servers you control: APIs, business logic, databases, background jobs. The split matters for design because the two sides have opposite trust and update properties:

- **Trust.** Anything on the client can be read and modified by the user. Validation in the frontend is a usability feature; validation and authorization in the backend are security features. Never trust a price, a user ID or a role sent by a client.

- **Update speed.** You can redeploy the backend in minutes. A web frontend updates on the next page load. A mobile app updates only when users install the new version, so versions that are months or years old stay in use and your API must keep serving them (§8.15).

8.4.2 Rendering strategies

Where the HTML is produced determines how many round trips the user waits for, how much work the server does and how search engines see the page.

DEFINITION

Definition — Server-side rendering (SSR). The server produces complete HTML for each request; the browser displays it immediately and then loads JavaScript to make it interactive (**hydration**).

DEFINITION

Definition — Single-page application (SPA) / client-side rendering (CSR). The server sends a nearly empty HTML shell plus a JavaScript bundle; the JavaScript calls JSON APIs and builds the page in the browser. Navigation afterwards happens without full page loads.

DEFINITION

Definition — Static site generation (SSG). HTML is produced at build time and served as static files, usually from a CDN (Chapter 21). Pages that change per user cannot be fully static.

In restaurant terms: SSR is a plated dish (ready to eat, but the kitchen does all the work for every order); SPA is a meal kit (one trip to fetch the kit, then the diner assembles everything, quick to re-assemble but slow to the first bite); SSG is the pre-made sandwich in the display fridge (instant, but everyone gets the same sandwich).

Table 8.2 — Rendering strategies compared.

Aspect	SSR	SPA (CSR)	SSG	Native mobile
Where HTML/UI is built	Server, per request	Browser	Build server, once	Device (compiled app)
Round trips before content	1 (HTML)	≥ 2–3 (shell, JS bundle, API)	1, from a CDN edge	API calls only; UI is installed
Server CPU per page view	High	Low (JSON APIs only)	~0	Low (JSON/Protobuf APIs only)
SEO (crawler sees content)	Good	Weaker; depends on crawler running JS	Good	N/A
Personalized content	Yes	Yes	No (or via client-side calls)	Yes
Backend shape	Server renders templates and calls services	Pure API (REST/GraphQL)	Build pipeline + CDN	Pure API, must tolerate old versions
Typical use	Content and e-commerce pages	Dashboards, editors, apps behind login	Docs, marketing, blogs	Consumer apps

Modern frameworks blend these (SSR for the first page, SPA navigation afterwards; static pages with per-request “islands”). For a system designer the key consequence is the **backend shape**: an SPA or mobile app needs a well-designed JSON/Protobuf API, and SSR needs a rendering tier that itself is a client of your APIs.

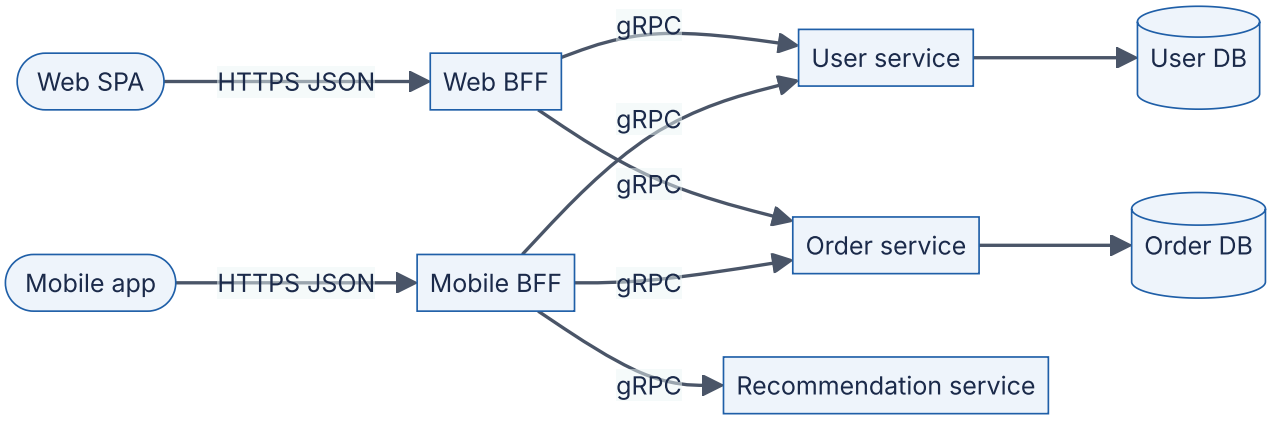
8.4.3 Mobile clients and the backend for frontend

Mobile clients add three constraints:

1. **Old versions never die quickly.** Expect several app versions live at once; any field you remove from a response may crash an old build.
2. **Networks are slow and flaky.** Cellular round-trip times of 50–150 ms are common (as of 2026; varies widely by network). Chatty APIs that need ten sequential calls to draw one screen add up to a second or more of waiting. Mobile clients therefore favor fewer, coarser calls, compact encodings and offline caches.
3. **Different screens need different data.** A phone’s feed card shows 3 fields; the desktop card shows 12.

One common answer is the **backend for frontend (BFF)** pattern: a thin server per client type that aggregates downstream services into exactly the payload that client needs (covered in §34.6). GraphQL (§8.7) is another answer to the same problem.

Figure 8.2 — Backend-for-frontend aggregation.



Reading the diagram. Each client type talks only to its own BFF over HTTPS with JSON. The BFFs call internal services over gRPC (binary, HTTP/2; §8.8) and merge results, so a phone makes one round trip over the slow cellular link instead of three. All calls are synchronous. Each service owns its own database (storage boundaries at the cylinders). Failure points: a slow recommendation service delays the mobile screen unless the BFF uses a deadline and degrades gracefully (§8.8.4). Scaling: BFFs are stateless and scale horizontally; the cost is one more service per client type to own and deploy.

8.5 The request–response lifecycle end to end

8.5.1 What happens when you press Enter

DEFINITION

Definition — Request-response lifecycle. The complete sequence of network and processing steps between a client issuing a request and receiving the full response, including name resolution, connection establishment, routing through intermediaries, application processing, data access and the return path.

First-principles explanation

Before your restaurant order is cooked, someone must find the restaurant's address (DNS), drive there (TCP connection), show ID at the door (TLS handshake), be seated by a host who picks a free waiter (load balancer), have the waiter take the order to the kitchen (web server to application), and wait while the kitchen fetches ingredients from the pantry (database). Only the last two steps are "real work". The others are setup, and for short requests setup often dominates.

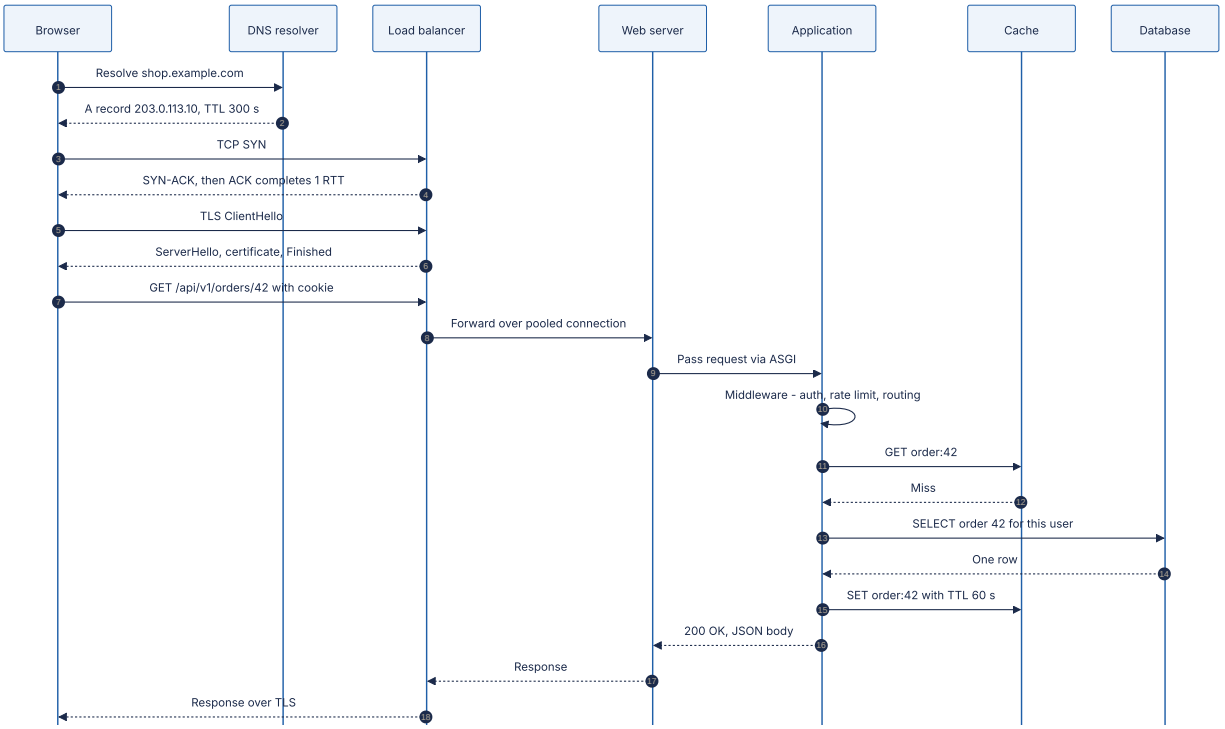
How it works internally

Take `GET https://shop.example.com/api/v1/orders/42` from a browser. (§7.18 follows a similar journey at the packet level; here the focus is the server side.)

1. **URL parsing and cache check.** The browser splits the URL into scheme (`https`), host (`shop.example.com`), path and query. If a fresh copy is in the HTTP cache (`Cache-Control: max-age`), it stops here (§20.5).
2. **DNS resolution** (§7.6). The browser asks the OS stub resolver, which asks a recursive resolver, which (on a cache miss) walks root → `.com` → `example.com` authoritative servers. The answer is an IP address, often of a CDN edge or a regional load balancer, cached for its TTL.
3. **TCP handshake** (§7.7). SYN, SYN-ACK, ACK: one round trip (RTT) before data can flow. With HTTP/3 this is replaced by QUIC, which combines transport and TLS setup (§7.9).
4. **TLS 1.3 handshake** (§7.10). One more RTT to agree keys and verify the server certificate (zero RTT on resumption, with replay caveats).
5. **HTTP request sent.** Method, path, headers (`Host`, `Cookie` or `Authorization`, `Accept`), and possibly a body. Over HTTP/2 this is a set of compressed frames on a stream within the connection.
6. **Load balancer** (Chapter 19). A layer-7 load balancer terminates TLS, reads the HTTP request, applies routing rules (path `/api/` → API pool), picks a healthy backend and forwards the request, often over a pooled keep-alive connection. It adds headers such as `X-Forwarded-For` so the backend knows the client IP.
7. **Web server / reverse proxy.** Something like Nginx or Envoy (or the application server's own HTTP layer) parses the request, enforces limits (body size, timeouts), may serve static files, and passes the request to the application process via HTTP, a socket or an in-process call (for Python, via the ASGI or WSGI interface).
8. **Application framework.** Middleware runs in order: request ID and tracing, authentication (cookie or token → user identity, §8.10–§8.13), rate limiting (Chapter 22), then the **router** maps `GET /api/v1/orders/{id}` to a handler function.
9. **Business logic and authorization.** The handler checks that this user may read order 42 (§8.12), then fetches data.
10. **Data access.** The handler borrows a connection from a pool (§7.16), sends SQL to the database (or reads the cache first), and waits. The database parses, plans, reads pages from its buffer pool or disk and returns rows (Chapter 11).
11. **Response built.** The handler serializes the result (JSON, §8.9), sets status (`200 OK`), headers (`Content-Type`, `Cache-Control`, `ETag`) and returns it through the middleware stack, web server and load balancer.
12. **Browser processes the response.** It decompresses, parses, updates its cache and cookie jar, and renders or hands the JSON to JavaScript. The TCP/TLS connection stays open (keep-alive) for later requests.

Architecture diagram

Figure 8.3 — End-to-end lifecycle of one HTTPS API request.



Reading the diagram. Time flows downward. Messages 1–2 are DNS over UDP (or DNS over HTTPS); 3–4 are the TCP handshake; 5–6 are the TLS 1.3 handshake. Message 7 is the actual HTTP request, carried over the encrypted connection. The load balancer forwards it (8) over a connection it already holds open to the web server, which hands it to the application process (9). The application runs middleware (10), tries the cache (11–12), falls through to the database (13–14) and populates the cache on the way out (15) in the cache-aside pattern (§20.7). Everything is synchronous: the browser waits for the whole chain. Storage boundaries are the cache and the database. Failure points: DNS (stale or failing resolvers), the load balancer, a slow database query that holds a pooled connection, and timeouts that are not aligned along the chain. Scaling options: CDN and HTTP caching remove steps 3–15 entirely for cacheable responses; connection reuse removes steps 3–6 for repeat requests; app servers scale horizontally; the database scales with replicas and partitions.

Mathematical foundations

FORMULA

End-to-end latency of a request on a new connection

$$T_{\text{total}} = T_{\text{DNS}} + T_{\text{TCP}} + T_{\text{TLS}} + T_{\text{req}} + T_{\text{server}} + T_{\text{transfer}}$$

with $T_{\text{TCP}} \approx 1 \times RTT$, $T_{\text{TLS 1.3}} \approx 1 \times RTT$, $T_{\text{req}} \approx 1 \times RTT$ and $T_{\text{transfer}} \approx \frac{S}{B}$ for a response that fits in the congestion window.

Symbol	Meaning	Units
T_{DNS}	DNS lookup time (≈ 0 if cached)	ms
RTT	Client-to-load-balancer round-trip time	ms
T_{server}	Time from the load balancer receiving the request to sending the response (app + DB)	ms
S	Response size	bytes
B	Bottleneck bandwidth	bytes/ms

WORKED EXAMPLE

Worked example — Cold versus warm request. A user is 40 ms RTT from the region. Uncached DNS takes 30 ms. The server spends 2 ms in the load balancer and web server, 8 ms in application code and one 3 ms database query: $T_{\text{server}} = 13$ ms. The 4 KB response transfers in well under 1 ms on a broadband link, so ignore it.

1. Cold (new DNS, new connection): $30 + 40 + 40 + 40 + 13 = 163$ ms.
2. Warm (DNS cached, connection reused): $0 + 0 + 0 + 40 + 13 = 53$ ms.
3. Share of the cold request spent on actual server work: $13/163 \approx 8\%$.

Interpretation. For short API calls, the network setup costs about ten times as much as the work. **Engineering implication:** before optimizing a 3 ms query, make sure clients reuse connections (HTTP keep-alive, HTTP/2 multiplexing), keep DNS TTLs reasonable, terminate TLS close to users (CDN edges, §21.3) and avoid designs that need several *sequential* round trips per screen.

Table 8.3 — Typical latency budget per hop (order-of-magnitude, as of 2026).

Hop	Typical cost	Dominated by
DNS lookup (cached in OS/browser)	~0 ms	—
DNS lookup (recursive resolver cache miss)	10–100 ms	RTTs to authoritative servers
TCP + TLS 1.3 setup	2 × RTT (e.g. 20–200 ms on the public internet)	Distance to the TLS terminator
Load balancer and reverse proxy	~0.1–1 ms	Parsing, TLS termination CPU
Application code (simple handler)	1–20 ms	Serialization, framework overhead, language runtime
Cache read in the same datacenter	~0.2–1 ms	Network RTT inside the datacenter
Indexed database point read	~0.5–5 ms	Network RTT + buffer-pool hit or disk read
Unindexed scan of a large table	100 ms–seconds	Rows read from disk (Chapter 11)

These figures are illustrative ranges for estimation; measure your own system (Chapter 23). See §4.17 and Appendix F for dated reference numbers.

Failure scenarios

Table 8.4 — Lifecycle failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Users hit old servers after a migration	DNS answers cached for the old TTL	Traffic still arriving at old IPs	Keep old endpoints serving until TTL expires	Lower TTL days before a planned change
502/504 from the load balancer	Backend crashed or slower than the LB timeout	LB 5xx metrics by backend	Remove unhealthy backends	Health checks; timeouts that shrink inward along the chain
Requests pile up, then everything times out	DB connection pool exhausted by slow queries	Pool wait time, active connections	Kill slow queries, shed load	Query timeouts, indexes, pool sizing (§14.13)
Client retries make an outage worse	Timeouts plus immediate retries multiply load	Request rate rises while success rate falls	Shed load, open circuit breakers	Exponential backoff with jitter, retry budgets (§22.12)

COMMON MISTAKE

"Latency is mostly the database." For a typical small API call, connection setup and round trips often cost more than the query. Count round trips first, then optimize server time.

8.6 REST API design

8.6.1 What REST is: Fielding's constraints

DEFINITION

Definition — REST (Representational State Transfer). An architectural style for distributed hypermedia systems, defined by Roy Fielding in his 2000 doctoral dissertation as a set of constraints on how components interact [Fielding 2000]. In everyday usage, a "REST API" is an HTTP API that models its domain as **resources** identified by URIs and manipulated with the standard HTTP methods.

First-principles explanation

A library does not give each patron a custom set of instructions. It has a uniform system: every book has a call number (a **resource identifier**), and there are a few standard actions — look up, borrow, return — that work the same for every book. You can walk into any library and use it. REST applies the same idea to networked software: instead of inventing a new verb per operation (`getOrder`, `cancelOrderV2`, `listAllOrdersForUser`), you name *things* (`/orders/42`) and use a small, fixed set of verbs that every client, proxy and cache already understands.

Why does this exist?

Fielding was describing why the web had scaled to millions of independently developed servers and clients. Its uniform interface lets intermediaries — caches, proxies, CDNs, load balancers — understand and optimize traffic without knowing anything about the application. A CDN can cache any `GET` response marked cacheable; a proxy can retry any idempotent request. Custom RPC protocols of the 1990s could not offer that.

Table 8.5 — Fielding's REST constraints.

Constraint	Meaning	What it buys you
Client–server	Separate the user interface from data storage	Independent evolution of client and server
Stateless	Each request contains all information needed to understand it; no session state on the server	Visibility, reliability, horizontal scalability
Cache	Responses label themselves cacheable or not	Fewer interactions; lower latency
Uniform interface	Resource identification, manipulation through representations, self-descriptive messages, hypermedia as the engine of application state (HATEOAS)	Generic intermediaries and clients
Layered system	A client cannot tell whether it talks to the origin or an intermediary	Load balancers, caches, gateways can be inserted transparently
Code on demand (optional)	Servers may send executable code (e.g. JavaScript)	Extensible clients

NOTE

Note — "RESTful" in practice. Most public "REST" APIs implement the first five constraints partially and skip HATEOAS. Fielding has written that an API which is not hypertext-driven is not REST in his sense. This book uses "REST API" in the common, looser sense — resource-oriented HTTP + JSON — and flags HATEOAS separately (§8.6.8).

8.6.2 Resources and URIs

A **resource** is any named thing the API exposes: a user, an order, a collection of orders, the current exchange rate. A **representation** is a serialized snapshot of it (JSON, usually). Design rules that hold up in practice:

1. **Nouns, not verbs, in paths.** `POST /orders`, not `POST /createOrder`. The method is the verb.
2. **Plural collections, item by identifier.** `/orders` (collection) and `/orders/42` (item).
3. **Nest only for true containment, at most one level.** `/orders/42/items` is clear; `/users/7/orders/42/items/3/discounts` couples clients to your data model. Prefer `/order-items/3` once items have their own identity.
4. **Opaque, stable identifiers.** Prefer IDs that do not leak row counts or allow enumeration (UUIDs or Snowflake-style IDs, §17.10).
5. **Actions that do not fit CRUD** become sub-resources or state changes: `POST /orders/42/cancellation` or `PATCH /orders/42 {"status":"canceled"}`, rather than `POST /cancelOrder?id=42`.

6. **Consistent casing** (`snake_case` or `camelCase` in JSON, kebab-case in paths) across the whole API.

8.6.3 HTTP methods: safety and idempotency

Two properties of methods matter enormously for distributed systems, because networks lose responses and clients retry.

DEFINITION

Definition — Safe method. A method whose semantics are read-only: the client does not request, and does not expect, any state change on the server [RFC 9110 §9.2.1]. Logging or metrics side effects are allowed.

DEFINITION

Definition — Idempotent method. A method for which the intended effect on the server of sending the same request $N > 0$ times is the same as sending it once [RFC 9110 §9.2.2]. The *response* may differ (a second `DELETE` may return 404); the *state* does not.

Analogy: pressing a lift's call button is idempotent (pressing five times summons one lift); dropping a coin in a vending machine is not (five coins, five charges). If a client sends `POST /payments` and the connection drops before the response arrives, it cannot know whether the payment happened. Retrying a non-idempotent request risks a double charge. Retrying an idempotent one is always safe.

Table 8.6 — HTTP method properties [RFC 9110].

Method	Typical use	Safe	Idempotent	Request body	Cacheable
`GET`	Read a resource or collection	Yes	Yes	No (no defined semantics)	Yes
`HEAD`	`GET` without the body (check existence, size)	Yes	Yes	No	Yes
`OPTIONS`	Discover allowed methods; CORS preflight	Yes	Yes	Optional	No
`POST`	Create in a collection; any non-idempotent action	No	**No**	Yes	Only with explicit freshness; rare
`PUT`	Create or fully replace at a known URI	No	Yes	Yes	No
`PATCH`	Partial update [RFC 5789]	No	Not guaranteed	Yes	No
`DELETE`	Remove a resource	No	Yes	Rarely	No

What to notice:

- `PUT /users/7/avatar` with the full new representation is idempotent: sending it twice leaves the same avatar. `PATCH {"op":"increment","path":"/balance"}` is not.
- To make `POST` safe to retry, clients send an **idempotency key** header (for example a UUID per logical operation); the server stores the key with the result and returns the stored result for duplicates. Chapter 22 (§22.15) covers the full design.

8.6.4 Status codes

Status codes are part of the uniform interface: a load balancer, a retry library or a monitoring system can act on `503` without understanding your JSON.

Table 8.7 — Status codes every API designer uses [RFC 9110 unless noted].

Code	Meaning	Use it when	Client should
200 OK	Success with body	Successful `GET`, `PUT`, `PATCH`	Use the body
201 Created	New resource created	`POST` created something; include `Location` header	Follow `Location`
202 Accepted	Queued for asynchronous processing	Long jobs; return a status URL	Poll the status resource
204 No Content	Success, no body	`DELETE`, or update returning nothing	Nothing
301 / 308	Moved permanently	Resource has a new URI (308 preserves the method)	Update bookmarks
304 Not Modified	Cached copy still valid	Conditional `GET` with `If-None-Match` matched the `ETag`	Use cached copy
400 Bad Request	Malformed request	Unparseable JSON, invalid parameter syntax	Fix the request; do not retry as is
401 Unauthorized	Not authenticated	Missing, expired or invalid credentials; send `WWW-Authenticate`	Authenticate, then retry
403 Forbidden	Authenticated but not allowed	Lacks permission or scope	Do not retry
404 Not Found	No such resource (or hidden from you)	Unknown ID; also to avoid revealing existence	Do not retry
409 Conflict	Conflicts with current state	Duplicate unique key; version conflict	Re-read, resolve, retry
412 Precondition Failed	`If-Match` ETag did not match	Optimistic concurrency failure	Re-read and retry
422 Unprocessable Content	Well-formed but semantically invalid	Validation errors (end date before start date)	Fix input
429 Too Many Requests [RFC 6585]	Rate limited	Client exceeded quota; send `Retry-After`	Back off
500 Internal Server Error	Unexpected server bug	Unhandled exception	Retry only if idempotent, with backoff
502 / 504	Bad gateway / gateway timeout	An upstream failed or timed out	Retry idempotent requests with backoff
503 Service Unavailable	Temporarily overloaded or in maintenance	Load shedding; send `Retry-After`	Back off and retry

> COMMON MISTAKE
>
> **Returning `200 OK` with `{"error": "..."}` in the body.** Every intermediary and monitoring tool then counts failures as successes, retries never happen, and error-rate SLOs (§39.6) silently read 100%. Use the status code for the class of outcome and the body for detail.

8.6.5 Pagination: offset versus cursor

A collection such as `/orders` may hold millions of items. Returning all of them would take seconds, megabytes and a lot of database work, so APIs return **pages**.

Offset pagination

The client asks for `?limit=20&offset=40` (or `?page=3&per_page=20`). The SQL is straightforward:

```sql
-- Page 3 of 20 items, newest first (PostgreSQL)
SELECT id, title, created_at
FROM articles
ORDER BY created_at DESC, id DESC
LIMIT 20 OFFSET 40;
```

It is simple and supports "jump to page 37". It has two serious problems:

1. **Cost grows with depth.** The database cannot jump to row 40; it must produce and discard the first 40 rows in sorted order, then return 20. Deep pages read offset+limit rows.
2. **Results shift under concurrent writes.** If a new article is inserted while the user reads page 1, every item moves down one place: the last item of page 1 appears again at the top of page 2. Deletions cause items to be skipped silently.

Cursor (keyset) pagination

Instead of "skip N rows", the client says "give me rows *after this one*". The server returns an opaque **cursor** encoding the sort key of the last row it sent; the next query uses it in a `WHERE` clause that an index can seek to directly.

```
        -- Supporting index: the sort order, with id as a unique tie-breaker
        CREATE INDEX idx_articles_created_id ON articles (created_at DESC, id DESC);

        -- First page
        SELECT id, title, created_at
        FROM articles
        ORDER BY created_at DESC, id DESC
        LIMIT 21;                       -- one extra row tells us whether a next page
exists

        -- Next page: $1, $2 = created_at and id of the last row of the previous page
        SELECT id, title, created_at
        FROM articles
        WHERE (created_at, id) < ($1, $2)    -- row-value comparison: seek, don't skip
        ORDER BY created_at DESC, id DESC
        LIMIT 21;
```

What to notice:

- The `id` tie-breaker makes the sort order **total**. Without it, two rows with the same `created_at` could be skipped or duplicated at a page boundary.
- The row-value comparison `(created_at, id) < ($1, $2)` means “earlier timestamp, or same timestamp with smaller id”. PostgreSQL, MySQL 8 and SQLite support it; on databases that do not, expand it to `created_at < $1 OR (created_at = $1 AND id < $2)`.
- Fetching `limit + 1` rows answers “is there a next page?” without a separate `COUNT(*)`, which is itself expensive on large tables.

FORMULA

Rows touched per page

$$R_{\text{offset}} = o + \ell \qquad R_{\text{keyset}} \approx \ell + \log_b n$$

Symbol	Meaning	Units
o	Offset (rows skipped)	rows
ℓ	Page size (limit)	rows
n	Rows in the table or index	rows
b	B-tree fan-out (entries per index page, typically hundreds)	entries

WORKED EXAMPLE

Worked example — Page 50,000 of an activity feed. Table of $n = 10^7$ rows, page size $\ell = 20$, user (or a scraper) requests page 50,000, so $o = 49,999 \times 20 = 999,980$.

1. Offset: $R = 999,980 + 20 = 1,000,000$ index entries walked, 999,980 of them discarded.
2. Keyset: one B-tree descent of $\log_{200} 10^7 \approx 3$ levels, then 21 entries: about 24 entries.
3. Ratio: $10^6/24 \approx 40,000\times$ more work for the offset query.

Interpretation. Offset pagination is fine for shallow pages (an admin table with a few thousand rows) but degrades linearly with depth and is an easy denial-of-service vector. **Engineering implication:** use cursors for feeds, timelines, logs, sync and any public API; cap `offset` if you must offer it.

Table 8.8 — Offset versus cursor pagination.

Aspect	Offset / page number	Cursor (keyset)
Request	`?limit=20&offset=40`	`?limit=20&cursor=eyJ…`
Cost of deep pages	Grows linearly with offset	Constant (index seek)
Stable under inserts/deletes	No: duplicates and skips	Yes, relative to the last seen key
Jump to arbitrary page	Yes	No (only next/previous)
Total count	Often shown (costly `COUNT(*)`)	Usually omitted
Sort flexibility	Any `ORDER BY`	Needs an index matching the sort key plus a unique tie-breaker
Choose when	Small, mostly static datasets; UI needs page numbers	Large or fast-changing collections; infinite scroll; API sync

Code example

The following FastAPI service implements cursor pagination with an opaque, base64url-encoded cursor, optional filtering, and RFC 9457 error responses (§8.6.7). It runs as written with `pip install fastapi uvicorn` and `uvicorn articles_api:app`.

```
        # articles_api.py — run with:  pip install fastapi uvicorn  &&  uvicorn
articles_api:app
        import base64
        import json
        import sqlite3

        from fastapi import FastAPI, Query, Request
        from fastapi.responses import JSONResponse

        app = FastAPI(title="Articles API", version="1.0.0")

        # In-memory database so the example is self-contained.
        db = sqlite3.connect(":memory:", check_same_thread=False)
        db.row_factory = sqlite3.Row
        db.executescript("""
        CREATE TABLE articles (
            id         INTEGER PRIMARY KEY,
            title      TEXT    NOT NULL,
            status     TEXT    NOT NULL,
            created_at TEXT    NOT NULL           -- ISO-8601 UTC timestamp
        );
        CREATE INDEX idx_articles_created_id ON articles (created_at DESC, id DESC);
        """)
        db.executemany(
            "INSERT INTO articles (id, title, status, created_at) VALUES (?, ?, ?, ?)",
            [(i, f"Article {i}", "draft" if i % 3 == 0 else "published",
              f"2026-01-{i % 28 + 1:02d}T10:00:00Z") for i in range(1, 101)],
        )

        class Problem(Exception):
            """An error that is rendered as RFC 9457 problem details."""
            def __init__(self, status: int, title: str, detail: str,
                         type_: str = "about:blank"):
                self.status, self.title, self.detail, self.type_ = status, title, de-
tail, type_

        @app.exception_handler(Problem)
        async def problem_handler(request: Request, exc: Problem) -> JSONResponse:
            return JSONResponse(
                status_code=exc.status,
                media_type="application/problem+json",
                content={"type": exc.type_, "title": exc.title, "status": exc.status,
                         "detail": exc.detail, "instance": request.url.path},
            )

        def encode_cursor(created_at: str, row_id: int) -> str:
            raw = json.dumps([created_at, row_id]).encode()
            return base64.urlsafe_b64encode(raw).decode().rstrip("=")

        def decode_cursor(cursor: str) -> tuple[str, int]:
            try:
                padded = cursor + "=" * (-len(cursor) % 4)
```

```
                created_at, row_id = json.loads(base64.urlsafe_b64decode(padded))
                return str(created_at), int(row_id)
            except Exception:
                raise Problem(400, "Invalid cursor",
                              "The cursor parameter is malformed or expired.",
                              "https://api.example.com/problems/invalid-cursor")

        @app.get("/v1/articles")
        def list_articles(
            limit: int = Query(20, ge=1, le=100),
            cursor: str | None = None,
            status: str | None = Query(None, pattern="^(draft|published)$"),
        ):
            where, params = [], []
            if status is not None:
                where.append("status = ?")
                params.append(status)
            if cursor is not None:
                created_at, last_id = decode_cursor(cursor)
                where.append("(created_at, id) < (?, ?)")      # keyset predicate
                params += [created_at, last_id]

            sql = "SELECT id, title, status, created_at FROM articles"
            if where:
                sql += " WHERE " + " AND ".join(where)
            sql += " ORDER BY created_at DESC, id DESC LIMIT ?"
            params.append(limit + 1)                            # fetch one extra row

            rows = db.execute(sql, params).fetchall()
            has_more = len(rows) > limit
            rows = rows[:limit]
            next_cursor = (encode_cursor(rows[-1]["created_at"], rows[-1]["id"])
                           if has_more else None)
            return {"data": [dict(r) for r in rows], "next_cursor": next_cursor}

        @app.get("/v1/articles/{article_id}")
        def get_article(article_id: int):
            row = db.execute("SELECT id, title, status, created_at FROM articles WHERE
id = ?",
                             (article_id,)).fetchone()
            if row is None:
                raise Problem(404, "Not Found", f"No article with id {article_id} ex-
ists.")
            return dict(row)
```

What to notice:

- **The cursor is opaque.** Clients must treat it as a token, not parse it. That leaves you free to change its contents (add a sort field, sign or encrypt it, add an expiry) without a breaking change. In production, sign the cursor with an HMAC (as in §8.10.2) so clients cannot forge one that seeks to arbitrary positions.

- **`limit` is bounded** (`le=100`). An unbounded page size is a denial-of-service hole. FastAPI rejects `limit=500` with `422` automatically.
- **SQL parameters are bound with `?`**, never formatted into the string, which prevents SQL injection (§10.7).
- **Filters and cursors compose**: the `status` predicate and the keyset predicate are both in the `WHERE` clause. A production version would also bind the cursor to the filter that produced it, so a cursor from `status=draft` cannot be replayed against `status=published`.

Exercising it with curl:

```
        curl -s 'http://localhost:8000/v1/articles?limit=2'
        # {"data":[{"id":83,"title":"Article
83","status":"published","created_at":"2026-01-28T10:00:00Z"},
        #
{"id":55,...}],"next_cursor":"WyIyMDI2LTAxLTI4VDEwOjAwOjAwWiIsIDU1XQ"}

        curl -s 'http://localhost:8000/v1/articles?
limit=2&cursor=WyIyMDI2LTAxLTI4VDEwOjAwOjAwWiIsIDU1XQ'

        curl -si 'http://localhost:8000/v1/articles/999'
        # HTTP/1.1 404 Not Found
        # content-type: application/problem+json
        # {"type":"about:blank","title":"Not Found","status":404,
        #  "detail":"No article with id 999 exists.","instance":"/v1/articles/999"}
```

8.6.6 Filtering and sorting

Common conventions, any of which is fine if applied consistently:

- **Filtering by field:** `GET /orders?status=shipped&customer_id=c_17`. For ranges: `created_after=2026-01-01T00:00:00Z` or `created_at[gte]=…`.
- **Sorting:** `?sort=-created_at,id` (minus for descending).
- **Sparse fieldsets:** `?fields=id,title` to reduce payload size, a partial answer to the over-fetching that motivates GraphQL.
- **Search** is a different operation from filtering. Free-text search belongs on a search endpoint backed by a search engine (Chapter 16), not on `LIKE '%term%'` against the primary database.

Every filter and sort combination you allow is a query shape your database must serve efficiently. Allow-list the fields, and make sure each permitted combination has a supporting index; otherwise one creative client can trigger a full table scan per request. With cursor pagination, the cursor must encode the values of *every* sort column plus the tie-breaker.

8.6.7 Error format: RFC 9457 problem details

Ad-hoc error bodies (`{"err": 1}`, `{"message": "..."}`, `{"errors": [...]}`) force every client to write custom parsing per API. RFC 9457 (which obsoletes RFC 7807) defines a standard JSON shape served with media type `application/problem+json` [RFC 9457]:

```
{
  "type": "https://api.example.com/problems/insufficient-funds",
  "title": "Insufficient funds",
  "status": 403,
  "detail": "Your balance is 30.00 EUR; the transfer requires 50.00 EUR.",
  "instance": "/v1/transfers/7f9c2e",
  "balance_cents": 3000,
  "required_cents": 5000
}
```

What to notice:

- **`type`** is a URI that identifies the *kind* of problem; clients branch on it. It should ideally resolve to human-readable documentation. When omitted it defaults to `about:blank`, in which case `title` should be the HTTP status phrase.
- **`title`** is a short, stable summary of the type; **`detail`** explains *this* occurrence; **`instance`** identifies this occurrence (a request path or an error ID you can grep logs for).
- **Extension members** (`balance_cents`) carry machine-readable specifics. Never put stack traces, SQL or internal hostnames in error bodies.

8.6.8 HATEOAS, briefly

HATEOAS (Hypermedia as the Engine of Application State) means responses include links telling the client what it can do next, so the client follows links instead of constructing URLs:

```
{
  "id": "ord_42",
  "status": "placed",
  "_links": {
    "self":   { "href": "/v1/orders/ord_42" },
    "cancel": { "href": "/v1/orders/ord_42/cancellation", "method": "POST" },
    "items":  { "href": "/v1/orders/ord_42/items" }
  }
}
```

The `cancel` link disappears once the order ships, so the server, not the client, encodes the workflow rules. Full HATEOAS is rare in public JSON APIs because most clients are written against documentation and hard-code URL templates anyway. A lightweight and

widely used piece of it is pagination links in the HTTP `Link` header (`Link: <…?cursor=abc>; rel="next"`).

Real-world industry applications

INDUSTRY EXAMPLE

Stripe and GitHub list endpoints. Stripe's list endpoints use cursor-style pagination: the client passes the ID of the last object it saw in `starting_after` (or `ending_before`) together with `limit`, and the response carries `has_more` [Stripe API Docs: Pagination]. GitHub's REST API returns pagination URLs in the HTTP `Link` header with `rel="next"`, `rel="last"` and similar relations, and some endpoints use cursor-based `before` / `after` parameters [GitHub Docs: Using pagination in the REST API]. Both choices follow from the same problem: collections that are large and constantly changing, accessed by automated clients that page to the end. *Evidence: Primary* — [Stripe API Docs: Pagination]; [GitHub Docs: Using pagination in the REST API]

Failure scenarios

Table 8.9 — REST API failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate orders or charges	Client retried a timed-out `POST`	Duplicate rows with the same payload seconds apart	Refund / merge duplicates	Idempotency keys on all non-idempotent writes (§22.15)
Database CPU pinned by one client	Deep `offset` pages or unindexed sort	Slow-query log; per-client cost metrics	Rate-limit the client	Cursor pagination; allow-listed, indexed sorts
Lost update	Two clients `PUT` the same resource concurrently	Users report reverted changes	Restore from audit log	`ETag` + `If-Match`, return `412` on mismatch
Clients crash on new error	Error body shape changed	Client error reports by version	Roll back	One stable error format (RFC 9457) from day one

Common misconceptions

COMMON MISTAKE

"`PUT` is for updates, `POST` is for creates." The real distinction is idempotency and who chooses the URI. `PUT /articles/my-slug` creates *or* replaces at a client-chosen URI, idempotently. `POST /articles` lets the server choose the URI and is not idempotent. Partial updates are `PATCH`.

COMMON MISTAKE

“`401` means the user lacks permission.” `401 Unauthorized` (misleadingly named) means *not authenticated*. Lacking permission while authenticated is `403 Forbidden`. Many APIs return `404` instead of `403` for resources the caller should not even know exist.

8.7 GraphQL

8.7.1 Schema, operations and resolvers

DEFINITION

Definition — GraphQL. A query language for APIs and a runtime for executing those queries against a strongly typed **schema**. The client sends a document describing exactly the fields it wants; the server returns JSON of the same shape [GraphQL Spec].

First-principles explanation

A REST API is a set menu: `/users/7` returns whatever the kitchen decided a “user” contains. If you need the user, their last five posts and each post’s comment count, you either order three dishes (three round trips — **under-fetching**) or receive a platter of fields you never eat (**over-fetching**). GraphQL is ordering à la carte from one waiter: you write down precisely what you want, nested as deep as you like, and get exactly that back in one trip.

Why does this exist?

Facebook built GraphQL in 2012 for its native mobile apps, where many REST round trips over cellular networks made news-feed screens slow and every new screen needed a new endpoint; it was open-sourced in 2015 and is now governed by the GraphQL Foundation [Byron 2015]. The specification’s most recent edition at the time of writing is September 2025 [GraphQL Spec].

How it works internally

1. **Schema.** The server publishes types in the Schema Definition Language (SDL). Three root types are entry points: `Query` (reads), `Mutation` (writes) and `Subscription` (event streams).
2. **Parse and validate.** The server parses the query document into an abstract syntax tree and validates every field and argument against the schema *before* running any-

thing. Typos fail fast with a precise error.

3. **Execute.** The executor walks the query tree. For every field it calls a **resolver**: a function `(parent, args, context) → value`. The resolver for `Query.posts` returns a list of post objects; then, for *each* post, the resolver for `Post.author` runs with that post as `parent`.
4. **Respond.** The result is JSON shaped like the query, plus an `errors` array if some fields failed. Over HTTP, GraphQL servers usually expose one endpoint (`POST /graphql`) and often return `200 OK` even when `errors` is non-empty, which matters for monitoring.

```
"""A blog: users write posts; posts have comments."""
type Query {
  user(id: ID!): User
  posts(first: Int = 10, after: String): PostConnection!
}

type Mutation {
  createPost(input: CreatePostInput!): CreatePostPayload!
}

type User {
  id: ID!
  name: String!
  posts(first: Int = 10): [Post!]!
}

type Post {
  id: ID!
  title: String!
  body: String!
  author: User!
  comments(first: Int = 10): [Comment!]!
  publishedAt: String
}

type Comment {
  id: ID!
  text: String!
  author: User!
}

# Relay-style cursor pagination
type PostConnection {
  edges: [PostEdge!]!
  pageInfo: PageInfo!
}

type PostEdge {
  cursor: String!
  node: Post!
}

type PageInfo {
  hasNextPage: Boolean!
  endCursor: String
}

input CreatePostInput {
  title: String!
  body: String!
}

type CreatePostPayload {
  post: Post
```

```
  errors: [String!]!
}
```

A client query and the matching curl call:

```
curl -s https://api.example.com/graphql \
  -H 'Content-Type: application/json' \
  -H 'Authorization: Bearer eyJhbGciOi...' \
  -d '{"query":"query RecentPosts { posts(first: 5) { edges { node { title au-
thor { name } } } pageInfo { hasNextPage endCursor } } }"}'
```

What to notice:

- `!` means non-null; `[Post!]!` is a non-null list of non-null posts. Nullability is part of the contract: making a nullable field non-null later is safe for clients, the reverse is not.
- Pagination uses the cursor model of §8.6.5 (`first`, `after`, `endCursor`), in the "connection" shape popularized by Facebook's Relay client.
- Mutations return a payload type with a domain `errors` list, so business-rule failures are typed data rather than transport errors.

8.7.2 The N+1 problem and DataLoader

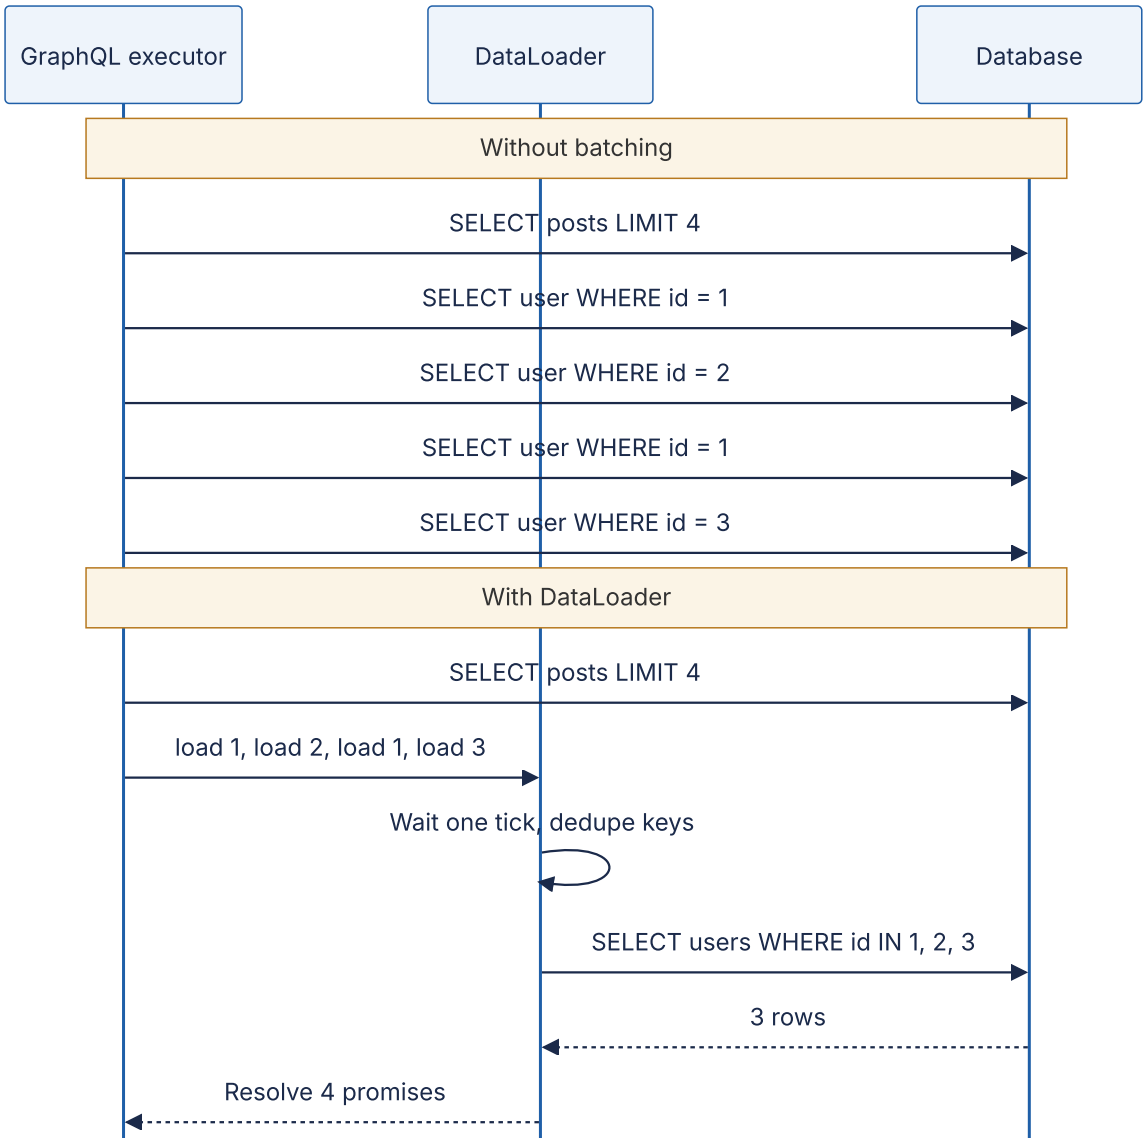
The resolver model is elegant but naive. For the query above, `posts` runs one SQL query that returns 5 posts; then `Post.author` runs **once per post**, each issuing `SELECT … FROM users WHERE id = ?`. That is $1 + N$ queries — the **N+1 problem**. Nesting multiplies it.

> WORKED EXAMPLE
>
> **Worked example — Query count for a nested feed.** A screen asks for 50 posts, the first 10 comments on each, and each comment's author. Each database round trip costs 1 ms.
>
> 1. Naive resolvers: 1 (posts) +50 (comments per post) $+50 \times 10 = 500$ (comment authors) $= 551$ queries, about 551 ms if executed one after another.
> 2. With batching per tree level: 1 query for posts, 1 for all comments `WHERE post_id IN (…50 ids…)`, 1 for all authors `WHERE id IN (…)`: 3 queries, about 3 ms.
>
> **Interpretation.** The difference is two orders of magnitude, and it grows with page size. **Engineering implication:** a GraphQL server without batching is a load generator pointed at your database.

DataLoader is the standard fix, published by Facebook as a small JavaScript library and re-implemented in every major language [DataLoader]. Resolvers do not query directly; they call `loader.load(id)`, which returns a promise. DataLoader collects every `load` is-

sued during one tick of the event loop, then calls a **batch function** once with all the keys, and resolves each promise from the result. It also memoizes keys for the duration of the request, so the same author requested 30 times is fetched once.

Figure 8.4 — N+1 resolution versus DataLoader batching.



Reading the diagram. In the first half, the executor issues one database query per post for the author field: five synchronous round trips, one of them a duplicate. In the second half, the four author resolvers each call `load` on a per-request DataLoader; it waits until the current tick ends, deduplicates the keys to `{1, 2, 3}`, makes one `IN` query, and fans the rows back out to the four waiting resolvers. The storage boundary is the database. Failure point: if the batch query fails, every waiting resolver must receive the error. Scaling: batching turns $O(N)$ round trips into $O(\text{depth})$.

A minimal DataLoader in Python's `asyncio` shows the mechanism:

```
        import asyncio

        class DataLoader:
            """Coalesce every load(key) issued in the same event-loop tick into one
batch call."""

            def __init__(self, batch_fn):
                self.batch_fn = batch_fn          # async fn: list[key] -> list[value],
same order
                self.cache = {}                   # key -> Future (per-request memoiza-
tion)
                self.queue = []                   # keys waiting for the next dispatch

            def load(self, key):
                if key in self.cache:
                    return self.cache[key]
                fut = asyncio.get_running_loop().create_future()
                self.cache[key] = fut
                self.queue.append(key)
                if len(self.queue) == 1:          # first key in this tick: schedule a
dispatch
                    asyncio.get_running_loop().call_soon(
                        lambda: asyncio.ensure_future(self._dispatch()))
                return fut

            async def _dispatch(self):
                keys, self.queue = self.queue, []
                try:
                    values = await self.batch_fn(keys)
                    for k, v in zip(keys, values):
                        self.cache[k].set_result(v)
                except Exception as exc:           # fail every waiter, not just one
                    for k in keys:
                        self.cache[k].set_exception(exc)

        queries = []
        AUTHORS = {1: "Ada", 2: "Linus", 3: "Grace"}

        async def fetch_authors(ids):
            queries.append(f"SELECT id, name FROM authors WHERE id IN {tuple(ids)}")
            return [AUTHORS.get(i) for i in ids]

        async def main():
            loader = DataLoader(fetch_authors)    # create one loader PER REQUEST
            posts = [{"id": 10, "author_id": 1}, {"id": 11, "author_id": 2},
                     {"id": 12, "author_id": 1}, {"id": 13, "author_id": 3}]
            names = await asyncio.gather(*(loader.load(p["author_id"]) for p in posts))
            print(names)     # ['Ada', 'Linus', 'Ada', 'Grace']
            print(queries)   # ['SELECT id, name FROM authors WHERE id IN (1, 2, 3)']
```

```
        asyncio.run(main())
```

What to notice:

- `call_soon` defers the dispatch until every resolver running in the current tick has called `load`; that is the whole trick.
- The batch function must return values **in the same order as the keys**, with `None` (or an error) for missing keys.
- The loader is created **per request**. A process-wide loader would leak one user's cached data to another user and would never notice updates.

8.7.3 Caching and security challenges

REST gets HTTP caching almost for free: `GET /posts/7` has a URL, so browsers and CDNs can cache it by URL with `Cache-Control` and `ETag`. GraphQL makes this harder:

- **One URL, usually `POST`.** CDNs and browsers do not cache `POST` responses by default, and the cache key would have to include the query body.
- **Every query is unique.** Two clients requesting slightly different fields produce different responses, so shared-cache hit ratios are low.
- **Mixed freshness.** One response may combine a user's name (cacheable for hours) and their unread count (seconds); the whole response gets the most restrictive policy.

Mitigations: **persisted queries** (clients send a hash of a pre-registered query via `GET /graphql?id=<sha256>`, which is cacheable by URL and also blocks arbitrary queries); **normalized client caches** (Apollo Client and Relay store objects by type and ID and reuse them across queries); and **server-side caching in resolvers or DataLoader batch functions** using the techniques of Chapter 20.

The same flexibility creates a security problem: one small request can ask for an enormous result (`friends { friends { friends { … } } }`). Production servers enforce **depth limits**, **query cost analysis** (estimate cost from the schema and arguments before executing; reject or rate-limit by cost, not by request count), pagination maximums on every list field, and timeouts. GitHub's public GraphQL API, for example, rate-limits by a computed per-query cost rather than by request count [GitHub Docs: GraphQL rate limits].

> COMMON MISTAKE
>
> **"GraphQL is faster than REST."** GraphQL removes client round trips and overfetching; it does not make the server faster. Without batching and cost limits it is frequently slower and harder to protect. It moves complexity from the client to the server.

8.8 gRPC and RPC

8.8.1 Remote procedure calls

DEFINITION

Definition — Remote procedure call (RPC). A mechanism that lets a program call a function in another process, usually on another machine, with syntax that resembles a local function call. Generated **stubs** serialize the arguments, send them over the network, and deserialize the result [Birrell and Nelson 1984].

Instead of resources and verbs, RPC exposes **operations**: `GetOrder(order_id)`, `ReserveInventory(sku, qty)`. That maps naturally to how programmers think inside one codebase, which is why internal service-to-service APIs often use RPC. The danger is the illusion of locality: a remote call can be a million times slower than a local one, can fail halfway, and can succeed on the server while the response is lost (see the fallacies of distributed computing, §24.5). Good RPC frameworks make these differences explicit through deadlines, status codes and retries.

8.8.2 gRPC: Protocol Buffers over HTTP/2

DEFINITION

Definition — gRPC. An open-source RPC framework, originally developed at Google and released in 2015, that uses Protocol Buffers as its interface definition language and message format and HTTP/2 as its transport [gRPC Docs].

You describe the service once in a `.proto` file; the `protoc` compiler generates client stubs and server interfaces in a dozen or so languages.

```
syntax = "proto3";

package shop.v1;

import "google/protobuf/timestamp.proto";

// The service contract: four methods, one per gRPC streaming mode.
service OrderService {
  // Unary: one request, one response.
  rpc GetOrder(GetOrderRequest) returns (Order);
  // Server streaming: one request, a stream of responses.
  rpc WatchOrderStatus(GetOrderRequest) returns (stream OrderStatusEvent);
  // Client streaming: a stream of requests, one response.
  rpc UploadLineItems(stream LineItem) returns (UploadSummary);
  // Bidirectional streaming: both sides stream independently.
  rpc Chat(stream ChatMessage) returns (stream ChatMessage);
}

message GetOrderRequest {
  string order_id = 1;
}

enum OrderStatus {
  ORDER_STATUS_UNSPECIFIED = 0;   // proto3 enums must start at zero
  ORDER_STATUS_PLACED = 1;
  ORDER_STATUS_SHIPPED = 2;
  ORDER_STATUS_DELIVERED = 3;
}

message Order {
  string order_id = 1;
  string customer_id = 2;
  repeated LineItem items = 3;
  OrderStatus status = 4;
  google.protobuf.Timestamp created_at = 5;
  reserved 6;                     // field 6 was deleted; never reuse the number
  reserved "coupon_code";
}

message LineItem {
  string sku = 1;
  int32 quantity = 2;
  int64 unit_price_cents = 3;    // money as integer cents, never float
}

message OrderStatusEvent {
  string order_id = 1;
  OrderStatus status = 2;
}

message UploadSummary {
  int32 items_received = 1;
}

message ChatMessage {
```

```
  string text = 1;
}
```

What to notice:

- The numbers (`= 1`, `= 2`) are **field numbers**, not default values. They, not the names, are written on the wire (§8.9.2), so they must never change or be reused; `reserved` enforces that for deleted fields.
- The version lives in the package name (`shop.v1`), so a breaking redesign becomes `shop.v2` alongside it (§8.15).
- `stream` on the request, the response or both selects the streaming mode.

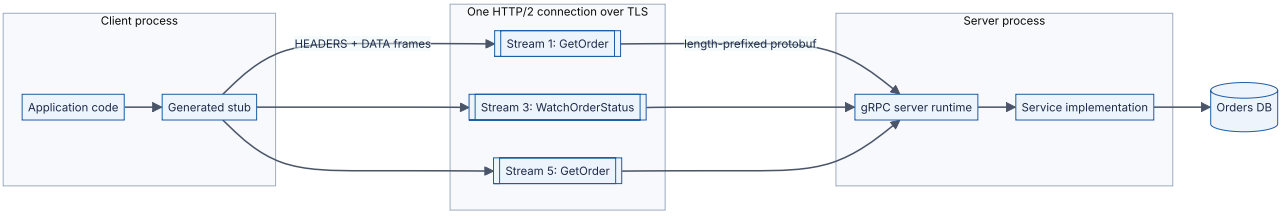
How it works internally

Each call maps onto HTTP/2 (§7.9):

1. The client opens (or reuses) one long-lived HTTP/2 connection, called a **channel**, to the server.
2. Each RPC becomes an HTTP/2 **stream**: a `POST` to the path `/shop.v1.OrderService/GetOrder` with `content-type: application/grpc` and, if the client set one, a `grpc-timeout` header carrying the deadline.
3. Each message is **length-prefixed**: 1 byte compression flag + 4-byte big-endian length + the Protobuf bytes, carried in HTTP/2 DATA frames.
4. The server replies with headers, zero or more length-prefixed messages, and **trailers** containing `grpc-status` (0 = OK, 4 = DEADLINE_EXCEEDED, 14 = UNAVAILABLE, and so on) and an optional `grpc-message`.

Because HTTP/2 multiplexes many streams over one TCP connection, hundreds of concurrent RPCs share a connection without head-of-line blocking at the HTTP layer (TCP-level head-of-line blocking remains; §7.7).

Figure 8.5 — gRPC call mapped onto an HTTP/2 connection.



Reading the diagram. Application code calls a generated stub as if it were local. The stub serializes the request to Protobuf and sends it as HEADERS and DATA frames on a new stream of a single shared HTTP/2 connection; three concurrent calls occupy streams 1, 3 and 5 (client-initiated HTTP/2 streams use odd numbers). The server runtime reassembles each stream, deserializes the message, invokes the implementation and streams the response back with a trailing `grpc-status`. Unary calls are synchronous

request/response; stream 3 stays open while the server pushes events. Storage boundary: the database behind the implementation. Failure points: a single connection pins all of a client's traffic to one server, which defeats layer-4 load balancers; use layer-7 (HTTP/2-aware) proxies or client-side load balancing (§19.10). Scaling: add servers behind an L7 balancer that balances per stream, not per connection.

8.8.3 Streaming modes

Table 8.10 — The four gRPC call types.

Mode	Shape	Example use
Unary	1 request → 1 response	Fetch an order; most calls
Server streaming	1 request → stream of responses	Order status updates; large result sets in chunks; log tailing
Client streaming	Stream of requests → 1 response	Uploading telemetry or a file in chunks, then a summary
Bidirectional streaming	Two independent streams	Chat, collaborative editing, interactive speech recognition

Streams are flow-controlled by HTTP/2, so a slow receiver applies backpressure to a fast sender (§22.10) instead of buffering without bound.

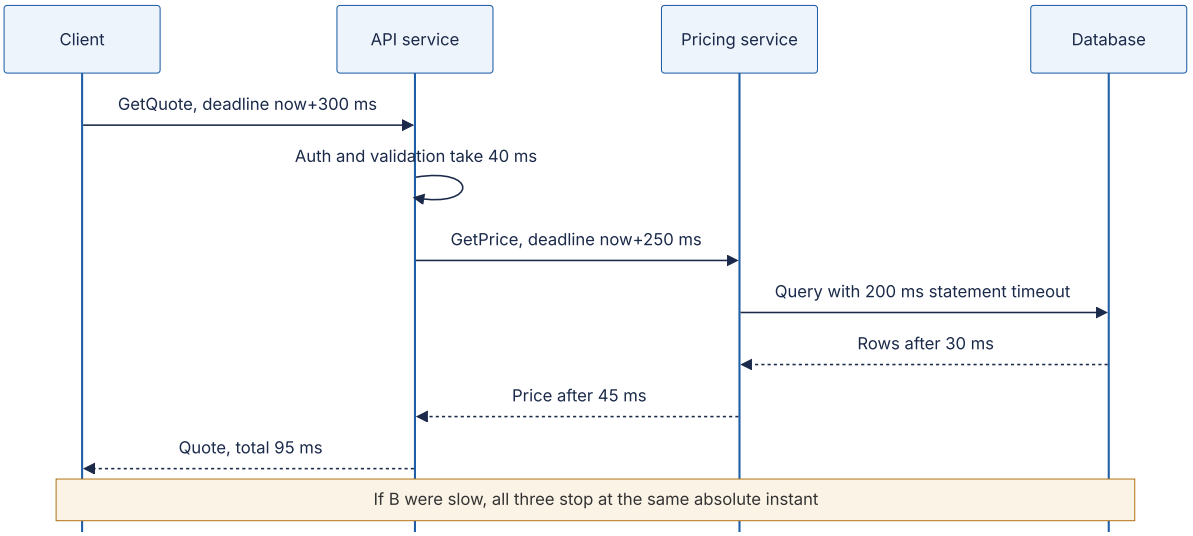
8.8.4 Deadlines and their propagation

DEFINITION

Definition — Deadline. An absolute point in time by which a client needs an RPC to complete. gRPC transmits it as a remaining timeout; when it passes, the client stops waiting with `DEADLINE_EXCEEDED` and the server can see that the call was canceled [gRPC Docs: Deadlines].

Without deadlines, a slow dependency makes callers wait indefinitely, holding threads, memory and connections until the whole call graph is exhausted (Chapter 22). gRPC's default is **no deadline**, so you must set one on every call. A deadline, unlike a per-hop timeout, should be **propagated**: if the front end has 300 ms left and has already spent 40 ms, it passes the remaining ~260 ms downstream, minus a margin for its own post-processing, so no service keeps working on an answer nobody is waiting for.

Figure 8.6 — Deadline propagation through a call chain.



Reading the diagram. The client sets an absolute deadline of 300 ms. The API service spends 40 ms, then calls the pricing service with the *remaining* budget minus a 10 ms reserve for building its own response. The pricing service in turn bounds its database query below its own remaining time. All calls are synchronous. Failure point: if any hop sets a longer timeout than its caller’s remaining budget, that hop does work whose result will be discarded. Scaling: deadlines plus cancellation free resources quickly under overload, which keeps a slow dependency from cascading.

Code example

```
        # pip install grpcio grpcio-tools
        # python -m grpc_tools.protoc -I. --python_out=. --grpc_python_out=.
orders.proto
        import grpc
        import orders_pb2
        import orders_pb2_grpc

        with grpc.insecure_channel("localhost:50051") as channel:   # use TLS creden-
tials in production
            stub = orders_pb2_grpc.OrderServiceStub(channel)

            # Unary call with a 200 ms deadline.
            try:
                order = stub.GetOrder(orders_pb2.GetOrderRequest(order_id="o-42"),
timeout=0.2)
                print(order.order_id, orders_pb2.OrderStatus.Name(order.status))
            except grpc.RpcError as err:
                if err.code() == grpc.StatusCode.DEADLINE_EXCEEDED:
                    print("gave up after 200 ms; serve a fallback")
                else:
                    raise

            # Server streaming: iterate over responses as they arrive.
            for event in stub.WatchOrderStatus(orders_pb2.GetOrderRequest(order_id="o-
42"),
                                               timeout=30):
                print(orders_pb2.OrderStatus.Name(event.status))
```

What to notice:

- `timeout=0.2` is converted by the library into the `grpc-timeout` header; the server can read the remaining time with `context.time_remaining()` and pass it on.
- Errors are typed status codes, not free-text. Retry `UNAVAILABLE` with backoff; do not retry `INVALID_ARGUMENT`; retry `DEADLINE_EXCEEDED` only if the operation is idempotent and budget remains.
- Browsers cannot speak raw gRPC because they do not expose HTTP/2 trailers and framing to JavaScript; **gRPC-Web** with a translating proxy, or a REST/JSON gateway, is used for browser clients.

Industry application

INDUSTRY EXAMPLE

Google Stubby → gRPC. gRPC's documentation describes it as the open-source successor to Stubby, the general-purpose RPC infrastructure Google used internally to connect its services, and it is now a Cloud Native Computing Foundation project [gRPC Docs]. The design goals that carried over — a compact binary IDL-based format, generated stubs in many languages, deadlines and cancellation as first-class concepts — come from operating very large internal call graphs where a slow or hung call would otherwise cascade. *Evidence: Primary* — [gRPC Docs]

8.8.5 Choosing REST, GraphQL or gRPC

Table 8.11 — REST versus GraphQL versus gRPC.

Row	REST	GraphQL	gRPC
What it is	Resource-oriented HTTP API style	Typed query language + runtime over one endpoint	RPC framework: Protobuf IDL over HTTP/2
How it works	URIs + standard methods + status codes; usually JSON	Client sends a query; resolvers assemble the response tree	Generated stubs; length-prefixed binary messages on HTTP/2 streams
Advantages	Universal tooling; HTTP caching and CDNs; easy to debug with curl	Exactly the data a screen needs in one round trip; strong typing; introspection	Compact and fast; streaming; deadlines; strict contracts and codegen
Disadvantages	Over/under-fetching; many round trips for complex screens; loose contracts unless documented	Hard to cache; N+1 risk; query-cost security; errors hidden in 200s	Not native in browsers; binary is harder to inspect; needs L7-aware load balancing
Performance	Good; JSON parsing cost; benefits from HTTP caching	Fewer client round trips; server work per request is higher and variable	Smallest payloads and lowest serialization cost of the three
Operational complexity	Low	Medium–high (cost limits, batching, schema governance)	Medium (proto management, L7 proxies, gRPC-Web for browsers)
Cost	Low; bandwidth higher than binary	Server CPU for resolution; engineering time	Low bandwidth and CPU; tooling investment
Use cases	Public APIs, CRUD services, webhooks, cacheable content	Product frontends aggregating many entities; mobile apps with diverse screens	Internal service-to-service calls; low-latency or streaming backends; polyglot microservices
Choose when	Third parties consume your API or responses are cacheable	Many client types need different shapes of a rich graph of data	You control both ends and need efficiency, streaming or strict typing

A common production pattern uses all three: gRPC between internal services, GraphQL or a BFF for first-party frontends, and REST for public and partner APIs.

8.9 Serialization: JSON, Protocol Buffers, Avro and Thrift

8.9.1 Why encoding matters

DEFINITION

Definition — Serialization (encoding). Translating an in-memory data structure into a sequence of bytes for storage or transmission; **deserialization (decoding)** is the reverse [Kleppmann 2017, ch. 4].

Objects in memory are full of pointers that mean nothing to another process. To send an order across the network you must flatten it into bytes that the receiver, possibly written in another language and deployed at a different time, can rebuild. Three questions decide the format: **How big and how fast?** (bandwidth and CPU at millions of messages per second), **Is it self-describing or schema-driven?**, and **How does it survive change?** — the last is the most important in practice, because in any system with rolling deployments, old and new code run side by side and read each other's data.

8.9.2 The formats

JSON is text, human-readable, universally supported and self-describing: field names travel with every message. Its costs are size (names repeated in every record), parsing CPU, and a weak type system: no distinction between integers and floats, no binary type (bytes must be base64-encoded, +33%), and numbers above 2^{53} lose precision in JavaScript, which is why many APIs send 64-bit IDs as strings.

Protocol Buffers (Protobuf) is Google's schema-driven binary format [Protocol Buffers Docs]. Each field is written as a **tag** followed by a value. The tag is a varint holding `(field_number << 3) | wire_type`, where the wire type tells the reader how to find the end of the value even if it does not recognize the field: 0 = VARINT, 1 = I64 (8 fixed bytes), 2 = LEN (length-delimited: strings, bytes, embedded messages, packed repeated fields), 5 = I32 (4 fixed bytes); 3 and 4 are deprecated group markers.

DEFINITION

Definition — Varint. A variable-length encoding of an unsigned integer in base 128: each byte carries 7 bits of the number, least-significant group first, and the most significant bit (MSB) of each byte is a continuation flag — 1 means "another byte follows" [Protocol Buffers Docs: Encoding].

Small numbers, which dominate real data (counts, enum values, field tags), take one byte instead of four or eight. Negative numbers in an `int32` / `int64` field always take 10 bytes, so signed fields that are often negative use `sint32` / `sint64`, which first apply **ZigZag** encoding, mapping $0, -1, 1, -2, \ldots$ to $0, 1, 2, 3, \ldots$.

FORMULA

Varint length

$$\text{bytes}(n) = \max\left(1, \left\lceil \frac{\lfloor \log_2 n \rfloor + 1}{7} \right\rceil\right)$$

Symbol	Meaning	Units
n	Non-negative integer being encoded	—
$\lfloor \log_2 n \rfloor + 1$	Number of significant bits in n (for $n \geq 1$)	bits
7	Payload bits per varint byte	bits/byte

WORKED EXAMPLE

Worked example — Encoding a record by hand. The record (the example used in [Kleppmann 2017, ch. 4]) is `user_name = "Martin"` (field 1, string), `favorite_number = 1337` (field 2, int64), `interests = ["daydreaming", "hacking"]` (field 3, repeated string).

1. Field 1: tag $(1 \ll 3) \mid 2 = 10 =$ `0a`; length $6 =$ `06`; then the 6 UTF-8 bytes `4d 61 72 74 69 6e`. Subtotal 8 bytes.
2. Field 2: tag $(2 \ll 3) \mid 0 = 16 =$ `10`. Value 1337 = binary `101 0011 1001` (11 bits → 2 bytes). Low 7 bits `0111001` = 0x39, set the continuation bit → `b9`; remaining bits `1010` = `0a`. Subtotal 3 bytes: `10 b9 0a`.
3. Field 3, twice: tag $(3 \ll 3) \mid 2 = 26 =$ `1a`, length `0b`, 11 bytes of “daydreaming” (13 bytes); then `1a 07` + 7 bytes of “hacking” (9 bytes).
4. Total: $8 + 3 + 13 + 9 = 33$ bytes. The same record as compact JSON, `{"userName":"Martin","favoriteNumber":1337,"interests":["daydreaming","hacking"]}`, is 81 bytes.

Interpretation. Protobuf is 2.5× smaller here because field names are replaced by one-byte tags and the number by two bytes instead of four ASCII digits.
Engineering implication: field numbers 1–15 fit in a one-byte tag; reserve them for the most frequent fields.

```
        def encode_varint(n: int) -> bytes:
            """Protocol Buffers base-128 varint for a non-negative integer."""
            out = bytearray()
            while True:
                byte = n & 0x7F               # take the low 7 bits
                n >>= 7
                if n:
                    out.append(byte | 0x80)   # more bytes follow: set the MSB
                else:
                    out.append(byte)          # last byte: MSB clear
                    return bytes(out)

        def encode_tag(field_number: int, wire_type: int) -> bytes:
            return encode_varint((field_number << 3) | wire_type)

        def encode_string(field_number: int, s: str) -> bytes:
            data = s.encode("utf-8")
            return encode_tag(field_number, 2) + encode_varint(len(data)) + data

        msg = (encode_string(1, "Martin")
               + encode_tag(2, 0) + encode_varint(1337)
               + encode_string(3, "daydreaming")
               + encode_string(3, "hacking"))
        print(msg.hex(" "), len(msg), "bytes")
        # 0a 06 4d 61 72 74 69 6e 10 b9 0a 1a 0b 64 61 79 64 72 65 61 6d 69 6e 67 1a 07
68 61 63 6b 69 6e 67 33 bytes
```

What to notice: this output is byte-for-byte identical to what the official Protobuf library produces for the equivalent `.proto` message; and because every field carries its own tag and wire type, a reader that does not know field 3 can still skip exactly the right number of bytes.

Apache Avro takes the opposite approach: the binary data contains **no field tags or names at all**, just values concatenated in schema order (integers as ZigZag varints, strings as length + bytes). The same record encodes to 32 bytes [Kleppmann 2017, ch. 4]. The reader therefore needs the exact **writer's schema** to parse the bytes; it then **resolves** that schema against its own **reader's schema** by field *name*, filling defaults for fields the writer lacked and ignoring fields the reader does not know [Apache Avro Spec]. The writer's schema travels in the file header (Avro object container files), or a short schema ID is prefixed to each message and looked up in a **schema registry**, the usual arrangement with Kafka (Chapter 31). Because Avro has no hand-assigned tags, schemas can be generated from database tables, which suits data pipelines (Chapter 61).

Apache Thrift, created at Facebook [Slee et al. 2007], is an IDL plus RPC framework like gRPC. Fields carry numeric tags as in Protobuf; it offers several encodings, including

BinaryProtocol (fixed-width numbers; 59 bytes for the example record) and CompactProtocol (varints and packed field headers; 34 bytes) [Kleppmann 2017, ch. 4].

Table 8.12 — Serialization formats compared (sizes for the 3-field example record).

Format	Schema	Field identity on wire	Example size	Human-readable	Typical use
JSON	Optional (JSON Schema)	Names, every record	81 B	Yes	Public APIs, browsers, config
Thrift Binary	Required (IDL)	Numeric tags	59 B	No	Thrift RPC
Thrift Compact	Required (IDL)	Numeric tags, packed	34 B	No	Thrift RPC, storage
Protobuf	Required (`.proto`)	Numeric tags	33 B	No	gRPC, internal APIs, storage
Avro	Required, writer's schema needed to read	None (schema order)	32 B	No	Kafka with schema registry, data lakes

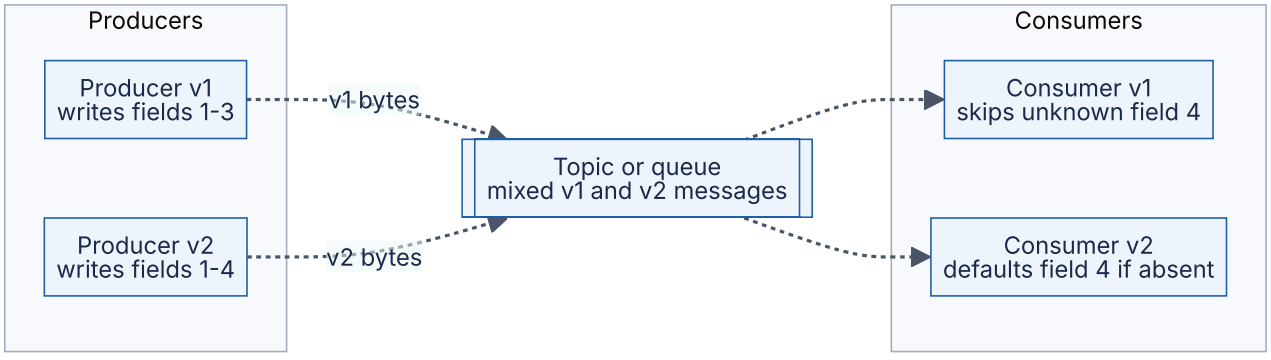
8.9.3 Schema evolution and compatibility

DEFINITION

Definition — Backward and forward compatibility. Backward compatibility: newer code can read data written by older code. **Forward compatibility**: older code can read data written by newer code [Kleppmann 2017, ch. 4].

During a rolling deployment both hold at once: new servers read messages from old servers (backward) and old servers, not yet upgraded, read messages from new ones (forward). Mobile apps and long-lived data on disk or in Kafka stretch the window from minutes to years.

Figure 8.7 — Mixed versions during a rolling deployment.



Reading the diagram. Two producer versions write to the same queue during a deployment, so the queue (the storage boundary) holds both message versions; arrows are dotted because the path is asynchronous. The old consumer must ignore field 4, which it has never heard of (forward compatibility); the new consumer must cope with messages lacking field 4 (backward compatibility). Failure point: if either assumption breaks, a deployment that looked fine in testing fails only when versions mix. Scaling: the same rules let independent teams deploy producers and consumers on separate schedules.

Table 8.13 — Schema-evolution rules by format.

Change	Protobuf (proto3)	Avro	Thrift	JSON API
Add a field	Safe: old readers skip unknown tags; new readers see the default	Safe only if the new field has a default	Safe if `optional`	Safe if clients ignore unknown fields
Remove a field	Safe; mark its number and name `reserved`	Safe only if the field had a default	Safe for `optional`; never reuse the tag	Breaking for clients that read it
Rename a field	Wire-safe (names not encoded); breaks the JSON mapping and code	Use `aliases` in the reader's schema	Wire-safe	Breaking
Change a field number / tag	Breaking	n/a	Breaking	n/a
Change type	Only between compatible types (e.g. `int32` ↔ `int64`, with truncation risk)	Only defined promotions (`int` → `long` → `float` → `double`)	Limited	Usually breaking
Add a required field	Not possible in proto3 (no `required`)	Breaking unless defaulted	Breaking	Breaking for requests

RECOMMENDATION

Practical rules. Only add optional fields with sensible defaults. Never reuse a deleted field number or name. Never change a field's meaning while keeping its name. Treat `required` as permanent. Run an automated compatibility check (schema-registry compatibility modes, `buf breaking` for Protobuf, OpenAPI diff tools) in CI, so incompatible changes fail the build instead of production.

COMMON MISTAKE

“Binary formats are always better.” For a public API consumed by browsers and third parties, JSON’s readability, tooling and zero-setup debugging usually outweigh a 2–3× size difference, especially after HTTP compression (gzip/Brotli) shrinks repeated field names. Binary formats win for high-volume internal traffic and stored data.

8.10 Cookies and sessions

8.10.1 Cookies

DEFINITION

Definition — HTTP cookie. A small name–value pair that a server asks the browser to store, via the `Set-Cookie` response header, and that the browser automatically returns in the `Cookie` request header on later requests to matching URLs [RFC 6265].

HTTP is stateless: each request arrives without memory of the previous one. A cookie is the coat-check ticket: the server hands you a numbered ticket once, you show it every time you come back, and the cloakroom (the server) knows which coat is yours. Cookies power sessions, preferences and tracking. Because browsers attach them **automatically**, including to requests triggered by other websites, their attributes are security-critical.

```
Set-Cookie: __Host-sid=8f2c1e9a7b; Path=/; Secure; HttpOnly; SameSite=Lax; Max-Age=3600
```

Table 8.14 — Cookie attributes.

Attribute	Effect	Why it matters
`Expires` / `Max-Age`	When the browser deletes the cookie; absent → deleted when the browser session ends	Bounds the lifetime of a stolen cookie
`Domain`	Send to this domain *and its subdomains*; absent → exact host only	Setting `Domain=example.com` exposes the cookie to every subdomain
`Path`	Send only for URLs under this path	Organization, not a security boundary
`Secure`	Send only over HTTPS	Prevents leakage over plaintext networks
`HttpOnly`	Not readable by JavaScript (`document.cookie`)	Limits theft via cross-site scripting (XSS)
`SameSite=Strict`	Never sent on cross-site requests	Strongest CSRF protection; breaks inbound links that need login
`SameSite=Lax`	Sent on top-level cross-site navigations using safe methods (`GET`), not on cross-site `POST`, iframes or fetches	Good default for session cookies
`SameSite=None`	Sent on all requests; must be combined with `Secure`	Needed only for genuine cross-site use (embedded widgets, some SSO)
`__Host-` name prefix	Browser enforces `Secure`, `Path=/` and no `Domain`	Stops subdomains from overwriting the cookie

Cross-site request forgery (CSRF) is the attack that `SameSite` targets: a malicious page makes your browser submit `POST https://bank.example/transfer`, and the browser helpfully attaches your bank session cookie. `SameSite=Lax` or `Strict` stops the cookie being sent; anti-CSRF tokens (a per-session random value the server embeds in forms and checks on submission) are the traditional complement. `SameSite` was specified after RFC 6265 and is defined in its revision draft (“RFC 6265bis”). As of 2026, Chromium-based browsers treat cookies without a `SameSite` attribute as `Lax`, but not every browser does, so always set it explicitly.

RFC 6265 requires browsers to support at least 4,096 bytes per cookie and 50 cookies per domain [RFC 6265 §6.1]. Every cookie is sent on every matching request, so 4 KB of cookies on a page with 80 asset requests to the same domain uploads 320 KB of headers. Serve static assets from a separate cookie-less domain or CDN.

8.10.2 Sessions

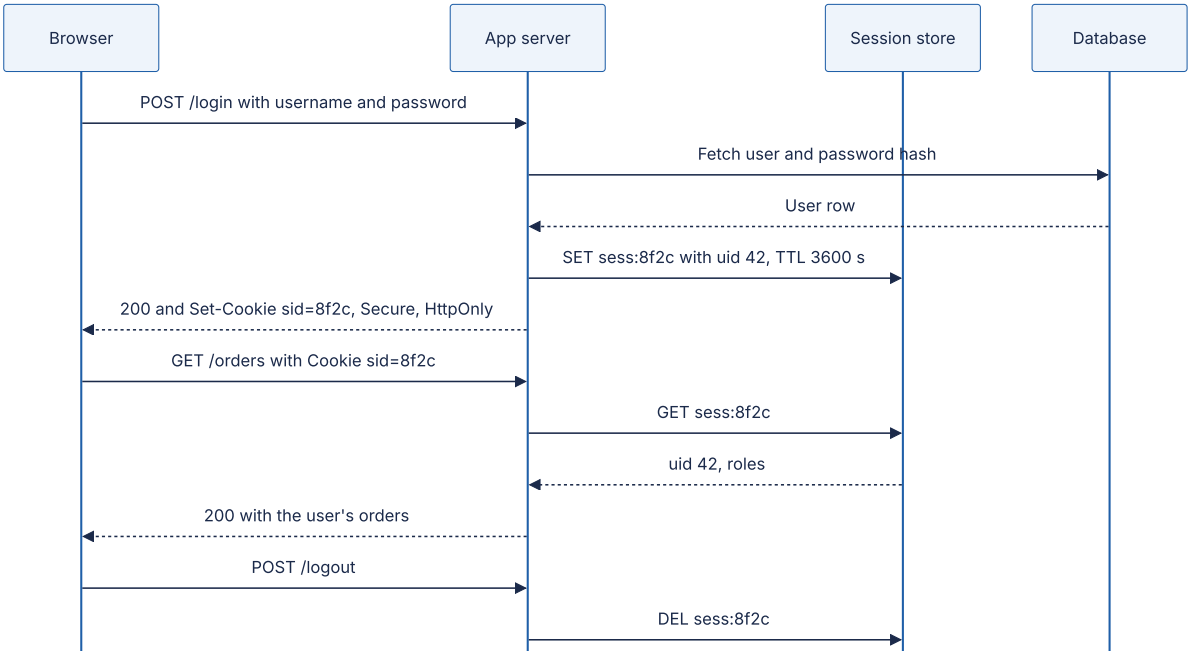
DEFINITION

Definition — Session. Server-recognized state that links a series of requests to one authenticated user (or anonymous visitor) over time, typically identified by a cookie.

There are two ways to store it.

Server-side session store. The cookie holds only a long random **session ID** (at least 128 bits of entropy). Session data — user ID, roles, CSRF token, cart — lives in a shared store such as Redis, keyed by that ID. Every request costs one lookup; logging out or revoking a session is a single `DELETE`.

Figure 8.8 — Server-side session lookup.



Reading the diagram. Login verifies the password against the database, creates a session record in the store with a TTL, and sends only the opaque ID to the browser. Every later request costs one synchronous session-store read (about 0.5 ms in the same datacenter). Logout deletes the record, so a copied cookie stops working immediately. Storage boundaries: the user database and the session store. Failure point: the session store is on the critical path of every authenticated request, so it must be replicated (Chapter 20); if it fails, everyone is logged out. Scaling: 10 million active sessions × ~500 bytes ≈ 5 GB, which fits in a single replicated Redis primary; partition by session ID beyond that.

Signed cookie (client-side session). The session data itself is in the cookie, with a **MAC** (message authentication code) computed with a server-side secret key. The server needs no store: it recomputes the MAC and rejects any cookie whose contents were al-

tered. The data is *not* encrypted — the user can read it — only protected against tampering.

```
        import base64, hashlib, hmac, json, time

        SECRET_KEY = b"load-me-from-a-secrets-manager-32+bytes"   # never hard-code in
production

        def _b64(data: bytes) -> str:
            return base64.urlsafe_b64encode(data).rstrip(b"=").decode()

        def _unb64(text: str) -> bytes:
            return base64.urlsafe_b64decode(text + "=" * (-len(text) % 4))

        def sign_session(data: dict, ttl_s: int = 3600) -> str:
            body = _b64(json.dumps({**data, "exp": int(time.time()) + ttl_s}).encode())
            mac = hmac.new(SECRET_KEY, body.encode(), hashlib.sha256).digest()
            return f"{body}.{_b64(mac)}"

        def verify_session(cookie: str) -> dict | None:
            try:
                body, mac = cookie.split(".")
            except ValueError:
                return None
            expected = hmac.new(SECRET_KEY, body.encode(), hashlib.sha256).digest()
            if not hmac.compare_digest(expected, _unb64(mac)):    # constant-time com-
pare
                return None
            data = json.loads(_unb64(body))
            return data if data["exp"] >= time.time() else None
```

What to notice: `hmac.compare_digest` compares in constant time, so an attacker cannot learn the correct MAC byte by byte from response timing; the expiry is *inside* the signed body, so it cannot be extended by the client; and there is no way to revoke one cookie before `exp` except rotating `SECRET_KEY`, which logs out everyone. Web frameworks implement exactly this; Flask's default session is a signed cookie, configured as follows:

```
        from flask import Flask
        import os

        app = Flask(__name__)
        app.config.update(
            SECRET_KEY=os.environ["SECRET_KEY"],
            SESSION_COOKIE_SECURE=True,      # only sent over HTTPS
            SESSION_COOKIE_HTTPONLY=True,    # invisible to JavaScript
            SESSION_COOKIE_SAMESITE="Lax",   # not sent on cross-site POSTs
            PERMANENT_SESSION_LIFETIME=3600, # seconds
        )
        # After login, Flask emits for example:
        # Set-Cookie: session=eyJ1aWQiOiJhZGEifQ.auQy5w.2G2C9...; Expires=...; Secure;
HttpOnly; Path=/; SameSite=Lax
```

Table 8.15 — Server-side sessions versus signed cookies.

Aspect	Server-side session store	Signed cookie
Cookie contents	Random ID only	Data + MAC (readable, tamper-evident)
Per-request cost	One store lookup (~0.5–1 ms)	One HMAC computation (microseconds)
Revocation / logout everywhere	Immediate (`DEL`)	Not possible before expiry without key rotation or a deny-list
Size limit	Unlimited server-side	~4 KB, sent on every request
Infrastructure	Replicated store on the critical path	None beyond key management
Choose when	You need instant revocation, large session state, or admin “log out this device”	Small, short-lived state; minimal infrastructure

COMMON MISTAKE

Keeping the same session ID across login. If an attacker can plant a known session ID in a victim’s browser before login and the server keeps it afterwards, the attacker shares the authenticated session (**session fixation**). Always issue a fresh session ID (or clear the signed session) at login and at privilege changes.

8.11 Authentication

DEFINITION

Definition — Authentication (AuthN). Verifying *who* a client is. **Authorization (AuthZ)** is deciding *what* that verified identity may do (§8.12). AuthN failures return `401` ; AuthZ failures return `403` .

At a hotel, the front desk checks your passport (authentication) and gives you a key card; the card then opens only your room and the gym (authorization). Keep the two separate in code too: authentication middleware turns credentials into an identity once per request; authorization checks run in every handler that touches a resource.

Authentication factors fall into three classes: something you **know** (password, PIN), something you **have** (phone, hardware security key), something you **are** (fingerprint, face). **Multi-factor authentication (MFA)** requires factors from at least two classes, so a phished or leaked password alone is not enough.

Passwords. Never store passwords, or fast hashes of them. Store the output of a deliberately slow, salted **password-hashing function** (Argon2id, scrypt, bcrypt or PBKDF2), tuned so one guess costs tens to hundreds of milliseconds; §10.6 covers parameters and the arithmetic of offline cracking. Compare in constant time, rate-limit login attempts per account and per IP, and check new passwords against lists of breached passwords, as NIST's guidance recommends [NIST SP 800-63B-4].

```
        import hashlib, hmac, os

        def hash_password(password: str) -> str:
            salt = os.urandom(16)                                    # unique per user
            dk = hashlib.scrypt(password.encode(), salt=salt, n=2**17, r=8, p=1,
                                maxmem=256 * 1024 * 1024)            # ~128 MiB of mem-
ory per guess
            return f"scrypt$131072$8$1${salt.hex()}${dk.hex()}"

        def verify_password(password: str, stored: str) -> bool:
            _, n, r, p, salt_hex, dk_hex = stored.split("$")
            dk = hashlib.scrypt(password.encode(), salt=bytes.fromhex(salt_hex),
                                n=int(n), r=int(r), p=int(p), maxmem=256 * 1024 * 1024)
            return hmac.compare_digest(dk, bytes.fromhex(dk_hex))
```

What to notice: the parameters ($N = 2^{17}$, $r = 8$, $p = 1$, the OWASP minimum for scrypt listed in Table 10.8) are stored with the hash so they can be raised later; on a typical server core this takes a few hundred milliseconds per call, which is negligible for one login and crippling for an attacker trying billions of guesses.

Second factors, from weakest to strongest:

- **SMS or email one-time codes.** Better than nothing; vulnerable to SIM-swap, interception and phishing.
- **TOTP** (time-based one-time passwords, RFC 6238): an authenticator app and the server share a secret and each compute a 6-digit code from the current 30-second time window. Not phishing-resistant: a fake site can relay the code within its window.
- **WebAuthn / passkeys** (W3C WebAuthn with FIDO2): the device holds a private key per site and signs a server challenge; the browser binds the signature to the real

site's origin, so a look-alike domain cannot obtain a usable response. This is **phishing-resistant** and can replace passwords entirely.

8.11.1 Sessions versus tokens

After login, the client needs something to present on each request. There are two families:

- **Session (reference) credentials:** an opaque random ID that means nothing by itself; the server looks it up (§8.10.2).
- **Self-contained (value) tokens:** a signed token, typically a JWT (§8.13), carrying the identity and claims; any server with the key can verify it without a lookup.

Table 8.16 — Session IDs versus self-contained tokens.

Aspect	Opaque session ID	Self-contained token (JWT)
Validation	Lookup in a shared store	Signature check, local, no network call
Revocation	Immediate	Hard: valid until `exp` (§8.13.4)
Size on each request	~32–64 bytes	Hundreds of bytes to over 1 KB
Works across services and organizations	Only those that can reach the store	Any party with the verification key
Typical transport	`Cookie` header (browsers)	`Authorization: Bearer` header (APIs, mobile, service-to-service)
Choose when	First-party web apps, especially with server rendering	Distributed APIs, third-party access (OAuth), short-lived service credentials

A common hybrid: the browser holds an opaque session cookie with the BFF or web tier; behind it, services exchange short-lived JWT access tokens.

8.12 Authorization: RBAC, ABAC and ReBAC

8.12.1 Three models

DEFINITION

Definition — Access-control model. A rule system that answers "may subject S perform action A on resource R (in context C)?" The three models in common use differ in what the rules are written in terms of: **roles** (RBAC), **attributes** (ABAC) or **relationships** (ReBAC).

Role-based access control (RBAC). Permissions attach to roles (`viewer`, `editor`, `admin`); users are assigned roles. It is what most company org charts look like: anyone with the "nurse" badge can open the medicine cabinet. RBAC is simple to audit ("who has admin?") but coarse: "editor" usually means editor of *everything*. Scoping roles per tenant or per project (`editor@project-7`) helps until the number of role assignments explodes.

Attribute-based access control (ABAC). A policy is a predicate over attributes of the subject, the resource, the action and the environment: "a user may read a document if their department equals the document's department, their clearance ≥ its classification, and it is business hours". ABAC is expressive and handles context (time, location, device posture), but policies become hard to reason about and audit, and every check needs all the attributes at hand. Policy engines such as Open Policy Agent evaluate such rules outside application code.

```
        ROLE_PERMISSIONS = {
            "viewer": {"doc:read"},
            "editor": {"doc:read", "doc:write"},
            "admin":  {"doc:read", "doc:write", "doc:delete", "user:manage"},
        }

        def rbac_allows(user_roles: set[str], permission: str) -> bool:
            return any(permission in ROLE_PERMISSIONS.get(r, set()) for r in user_roles)

        def abac_allows(sub: dict, action: str, res: dict, ctx: dict) -> bool:
            if action == "read":
                return (sub["department"] == res["department"]
                        and sub["clearance"] >= res["classification"]
                        and 8 <= ctx["hour_utc"] < 20)          # business hours only
            if action == "write":
                return sub["id"] == res["owner_id"]
            return False
```

Relationship-based access control (ReBAC). Permissions follow from a graph of relationships: Alice can view this document because she is a member of a group that is a viewer of the folder that contains it. This is how sharing works in collaboration products ("anyone in Engineering can comment"), and neither roles nor flat attributes express it naturally.

8.12.2 Google Zanzibar

INDUSTRY EXAMPLE

Zanzibar: Google's consistent, global authorization system. Google built one authorization service to serve the access-control checks of many products (the paper lists Calendar, Cloud, Drive, Maps, Photos and YouTube among its clients). It stores permissions as **relation tuples** of the form `object#relation@user`, where the user may itself be a set of users such as `group:eng#member`. A per-namespace configuration of **userset rewrite rules** derives relations from others — for example, every `editor` is also a `viewer`, and a document's viewers include the viewers of its parent folder. A **check** is a graph search over tuples and rewrites. The paper reports trillions of stored ACL tuples (more than two trillion), millions of authorization checks per second, 95th-percentile latency under 10 ms and availability above 99.999% over three years of production. Data is stored in Spanner; aggressive caching, request deduplication and a specialized index (Leopard) for deeply nested groups keep latency low. To avoid the **"new enemy" problem** — checking an old ACL against new content, for example after removing a user and then adding sensitive content — clients store an opaque consistency token, the **zookie**, with content updates, and later checks are evaluated at a snapshot at least as fresh as that zookie [Pang et al. 2019]. Open-source systems inspired by the paper, such as OpenFGA and SpiceDB, exist as of 2026. *Evidence: Primary* — [Pang et al. 2019]

A toy check function shows the core idea of tuples plus rewrite rules:

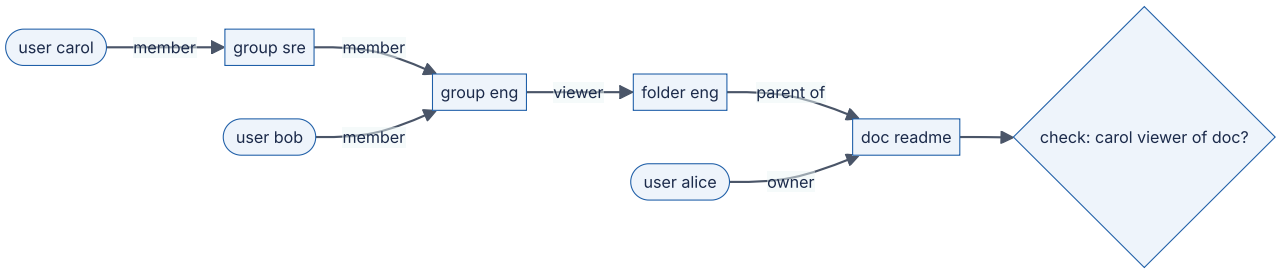
```
        # Relation tuples: (object, relation, subject). A subject is a user or a userset
"obj#rel".
        TUPLES = {
            ("doc:readme", "owner",  "user:alice"),
            ("doc:readme", "parent", "folder:eng"),          # doc lives in a folder
            ("folder:eng", "viewer", "group:eng#member"),    # eng members can view the
folder
            ("group:eng",  "member", "user:bob"),
            ("group:eng",  "member", "group:sre#member"),    # nested group
            ("group:sre",  "member", "user:carol"),
        }
        # Rewrite rules: an editor is an owner or editor; a viewer is an editor,
        # or a viewer of the parent folder.
        REWRITES = {"editor": ["owner"], "viewer": ["editor", ("parent", "viewer")]}

        def check(obj: str, relation: str, user: str, depth: int = 0) -> bool:
            if depth > 25:                                    # guard against cycles
                return False
            for (o, r, s) in TUPLES:
                if o == obj and r == relation:
                    if s == user:                             # direct tuple
                        return True
                    if "#" in s and check(*s.split("#"), user, depth + 1):   # userset
                        return True
            for rule in REWRITES.get(relation, []):
                if isinstance(rule, str):                     # same object, implied re-
lation
                    if check(obj, rule, user, depth + 1):
                        return True
                else:                                         # follow a pointer, e.g.
parent
                    via, target_rel = rule
                    if any(o == obj and r == via and check(s, target_rel, user, depth +
1)
                           for (o, r, s) in TUPLES):
                        return True
            return False

        print(check("doc:readme", "viewer", "user:alice"))   # True: owner -> editor ->
viewer
        print(check("doc:readme", "viewer", "user:carol"))   # True: sre in eng; eng
views folder
        print(check("doc:readme", "editor", "user:bob"))     # False: bob can only view
```

What to notice: the answer for Carol required walking five edges across three objects, which is why a real system needs indexing, caching and a depth limit; and sharing a folder with a group is one tuple write, not millions of per-document ACL updates.

Figure 8.9 — Relationship graph for a Zanzibar-style check.



Reading the diagram. Users (stadium shapes) are linked by `member` edges to groups, groups to a folder by a `viewer` edge, and the folder to the document by a `parent` edge. Answering "is Carol a viewer of the document?" is a search from the document back to Carol: viewer of doc ⇐ viewer of parent folder ⇐ member of group eng ⇐ member of group sre ⇐ Carol. All edges are stored tuples in one logical database (the storage boundary). Failure points: very deep or wide group nesting makes checks slow, and stale caches can grant access that was just revoked (hence zookies). Scaling: partition tuples by object, cache sub-results, and precompute group membership closure for hot nested groups.

Table 8.17 — RBAC, ABAC and ReBAC compared.

Aspect	RBAC	ABAC	ReBAC
Rules written in terms of	Roles	Attributes of subject, resource, environment	Relationships between objects and subjects
Example	"Editors can publish"	"Same department and business hours"	"Viewers of the parent folder can view"
Strength	Simple, auditable	Context-aware, fine-grained	Natural sharing and hierarchy; per-object
Weakness	Coarse; role explosion	Hard to audit; needs attributes at check time	Needs a graph store; check latency
Choose when	Internal tools, admin consoles, B2B tenants	Regulatory or contextual rules	Collaboration and sharing products

Real systems combine them: ReBAC for per-object sharing, RBAC for administrative roles, ABAC conditions (IP range, MFA freshness) on top.

COMMON MISTAKE

Checking authorization only in the frontend, or only on the list page. Hiding a button does not stop a direct API call, and checking permission when listing orders does not protect `GET /orders/43`. Every handler that touches a resource must check it; **broken object-level authorization** — returning object 43 because the caller asked for it — is one of the most common API vulnerabilities (§10.7).

8.13 JSON Web Tokens (JWT)

8.13.1 Structure

DEFINITION

Definition — JSON Web Token (JWT). A compact, URL-safe string representing a set of **claims** (statements about a subject) as a JSON object, digitally signed (JWS) or encrypted (JWE) so its integrity can be verified [RFC 7519]. This section covers the signed form, which is by far the most common.

A signed JWT is like a festival wristband: the organizer prints your ticket type and the dates on it and seals it with a tamper-evident clasp. Any steward can check it at any gate without phoning the box office. The flip side: if you are banned mid-festival, every steward will still honor the wristband until it expires.

A JWT has three base64url-encoded parts separated by dots: `header.payload.signature`.

```
{"alg": "RS256", "typ": "JWT", "kid": "2026-10-key-1"}
```

```
{
  "iss": "https://auth.example.com",
  "sub": "user-123",
  "aud": "https://api.example.com",
  "iat": 1793340000,
  "nbf": 1793340000,
  "exp": 1793340900,
  "jti": "7d1e4c1a-3b9e-4f0a-9b8e-2f6c0f1e5a77",
  "scope": "articles:read articles:write"
}
```

The registered claims are **`iss`** (issuer), **`sub`** (subject, the user or client), **`aud`** (audience: which API the token is for), **`exp`** (expiry, seconds since the Unix epoch), **`nbf`** (not before), **`iat`** (issued at) and **`jti`** (unique token ID) [RFC 7519 §4.1]. The **signature** is computed over `base64url(header) + "." + base64url(payload)`.

WARNING / TRADE-OFF

A JWT is signed, not encrypted. Anyone holding the token can base64-decode and read every claim. Never put secrets or sensitive personal data in a JWT payload.

8.13.2 Signing: HS256 versus RS256

Table 8.18 — HS256 versus RS256.

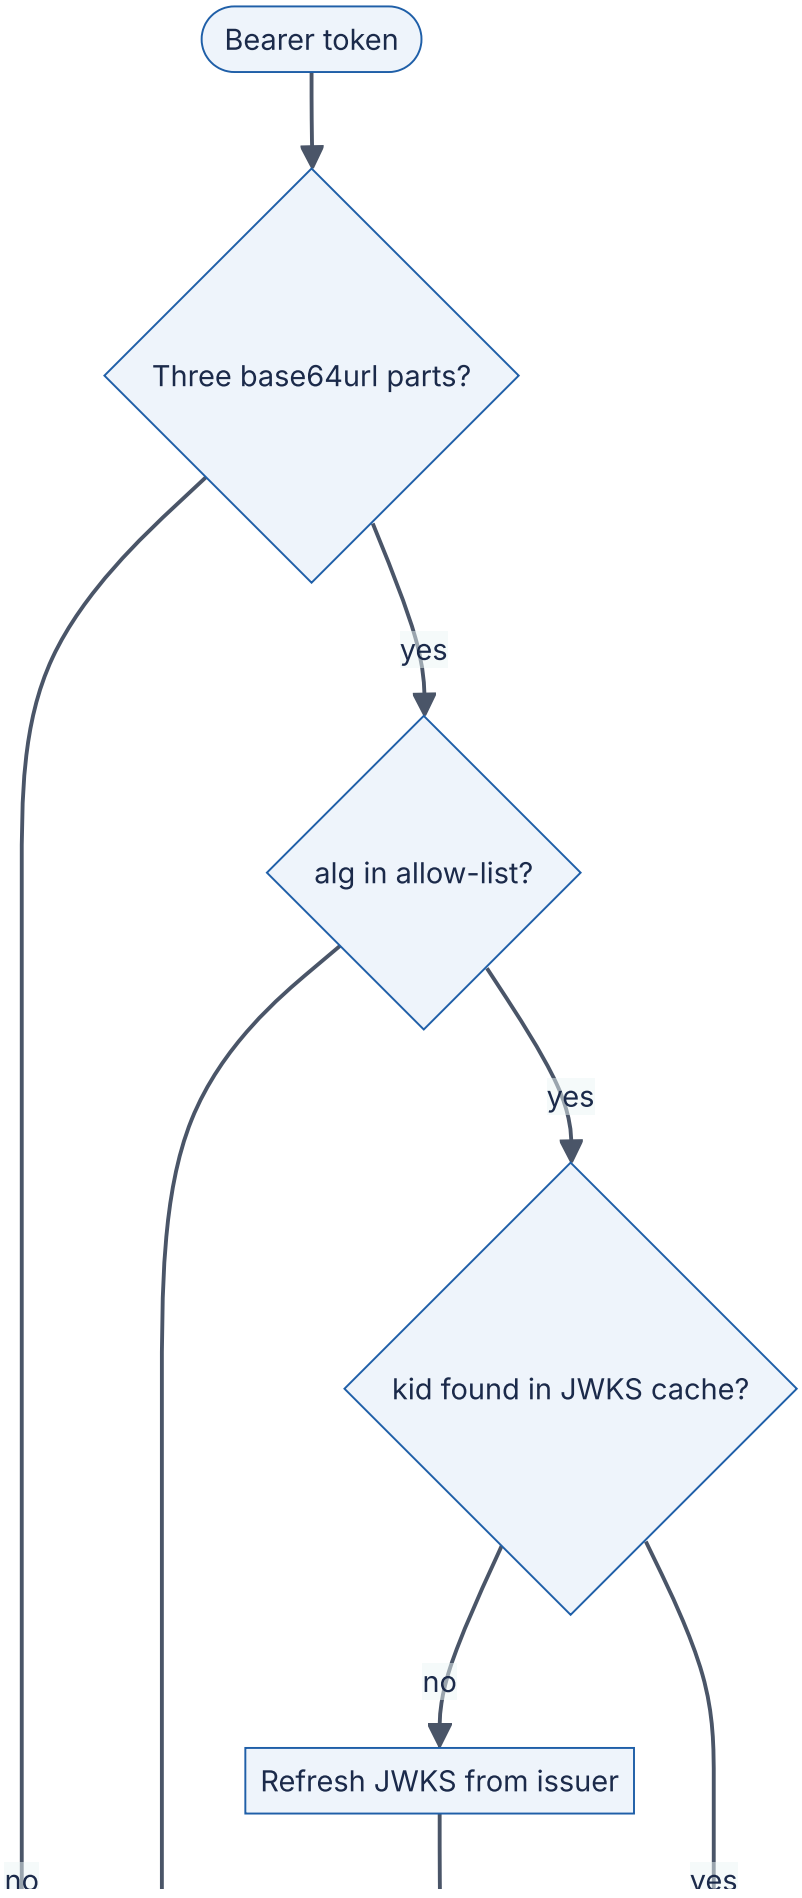
Aspect	HS256 (HMAC with SHA-256)	RS256 (RSA PKCS#1 v1.5 signature with SHA-256)
Key type	One shared secret	Private key signs; public key verifies
Who can create tokens	Anyone who can verify them	Only the private-key holder
Signature size	32 bytes (43 base64url chars)	256 bytes with a 2048-bit key (342 chars)
Speed	Very fast	Signing slower; verification fast
Key distribution	Secret must reach every verifier	Public keys published at a JWKS endpoint; rotated by `kid`
Choose when	One service issues and verifies its own tokens	An identity provider issues tokens many services verify

Elliptic-curve signatures (ES256, EdDSA) offer the asymmetric property of RS256 with much smaller keys and signatures; check that your libraries and partners support them.

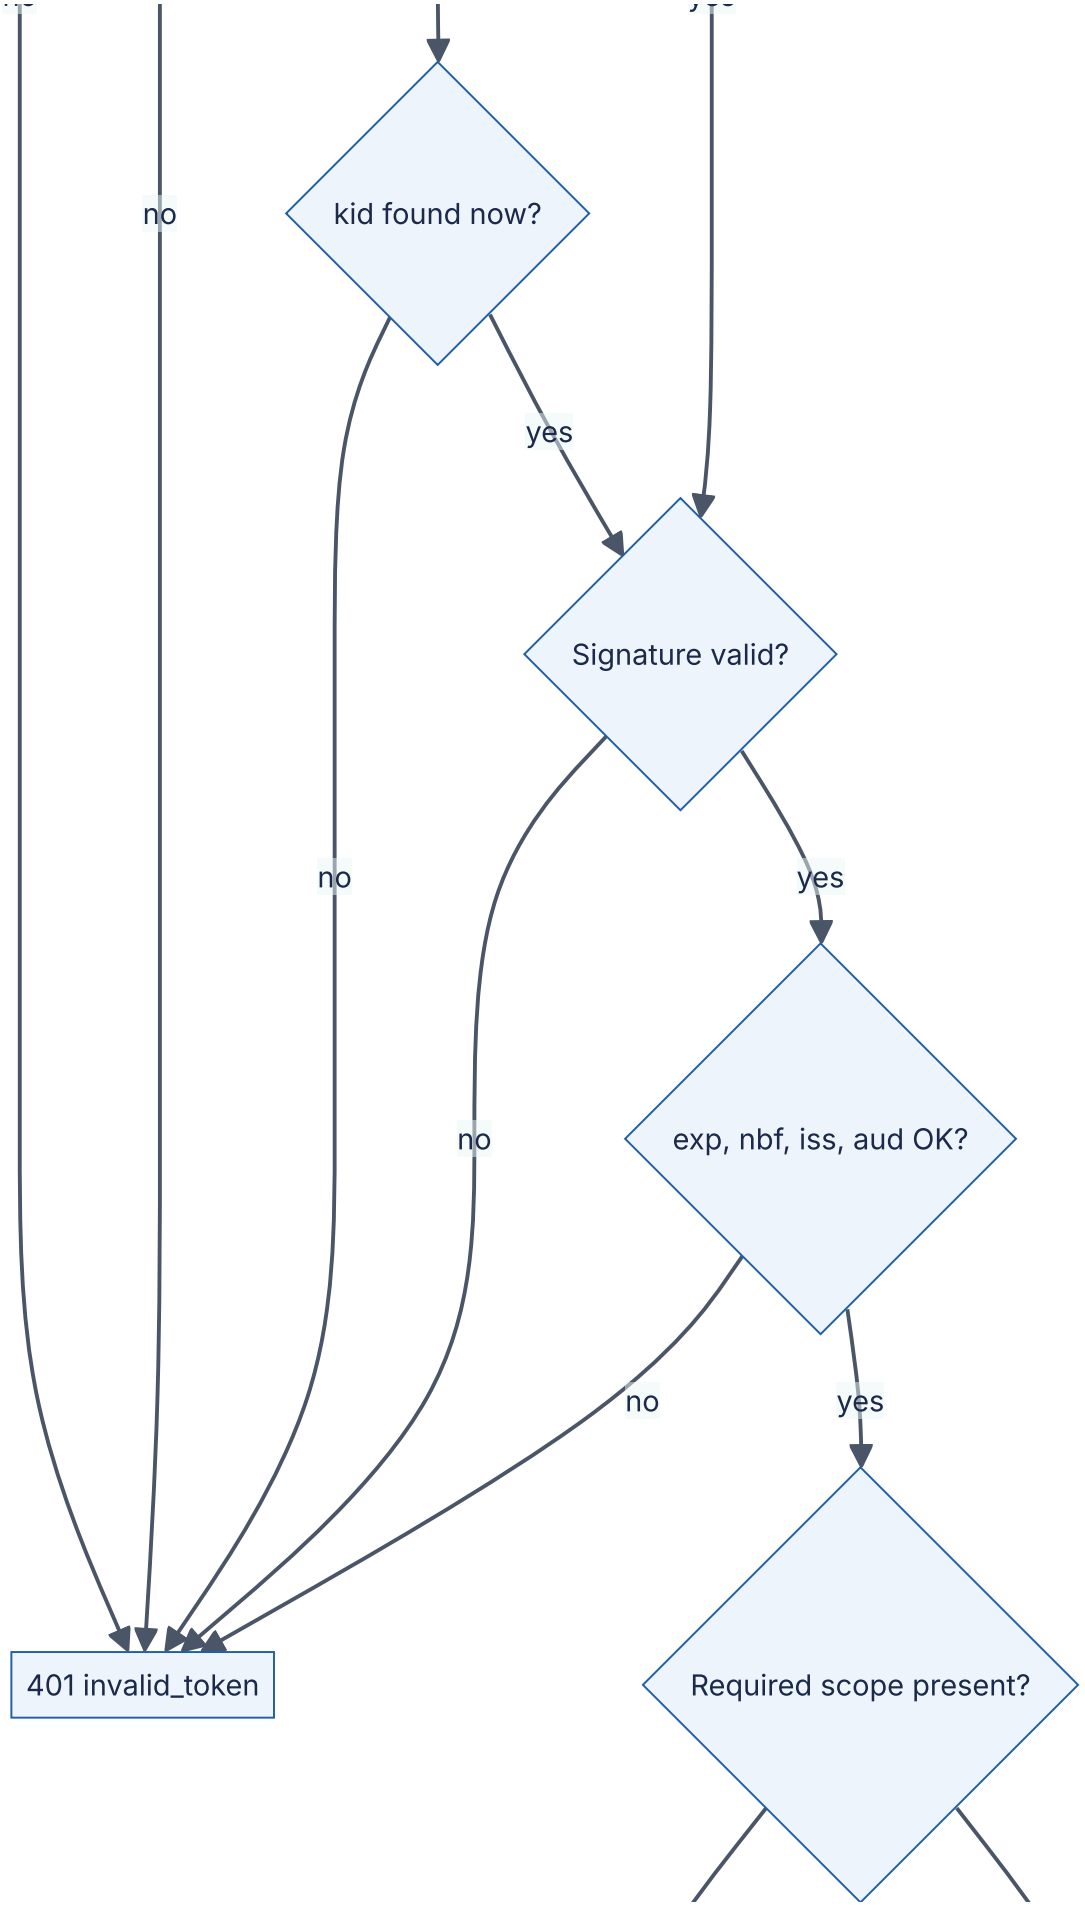
8.13.3 Validation

Validation must check, in order: the token is well-formed; the `alg` is one you **expect** (taken from configuration, never from the token's header); the signature verifies with the right key (selected by `kid` from a trusted JWKS); `exp` is in the future and `nbf` is in the past, with a small clock-skew leeway; `iss` is your trusted issuer; `aud` contains *this* API; and only then do you read scopes and claims.

Figure 8.10 — JWT validation pipeline.



Bearer token
Three base64url parts?
yes
alg in allow-list?
yes
kid found in JWKS cache?
no
Refresh JWKS from issuer
no
yes



no
kid found now?
yes
Signature valid?
no
yes
no
exp, nbf, iss, aud OK?
no
yes
401 invalid_token
Required scope present?

Reading the diagram. A bearer token enters at the top and passes a series of local checks; only the JWKS refresh involves a network call (to the issuer's key endpoint), and it happens only when an unknown `kid` appears — typically just after the issuer rotates keys. Failures before the scope check produce `401` with `WWW-Authenticate: Bearer error="invalid_token"`; a valid token lacking the scope produces `403 insufficient_scope` [RFC 6750 §3.1]. Failure points: an attacker sending random `kid` values can force repeated JWKS fetches, so rate-limit refreshes. Scaling: validation is CPU-only and stateless, which is the whole appeal.

```
        import time, uuid
        import jwt                                      # pip install "pyjwt[crypto]"
        from cryptography.hazmat.primitives import serialization
        from cryptography.hazmat.primitives.asymmetric import rsa

        ISSUER, AUDIENCE = "https://auth.example.com", "https://api.example.com"

        # Authorization server: holds the private key.
        private_key = rsa.generate_private_key(public_exponent=65537, key_size=2048)
        public_pem = private_key.public_key().public_bytes(
            serialization.Encoding.PEM, serialization.PublicFormat.SubjectPublicKeyInfo)

        def issue_access_token(user_id: str, scopes: list[str], ttl_s: int = 900) ->
str:
            now = int(time.time())
            claims = {"iss": ISSUER, "aud": AUDIENCE, "sub": user_id, "iat": now, "nbf":
now,
                      "exp": now + ttl_s, "jti": str(uuid.uuid4()), "scope": "
".join(scopes)}
            return jwt.encode(claims, private_key, algorithm="RS256",
                              headers={"kid": "2026-10-key-1"})

        # Resource server: holds only the public key.
        def validate_access_token(token: str) -> dict:
            return jwt.decode(
                token, public_pem,
                algorithms=["RS256"],               # pin the algorithm; never trust the
header
                audience=AUDIENCE, issuer=ISSUER,
                leeway=30,                          # tolerate 30 s of clock skew
                options={"require": ["exp", "iat", "sub", "aud", "iss"]},
            )

        token = issue_access_token("user-123", ["articles:read", "articles:write"])
        print(len(token), validate_access_token(token)["scope"])   # ~700 articles:read
articles:write
```

What to notice:

- `algorithms=["RS256"]` defends against two classic attacks: tokens with `"alg": "none"` (no signature at all), and **algorithm confusion**, where an attacker signs an HS256 token using the server's *public* RSA key as the HMAC secret and a careless library verifies it [RFC 8725].
- The token is about 700 characters; at 10,000 requests per second that is about 7 MB/s of header bytes, which HTTP/2 header compression reduces on reused connections.
- In a FastAPI service, the same validation sits in a dependency that returns `401` or `403` with RFC 6750 `WWW-Authenticate` errors:

```
        from fastapi import Depends, FastAPI, HTTPException
        from fastapi.security import HTTPAuthorizationCredentials, HTTPBearer

        app = FastAPI()
        bearer = HTTPBearer(auto_error=False)

        def current_claims(creds: HTTPAuthorizationCredentials | None = Depends(bearer))
-> dict:
            if creds is None:
                raise HTTPException(401, "Missing bearer token",
                                    headers={"WWW-Authenticate": 'Bearer realm="api"'})
            try:
                return validate_access_token(creds.credentials)
            except jwt.InvalidTokenError:
                raise HTTPException(401, "Invalid or expired token",
                                    headers={"WWW-Authenticate": 'Bearer
error="invalid_token"'})

        def require_scope(scope: str):
            def checker(claims: dict = Depends(current_claims)) -> dict:
                if scope not in claims.get("scope", "").split():
                    raise HTTPException(403, f"Requires scope {scope}", headers={
                        "WWW-Authenticate": f'Bearer error="insufficient_scope", scope="
{scope}"'})
                return claims
            return checker

        @app.delete("/v1/articles/{article_id}", status_code=204)
        def delete_article(article_id: int, claims: dict =
Depends(require_scope("articles:delete"))):
            ...   # delete, recording claims["sub"] in the audit log
```

8.13.4 The revocation problem

Because verification is local, a server cannot know that a token was revoked — after logout, a password change, or a stolen laptop — until it expires. Mitigations, usually combined:

1. **Short access-token lifetimes** (5–15 minutes) plus refresh tokens (§8.14.4), which *are* checked against a server-side store on each refresh.
2. **Deny-list by `jti`** (or by `sub` + "tokens issued before time T") in a fast replicated store, checked on each request. This reintroduces a lookup, but the list holds only revoked, not-yet-expired tokens.
3. **Token introspection** (RFC 7662): the resource server asks the authorization server whether a token is active, which trades the local-verification advantage for immediacy; often used only for high-risk operations.

WORKED EXAMPLE

Worked example — Revocation window and deny-list size. Access tokens live $T = 15$ min. Users revoke sessions at $r = 100$ per minute.

1. Worst-case exposure after revocation without a deny-list: up to 15 min; if revocation times are uniformly distributed relative to issuance, on average 7.5 min.
2. Deny-list size: entries need be kept only until the token would have expired anyway, so $N = r \times T = 100 \times 15 = 1,500$ entries — about 1,500 × ~50 bytes ≈ 75 KB.

Interpretation. A deny-list is tiny and can be replicated into every service's memory and refreshed every few seconds. **Engineering implication:** "JWTs cannot be revoked" is false; the cost is a small, bounded amount of shared state.

COMMON MISTAKE

Storing JWTs in `localStorage` because "cookies are old-fashioned". Any XSS bug can read `localStorage` and exfiltrate the token. For browser apps, an `HttpOnly`, `Secure`, `SameSite` session cookie to your own backend (which holds the tokens server-side, the BFF pattern) is usually safer.

8.14 OAuth 2.0 and OpenID Connect

8.14.1 The delegation problem

DEFINITION

Definition — OAuth 2.0. An authorization framework that lets a third-party application obtain *limited* access to an HTTP service on behalf of a resource owner, by obtaining an **access token** from an authorization server instead of using the owner's credentials [RFC 6749].

Many cars come with a **valet key**: it starts the engine but cannot open the boot or the glovebox. You hand the valet a limited key instead of your full key ring. Before OAuth, a photo-printing site that wanted your photos from another service asked for your password — your full key ring — and could then do anything, forever, until you changed it. OAuth gives the printing site a valet key: a token scoped to “read photos”, time-limited, revocable, and issued without the site ever seeing your password.

8.14.2 Roles and grants

OAuth defines four roles [RFC 6749 §1.1]:

- **Resource owner** — the user who owns the data.
- **Client** — the application requesting access (the photo printer). A **confidential client** (a server-side app) can keep a client secret; a **public client** (SPA, mobile app) cannot, because its code is in users’ hands.
- **Authorization server (AS)** — authenticates the owner, asks for consent and issues tokens.
- **Resource server (RS)** — the API that accepts access tokens.

Tokens are presented as **bearer tokens** — “whoever bears this token may use it” — in the `Authorization: Bearer <token>` header, so they must only travel over TLS [RFC 6750].

Table 8.19 — OAuth 2.0 grant types and their status.

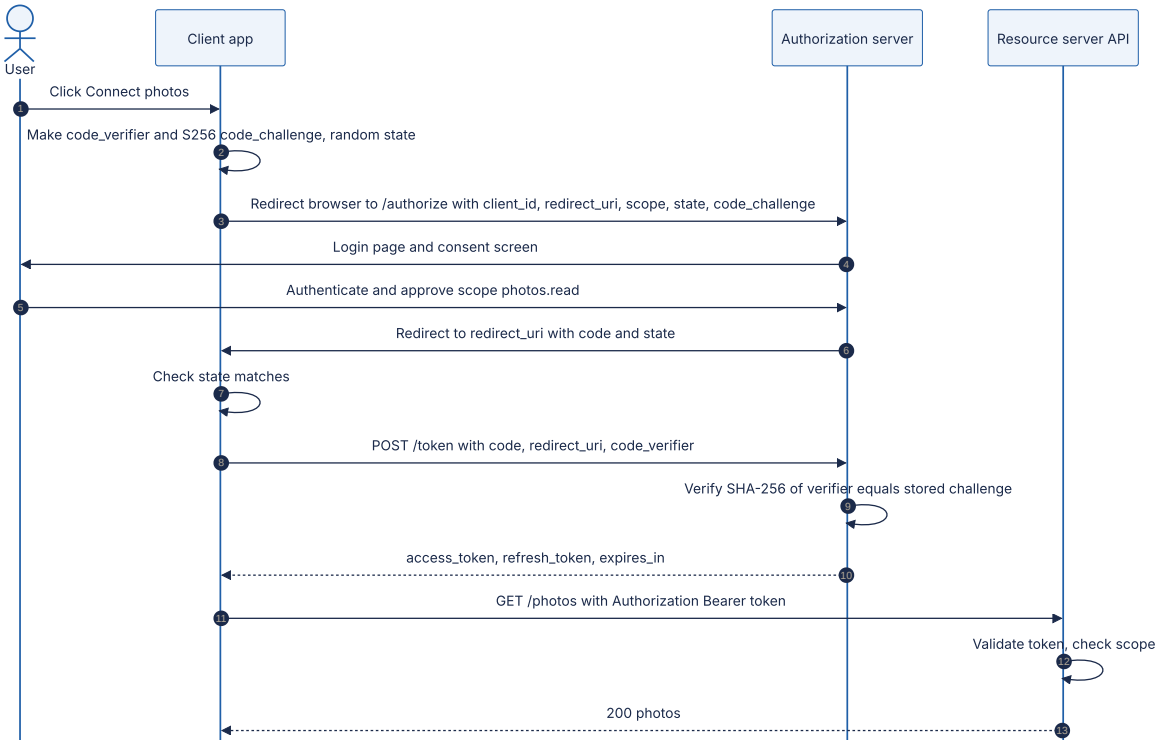
Grant	Who uses it	Status (as of 2026)
Authorization code + PKCE	Web apps, SPAs, mobile and desktop apps acting for a user	Recommended for all user-facing clients
Client credentials	A service acting for itself (machine-to-machine)	Recommended
Refresh token	Any client renewing an access token	Recommended, with rotation for public clients
Device authorization (RFC 8628)	TVs and CLIs without a convenient browser	Recommended for those devices
Implicit	Old SPAs (token returned in the URL fragment)	Deprecated; omitted from OAuth 2.1
Resource owner password credentials	Client collects the user’s password	Deprecated; omitted from OAuth 2.1

8.14.3 Authorization code flow with PKCE

DEFINITION

Definition — PKCE (Proof Key for Code Exchange, “pixy”). An extension in which the client creates a random secret, the **code verifier**, sends only its SHA-256 hash, the **code challenge**, with the authorization request, and must present the verifier when redeeming the authorization code. An attacker who intercepts the code cannot redeem it without the verifier [RFC 7636].

Figure 8.11 — OAuth 2.0 authorization code flow with PKCE.



Reading the diagram. Steps 3–6 happen through the user’s browser via redirects (the **front channel**), where URLs can leak through history, logs and malicious apps registered for the same redirect scheme on mobile devices. The authorization server only ever sees the *hash* of the verifier there. Step 8 is a direct HTTPS call from client to authorization server (the **back channel**), where the client proves possession of the verifier; an attacker who stole the code in step 6 lacks it. The `state` value checked in step 7 stops an attacker from injecting their own authorization response into the user’s session (CSRF against the redirect endpoint). Steps 11–13 are ordinary API calls with a bearer token, validated as in §8.13.3 or by introspection. All calls are synchronous. Storage boundaries: the authorization server stores codes (single use, short-lived, typically under a minute), challenges, grants and refresh tokens. Failure points: the authorization server is on the login path for every user and must be highly available; resource servers that validate JWTs locally keep working during a brief AS outage until tokens expire. Scaling: token validation scales

with the number of resource servers; the token endpoint scales like any stateless service backed by a replicated store.

```
        import base64, hashlib, secrets

        def make_pkce_pair() -> tuple[str, str]:
            # 32 random bytes -> 43-character base64url verifier (RFC 7636 allows 43-128
chars)
            verifier =
base64.urlsafe_b64encode(secrets.token_bytes(32)).rstrip(b"=").decode()
            return verifier, challenge_for(verifier)

        def challenge_for(verifier: str) -> str:
            digest = hashlib.sha256(verifier.encode("ascii")).digest()
            return base64.urlsafe_b64encode(digest).rstrip(b"=").decode()

        # Test vector from RFC 7636 Appendix B:
        assert challenge_for("dBjftJeZ4CVP-mB92K27uhbUJU1p1r_wW1gFWFOEjXk") == \
            "E9Melhoa2OwvFrEMTJguCHaoeK1t8URWbuGJSstw-cM"
```

The token exchange (step 8) on the wire:

```
        curl -s https://auth.example.com/oauth/token \
          -d grant_type=authorization_code \
          -d code=SplxlOBeZQQYbYS6WxSbIA \
          -d redirect_uri=https://app.example.com/callback \
          -d client_id=photo-printer \
          -d code_verifier=dBjftJeZ4CVP-mB92K27uhbUJU1p1r_wW1gFWFOEjXk
        # {"access_token":"eyJhbGciOi...","token_type":"Bearer","expires_in":900,
        #  "refresh_token":"8xLOxBtZp8...","scope":"photos.read"}
```

What to notice: PKCE was designed for public clients, which have no secret; current guidance recommends it for confidential clients too [RFC 9700]. Redirect URIs must be registered in advance and matched exactly, since a loose match lets an attacker redirect codes to their own site.

8.14.4 Client credentials and refresh tokens

Client credentials grant. No user is involved: a backend service authenticates as itself (client ID plus secret, a signed JWT assertion, or mutual TLS) and receives a token scoped to the APIs it may call. This is the standard pattern for machine-to-machine calls between organizations or between internal services when not using mTLS identities (§10.10).

```
        curl -s -u billing-service:$CLIENT_SECRET https://auth.example.com/oauth/token \
          -d grant_type=client_credentials -d scope=invoices.write
```

Refresh tokens let a client obtain new short-lived access tokens without user interaction. Because the refresh token is long-lived and is checked by the authorization server on

each use, it is where revocation actually happens: revoke the refresh token and the client loses access within one access-token lifetime. For public clients, **refresh-token rotation** issues a new refresh token on every use and invalidates the old one; if an old one is ever presented again, the server assumes theft and revokes the whole token family [RFC 9700].

8.14.5 OAuth 2.1

OAuth 2.1 is an IETF Internet-Draft that consolidates RFC 6749, RFC 6750, PKCE and the security best current practice into one document: PKCE required for the authorization code grant, implicit and password grants removed, exact redirect-URI matching, and no bearer tokens in query strings. As of October 2026 it is still a draft (revision -16, September 2026), not an RFC [OAuth 2.1 draft]; in practice, following RFC 9700 gets you the same behavior today.

8.14.6 OpenID Connect

OAuth answers “may this app access these photos?” It deliberately says nothing about *who the user is*; an access token is meant for the resource server and may be opaque to the client. Applications nonetheless abused OAuth for “Sign in with …”, which caused vulnerabilities. **OpenID Connect (OIDC)** is a thin identity layer on top of OAuth 2.0 that standardizes login [OpenID Connect Core 1.0]:

- The client requests `scope=openid` (plus `profile`, `email` as needed).
- The token response additionally contains an **ID token**: a JWT *for the client* (its `aud` is the client ID) asserting who logged in — `iss`, `sub` (stable user identifier at that issuer), `aud`, `exp`, `iat`, `auth_time`, and the `nonce` the client sent, which prevents replay of an ID token into a different login.
- A **UserInfo endpoint** returns profile claims for the access token.
- **Discovery** (`/.well-known/openid-configuration`) publishes the issuer’s endpoints and its JWKS URL, so clients configure themselves from one URL.

> COMMON MISTAKE
>
> **Sending the ID token to your API as an access token, or accepting any provider’s access token as proof of login.** The ID token’s audience is the *client*; the access token’s audience is the *API*. Validate each only for its intended audience. Identify users by the pair (`iss`, `sub`), never by email address alone, which can change or be reassigned.

8.15 API versioning and compatibility

8.15.1 What breaks clients

An API is a promise to every client that ever integrated with it. You cannot redeploy those clients; you can only stop breaking them. Applying the rules of §8.9.3 to HTTP APIs:

Table 8.20 — Breaking and non-breaking API changes.

Non-breaking (additive)	Breaking
Add a new endpoint	Remove or rename an endpoint or field
Add an optional request parameter	Add a required request parameter
Add a field to a response	Change a field's type, format or meaning
Add a new enum value *if* clients were told to tolerate unknown values	Add an enum value clients switch on exhaustively
Relax a validation rule	Tighten validation; change defaults; change error codes
Add a new error `type` within an existing status	Change pagination or authentication scheme

Clients share responsibility: a **tolerant reader** ignores unknown fields and unknown enum values instead of failing. Document that obligation explicitly.

8.15.2 Versioning strategies

Table 8.21 — API versioning strategies.

Strategy	Example	Advantages	Disadvantages
URI path	`GET /v2/orders/42`	Obvious; easy to route, cache and test in a browser	A version is a whole parallel API; encourages big-bang versions
Custom header	`Api-Version: 2`	Clean URIs	Invisible in logs and links; caches must `Vary` on the header
Media type	`Accept: application/vnd.example.v2+json`	Most aligned with HTTP content negotiation	Awkward tooling; rarely understood by clients
Date-based, pinned per client	`Stripe-Version: 2024-06-20`	Small, frequent changes; each client upgrades on its own schedule	Server must maintain transformations for every live version

Two practices that work regardless of the mechanism: use **major versions only** for breaking changes (additive changes need no new version), and keep the number of live major versions small (one or two).

INDUSTRY EXAMPLE

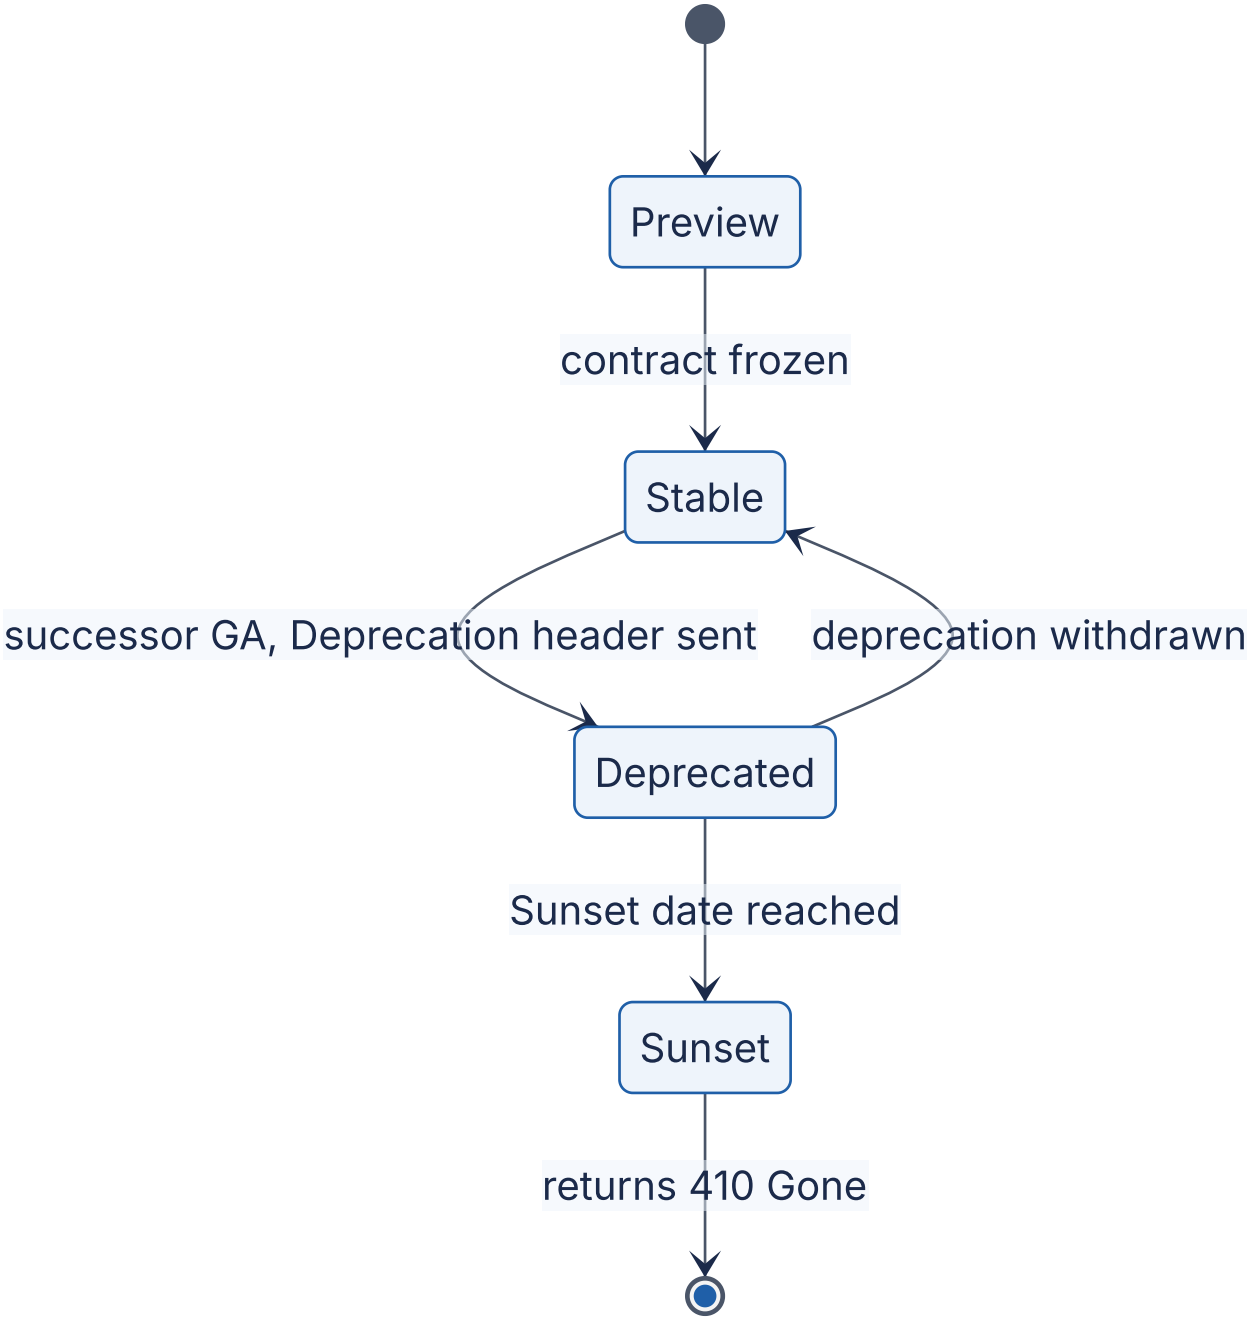
Stripe's date-based versions. Stripe pins each account to the API version current when it first made a request, and lets requests override it with a `Stripe-Version` header. Internally the latest code produces the latest response shape, and a chain of small "version change" modules transforms responses backwards, one step per version, to whatever version the client is pinned to. This lets Stripe ship breaking improvements frequently without forcing integrations to change [Leach 2017]. GitHub's REST API similarly uses date-named versions selected by the `X-GitHub-Api-Version` header [GitHub Docs: API versions]. *Evidence: Primary* — [Leach 2017]; [GitHub Docs: API versions]

8.15.3 Deprecation

Deprecation is a process, not an event:

1. **Announce** in the changelog and documentation, with a date.
2. **Signal in-band.** Send the `Deprecation` response header [RFC 9745] on deprecated endpoints, a `Link` with `rel="deprecation"` pointing to migration docs, and the `Sunset` header [RFC 8594] with the date the endpoint will stop working.
3. **Measure.** Log usage of deprecated endpoints per client ID; contact the remaining heavy users directly.
4. **Brown-outs.** Before the sunset date, fail a small, increasing fraction of calls for short scheduled windows, so forgotten integrations surface while there is time to fix them.
5. **Remove**, returning `410 Gone` with a problem-details body that links to the migration guide.

Figure 8.12 — Lifecycle of an API version.



Reading the diagram. A version starts as a preview (no compatibility promise), becomes stable when its contract is frozen, and is deprecated once a successor is generally available; from then on responses carry `Deprecation` and `Sunset` headers. At the sunset date it is removed and answers `410 Gone`. The transitions are driven by policy and calendar, not by traffic. Failure point: removing a version that still carries significant traffic; usage metrics per client must gate the final transition.

8.16 API documentation: OpenAPI

DEFINITION

Definition — OpenAPI Specification (OAS). A vendor-neutral, machine-readable format (YAML or JSON) for describing HTTP APIs: paths, operations, parameters, request and response bodies (as JSON Schema), status codes and security schemes [OpenAPI Specification]. It grew out of Swagger and is maintained by the OpenAPI Initiative; version 3.1 aligned its schemas with JSON Schema, and version 3.2.0 was released in September 2025.

An OpenAPI document is the API's contract in a form that tools can use: generating interactive documentation, client SDKs and server stubs, mock servers, request validation at gateways, and **contract tests** and **breaking-change detection** in CI (diffing the spec against the previous release flags the changes in Table 8.20 automatically).

```yaml
openapi: 3.1.0
info:
  title: Articles API
  version: 1.0.0
paths:
  /v1/articles:
    get:
      summary: List articles, newest first
      parameters:
        - name: limit
          in: query
          schema: { type: integer, minimum: 1, maximum: 100, default: 20 }
        - name: cursor
          in: query
          description: Opaque cursor from a previous response's next_cursor.
          schema: { type: string }
      security:
        - bearerAuth: []
      responses:
        "200":
          description: A page of articles.
          content:
            application/json:
              schema:
                type: object
                required: [data, next_cursor]
                properties:
                  data:
                    type: array
                    items: { $ref: "#/components/schemas/Article" }
                  next_cursor: { type: [string, "null"] }
        "400":
          description: Invalid cursor.
          content:
            application/problem+json:
              schema: { $ref: "#/components/schemas/Problem" }
components:
  securitySchemes:
    bearerAuth: { type: http, scheme: bearer, bearerFormat: JWT }
  schemas:
    Article:
      type: object
      required: [id, title, status, created_at]
      properties:
        id: { type: integer }
        title: { type: string }
        status: { type: string, enum: [draft, published] }
        created_at: { type: string, format: date-time }
    Problem:
      type: object
      properties:
        type: { type: string, format: uri }
        title: { type: string }
        status: { type: integer }
```

```
                detail: { type: string }
                instance: { type: string }
```

What to notice: `next_cursor` is typed `[string, "null"]`, OpenAPI 3.1's JSON Schema way of saying "nullable"; errors are documented with the `application/problem+json` media type of §8.6.7; and the bearer scheme declares that operations need a JWT.

There are two workflows. In **design-first**, teams write and review the OpenAPI document before code, then generate stubs; this suits public APIs where the contract matters most. In **code-first**, the framework derives the document from code: FastAPI, for example, serves the document generated from the `articles_api.py` example of §8.6.5 at `/openapi.json` and interactive documentation at `/docs`, with no extra work. Either way, keep the spec in version control and treat changes to it as API changes that require review. GraphQL APIs are self-describing through **introspection**, and gRPC APIs through their `.proto` files, which play the same role.

8.17 Summary and revision notes

SUMMARY

- **Client–server**: clients initiate, servers own shared state. Keep the application tier **stateless**; state lives in databases, caches, cookies or tokens.
- **Rendering**: SSR (server builds HTML), SPA (browser builds UI from JSON APIs), SSG (built once, served from a CDN), native mobile (old versions live for years). SPAs and mobile apps need a well-designed API; BFFs tailor it per client.
- **Lifecycle**: DNS → TCP → TLS → load balancer → web server → app middleware → handler → cache/DB → response. On a cold connection, setup round trips often cost more than server work; reuse connections.
- **REST**: resources named by URIs, standard methods, status codes. Know which methods are **safe** (GET, HEAD, OPTIONS) and **idempotent** (those plus PUT, DELETE). Make POST retryable with idempotency keys.
- **Pagination**: offset costs $O(\text{offset} + \text{limit})$ and shifts under writes; **cursor/keyset** pagination with `WHERE (sort_key, id) < (…)` and a matching index is constant-cost and stable.
- **Errors**: use status codes for the class of outcome and RFC 9457 `application/problem+json` for detail.
- **GraphQL**: typed schema, client-chosen fields, one round trip. Fix **N+1** with per-request **DataLoader** batching; HTTP caching is hard (use persisted queries); enforce depth and cost limits.
- **gRPC**: Protobuf IDL, generated stubs, HTTP/2 streams; unary, server-, client- and bidirectional streaming. Always set and propagate **deadlines**; use L7 load balancing.
- **Serialization**: JSON is readable and universal; Protobuf and Thrift use numeric tags and varints; Avro has no tags and resolves writer's against reader's schema. Evolve by adding optional fields with defaults; never reuse field numbers.
- **Cookies**: `Secure`, `HttpOnly`, `SameSite=Lax` (or Strict), `__Host-` prefix. Sessions are server-side (instant revocation, one lookup) or signed cookies (no store, no early revocation).
- **AuthN vs AuthZ**: who you are (401) vs what you may do (403). Hash passwords with slow salted functions (§10.6); prefer phishing-resistant MFA (WebAuthn/passkeys).
- **Authorization models**: RBAC (roles), ABAC (attribute predicates), ReBAC (relationship graph; Zanzibar's tuples, rewrites and zookies).
- **JWT**: header.payload.signature, signed not encrypted. Pin the algorithm; validate `exp`, `iss`, `aud`. HS256 = shared secret; RS256/ES256 = private signs, public verifies. Revocation needs short TTLs, refresh tokens and/or deny-lists.

- **OAuth 2.0**: delegated, scoped access via tokens. Use authorization code + PKCE for user-facing apps, client credentials for machines, rotating refresh tokens. OAuth 2.1 is still a draft (as of 2026). **OIDC** adds the ID token and standard login.
- **Versioning**: additive changes need no new version; breaking changes do. URI, header, media-type or date-based pinning; deprecate with `Deprecation` / `Sunset` headers, usage metrics and brown-outs.
- **OpenAPI** is the machine-readable contract: docs, SDKs, validation and breaking-change detection in CI.

8.18 Knowledge checkpoint

1. Why does making the application tier stateless make horizontal scaling easy, and where does the state go?
2. Name two backend consequences of supporting a native mobile client that an SSR website does not impose.
3. A user 50 ms RTT away makes a first request needing an uncached DNS lookup (20 ms), TCP and TLS 1.3 setup, and 15 ms of server time. Estimate the latency, and the latency of the next request.
4. Which HTTP methods are safe? Which are idempotent? Why does the distinction matter to a retry library?
5. When should an API return 401, 403, 404, 409, 422 and 429?
6. Write the keyset-pagination `WHERE` clause for sorting by `created_at DESC, id DESC`, and explain why `id` is included.
7. Page size 50, page 10,001 with offset pagination: how many rows does the database walk? Roughly how many with keyset pagination?
8. What are the five standard members of an RFC 9457 problem-details object?
9. A GraphQL query fetches 20 posts and each post's author. How many database queries run with naive resolvers and with DataLoader?
10. Why must a DataLoader instance be created per request?
11. What are the four gRPC call types? Give one use for each.
12. What happens to a gRPC call with no deadline when the server hangs?
13. Encode the integer 300 as a Protobuf varint in hex.
14. In Protobuf, why must you never reuse a deleted field number? What does Avro need instead of field numbers?
15. What does each of `Secure`, `HttpOnly` and `SameSite=Lax` protect against?
16. Give one advantage and one disadvantage of a signed-cookie session versus a server-side session store.
17. In a JWT, why must the server not use the `alg` value from the token header to choose the verification algorithm?

18. Why does PKCE stop an attacker who intercepts the authorization code?
19. What does OpenID Connect add to OAuth 2.0?
20. Classify as breaking or non-breaking: adding an optional query parameter; renaming a response field; adding a required request field.

Answers

1. Any instance can serve any request, so instances can be added, removed or replaced behind a load balancer without losing anything. State moves to databases, caches, a session store, or the client (cookies, tokens).
2. Old app versions remain in use for months or years, so the API must stay backward compatible; slow cellular links make round trips expensive, favoring coarse-grained or aggregated endpoints (BFF, GraphQL) and compact payloads.
3. Cold: $20 + 50 + 50 + 50 + 15 = 185$ ms. Next request on the same connection with cached DNS: $50 + 15 = 65$ ms.
4. Safe: GET, HEAD, OPTIONS (and TRACE). Idempotent: the safe methods plus PUT and DELETE. A retry library can automatically retry idempotent requests after a timeout; retrying POST may duplicate effects unless an idempotency key is used.
5. 401: not authenticated. 403: authenticated but not permitted. 404: no such resource (or hidden). 409: conflicts with current state, such as a duplicate key. 422: well-formed but semantically invalid input. 429: rate limit exceeded, with `Retry-After`.
6. `WHERE (created_at, id) < (:last_created_at, :last_id) ORDER BY created_at DESC, id DESC LIMIT :n`. `id` makes the order total, so rows sharing a timestamp are neither skipped nor repeated across pages.
7. Offset $= 10,000 \times 50 = 500,000$, so about 500,050 rows. Keyset: an index descent (~3–4 levels) plus 50–51 rows.
8. `type`, `title`, `status`, `detail`, `instance`.
9. Naive: $1 + 20 = 21$. DataLoader: 2 (one for posts, one batched `IN` query for distinct authors).
10. Its cache would otherwise serve one user's data (possibly unauthorized) to another user and return stale data across requests.
11. Unary (fetch an order); server streaming (status updates, tailing logs); client streaming (uploading telemetry in chunks); bidirectional (chat, live transcription).
12. The client waits indefinitely, holding a thread or connection and memory; under load such calls accumulate and can exhaust the caller, cascading up the call chain.
13. 300 = `1 0010 1100`. Low 7 bits `010 1100` = 0x2C, plus continuation bit → `ac`; remaining bits `10` → `02`. Result: `ac 02`.
14. Old data or old clients would interpret the new field's bytes as the old field, causing silent corruption. Avro needs the writer's schema (from a file header or schema registry) and resolves fields by name, using defaults.
15. `Secure`: leakage over unencrypted HTTP. `HttpOnly`: theft of the cookie by JavaScript injected through XSS. `SameSite=Lax`: the cookie being sent on cross-site POSTs and subresource requests, that is, CSRF.

16. Advantage: no store lookup and no shared infrastructure. Disadvantage: cannot be revoked individually before expiry; limited to ~4 KB sent on every request; contents readable by the user.
17. An attacker controls the header. They could set `alg: none`, or `HS256` and sign with the server's public RSA key as the HMAC secret (algorithm confusion). The server must use its configured algorithm allow-list.
18. The code is useless without the code verifier, which never travels through the browser; only its SHA-256 hash does, and the hash cannot be inverted.
19. A standard identity layer: the `openid` scope, the ID token (a JWT about the authenticated user with audience = client), the UserInfo endpoint, standard claims, nonce-based replay protection and discovery metadata.
20. Non-breaking; breaking; breaking.

8.19 Interview questions

Basic

Q1. Walk me through what happens when a user types a URL and presses Enter. Answer. The browser parses the URL and checks its HTTP cache. It resolves the host name through DNS (OS cache, then recursive resolver, then authoritative servers), opens a TCP connection (one RTT) and performs a TLS 1.3 handshake (one RTT), or a combined QUIC handshake on HTTP/3. It sends the HTTP request with headers and cookies. A load balancer terminates TLS, routes on host and path, and forwards to a healthy backend over a pooled connection. The web server passes it to the application, where middleware authenticates, rate-limits and routes to a handler; the handler authorizes, reads cache and database, serializes a response and returns it back through the chain. The browser parses and renders, fetching subresources, often over the same connection. Strong answers attach rough numbers to each hop and note which steps connection reuse and CDNs remove.

Q2. What is the difference between PUT, PATCH and POST? Answer. POST asks the target collection or resource to process the body, commonly creating a resource whose URI the server chooses; it is not idempotent. PUT creates or completely replaces the resource at the URI the client names; it is idempotent. PATCH applies a partial modification; it is not guaranteed idempotent (an "increment" patch is not). Retries are therefore safe for PUT but need idempotency keys for POST.

Q3. Cookies or tokens for authentication? Answer. For a first-party browser application, an opaque session ID in a `Secure; HttpOnly; SameSite` cookie is simple and secure and allows instant logout. For APIs consumed by mobile apps, other services or third parties, short-lived bearer tokens (often JWTs) obtained through OAuth fit better, because any service can verify them without a shared store. Many systems combine them: the

browser holds a session cookie with a BFF, which holds tokens and calls services with them.

Intermediate

Q4. Design pagination for an activity feed API with 500 million rows and constant inserts. Answer. Use cursor (keyset) pagination ordered by `(created_at DESC, id DESC)`, backed by a composite index (per user, if the feed is per user: `(user_id, created_at DESC, id DESC)`). The response returns `data` and an opaque `next_cursor` encoding the last row's sort key, base64url-encoded and HMAC-signed, optionally with an expiry and a hash of the filter parameters. Query with a row-value comparison and `LIMIT n+1` to detect more pages. Cap `limit` at, say, 100. Omit total counts or serve approximate ones. Explain why offset fails: cost grows linearly with depth (deep pages walk millions of rows) and inserts cause duplicates. Mention that cursors survive deletes of the boundary row because the comparison is on values, not on row existence.

Q5. Your GraphQL API's database load tripled after a new mobile screen launched. Diagnose and fix. Answer. Likely N+1 resolution on nested lists, possibly compounded by a query requesting large page sizes or deep nesting. Confirm with per-request query counts and resolver tracing. Fix with per-request DataLoaders for every relation field (batch by parent IDs, dedupe), enforce maximum `first` values, add query-cost analysis with per-client budgets, and use persisted queries so the expensive query can be reviewed and cached. Consider caching hot entities in the batch functions.

Q6. How do you revoke access for a user whose laptop was stolen, if your APIs use JWT access tokens? Answer. Revoke their refresh tokens at the authorization server (so no new access tokens are minted) and end their server-side sessions. For outstanding access tokens, either accept exposure until expiry (keep TTLs at 5–15 minutes) or push a deny-list entry — by `jti`, or "all tokens for `sub` issued before T" — to a replicated store or in-memory cache in every resource server, checked during validation. Entries can expire with the tokens, so the list stays small. High-risk operations can additionally require introspection or step-up authentication.

Advanced

Q7. Design authorization for a document-collaboration product with folders, nested groups and link sharing, serving 100,000 checks per second at p99 under 20 ms. Answer. Use ReBAC in the Zanzibar style. Store tuples `object#relation@subject` (subjects can be usersets like `group:eng#member`) in a partitioned, replicated store, partitioned by object ID. Define namespace rewrite rules: owner ⊂ editor ⊂ commenter ⊂ viewer, and viewer inherited from parent folder; link sharing is a tuple with a special subject such as `anyone-with-link`. A check service evaluates the rewrite graph with memoization of sub-results, request deduplication, depth limits and a precomputed membership

index for large nested groups. For freshness, return a consistency token with each ACL or content write and evaluate later checks at a snapshot at least that recent, avoiding the new-enemy problem; otherwise allow slightly stale cached results for latency. Provide list/filter APIs ("which of these 50 docs can Alice see?") as batched checks. Discuss failure modes: the authorization service on every read path must be multi-region and degrade by failing closed; audit logs of tuple changes; and the cost of deep nesting.

Q8. Your company runs 300 microservices with a mix of REST/JSON and gRPC. Propose an inter-service API strategy, including versioning and schema evolution. Answer. Default to gRPC with Protobuf for internal synchronous calls: compact, typed, streaming, deadline propagation. Keep all `.proto` files in a central schema repository with linting and breaking-change detection in CI; version by package (`orders.v1`), additive changes only within a version. Expose public and partner APIs as REST/JSON with OpenAPI, generated or transcoded from the same definitions where possible, with RFC 9457 errors and date-based or major-version URIs. Mandate deadlines on every call, propagation of deadline and trace context, and status-code-based retry policies with budgets. Use L7 or client-side load balancing for HTTP/2. For asynchronous events, use Avro or Protobuf with a schema registry enforcing backward/forward compatibility. Measure the usage of every deprecated field and method before removal.

Q9. Walk through the security of a SPA that signs users in with an external identity provider and calls your API. Answer. The SPA is a public client, so use the authorization code flow with PKCE (S256), a random `state`, and an OIDC `nonce`; register exact redirect URIs. Preferably run a BFF: the browser holds only an `HttpOnly; Secure; SameSite=Lax` (or Strict), `__Host-` session cookie with the BFF, which performs the code exchange as a confidential client and stores access and refresh tokens server-side, so XSS cannot steal tokens. Validate the ID token (signature via JWKS, `iss`, `aud` = client ID, `exp`, `nonce`) and identify users by (`iss`, `sub`). The API validates access tokens with pinned algorithms, `aud` = API, scopes, and short TTLs; refresh tokens rotate with reuse detection. Add CSRF protection for state-changing BFF endpoints, a strict Content Security Policy, and an authorization check on every object access.

8.20 Practical exercises

1. **Build a small REST API (2–4 h).** Extend `articles_api.py` (§8.6.5) into a FastAPI or Flask service backed by SQLite or PostgreSQL with `POST /v1/articles` (201 + `Location`), `GET` with cursor pagination and filtering by `status` and `author_id`, `PATCH` with `If-Match` ETags (412 on mismatch), and `DELETE` (204). Protect writes with the JWT dependency of §8.13.3 and scopes `articles:write` and `articles:delete`. Return RFC 9457 errors throughout. Write tests that page through 1,000 rows while inserting new ones, and assert that no row is returned twice.

2. **Measure offset versus keyset.** Load 5 million rows into PostgreSQL. Time `OFFSET` queries at offsets 0, 10^4, 10^5 and 10^6, and the equivalent keyset queries, and read `EXPLAIN (ANALYZE, BUFFERS)` for each. Plot latency against page depth.
3. **Encode by hand.** Write a decoder for the varint encoder of §8.9.2 that turns the 33-byte message back into fields, skipping unknown field numbers using the wire type. Add `sint64` ZigZag support and verify against the official `protobuf` library.
4. **Fix an N+1.** Implement the blog schema of §8.7.1 with Strawberry or Ariadne (Python) over SQLite, log every SQL statement, and count queries for a request of 50 posts with comments and authors. Add DataLoaders and compare.
5. **OAuth end to end.** Run an open-source identity provider (for example Keycloak) locally, register a public client, and implement the authorization code + PKCE flow from a small Python web app, including `state`, `nonce` and ID-token validation. Then demonstrate that replaying a stolen code without the verifier fails.

8.21 Design challenges

1. **Public API for a payments startup.** Design the external API for creating charges, refunds and listing transactions: resource model, idempotency keys, pagination, error types, webhooks, authentication for merchants (API keys vs OAuth for platforms), versioning and deprecation policy. Justify every status code.
2. **One backend, three frontends.** A retailer has an SSR website, an iOS/Android app with five live versions, and partner integrations. Choose between REST, GraphQL, BFFs and gRPC for each layer, draw the architecture, and explain how a schema change to “product price” rolls out without breaking any client.
3. **Authorization at scale.** A B2B SaaS product needs per-tenant roles, per-project sharing and conditional rules (“contractors only from the corporate network”). Combine RBAC, ReBAC and ABAC; specify the data model, the check API, caching and consistency, and how you would audit “who can see project X?”.

8.23 Open verification items

- Zanzibar throughput: the chapter says "millions of authorization checks per second"; confirm the exact figure in the paper's abstract (secondary sources quote "more than 10 million client queries per second").
- `SameSite` default: confirm current (2026) behavior of Chromium, Firefox and Safari for cookies without a `SameSite` attribute, and the publication status of RFC 6265bis.
- OAuth 2.1: re-check the draft revision (or RFC number, if published) at the time of book publication; -16 was current in September 2026.
- NIST SP 800-63B-4: reference aligned with Chapter 10 (§10.6); confirm final wording at publication time.

- Exact URLs and titles of [Byron 2015], the GitHub GraphQL rate-limit page, and the Stripe pagination page.
- Table 8.3 latency ranges are illustrative estimation figures; cross-check against Appendix F when it is written.
- The “few hundred milliseconds per scrypt hash” figure was measured once (≈0.4 s at $N = 2^{17}$, $r = 8$, $p = 1$) on a single cloud vCPU in 2026; Chapter 10 (§10.6.2) owns the authoritative parameter guidance.

Chapter 9 — Real-Time Communication

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3 h

The web was built as a conversation in which only one side may speak first. A browser asks; a server answers; the exchange ends. That model, described in §8.5 (The request–response lifecycle), works well for loading a page or submitting a form. It works badly when the *server* is the first to know something: a new chat message has arrived, a stock price has moved, a driver is two minutes away, a colleague has started typing. This chapter is about the family of techniques that let a server tell a client about something *now*, without waiting to be asked.

Picture a restaurant kitchen and a diner. **Short polling** is the diner walking to the kitchen every five minutes to ask “is my food ready?”. **Long polling** is the diner asking once and the chef saying “wait here, I’ll tell you as soon as it is”. **Server-Sent Events** is a waiter assigned to the diner’s table who walks over every time a course is ready. **WebSockets** is a telephone line between table and kitchen that either side can talk into at any moment. **WebRTC** lets two diners talk to each other directly across the room instead of passing notes through the kitchen. **Mobile push** is the restaurant sending a text message to a diner who has gone home: the phone company decides when it arrives, and it might not arrive at all. Every technique in this chapter is a trade between how quickly the news arrives, how much it costs to keep the line open, and how much infrastructure must understand the line.

9.1 Learning objectives

After this chapter you should be able to:

- Explain the mechanism, wire format and failure modes of short polling, long polling, Server-Sent Events (SSE), WebSockets, WebRTC and mobile push.
- Calculate the request rate, wasted requests and added latency of a polling design from the number of clients and the polling interval.
- Walk through the RFC 6455 WebSocket opening handshake, compute `Sec-WebSocket-Accept`, and decode a WebSocket frame byte by byte, including masking.
- Describe how ICE, STUN and TURN establish a peer-to-peer WebRTC session, and choose between mesh, SFU and MCU topologies with bandwidth arithmetic.
- Design a mobile push pipeline using APNs and FCM that tolerates dropped notifications, stale device tokens and collapsed messages.

- Size a connection gateway fleet for 10 million concurrent connections, including memory, server count, heartbeat load and reconnect-storm behavior.
- Design a pub/sub backplane, a presence system and a graceful-drain deployment procedure for long-lived connections.
- Choose the right real-time technique for a given product requirement and defend the choice with a comparison of cost, latency and operational complexity.

9.2 Prerequisites

- TCP connections, the three-way handshake and head-of-line blocking — §7.7 (needed because every technique here rides on long-lived TCP or UDP flows).
- HTTP/1.1, HTTP/2, HTTP/3 and QUIC — §7.9 (SSE and WebSockets interact with HTTP versions in non-obvious ways).
- TLS 1.3 — §7.10 (handshake cost dominates reconnect storms).
- WebSockets introduction — §7.11 (this chapter is the deep dive).
- Proxies, reverse proxies and NAT — §7.12, §7.13 (they break long-lived connections and motivate STUN/TURN).
- I/O models and event loops (epoll, kqueue, async/await) — §6.13, §6.15 (how one server holds hundreds of thousands of idle connections).
- Little's Law — §4.11 (concurrent connections = arrival rate × connection lifetime).
- Load balancing and session affinity — §19.3, §19.6 (sticky routing for connections).
- Retries with exponential backoff and jitter — §22.12 (reconnect storms).

9.3 Short polling

9.3.1 What short polling is

> DEFINITION
>
> **Definition — Short polling.** A technique in which the client sends an ordinary HTTP request at a fixed interval T to ask whether new data exists; the server answers immediately, either with the new data or with an empty response, and the connection's request ends.

First-principles explanation

A child in the back seat asking "are we there yet?" every minute is short polling. The parent answers right away, almost always with "no". The child learns of arrival at most one minute late, and the parent spends most of the trip answering a question whose answer has not changed. Nothing about the car or the road had to change to support this protocol, which is precisely why it is popular.

Why does this exist?

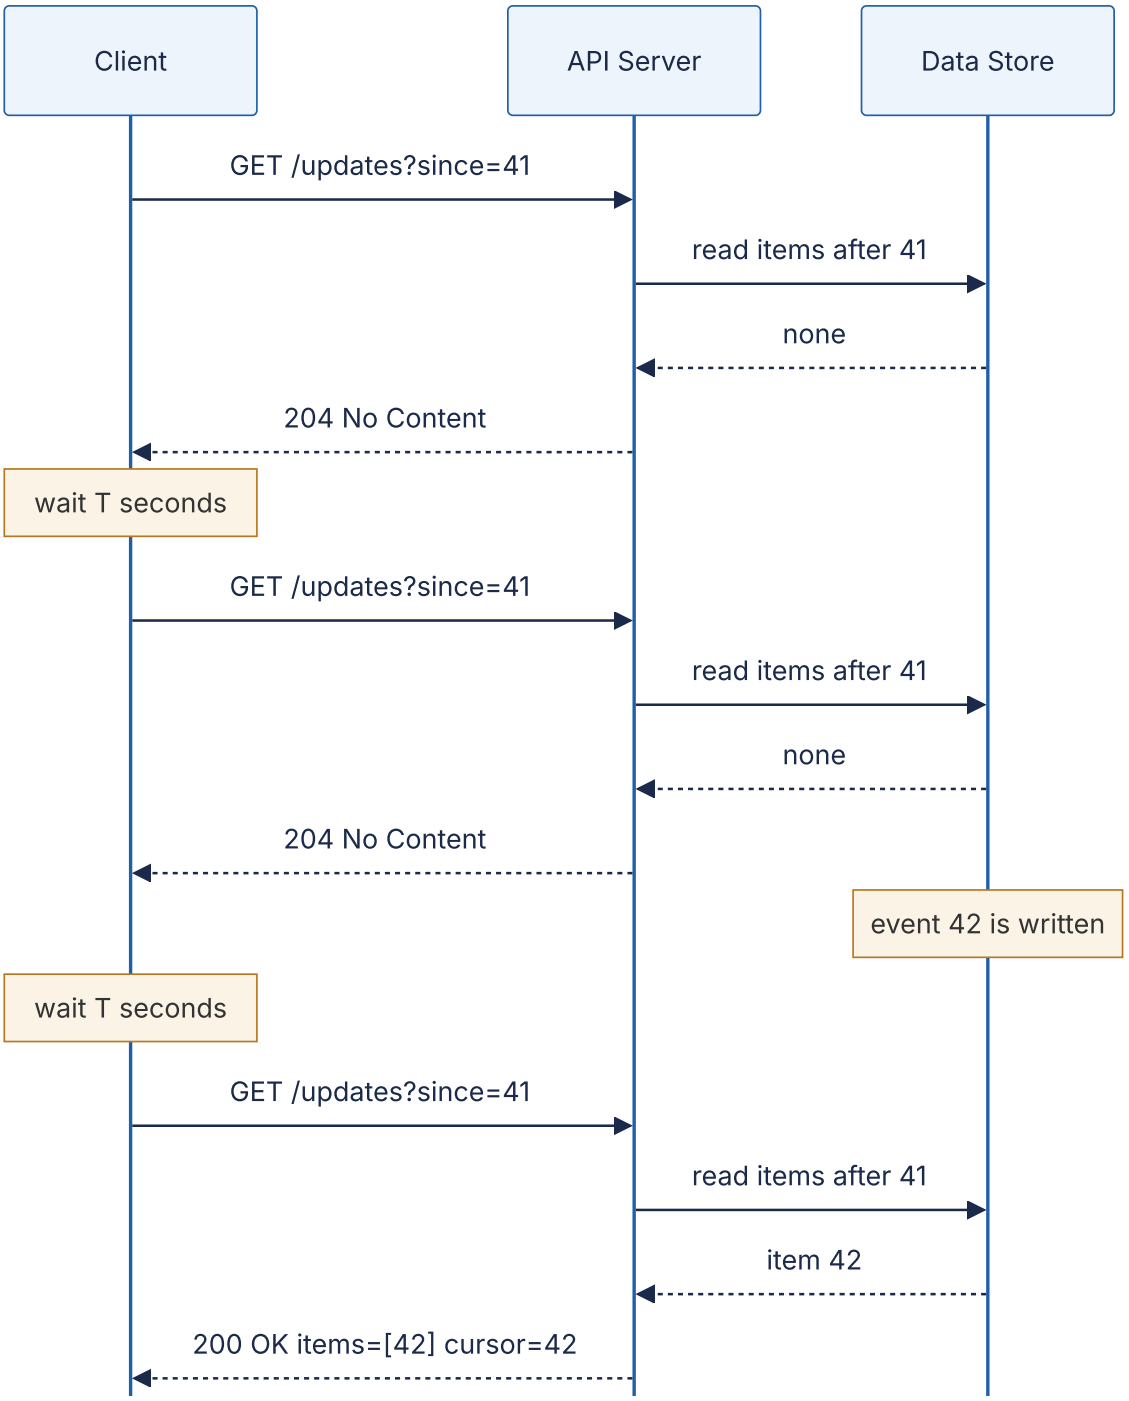
Short polling needs nothing beyond what every HTTP client, proxy, CDN, firewall and load balancer already supports. It was the first way web pages showed “live” data, and it remains the right answer when updates are infrequent, a few seconds of staleness is acceptable and clients are few — a build-status page polled every 30 seconds by a few hundred engineers, for example.

How it works internally

1. The client starts a timer with period T (for example, 5 seconds).
2. When the timer fires, the client sends `GET /updates?since=<cursor>`. The **cursor** is an opaque value (a sequence number or timestamp) identifying the last item the client has seen.
3. The server looks up anything newer than the cursor and responds immediately: `200 OK` with items and a new cursor, or `204 No Content` (or `200` with an empty list, or `304 Not Modified` with an `ETag`) when nothing changed.
4. The client applies the items, stores the new cursor and waits for the next tick.
5. With HTTP keep-alive (§7.16), the TCP and TLS connection is reused across polls, so each poll costs one request/response round trip rather than a full handshake.

Architecture diagram

Figure 9.1 — Short polling.



Reading the diagram. The client, a stateless API server and the data store exchange only synchronous HTTP over a reused keep-alive connection (solid = request, dashed = response); the server never initiates. Event 42 is written between polls, so the client learns of it up to T seconds late — inherent, not a bug. The data store receives one read per poll whether or not anything changed, which is the failure point at scale. Scaling is easy: stateless servers behind a load balancer, with a cache in front of the “anything new?” query.

Mathematical foundations

FORMULA

Short-polling request rate

$$R = \frac{N}{T}$$

Symbol	Meaning	Units
R	Request rate arriving at the servers	requests/second
N	Number of concurrently active (polling) clients	clients
T	Polling interval	seconds

FORMULA

Fraction of wasted (empty) polls and added latency

If updates for a client arrive as a Poisson process with rate λ, the probability that a given interval contains no update is

$$P_{\text{empty}} = e^{-\lambda T} \approx 1 - \lambda T \quad (\text{when } \lambda T \ll 1)$$

and the average delay between an event occurring and the client seeing it is

$$D_{\text{avg}} = \frac{T}{2} + t_{\text{rtt}}$$

Symbol	Meaning	Units
P_{empty}	Fraction of polls that return nothing	dimensionless (0–1)
λ	Average update rate per client	events/second
T	Polling interval	seconds
D_{avg}	Average notification delay	seconds
t_{rtt}	Network round-trip time for one poll	seconds

WORKED EXAMPLE

Worked example — A notification badge polled every 5 seconds.

A web app has $N = 1,000,000$ users online at peak. Each tab polls `/notifications` every $T = 5$ s. A typical user receives one notification every 10 minutes, so $\lambda = 1/600 \approx 0.00167$ events/s.

1. Request rate: $R = 1,000,000/5 = 200,000$ requests/s.
2. Empty fraction: $\lambda T = 5/600 = 0.00833$; $P_{\text{empty}} = e^{-0.00833} \approx 0.9917$. So **99.2 %** of requests — about 198,300 per second — return nothing.
3. Useful requests: $200,000 \times 0.0083 \approx 1,700$ per second actually carry a notification.
4. Header overhead: assume about 800 bytes of request headers (cookies, user-agent, auth token) and 200 bytes of response headers on HTTP/1.1 — about 1 KB per poll (SI units, 1 KB = 1,000 bytes). $200,000 \times 1$ KB $= 200$ MB/s ≈ 1.6 Gbit/s of traffic that mostly says “nothing new”. HTTP/2 header compression (HPACK) shrinks repeated headers considerably, but the request count and server work remain.
5. Average delay: $D_{\text{avg}} \approx 2.5$ s plus one round trip.

Interpretation. You are paying for 200,000 requests per second of capacity — load balancers, TLS termination, application threads and a database or cache lookup each — to deliver about 1,700 useful updates per second. Halving the interval to 2.5 s to improve freshness *doubles* the bill.

Engineering implication. Short polling’s cost scales with N/T, not with the rate of real events. When λT is small (rare events, short interval), switch to a push technique; when events are frequent relative to the interval (for example, a dashboard that changes every second and is polled every 10 s), polling’s waste is low and its simplicity wins.

Table 9.1 — Short-polling cost for 1 million clients as the interval shrinks (λ = 1 event per 10 minutes per client).

Interval T	Requests/s	Empty polls	Avg. delay	Header traffic (≈1 KB/poll)
60 s	16,667	90.5 %	30 s	16.7 MB/s
30 s	33,333	95.1 %	15 s	33.3 MB/s
10 s	100,000	98.3 %	5 s	100 MB/s
5 s	200,000	99.2 %	2.5 s	200 MB/s
1 s	1,000,000	99.8 %	0.5 s	1 GB/s

The table shows the central tension: every halving of delay doubles the cost, while the useful work stays constant at about 1,667 notifications per second.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Status dashboards and job progress pages.** A CI system's build page or a cloud console's "creating instance…" spinner typically polls a status endpoint every few seconds. The number of watchers is small, staleness of a few seconds is invisible to users, and the endpoint can be served from a cache, so the waste is cheap and the operational simplicity (no long-lived connections, works through every proxy) dominates. *Evidence: Illustrative* — a common pattern used for teaching; not a claim about any specific product.

Advantages and disadvantages

- **Advantages:** works everywhere (every proxy, CDN, firewall, HTTP version); servers stay stateless; trivially cacheable (`ETag`, `Cache-Control: max-age`); easy to rate-limit and to reason about; failures are self-healing because the next poll simply retries.
- **Disadvantages:** latency is bounded below by $T/2$ on average; cost grows with clients and polling frequency rather than with real events; mobile radios are woken on every poll, draining battery; synchronized clients (for example, all tabs opened at 09:00) create load spikes unless the timer is jittered.

Alternatives and trade-offs

Long polling (§9.4) removes empty responses and the $T/2$ delay; SSE (§9.5) and WebSockets (§9.6) remove per-update request overhead. **Adaptive polling** — lengthening T while nothing changes, or honoring a server-supplied `Retry-After` hint — is a cheap middle ground.

Failure scenarios

Table 9.2 — Short-polling failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Synchronized poll spikes	Clients start timers at the same moment (deploy, page load at shift start)	Request-rate graph shows sawtooth at multiples of T	Shed load with `429` + `Retry-After`	Add ±20 % random jitter to every timer
Database overload	Every empty poll hits the database	DB CPU tracks request rate, not write rate	Cache "latest cursor per user" in memory	Serve "anything new?" from a cache or version counter
Missed updates	Client uses wall-clock timestamps as cursor; clock skew or same-millisecond writes	Users report gaps	Re-fetch from an earlier cursor	Use monotonically increasing sequence numbers

Common misconceptions

COMMON MISTAKE

"Polling every second is fine; requests are cheap." A request that returns nothing still costs a TLS record, a load-balancer decision, an application thread slot, an authentication check and usually a cache or database lookup. Multiplied by N/T, "cheap" becomes the dominant load on the system. Always compute $R = N/T$ before choosing an interval.

9.4 Long polling

9.4.1 What long polling is

DEFINITION

Definition — Long polling. A technique in which the client sends an HTTP request that the server deliberately does not answer until either new data is available or a server-side timeout T_{hold} expires; on receiving any response, the client immediately sends the next request.

First-principles explanation

Now the child asks once and the parent says "I'll tell you when we arrive — and if nothing happens in half an hour I'll say so anyway". The news arrives the instant it happens, but the parent must *remember* that a question is pending — that memory is the new cost.

Why does this exist?

Mid-2000s webmail and chat needed sub-second updates, but browsers could only make JavaScript-initiated HTTP requests. Nothing in HTTP forbids a server from answering slowly, so holding the request open approximates push using only standard HTTP. Alex Russell named this family of techniques **Comet** in 2006 [Russell 2006]; the CometD project's **Bayeux** protocol standardized a message format, and RFC 6202 documented the pitfalls [Loreto et al. 2011]. Long polling survives as the universal fallback transport in libraries such as Socket.IO.

How it works internally

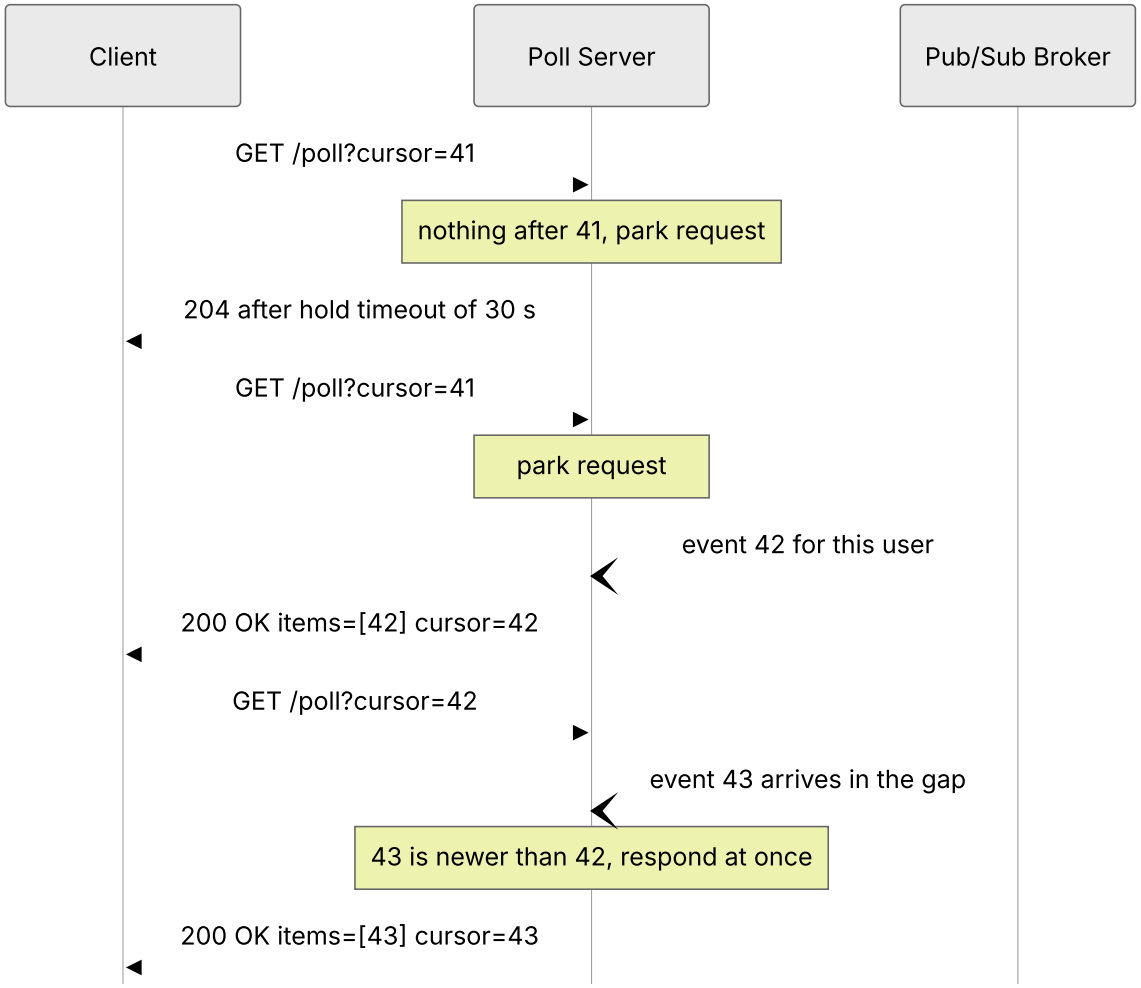
1. The client sends `GET /poll?cursor=41`.
2. The server checks for items after cursor 41. If any exist, it responds immediately (this is exactly short polling's fast path).
3. If none exist, the server *parks* the request in an in-memory waiter list keyed by user or topic. On an event-loop server (§6.13) a parked request costs only memory, not a thread.
4. When an event for that user arrives from a broker, the server wakes the waiter and responds with the new items and cursor.
5. If no event arrives within T_{hold} (commonly 20–55 seconds), the server responds `204 No Content` or an empty list with the same cursor.
6. On any response the client immediately re-polls with the latest cursor (after a back-off delay if the response was an error).

Timeouts. T_{hold} must be shorter than every idle timeout on the path. The AWS Application Load Balancer's default idle timeout is 60 s and NGINX's `proxy_read_timeout` defaults to 60 s (as of 2024); corporate proxies may be shorter, so 25–30 s is a common safe choice. If an intermediary cuts the request first, the client sees an error instead of a clean empty response — and if it retries without backoff, an error storm.

Ordering and loss. Between response k and request k+1 there is a one-round-trip gap with no outstanding request. The cursor closes it: the server keeps a per-user buffer of recent events with monotonically increasing sequence numbers, and each request asks for "everything after c". Clients apply items in sequence order and discard duplicates (an event racing a timeout may be sent twice). Never run two concurrent long polls per client: responses can arrive out of order. A parked request also occupies one of the browser's roughly six HTTP/1.1 connections per origin [Loreto et al. 2011].

Architecture diagram

Figure 9.2 — Long polling with cursors and a hold timeout.



Reading the diagram. The poll server receives events asynchronously (open arrowheads) from a pub/sub broker. The first request parks and ends empty after the 30 s hold timeout; the second is answered the moment event 42 arrives — one network hop instead of $T/2$. Event 43 arrives while the client is re-polling; the cursor and the server-side buffer ensure nothing is lost. If the client reconnects to a *different* server, that server must answer "after 42", so the buffer must be shared or routing sticky (§9.9.4). Failure points: intermediaries that time out first, and in-memory buffers lost on restart. Capacity is planned in concurrent held connections.

Mathematical foundations

FORMULA

Long-polling request rate

With Poisson events at rate λ per client and hold timeout T_h, each request lasts $\min(T_h, X)$ where X is the time to the next event. Its mean is

$$E[\text{duration}] = \frac{1 - e^{-\lambda T_h}}{\lambda}, \qquad R = \frac{N}{E[\text{duration}]}, \qquad C_{\text{open}} \approx N$$

Symbol	Meaning	Units
λ	Average update rate per client	events/second
T_h	Server hold timeout	seconds
$E[\text{duration}]$	Mean lifetime of one long-poll request	seconds
N	Number of connected clients	clients
R	Request rate at the servers	requests/second
C_{open}	Concurrently open requests (Little's Law: $R \times E[\text{duration}]$)	requests

WORKED EXAMPLE

Worked example — The same 1 million users, now with long polling.

Use the numbers from §9.3: $N = 1,000,000$, $\lambda = 1/600$ events/s, and a hold timeout $T_h = 30$ s.

1. $\lambda T_h = 30/600 = 0.05$; $e^{-0.05} = 0.9512$.
2. $E[\text{duration}] = (1 - 0.9512)/(1/600) = 0.0488 \times 600 \approx 29.3$ s.
3. $R = 1,000,000/29.3 \approx 34,000$ requests/s, versus 200,000 requests/s for 5-second short polling — about **5.9× fewer** requests.
4. Average notification delay: about one network round trip (tens of milliseconds) instead of 2.5 s.
5. Concurrent open requests: $34,000 \times 29.3 \approx 1,000,000$ — every client holds one open request at all times.

Interpretation. Long polling improves both cost and latency, but it shifts the bottleneck from request throughput to *concurrent held connections*. 95 % of responses are still empty timeouts ($e^{-0.05}$), each carrying full HTTP headers.

Engineering implication. Long polling needs an asynchronous server that can park a million requests and an event-routing layer that wakes the right one — the same infrastructure as a WebSocket gateway (§9.9). Once you have built that, SSE or WebSockets usually deliver more for the same effort.

Real-world industry applications

INDUSTRY EXAMPLE

Universal fallback transports. Real-time libraries such as Socket.IO and SockJS offer long polling as a transport for networks where WebSockets are blocked by proxies or firewalls. Socket.IO's documentation notes that when HTTP long-polling is enabled with several server nodes, the load balancer must use sticky sessions, because successive polls of one session must reach the node that holds its state. *Evidence: Primary* — Socket.IO documentation, "Using multiple nodes" [Socket.IO Docs].

Advantages and disadvantages

- **Advantages:** near-instant delivery over plain HTTP; works through almost every proxy; client logic is simple; degrades to polling when events are frequent.
- **Disadvantages:** every message still carries full HTTP headers and costs a new request; a round-trip gap after each response (mitigated by cursors); holds a connection per client, so servers must be asynchronous; intermediary timeouts must be un-

derstood; occupies one of the browser's HTTP/1.1 connections per origin; strictly server-to-client (client-to-server messages need separate requests).

Alternatives and trade-offs

SSE (§9.5) gives the same reach for server-to-client data with one request for many messages and built-in resumption; WebSockets (§9.6) remove per-message HTTP overhead for bidirectional traffic. Long polling wins where streaming responses are broken — some antivirus products and corporate proxies buffer responses until they complete, which ruins SSE but leaves long polling intact.

Failure scenarios

Table 9.3 — Long-polling failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Requests cut off at 60 s with 504	Hold timeout exceeds a proxy or LB idle timeout	Spike in 504/502 at exactly the intermediary's timeout	Lower hold timeout	Keep hold timeout below the smallest idle timeout on the path
Lost events	Server buffers in memory and restarts; client lands on another node	Sequence gaps detected by client	Client resyncs with a full fetch	Shared event store or sticky routing plus resync-on-gap
Retry storm	Clients re-poll instantly after errors	Request rate jumps far above N/T_h	Shed with 503 + `Retry-After`	Exponential backoff with jitter on errors (§22.12)

Common misconceptions

> COMMON MISTAKE
>
> **"Long polling is just polling with a longer interval."** No — the interval is not a client timer at all. The *server* decides when to answer, so delivery latency is one hop, not $T/2$. What it shares with polling is the per-message HTTP cost and the reconnect after every response.

9.5 Server-Sent Events

9.5.1 What SSE is

> DEFINITION
>
> **Definition — Server-Sent Events (SSE).** A W3C/WHATWG-standardized mechanism in which a client opens one long-lived HTTP request and the server streams a sequence of UTF-8 text events down the response body using the `text/event-stream` format; browsers expose it through the `EventSource` API, which parses events and reconnects automatically, resuming from the last received event ID [WHATWG HTML §9.2].

First-principles explanation

Long polling is like ordering a newspaper one issue at a time: each issue arrives, and then you must place the next order. SSE is a newspaper subscription: you sign up once and issues keep arriving at your door. If you move house (the connection drops), you tell the newspaper "the last issue I received was number 1,042", and they send you everything from 1,043 onward.

Why does this exist?

Long polling wastes a full request per message. Many features need only server-to-client data: feeds, notifications, live scores, progress bars, and the token-by-token output of large language models (Chapter 73). SSE standardizes "keep the response open and keep writing", adds a tiny text framing, and builds reconnection and resumption into the browser.

How it works internally

1. The client creates `new EventSource("/events")` (optionally `{ withCredentials: true }` for cross-origin cookies). The browser sends `GET /events` with `Accept: text/event-stream`.
2. The server responds `200 OK` with `Content-Type: text/event-stream` and `Cache-Control: no-cache`, then **does not end the response**. It writes events as they occur.
3. Each event is a block of `field: value` lines terminated by a blank line. The fields are:
   - `data:` — the payload; several `data:` lines are joined with newline characters.
   - `event:` — an event type; the browser dispatches it to listeners registered with `addEventListener("<type>", …)`; without it the event fires `onmessage`.
   - `id:` — sets the stream's **last event ID**.
   - `retry:` — an integer in milliseconds; sets the reconnection delay.

    - A line beginning with `:` is a **comment**, ignored by the parser — servers send one every 15–30 seconds as a heartbeat to stop intermediaries from closing an idle connection.
4. If the connection drops because of a network error, the browser waits the reconnection time (initially an implementation-defined value of a few seconds, or whatever `retry:` set) and re-sends the request with a `Last-Event-ID` header containing the last `id:` it received. The server replays events after that ID from a buffer and then continues live.
5. The server can stop reconnection permanently by responding `204 No Content`. A response with a status other than 200, or a wrong `Content-Type`, makes the browser *fail* the connection rather than retry — so a load balancer returning `503` during an outage silently turns off auto-reconnect, and your application code must notice (`readyState === EventSource.CLOSED`) and recreate the `EventSource` with backoff.

A stream on the wire looks like this:

```
HTTP/1.1 200 OK
Content-Type: text/event-stream
Cache-Control: no-cache

retry: 5000

: heartbeat

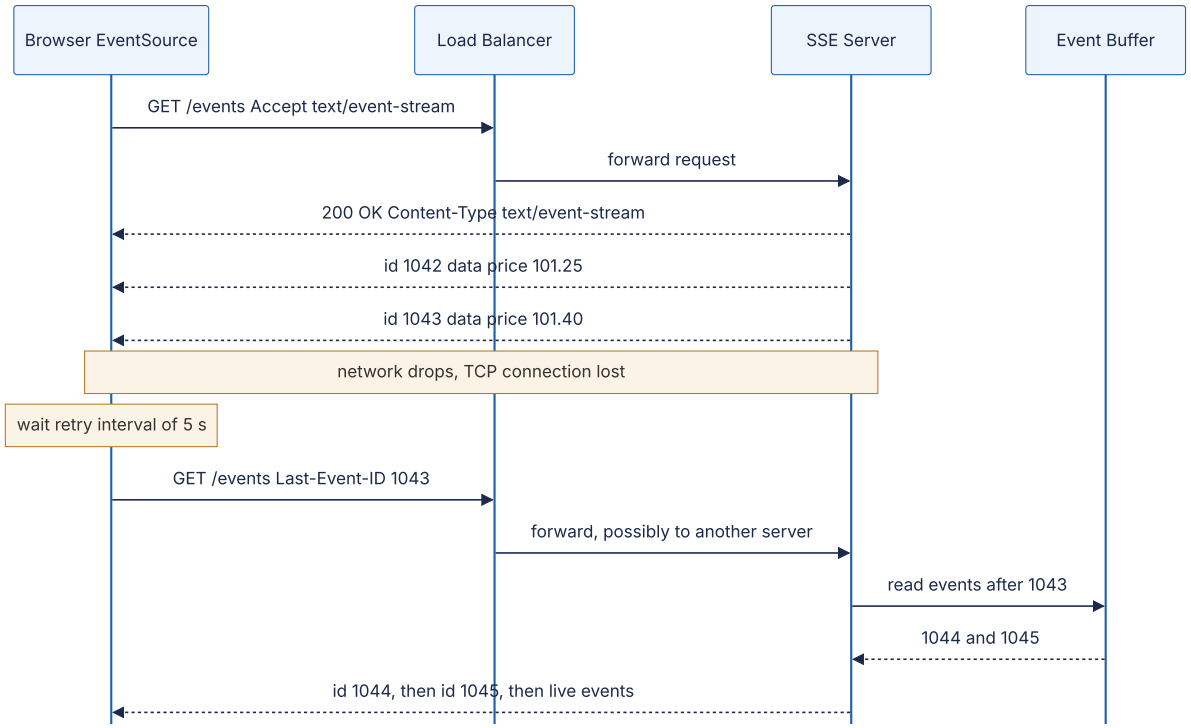
id: 1042
event: price
data: {"symbol":"ACME","price":101.25}

id: 1043
event: price
data: {"symbol":"ACME","price":101.40}
```

Interaction with HTTP versions. Over HTTP/1.1 each `EventSource` holds a whole TCP connection, and browsers allow only about six HTTP/1.1 connections per origin *across all tabs*, so a seventh tab can stall. Over HTTP/2 (§7.9) each stream is multiplexed on one shared connection, limited by the server's `SETTINGS_MAX_CONCURRENT_STREAMS` (commonly 100 or more), and a new stream needs no TCP or TLS handshake; the price is TCP head-of-line blocking across all streams, which HTTP/3 removes. Finally, reverse proxies that **buffer** responses (NGINX does by default) hold events back: disable buffering on stream routes (`proxy_buffering off;` or the header `X-Accel-Buffering: no`) and keep compression middleware off them.

Architecture diagram

Figure 9.3 — SSE streaming, disconnection and resumption with `Last-Event-ID`.



Reading the diagram. Every dashed arrow from the server is a chunk of the *same* streamed response. After a network failure the browser reconnects by itself with `Last-Event-ID`; the load balancer may pick a different server, which is why the event buffer (Redis Streams, Kafka, a replicated ring) lives outside the SSE server. Data flows only server-to-client; client actions use ordinary HTTP requests. Failure points: buffering proxies, idle timeouts on silent streams (fixed by heartbeat comments), and a buffer that no longer reaches back to the client's ID (force a full resync). SSE servers scale like the gateways in §9.9.

Code example

The following SSE endpoint uses only the Python standard library and has been run and tested with `curl -N`. It keeps a bounded history so that reconnecting clients resume from `Last-Event-ID`.

```
        """Minimal Server-Sent Events endpoint using only the standard library.

        Run:   python3 sse_server.py
        Test:  curl -N http://127.0.0.1:8080/events
               curl -N -H "Last-Event-ID: 3" http://127.0.0.1:8080/events
        """
        import asyncio
        import json
        import time

        HISTORY: list[tuple[int, str]] = []    # (event id, JSON payload) ring buffer
        HISTORY_LIMIT = 1000
        new_event = asyncio.Condition()

        async def producer() -> None:
            """Pretend to be a business event source: one price tick per second."""
            event_id = 0
            while True:
                await asyncio.sleep(1)
                event_id += 1
                payload = json.dumps({"symbol": "ACME", "price": 100 + event_id, "ts":
time.time()})
                async with new_event:
                    HISTORY.append((event_id, payload))
                    del HISTORY[:-HISTORY_LIMIT]          # keep the buffer bounded
                    new_event.notify_all()

        def format_event(event_id: int, data: str) -> bytes:
            return f"id: {event_id}\nevent: price\ndata: {data}\n\n".encode()

        async def handle(reader: asyncio.StreamReader, writer: asyncio.StreamWriter) ->
None:
            # 1. Read the request line and headers (no body for GET).
            request_line = await reader.readline()
            headers = {}
            while (line := await reader.readline()) not in (b"\r\n", b"\n", b""):
                name, _, value = line.decode().partition(":")
                headers[name.strip().lower()] = value.strip()
            if not request_line.startswith(b"GET /events"):
                writer.write(b"HTTP/1.1 404 Not Found\r\nContent-Length: 0\r\n\r\n")
                await writer.drain(); writer.close(); return

            # 2. Resume point: the browser sends Last-Event-ID automatically on recon-
nect.
            try:
                last_seen = int(headers.get("last-event-id", "0"))
            except ValueError:
                last_seen = 0

            writer.write(b"HTTP/1.1 200 OK\r\n"
                         b"Content-Type: text/event-stream\r\n"
                         b"Cache-Control: no-cache\r\n"
                         b"Connection: keep-alive\r\n\r\n"
                         b"retry: 5000\n\n")          # ask client to wait 5 s before
reconnecting
            try:
```

```
                while True:
                    # 3. Send everything newer than last_seen (replay, then live).
                    pending = [(i, d) for i, d in HISTORY if i > last_seen]
                    for event_id, data in pending:
                        writer.write(format_event(event_id, data))
                        last_seen = event_id
                    if not pending:
                        writer.write(b": keep-alive\n\n")   # comment line; defeats idle
timeouts
                    await writer.drain()                   # backpressure: wait if
socket buffer full
                    async with new_event:
                        try:
                            await asyncio.wait_for(new_event.wait(), timeout=15)
                        except asyncio.TimeoutError:
                            pass
            except (ConnectionResetError, BrokenPipeError):
                pass
            finally:
                writer.close()

        async def main() -> None:
            asyncio.create_task(producer())
            server = await asyncio.start_server(handle, "127.0.0.1", 8080)
            async with server:
                await server.serve_forever()

        if __name__ == "__main__":
            asyncio.run(main())
```

On the browser side, consuming this stream takes four lines:

```
const es = new EventSource("/events");
es.addEventListener("price", (e) => render(JSON.parse(e.data)));
es.onerror = () => { if (es.readyState === EventSource.CLOSED) scheduleRecreate(); };
// the browser reconnects by itself after network errors and sends Last-Event-ID
```

What to notice:

- The response never ends; the server writes `id:` / `event:` / `data:` blocks separated by blank lines. Curl started with `-H "Last-Event-ID: 2"` received events 3, 4, 5… — the replay-then-live behavior the browser gets for free.
- `await writer.drain()` is the backpressure point: if a client reads slowly, the coroutine pauses instead of letting the process buffer unbounded data (§9.6.7).
- The `: keep-alive` comment is invisible to `EventSource` but keeps proxies and load balancers from closing an idle connection.
- The in-memory `HISTORY` would be lost on restart and is not shared between servers; production systems put it in Redis Streams, Kafka or a database so any server can replay.

Real-world industry applications

INDUSTRY EXAMPLE

Streaming responses from large-language-model APIs. Several widely used LLM HTTP APIs stream generated tokens to clients as `text/event-stream` responses, because generation is strictly one-directional (server to client), each response is short-lived (seconds to minutes), and SSE passes through standard HTTP infrastructure, authentication and rate limiting unchanged. Chapter 73 discusses time to first token (TTFT) and inter-token latency (ITL), which is what this streaming exposes to users. *Evidence: Illustrative* — a widely observed pattern; consult each provider's API documentation for specifics.

Advantages and disadvantages

- **Advantages:** plain HTTP (works with existing auth, cookies, CORS, load balancers, HTTP/2 and HTTP/3); automatic reconnection and resumption built into browsers; tiny per-event framing (tens of bytes); simple to implement on any server that can flush a response; easy to debug with `curl -N`.
- **Disadvantages:** server-to-client only; UTF-8 text only (binary must be base64-encoded, +33 %); the standard `EventSource` cannot set custom request headers (use cookies, a short-lived token in the URL, or a `fetch`-based stream reader instead); HTTP/1.1 connection-per-origin limits; buffering proxies and compression can delay events; non-200 responses stop automatic reconnection.

Failure scenarios

Table 9.4 — SSE failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Events arrive in bursts minutes late	Reverse proxy or compression buffers the response	Server log timestamps vs. client receipt times diverge	Disable buffering on the route	`proxy_buffering off` / `X-Accel-Buffering: no`; no gzip on streams
Streams die every 60 s	Idle timeout on LB or proxy	Reconnect rate ≈ connections / 60 s	Send heartbeats	Comment line every 15–30 s, below every idle timeout
Clients never reconnect after outage	LB returned 502/503; `EventSource` fails permanently on non-200	Connected-client gauge drops and stays low	Application recreates `EventSource` with jittered backoff	Handle `readyState === CLOSED` in `onerror`
Seventh tab hangs	HTTP/1.1 six-connection limit per origin	Requests pending in browser dev tools	Close tabs	Serve SSE over HTTP/2; share one stream across tabs (`BroadcastChannel`, `SharedWorker`)

Common misconceptions

COMMON MISTAKE

"SSE is obsolete because WebSockets exist." SSE is the better tool for one-directional streams: it rides on ordinary HTTP (so HTTP/2 multiplexing, standard authentication and observability all apply), it resumes automatically, and it needs no special proxy configuration. Choose WebSockets when the *client* also sends frequent low-latency messages, or when you need binary frames.

9.6 WebSockets in depth

9.6.1 What a WebSocket is

DEFINITION

Definition — WebSocket. A protocol, standardized in RFC 6455 [Fette & Melnikov 2011], that starts as an HTTP/1.1 request, *upgrades* the underlying TCP connection, and thereafter carries a full-duplex sequence of framed messages in both directions with 2–14 bytes of framing overhead per frame. URLs use the schemes `ws://` (plain TCP, default port 80) and `wss://` (over TLS, default port 443).

First-principles explanation

HTTP is a postal system: every letter needs a full envelope, and the recipient can only reply, never write first. A WebSocket is a telephone call that begins with a short postal exchange — "may we switch to the telephone?", "yes" — after which either party speaks whenever it likes for a few bytes of overhead. Because the call starts as a letter, it passes through the same post offices (ports 80/443, HTTP proxies).

Why does this exist?

Before RFC 6455 (2011), bidirectional browser communication meant gluing a long poll (downstream) to separate POSTs (upstream), each carrying hundreds of bytes of headers. Games, collaborative editors, trading screens and chat needed many small messages per second both ways. RFC 6455 reuses HTTP's ports for the initial connection, keeps framing minimal, keeps the browser's origin-based security model, and avoids giving web pages a raw TCP socket that could attack other protocols.

9.6.2 The opening handshake

How it works internally

1. The client opens a TCP connection (and, for `wss://`, a TLS session) to the server.
2. It sends an HTTP/1.1 `GET` with these headers:
    - `Upgrade: websocket` and `Connection: Upgrade` — ask to switch protocols.
    - `Sec-WebSocket-Key:` — 16 random bytes, base64-encoded, fresh for each connection.
    - `Sec-WebSocket-Version: 13` — the only version in RFC 6455.
    - `Origin:` — set by browsers; the server must check it (see the security note below).
    - Optionally `Sec-WebSocket-Protocol:` (application subprotocols, for example `graphql-transport-ws` or `mqtt`) and `Sec-WebSocket-Extensions:` (for example `permessage-deflate`, RFC 7692).
3. The server validates the request and responds `HTTP/1.1 101 Switching Protocols` with `Upgrade: websocket`, `Connection: Upgrade` and **`Sec-WebSocket-Accept`**, computed as base64(SHA-1(key + `258EAFA5-E914-47DA-95CA-C5AB0DC85B11`)). That fixed GUID appears in RFC 6455; the computation proves that the server actually understood a WebSocket handshake (and was not, say, an unsuspecting HTTP server or cache replaying a response). It is not an authentication mechanism.
4. From the next byte onward, both sides speak the WebSocket framing protocol on the same TCP connection. HTTP is gone.

```
GET /chat HTTP/1.1
Host: server.example.com
Upgrade: websocket
Connection: Upgrade
Sec-WebSocket-Key: dGhlIHNhbXBsZSBub25jZQ==
Origin: https://example.com
Sec-WebSocket-Version: 13

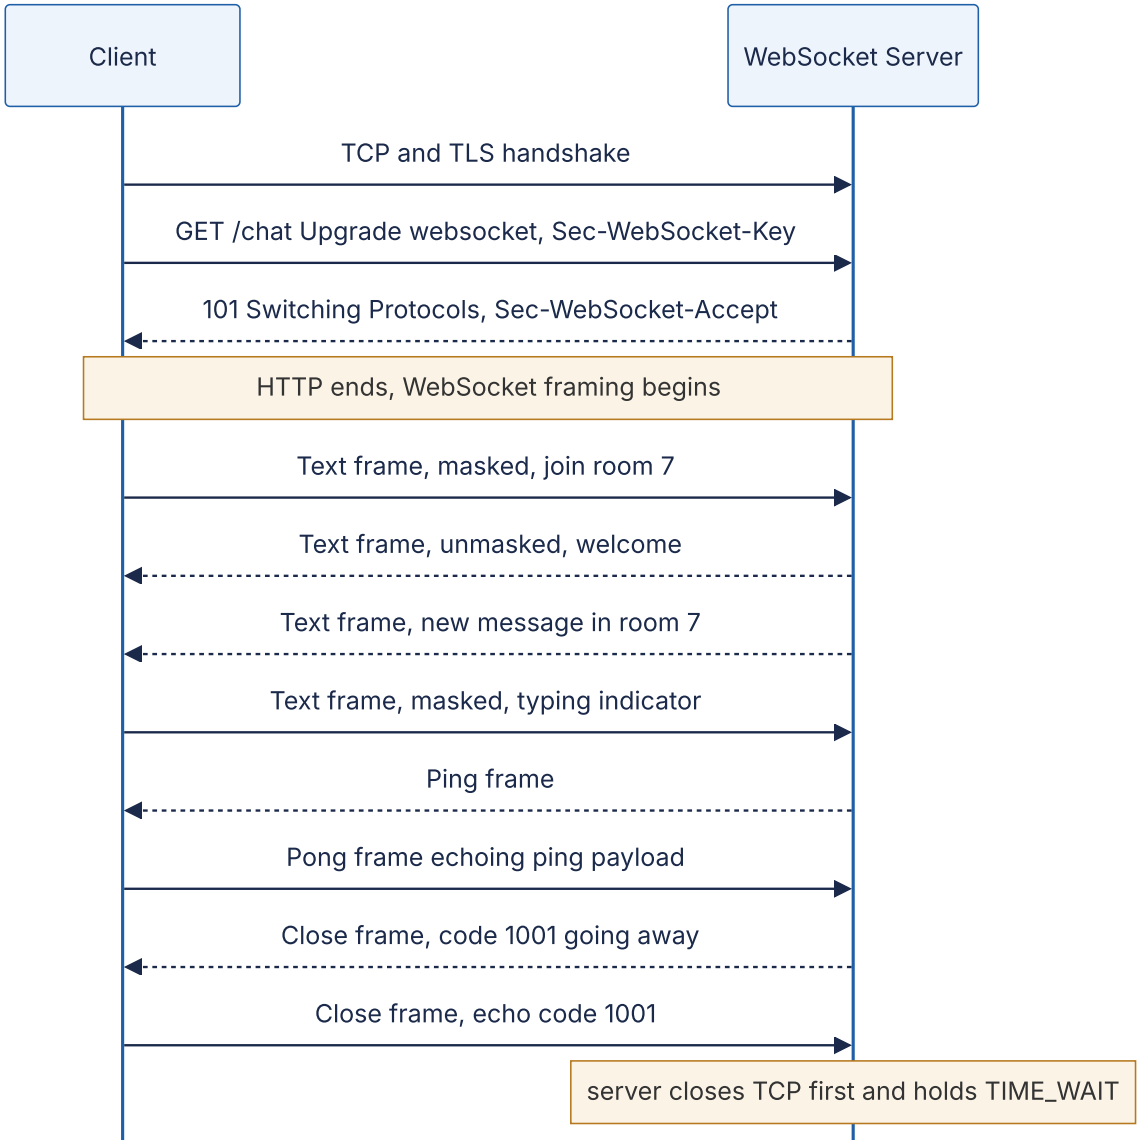
HTTP/1.1 101 Switching Protocols
Upgrade: websocket
Connection: Upgrade
Sec-WebSocket-Accept: s3pPLMBiTxaQ9kYGzzhZRbK+xOo=
```

WARNING / TRADE-OFF

Cross-Site WebSocket Hijacking. Browsers attach cookies to the WebSocket handshake but WebSockets are not subject to CORS. If your server authenticates the handshake by cookie and does not check `Origin` against an allow-list, any website the user visits can open an authenticated WebSocket to your service. Check `Origin`, or authenticate with a short-lived token sent in the first message or in the URL rather than relying on cookies alone.

HTTP/2 and HTTP/3. RFC 6455's `Upgrade` mechanism exists only in HTTP/1.1. RFC 8441 defines an "extended CONNECT" method that carries a WebSocket over a single HTTP/2 stream, and RFC 9220 does the same for HTTP/3; support across browsers, proxies and servers is uneven (as of 2024), so most deployments still run WebSockets over a dedicated HTTP/1.1-upgraded TCP connection.

Figure 9.4 — WebSocket opening handshake, message exchange, heartbeat and closing handshake.



Reading the diagram. One TCP connection carries the whole session. Only the upgrade request and the `101` response are HTTP; afterward frames flow independently in both directions — the server pushes a chat message unasked, the client sends a typing indicator without waiting. Client frames are masked, server frames are not (§9.6.4). Ping/Pong is a protocol-level liveness check. In the closing handshake each side sends one Close frame and the server closes TCP first, so `TIME_WAIT` (§7.7) accumulates on the server. Failure points: proxies that do not understand `Upgrade`, idle timeouts, and abrupt TCP loss with no Close frame (reported locally as 1006). The server is stateful for the connection's lifetime, which drives §9.9.

Code example

```
import base64
import hashlib

GUID = "258EAFA5-E914-47DA-95CA-C5AB0DC85B11"  # fixed by RFC 6455

def accept_key(sec_websocket_key: str) -> str:
    """Compute Sec-WebSocket-Accept from the client's Sec-WebSocket-Key."""
    digest = hashlib.sha1((sec_websocket_key + GUID).encode("ascii")).digest()
    return base64.b64encode(digest).decode("ascii")

print(accept_key("dGhlIHNhbXBsZSBub25jZQ=="))   # s3pPLMBiTxaQ9kYGzzhZRbK+xOo=
```

What to notice: the output matches the example in RFC 6455 exactly. SHA-1's known collision weaknesses do not matter here because the value is a protocol-confirmation nonce, not a security signature.

9.6.3 Frames

How it works internally

After the handshake, every message is sent as one or more **frames**. The header is at least 2 bytes:

Table 9.5 — WebSocket frame header fields (RFC 6455 §5.2).

Field	Size	Meaning
FIN	1 bit	1 = this is the final fragment of a message
RSV1–3	3 bits	Reserved for extensions (RSV1 marks a compressed message under `permessage-deflate`)
Opcode	4 bits	Frame type (Table 9.6)
MASK	1 bit	1 = payload is masked; must be 1 for client→server, 0 for server→client
Payload length	7 bits	0–125 = actual length; 126 = next 2 bytes hold length; 127 = next 8 bytes hold length
Extended length	0, 2 or 8 bytes	Present when length field is 126 or 127
Masking key	0 or 4 bytes	Present when MASK = 1
Payload	variable	Application data (after unmasking)

Table 9.6 — WebSocket opcodes.

Opcode	Type	Notes
0x0	Continuation	Subsequent fragment of a fragmented message
0x1	Text	Payload must be valid UTF-8
0x2	Binary	Arbitrary bytes (Protocol Buffers, MessagePack, media)
0x8	Close	Optional 2-byte status code + UTF-8 reason
0x9	Ping	Receiver must answer with a Pong carrying the same payload
0xA	Pong	Reply to Ping, or unsolicited one-way heartbeat

Control frames (Close, Ping, Pong) carry at most 125 bytes of payload, must not be fragmented, and may be injected *between* the fragments of a large data message — so a 100 MB upload does not delay a heartbeat. **Fragmentation** lets a sender stream a message of unknown length: the first frame has opcode Text or Binary with FIN = 0, middle frames use opcode Continuation, and the last frame sets FIN = 1. Note that WebSocket gives you *messages*, not a byte stream: the receiver's API delivers whole messages, which is one of its key conveniences over raw TCP.

Mathematical foundations

FORMULA

WebSocket framing overhead per frame

$$H = 2 + L_{\text{ext}} + 4m, \qquad L_{\text{ext}} = \begin{cases} 0 & n \le 125 \\ 2 & 126 \le n \le 65,535 \\ 8 & n \ge 65,536 \end{cases}$$

Symbol	Meaning	Units
H	Header bytes per frame	bytes
n	Payload length	bytes
L_{ext}	Extended-length bytes	bytes
m	1 if masked (client→server), 0 otherwise	dimensionless

WORKED EXAMPLE

Worked example — Sending a 60-byte chat message.

1. Server→client: $n = 60 \le 125$, unmasked → $H = 2$ bytes. Total 62 bytes, 3 % overhead.
2. Client→server: masked → $H = 2 + 4 = 6$ bytes. Total 66 bytes.
3. The same message as an HTTP/1.1 long-poll response would carry roughly 200–800 bytes of headers — 3× to 13× the payload.
4. TLS 1.3 with AES-GCM adds about 22 bytes per record (5-byte record header, 1-byte inner content type, 16-byte authentication tag), and TCP/IP adds 40+ bytes per packet, so for tiny messages the transport, not WebSocket, dominates.

Engineering implication. For high-frequency small messages (cursor positions, game state, typing indicators) WebSocket framing is close to free, which is why chat and multiplayer systems prefer it. To save more, batch several small updates into one frame every 50–100 ms.

Code example

The following encoder/decoder is runnable with the standard library and reproduces the byte layout from Table 9.5.

```
        import os
        import struct

        def encode_frame(payload: bytes, opcode: int = 0x1, mask: bool = True) -> bytes:
            """Build a single, unfragmented frame (FIN=1)."""
            first = 0x80 | opcode                       # FIN bit + opcode
            n = len(payload)
            mask_bit = 0x80 if mask else 0x00
            if n <= 125:
                header = struct.pack("!BB", first, mask_bit | n)
            elif n <= 0xFFFF:
                header = struct.pack("!BBH", first, mask_bit | 126, n)
            else:
                header = struct.pack("!BBQ", first, mask_bit | 127, n)
            if not mask:
                return header + payload
            key = os.urandom(4)                         # fresh masking key per frame
            masked = bytes(b ^ key[i % 4] for i, b in enumerate(payload))
            return header + key + masked

        def decode_frame(frame: bytes):
            """Parse one complete frame; return (fin, opcode, payload)."""
            b0, b1 = frame[0], frame[1]
            fin, opcode = bool(b0 & 0x80), b0 & 0x0F
            masked, n = bool(b1 & 0x80), b1 & 0x7F
            pos = 2
            if n == 126:
                (n,) = struct.unpack("!H", frame[pos:pos + 2]); pos += 2
            elif n == 127:
                (n,) = struct.unpack("!Q", frame[pos:pos + 8]); pos += 8
            key = b""
            if masked:
                key = frame[pos:pos + 4]; pos += 4
            data = frame[pos:pos + n]
            if masked:
                data = bytes(b ^ key[i % 4] for i, b in enumerate(data))
            return fin, opcode, data

        print(encode_frame(b"Hello", mask=False).hex(" "))  # 81 05 48 65 6c 6c 6f
        f = encode_frame(b"Hello")                          # 11 bytes: 2 header + 4
key + 5
        print(len(f), decode_frame(f))                      # 11 (True, 1, b'Hello')
```

What to notice:

- `0x81` = FIN (0x80) + Text opcode (0x1); `0x05` = unmasked, length 5. This is the unmasked "Hello" example given in RFC 6455 §5.7.
- A masked frame is 4 bytes longer, and the masked payload bytes look random on the wire even though the plaintext is "Hello".
- A 70,000-byte binary frame uses the 8-byte extended length: 2 + 8 + 4 = 14 header bytes (the maximum).

- Production libraries also validate UTF-8 in text frames, enforce maximum message sizes, reassemble fragments and reject unmasked client frames — never hand-roll this in production.

9.6.4 Masking: why the client scrambles its own data

Every client-to-server frame is XORed with a fresh, unpredictable 4-byte **masking key** chosen by the browser. Masking is *not* encryption — the key travels in the frame header in clear. It exists to protect **intermediaries**. Researchers showed that if a malicious script could choose the exact bytes a browser puts on the wire, it could craft WebSocket payloads that a confused transparent proxy would parse as a separate HTTP request, poisoning that proxy's cache for other users [Huang et al. 2011]. Because the script cannot predict the masking key, it cannot control the bytes that appear on the wire. RFC 6455 §10.3 explains this rationale. Server-to-client frames are not masked because the threat is script-controlled *upstream* bytes. Servers must close the connection (code 1002) if a client sends an unmasked frame.

9.6.5 Heartbeats (ping/pong) and the closing handshake

A TCP connection can die silently: a phone moves into a tunnel, a NAT device forgets its mapping after a few minutes of idleness, a load balancer reaps an idle flow. Neither endpoint is told. **Heartbeats** solve two problems at once: they *detect* dead peers (no pong within a deadline ⇒ close and clean up), and they *prevent* idle-timeout disconnections by keeping traffic flowing.

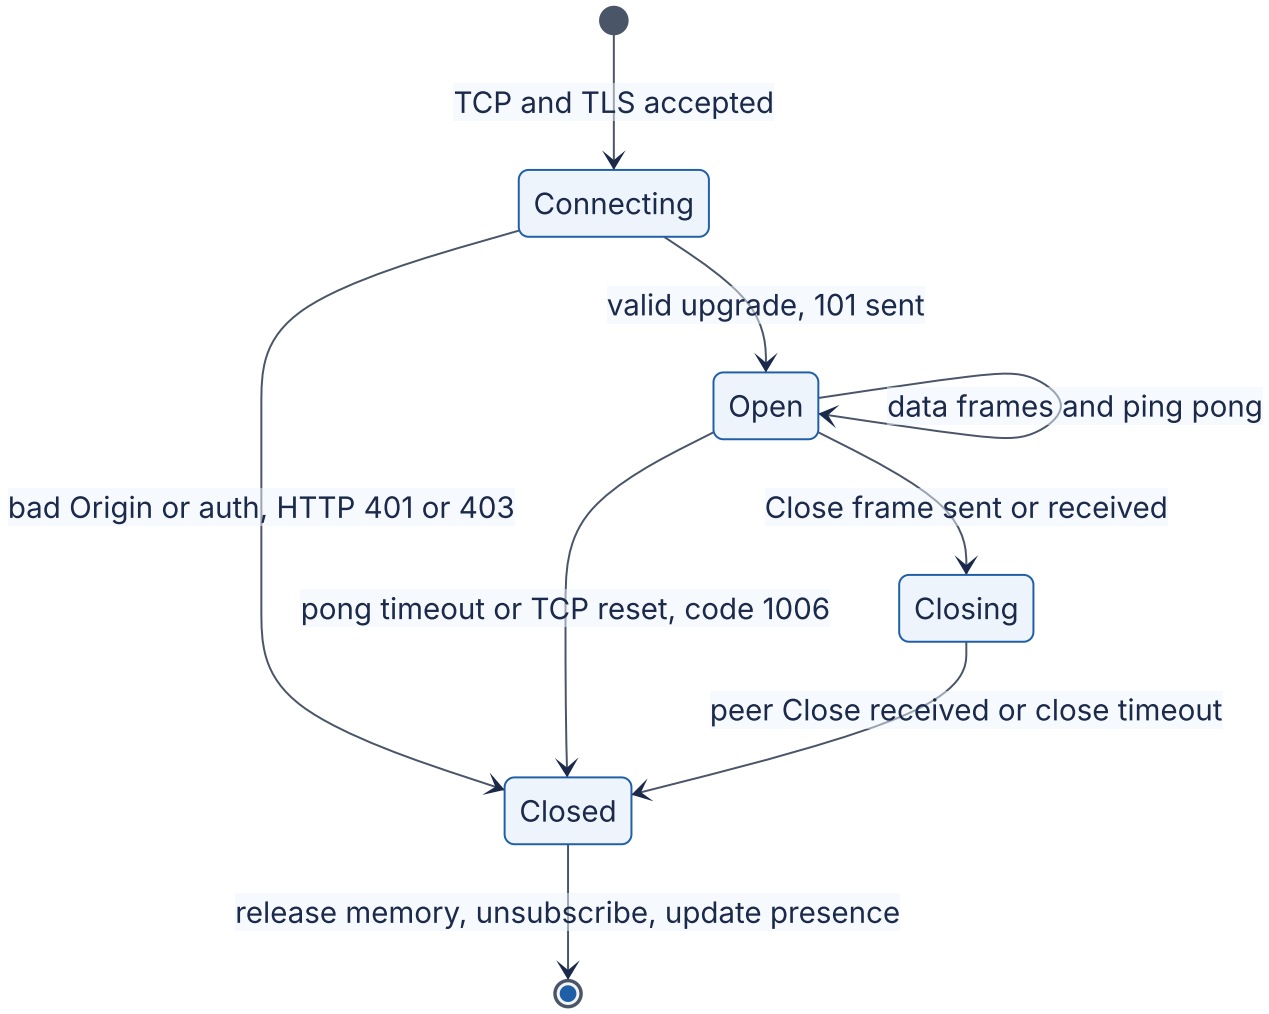
- The server sends a Ping every H seconds (commonly 20–30 s) and closes the connection if no Pong arrives within a timeout. Browsers answer Pings automatically.
- The browser `WebSocket` API does **not** let JavaScript send Pings, so client-side liveness detection needs an application-level heartbeat (for example, a `{"type":"ping"}` text message every 25 s and a "reconnect if nothing received for 60 s" rule).
- H must be smaller than the smallest idle timeout on the path (NAT, mobile carrier, load balancer).

Closing. Either side sends a Close frame with a status code; the other replies with a Close frame; then the TCP connection closes, ideally server first. The codes matter operationally because clients decide whether and how fast to reconnect based on them.

Table 9.7 — WebSocket close codes you will meet in practice.

Code	Name	Meaning and typical client reaction
1000	Normal closure	Purpose fulfilled; do not reconnect automatically
1001	Going away	Server shutting down or browser navigating away; reconnect with jitter
1002	Protocol error	Malformed frame; reconnect, report bug
1003	Unsupported data	For example binary sent to a text-only endpoint
1005	No status received	Reserved: reported locally when Close had no code; never sent
1006	Abnormal closure	Reserved: reported locally when TCP dropped without a Close frame; reconnect with backoff
1007	Invalid payload data	For example invalid UTF-8 in a text frame
1008	Policy violation	Generic rejection (auth failure, slow consumer); reconnect only after fixing cause
1009	Message too big	Exceeded server's maximum message size
1011	Internal error	Server-side failure; reconnect with backoff
1012	Service restart	IANA-registered (not in RFC 6455 text); reconnect with jitter
1013	Try again later	IANA-registered; overload — reconnect with longer backoff
4000–4999	Private use	Application-defined, for example 4001 "token expired"

Figure 9.5 — Lifecycle of a WebSocket connection as seen by a gateway.



Reading the diagram. Authentication and `Origin` checks belong in *Connecting*, before `101` — rejecting there is cheapest. *Open* loops on data and heartbeat frames. The orderly exit passes through *Closing*; heartbeat failure or TCP reset jumps straight to *Closed*. The exit action from *Closed* — unsubscribe from the backplane, update presence (§9.9) — is where leaks and "ghost online" bugs live. A close timeout of a few seconds stops an unresponsive peer from holding resources.

9.6.6 Proxies and load balancers

Long-lived, upgraded connections stress infrastructure built for short HTTP exchanges:

- **Hop-by-hop headers.** Proxies strip `Upgrade` and `Connection` unless configured otherwise; NGINX needs `proxy_http_version 1.1;`, `proxy_set_header Upgrade $http_upgrade;` and `proxy_set_header Connection "upgrade";`. Managed L7 load balancers generally support WebSockets natively.
- **Idle timeouts.** The 60 s defaults from §9.4 apply; keep heartbeats more frequent than the smallest timeout.

- **Use `wss://`.** Old transparent proxies and carrier middleboxes mangle unrecognized traffic on port 80 but cannot see inside TLS [Grigorik 2013].
- **L4 vs L7.** An L4 load balancer passes TCP through and scales to millions of flows; an L7 proxy terminates TLS and HTTP (path routing, central certificates) but holds two sockets per connection, and its upstream connections from one IP to one gateway IP:port are limited by the ephemeral port range (Linux default 32768–60999, about 28,000 ports) — add upstream IPs or ports beyond that.
- **Balancing happens only at connect time.** A newly added gateway gets no load until clients reconnect, so least-connections beats round robin (§19.4); deploys need draining (§9.9.7).

9.6.7 Backpressure

Backpressure is a slow receiver pushing back on a fast sender (§22.10). TCP provides it at the transport layer: when a receiver stops reading, the sender's kernel buffer fills and `await send()` stops completing. The danger is the layer above: a gateway fanning a room message out to 10,000 connections must queue data for the one client on a congested mobile link. Unbounded, a few hundred slow clients can exhaust memory and kill every healthy connection on the gateway. Browsers have the mirror problem: `WebSocket.send()` never blocks; it just grows `bufferedAmount`. Policies for a full per-connection queue:

1. **Disconnect the slow consumer** (close 1008 or an application code) and let it reconnect and resync from durable storage — simplest and safest; protects the gateway.
2. **Drop or coalesce** — for "latest value wins" data (prices, cursor positions, presence), keep only the newest value per key.
3. **Degrade** — switch the client to a lower update rate or a summary feed.

The chat server in Exercise 9.2 (§9.14) implements policy 1 with a bounded `asyncio.Queue` per connection.

Real-world industry applications

INDUSTRY EXAMPLE

Slack's real-time messaging. Slack's engineering blog describes clients holding WebSocket connections to stateful **Gateway Servers** (user information and channel subscriptions in memory), which subscribe to **Channel Servers** that own channels via consistent hashing; separate Presence Servers track who is online. A message goes to the owning Channel Server, which pushes it to every subscribed Gateway Server, which writes it to local sockets. A separate post describes migrating millions of concurrent WebSockets at the edge from HAProxy to Envoy, motivated largely by operational problems such as configuration reloads. *Evidence: Primary* — [Slack Engineering 2023]; [Slack Engineering 2021].

Advantages and disadvantages

- **Advantages:** full duplex with minimal per-message overhead (2–14 bytes); binary and text messages; message boundaries preserved; universal browser support; passes through ports 80/443.
- **Disadvantages:** stateful connections complicate load balancing, autoscaling and deploys; you must build heartbeats, reconnection, resumption, ordering and back-pressure yourself (none are in the protocol); bypasses HTTP-level caching, compression defaults and much of the HTTP observability tooling; security is easy to get wrong (Origin checks, message-size limits, authentication refresh on long sessions).

Failure scenarios

Table 9.8 — WebSocket failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Handshake fails with 400/426 behind proxy	Proxy strips `Upgrade` / `Connection`	101 rate ≈ 0 for one route	Fix proxy config	Configure WebSocket routes explicitly; integration test through the real proxy
"Ghost" connections	TCP peer vanished; no FIN received	Connection gauge grows, traffic per connection falls	Close on pong timeout	Server pings every 20–30 s with timeout
Gateway OOM	Unbounded per-connection send queues to slow clients	Memory rises with fan-out volume	Kill slow consumers	Bounded queues + slow-consumer policy
Reconnect storm after deploy	All connections on a node closed at once; clients retry immediately	Spike of handshakes and TLS CPU	Shed with 1013	Gradual drain + jittered backoff (§9.9.6–9.9.7)

Common misconceptions

COMMON MISTAKE

"TCP keepalive makes WebSocket heartbeats unnecessary." Linux TCP keepalive defaults to the first probe after 2 hours of idleness — far longer than NAT and load-balancer idle timeouts — and it is not visible to the application. Use WebSocket Ping/Pong (server side) and an application heartbeat (browser side).

9.7 WebRTC basics

9.7.1 What WebRTC is

DEFINITION

Definition — WebRTC. A set of IETF protocols (overview in RFC 8825 [Alvestrand 2021]) and a W3C browser API [W3C WebRTC] for real-time audio, video and arbitrary data directly between peers. Media travels over SRTP, data over SCTP data channels, both secured by DTLS, typically over UDP; peers discover a working network path using ICE with the help of STUN and TURN servers.

First-principles explanation

Everything so far routes through your servers. For a video call that is wasteful: two people in one city would send video to a data center and back. WebRTC lets browsers talk directly — but most devices sit behind **NAT** (§7.13), which drops unsolicited inbound packets. Think of two employees in different buildings whose receptionists only admit callers they have already phoned. They need a mutual friend to pass numbers (**signaling**), a way to learn the number the outside world sees (**STUN**), a trick of both calling at once so each receptionist expects the call (**ICE connectivity checks**, or hole punching), and as a last resort a switchboard that relays the call (**TURN**).

Why does this exist?

Conversation needs mouth-to-ear latency below roughly 150–200 ms and tolerates a little loss better than delay. TCP-based techniques retransmit lost packets and suffer head-of-line blocking — the wrong trade for live media. WebRTC gives browsers encrypted, congestion-controlled UDP media and data channels with NAT traversal built in.

How it works internally

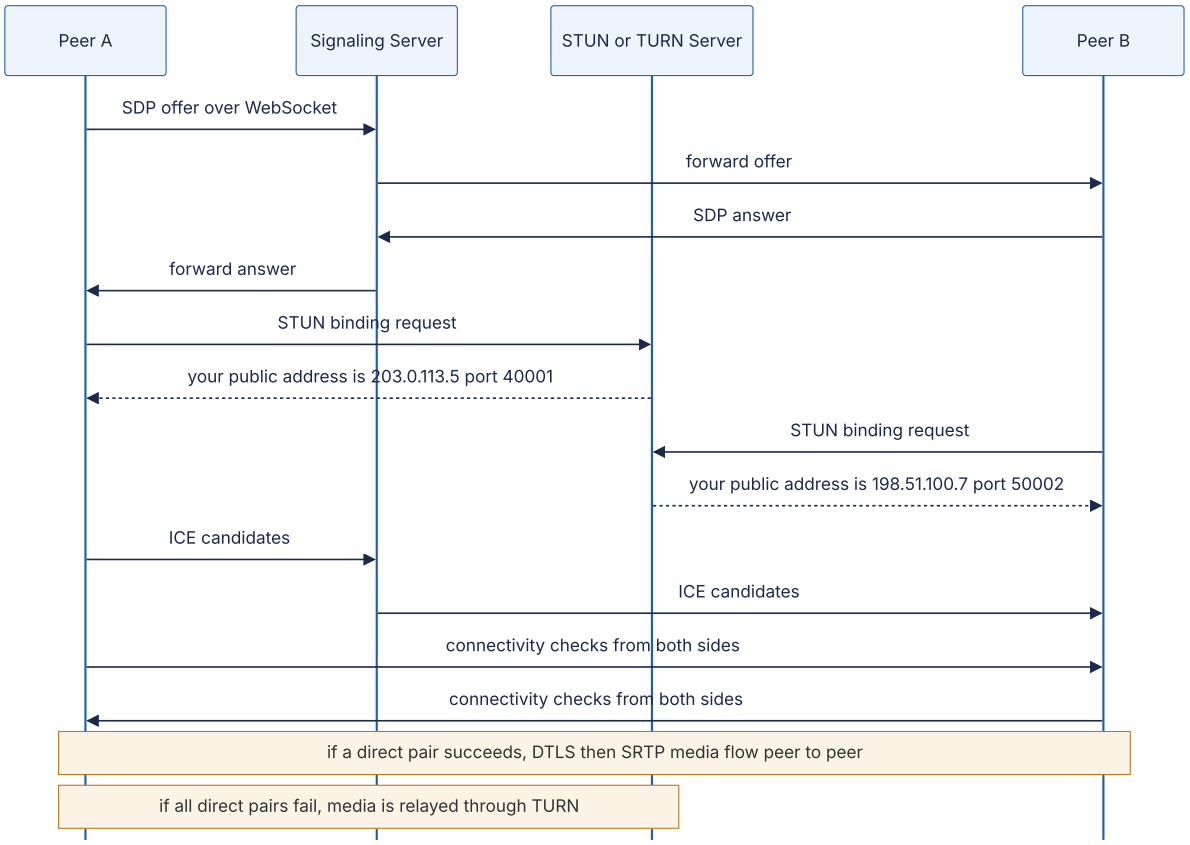
1. **Signaling (not specified by WebRTC).** Peers exchange session descriptions — **SDP offer** and **answer** listing codecs, encryption fingerprints and media streams —

through any channel you choose, commonly a WebSocket to your signaling server. The browser API that produces offers and answers is defined by JSEP [RFC 8829].

2. **Candidate gathering.** Each peer's ICE agent collects **candidates** (address:port pairs): *host* candidates (local interface addresses), *server-reflexive* candidates (the public address:port a **STUN** server reports seeing the request come from [RFC 8489]) and *relayed* candidates (an address allocated on a **TURN** relay server [RFC 8656]). Candidates are trickled to the other peer through signaling as they are found.
3. **Connectivity checks.** ICE [RFC 8445] pairs local and remote candidates, sends STUN binding requests on each pair simultaneously from both sides (punching holes through both NATs), and nominates the best pair that works, preferring direct paths over relayed ones.
4. **Security.** A DTLS handshake on the chosen path authenticates peers using the certificate fingerprints exchanged in SDP and derives keys for **SRTP** (media). Data channels run SCTP over DTLS. Encryption is mandatory.
5. **Media flow and adaptation.** Media flows peer to peer (or via TURN); congestion control and the codec adapt bitrate continuously; RTCP feedback reports loss and jitter.

When NATs allocate a new external port per destination (often called symmetric NAT) or firewalls block UDP, direct paths fail and traffic relays through TURN (over UDP, TCP or TLS on 443). TURN carries every media byte, so it is the most expensive component of a WebRTC deployment.

Figure 9.6 — WebRTC session establishment: signaling, STUN, ICE and TURN fallback.



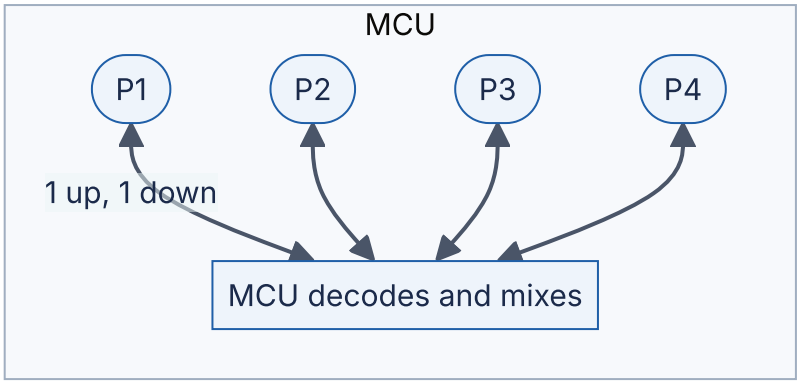
Reading the diagram. The signaling server is *your* service (often a WebSocket gateway) and relays only offers, answers and candidates over TCP — never media. The STUN server answers "what address do you appear to come from?" with one small UDP exchange. The peers then run simultaneous connectivity checks; if any direct pair works, encrypted media flows peer to peer over UDP and your infrastructure carries nothing. Otherwise TURN relays every media packet — the fallback path and the main cost driver, best deployed in several regions close to users.

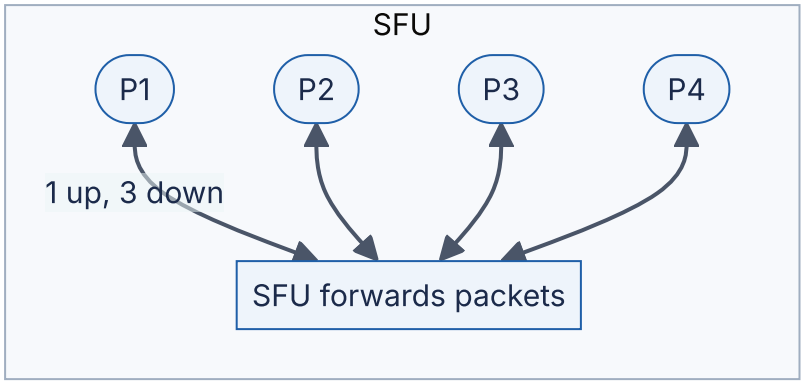
9.7.2 Group calls: mesh, SFU and MCU

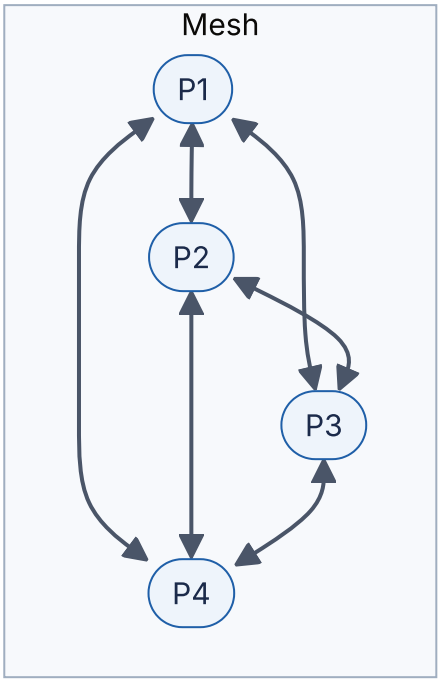
Peer-to-peer works for two people. For N participants there are three topologies:

- **Mesh** — every participant sends its stream to every other participant directly.
- **SFU (Selective Forwarding Unit)** — every participant sends one stream (often several resolutions at once, called **simulcast**) to a server, which *forwards* packets to each receiver without decoding them, choosing a resolution per receiver.
- **MCU (Multipoint Control Unit)** — the server *decodes* all streams, mixes them into one composite (a grid video, a mixed audio track), re-encodes and sends one stream to each participant.

Figure 9.7 — Mesh, SFU and MCU topologies for a four-person call.







Reading the diagram. In the mesh, each participant uploads three copies of its video, so home upstream bandwidth is the bottleneck. With an SFU, each participant uploads once and downloads three streams; the server only copies packets (cheap CPU, high bandwidth). With an MCU, each participant uploads and downloads one stream, but the server

decodes, mixes and re-encodes everything (expensive CPU, added latency, no end-to-end encryption). All arrows are asynchronous UDP media; signaling (not shown) runs through your WebSocket service.

FORMULA

Per-participant bandwidth by topology

Topology	Upload per participant	Download per participant	Server work
Mesh	$(N-1)\,b$	$(N-1)\,b$	none
SFU	b (or $\approx 1.5b$–$2b$ with simulcast)	$(N-1)\,b$ (less if receivers get lower layers)	forward $N(N-1)$ streams
MCU	b	b	decode N, mix, encode up to N

Symbol	Meaning	Units
N	Participants in the call	participants
b	Bitrate of one participant's stream	Mbit/s

WORKED EXAMPLE

Worked example — Six-person video call at 1.5 Mbit/s per stream.

1. Mesh upload per participant: $(6-1)\times 1.5 = 7.5$ Mbit/s. Many residential connections upload less than this, so the call degrades — mesh is practical for about 2–4 participants.
2. SFU upload: 1.5 Mbit/s (say 2.5 Mbit/s with three simulcast layers). Download: $5\times 1.5 = 7.5$ Mbit/s at full quality; with the SFU sending low layers for thumbnails and full quality only for the active speaker, perhaps $1.5 + 4\times 0.3 = 2.7$ Mbit/s.
3. SFU server egress for this one call: $6\times 7.5 = 45$ Mbit/s at full quality. A server with 10 Gbit/s of egress at 70 % target utilization carries about $7,000/45 \approx 155$ such calls — bandwidth, not CPU, is the SFU's limit.
4. MCU: each participant sends and receives 1.5 Mbit/s, but the server must decode six and encode up to six video streams per call — CPU-bound, typically far fewer calls per server than an SFU.

Engineering implication. Most modern group-video services use SFUs (often cascaded across regions) because they scale better per dollar and preserve per-receiver adaptation; MCUs survive for interop with legacy room systems and very weak clients.

Table 9.9 — Group-call topologies compared.

Aspect	Mesh	SFU	MCU
How it works	Every peer sends to every peer	Server forwards packets selectively	Server decodes, mixes, re-encodes
Advantages	No media servers; lowest latency for 2–3 people	Scales to large calls; per-receiver quality; cheap CPU	Minimal client bandwidth and CPU
Disadvantages	Upload grows with *N*	Download grows with *N*; server bandwidth heavy	Very high server CPU; extra latency; breaks end-to-end encryption
Choose when	1:1 or ≤ 4 people	Default for group calls and webinars	Legacy endpoints, recording composites, very weak clients

Failure scenarios and misconceptions

Table 9.10 — WebRTC failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Call never connects for some users	Symmetric NAT or UDP-blocking firewall; no TURN configured	ICE state `failed`; failures cluster by network	Retry with TURN over TCP/TLS 443	Always deploy TURN with TCP/TLS fallback
TURN bill explodes	Many sessions relay media	Relay bandwidth per session metric	—	Regional TURN, short-lived credentials, monitor relay ratio
Media freezes on network change	Wi-Fi → cellular changes the address	ICE disconnected	ICE restart via signaling	Handle `iceconnectionstatechange`; trigger ICE restart
Open TURN relay abused	Static TURN credentials leaked	Unknown traffic on relays	Rotate credentials	Time-limited, HMAC-derived TURN credentials per session

COMMON MISTAKE

“WebRTC means I don’t need servers.” You always need a signaling service, STUN, and — for reliable connectivity — TURN; group calls need SFUs. WebRTC removes servers from the *media path* only in the best case.

9.8 Mobile push: APNs and FCM

9.8.1 What mobile push is

> DEFINITION
>
> **Definition — Mobile push notification.** A message sent by an application's server to a platform-operated push service — Apple Push Notification service (**APNs**) for Apple platforms, Firebase Cloud Messaging (**FCM**) for Android (and optionally iOS and web) — which delivers it, on a best-effort basis, over a single persistent connection that the operating system maintains to that service on behalf of all apps.

Browsers have an analogous, standardized mechanism, Web Push [Thomson et al. 2016], in which a service worker receives messages relayed by the browser vendor's push service; the design principles below apply to it as well.

First-principles explanation

If every app kept its own background WebSocket, heartbeats would wake the cellular radio constantly and drain the battery in hours. So mobile operating systems suspend background apps and keep **one** connection to the platform push service, multiplexing every app's notifications over it — one mailroom for the whole apartment building. You hand your letter to the mailroom; it decides when to deliver, may combine or discard letters, and never sends a receipt.

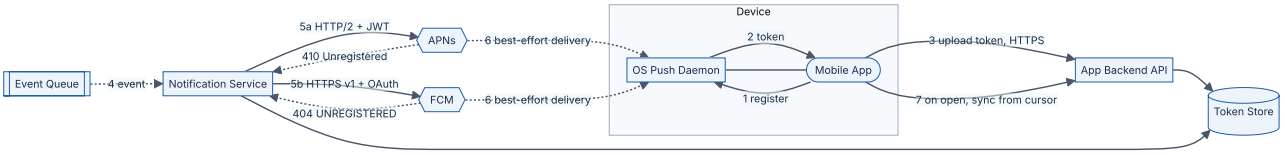
How it works internally

1. **Registration.** On launch, the app asks the OS for a push **token** (APNs device token, FCM registration token). The token identifies *this app on this device* to the push service.
2. **Token upload.** The app sends the token, with the user ID and a timestamp, to your backend, which stores it (a user typically has several tokens: phone, tablet, reinstalls).
3. **Send.** When an event occurs, your **notification service** (§52.7 designs one) looks up the user's tokens and calls the provider:
   - **APNs:** an HTTP/2 `POST /3/device/<token>` to `api.push.apple.com` (or `api.sandbox.push.apple.com` for development), authenticated by a JWT signed with your `.p8` key (token-based) or by a TLS client certificate. Headers include `apns-topic` (the app bundle ID), `apns-push-type` (`alert`, `background`, `voip`, …), `apns-priority` (10 = send immediately, 5 = send at a power-efficient time), `apns-expiration` and `apns-collapse-id` [Apple: Sending notification requests to APNs].

- **FCM:** an HTTPS `POST` `https://fcm.googleapis.com/v1/projects/<project>/messages:send` (the HTTP v1 API) with an OAuth 2.0 access token from a service account. The JSON body names the token (or a topic) and carries `notification` and/or `data` payloads plus platform options such as `android.collapse_key`, `android.ttl` and `android.priority` [FCM Docs].

4. **Store and forward.** If the device is offline, the provider stores the message for a limited time and delivers it when the device reconnects — with strict limits (below).
5. **Feedback.** The provider's response tells you whether the token is still valid. APNs returns HTTP 410 (`Unregistered`) for a token that is no longer active [Apple: Handling notification responses from APNs]; FCM returns `UNREGISTERED` (HTTP 404) or `INVALID_ARGUMENT` (HTTP 400). Delete or deactivate such tokens.

Figure 9.8 — Mobile push architecture.



Reading the diagram. The OS push daemon owns the device's single connection to the provider. Steps 1–3 obtain and upload the token over HTTPS into your token store. Events arrive asynchronously (dotted) at the notification service, which calls APNs or FCM synchronously. Provider-to-device delivery is asynchronous and best-effort — the dotted arrows mark where your guarantees end. Error responses (410/404) let the service prune dead tokens. Step 7 is the most important arrow: on open, the app syncs authoritative state with a cursor. Failure points: throttling, expired tokens, offline devices, OS suppression (Focus, battery saver). The notification service is a stateless worker pool scaled by send rate.

9.8.2 Delivery is not guaranteed — design for it

Push is a **hint**, never the source of truth:

- **Limited storage while offline.** APNs stores only the most recent notification per app for an offline device; sending a new one discards the stored one [Apple: Sending notification requests to APNs]. FCM stores up to 100 non-collapsible messages per device; past that it discards all of them and tells the app (on Android via a "deleted messages" callback) that it must sync with your server [FCM Docs: collapsible messages].
- **Expiry.** Messages older than their TTL (`apns-expiration`; FCM `ttl`, default and maximum 4 weeks) are dropped.
- **OS policy.** Low-priority and background ("silent") pushes may be delayed, batched or throttled by the OS to save power; Apple's guidance is to treat background notifi-

cations as low priority and to avoid sending more than a few per hour (as of 2024). Users can disable notifications entirely.
- **No delivery receipt.** A `200` from APNs or FCM means "accepted", not "displayed".

The robust pattern is **tickle, then fetch**: the push says "something changed" (optionally with display text), and the app, when opened or woken, fetches the authoritative state from your API since its last cursor — the same cursor idea as §9.4.

Collapse keys

When notifications about the same thing pile up — "3 new messages", "4 new messages" — only the latest matters. A **collapse key** tells the provider that a newer message *replaces* an older pending one. APNs uses the `apns-collapse-id` header (at most 64 bytes), and notifications sharing an ID are shown as one. FCM uses `collapse_key` and keeps at most **four** distinct collapse keys per device, with no guarantee which four survive [FCM Docs: collapsible messages]. Use collapse keys for state ("order status: shipped"), not for messages that each carry unique content.

Token lifecycle

Tokens change when users reinstall, restore a backup to a new device, clear app data, or when the platform rotates them. Rules of thumb (as of 2024–2025):

1. Fetch the token on every app start and upload it if changed, with a `last_seen` timestamp.
2. Delete tokens on `410` / `404 UNREGISTERED` responses immediately.
3. Expire tokens not refreshed for a period you choose; Google recommends treating tokens older than about one month as stale, and FCM itself treats Android tokens inactive for 270 days as expired [FCM Docs: token management].
4. Keep one row per (user, device, app) so that a user's ten old reinstall tokens do not each receive a copy.
5. Never put sensitive content in the payload when the lock screen could show it; payloads are limited to 4 KB (4,096 bytes) for regular notifications on both APNs and FCM.

Mathematical foundations

WORKED EXAMPLE

Worked example — Breaking-news push to 50 million devices.

Assume 50 million registered tokens, of which 8 % are stale (uninstalled apps), and you want delivery started within 5 minutes.

1. Required send rate: $50,000,000/300\ \text{s} \approx 167,000$ requests/s to APNs and FCM combined.
2. With HTTP/2 multiplexing, assume one worker connection sustains about 1,000 sends/s (an Illustrative figure; measure your own): $167,000/1,000 = 167$ concurrent provider connections across the worker fleet.
3. Wasted sends to stale tokens: $0.08 \times 50\ \text{M} = 4$ million requests, each returning 410/404 — prune them so that the next campaign is 8 % cheaper.
4. Return traffic: if 10 % of recipients open the app in the first minute and each open triggers a sync, your API sees $5,000,000/60 \approx 83,000$ extra requests/s. Stagger large sends, or put enough content in the payload that opening needs no immediate fetch.

Engineering implication. The bottleneck of a mass push is often *your own API* absorbing the return traffic, not the push provider.

Table 9.11 — APNs and FCM compared (as of 2024–2025).

Aspect	APNs	FCM
Platforms	iOS, iPadOS, macOS, watchOS, tvOS, Safari web push	Android; also iOS (via APNs) and web
Server API	HTTP/2, `POST /3/device/<token>`	HTTPS HTTP v1 `messages:send`
Authentication	JWT from `.p8` key, or TLS client certificate	OAuth 2.0 service-account access token
Max payload	4 KB (VoIP: 5 KB)	4 KB
Offline storage	Latest notification per app only	Up to 100 non-collapsible; 4 collapse keys
Collapse mechanism	`apns-collapse-id` (≤ 64 bytes)	`collapse_key`
Invalid-token signal	HTTP 410 `Unregistered`	`UNREGISTERED` (404)
Fan-out helpers	None (one request per token)	Topics and device groups

COMMON MISTAKE

"A 200 OK from APNs means the user saw the notification." It means APNs accepted the request. The device may be offline beyond the expiration, the notification may be replaced by a newer one, or the user may have disabled alerts. Track engagement through the app itself (for example, an "opened from notification" event), not through provider responses.

9.9 Connection management at scale

Sections 9.4–9.6 each ended with the same observation: once a server holds long-lived connections, it becomes *stateful*, and the problems shift from "how many requests per second?" to "how many connections, where are they, and what happens when they all move at once?". This section assembles the pieces into a production architecture.

9.9.1 Connection gateways

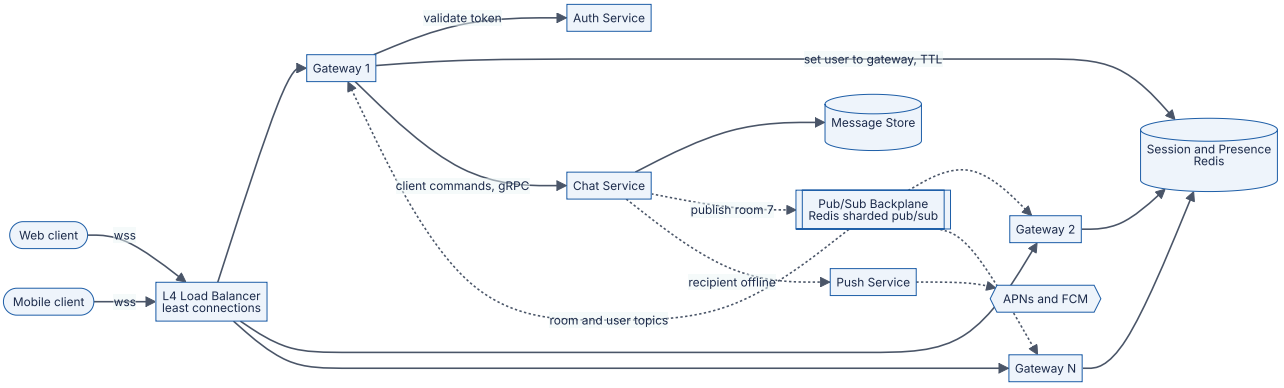
DEFINITION

Definition — Connection gateway. A dedicated, thin service tier whose only job is to terminate long-lived client connections (WebSocket, SSE, long polling), authenticate them, track which user and topics each connection belongs to, and move messages between those connections and back-end services through a messaging layer. It contains no business logic.

Why does this exist?

Put chat logic, feed ranking and the WebSocket server in one service, and every deploy of chat logic disconnects every user, every memory leak kills millions of connections, and CPU-based autoscaling adds instances that receive no connections until clients reconnect. Separating a **gateway tier** (stateful, memory-bound, simple, rarely deployed) from **business services** (stateless, CPU-bound, deployed many times a day) is the central design move of large real-time systems — an airport terminal that airlines can reschedule around without rebuilding it.

Figure 9.9 — Architecture of a connection gateway fleet.



Reading the diagram. Clients connect over `wss` through an L4 load balancer (least connections) and stay on the gateway they reach. On connect, the gateway validates the token and records "user → gateway" with a TTL in a Redis registry. Gateways subscribe to backplane topics for rooms with local members. A client message goes synchronously (gRPC) to the chat service, which persists it in the message store — the durable boundary — and *then* publishes it asynchronously (dotted); the backplane delivers only to subscribed gateways, which write to local sockets. Offline recipients go to the push service (§9.8). Failure points: a gateway crash drops its connections (clients reconnect and resync from the store); a backplane outage pauses live fan-out but loses no data; a registry outage breaks presence and targeted delivery. Gateways scale by connections, the chat service by request rate, the backplane by fan-out.

9.9.2 Memory per connection and capacity estimation

An idle connection consumes almost no CPU — on an event-loop server (§6.13), it is a file descriptor registered with `epoll` — so gateways are usually **memory-bound** and **blast-radius-bound** rather than CPU-bound. The C10K problem of the late 1990s [Kegel 1999] asked how to hold 10,000 connections on one server; modern kernels and runtimes routinely hold hundreds of thousands to millions.

Table 9.12 — Per-connection memory budget for a TLS WebSocket gateway (Illustrative assumptions; measure your own stack).

Component	Typical range	Assumed
Kernel socket structures, idle (buffers grow only while data is in flight)	2–10 KB	4 KB
TLS session state and record buffers (depends heavily on library and buffer-release settings)	5–40 KB	16 KB
Runtime task (goroutine stack, Erlang process, async task)	2–8 KB	4 KB
Application read/write buffers	4–16 KB	8 KB
Session state: user, auth claims, subscriptions, outbound queue	1–20 KB	8 KB
Total	**14–94 KB**	**40 KB**

Note the caveat in the first row: Linux autotunes socket buffers up to `tcp_rmem` / `tcp_wmem` maximums of several megabytes per socket. A burst of traffic to many slow clients can multiply kernel memory far above the idle figure; cap buffer maximums with `sysctl` and bound application queues (§9.6.7).

FORMULA

Gateway fleet sizing

$$n_{\text{conn,max}} = \min\left(\frac{f \cdot M}{m},\ c_{\text{blast}}\right) \qquad S = Z \cdot \left\lceil \frac{C}{(Z-1)\, n_{\text{conn,max}}} \right\rceil$$

Symbol	Meaning	Units
M	RAM per gateway server	bytes
f	Fraction of RAM budgeted for connections	dimensionless
m	Memory per connection	bytes/connection
c_{blast}	Maximum connections you accept losing in one server failure	connections
$n_{\text{conn,max}}$	Design ceiling of connections per server	connections
C	Peak concurrent connections	connections
Z	Availability zones; the fleet must survive loss of one	zones
S	Total gateway servers	servers

WORKED EXAMPLE

Worked example — 10 million concurrent connections.

Requirements: $C = 10,000,000$ concurrent WebSocket connections at peak; three availability zones ($Z = 3$); survive the loss of one zone; per-connection memory $m = 40$ KB from Table 9.12 (SI units: 1 KB = 1,000 bytes); servers with $M = 64$ GB RAM, of which $f = 50\,\%$ is budgeted for connections (the rest for the OS, runtime heap, garbage-collection headroom and traffic bursts).

1. **Memory limit per server:** 0.5×64 GB/40 KB $= 32 \times 10^9 / 40 \times 10^3 = 800,000$ connections.
2. **Blast-radius limit:** losing one server should disconnect at most about 5 % of users and produce a reconnect wave the rest of the fleet can absorb. Choose $c_{\text{blast}} = 500,000$. So $n_{\text{conn,max}} = \min(800,000, 500,000) = 500,000$.
3. **Zone-failure sizing:** after losing one zone, the remaining two must hold all 10 M: servers per zone $= \lceil 10,000,000/(2 \times 500,000) \rceil = 10$. Total $S = 3 \times 10 = 30$.
4. **Deploy and surge headroom:** during a rolling deploy one server per zone is draining, and traffic may exceed forecast by 10–20 %. Add two servers per zone: **36 servers (12 per zone)**.
5. **Normal load per server:** $10,000,000/36 \approx 278,000$ connections → $278,000 \times 40$ KB ≈ 11.1 GB of connection memory.
6. **After losing a zone:** $10,000,000/24 \approx 417,000$ connections per server → 16.7 GB — inside the 32 GB budget.
7. **Total connection memory:** $10,000,000 \times 40$ KB $= 400$ GB across the fleet.
8. **File descriptors:** each process needs more than 500,000 open files; set the `nofile` limit to about 1,000,000.
9. **Heartbeats:** with a 25 s ping interval, $10,000,000/25 = 400,000$ pings/s fleet-wide, about 11,000 per server — trivial CPU, but visible in packet-rate and NAT-table metrics.
10. **Message CPU:** if each connection receives on average one message every 10 s, a server at 278,000 connections sends about 27,800 frames/s plus 11,000 pongs/s to process — well within one multi-core server (Illustrative; benchmark with your payload size and TLS library).

Interpretation. Memory alone would allow about 13 servers (10 M/800 k); fault tolerance and blast radius nearly triple that. That is typical: connection fleets are sized by failure behavior, not by steady-state efficiency.

Engineering implication. Measure m on your real stack with a load generator holding idle TLS connections (resident memory ÷ connections), re-measure under message load, and state the blast-radius limit explicitly in the design document.

Real-world industry applications

INDUSTRY EXAMPLE

WhatsApp's per-server connection counts. In January 2012 WhatsApp's blog reported pushing a single server past 2 million concurrent TCP connections, following an earlier 1 million milestone; a contemporaneous Erlang Factory talk by Rick Reed described the Erlang/FreeBSD stack and the kernel and VM tuning involved. These figures show what a tuned stack *can* hold; production fleets generally run below such peaks to keep headroom for failures and deploys. *Evidence: Primary* — [WhatsApp 2012]; [Reed 2012].

INDUSTRY EXAMPLE

Discord's Elixir gateway. Discord's engineering blog describes scaling its Elixir/Erlang real-time system to nearly 5 million concurrent users, including fan-out problems in very large communities and bursts of reconnecting sessions overwhelming a few coordinating processes, plus libraries the team built in response (for example, Manifold to distribute message sending across nodes). *Evidence: Primary* — [Discord 2017].

9.9.3 Routing messages: registries and the pub/sub backplane

A message for room 7 is created by a chat service instance; its recipients' connections are scattered across 36 gateways. Two routing designs exist, and large systems use both:

1. **Topic-based pub/sub backplane.** Each gateway subscribes to `room:7` when its first local member of room 7 connects and unsubscribes when the last leaves; publishers send to `room:7` without knowing which gateways care. Redis Pub/Sub is the usual starting point: simple and sub-millisecond, but **fire-and-forget (at-most-once)** — a gateway whose subscription blips misses messages. In Redis Cluster, classic `PUBLISH` is broadcast to every node; **sharded pub/sub** (`SPUBLISH`/`SSUBSCRIBE`, Redis 7.0+) keeps a channel on the shard owning its hash slot [Redis Docs: Pub/Sub]. Kafka or NATS fit when you need replay or more throughput.
2. **Connection registry with direct routing.** A registry maps `user → (gateway, connection ID)`. For one-to-one messages the sender looks up the user's gateway(s) and calls them directly (gRPC). This avoids creating millions of per-user topics but needs a registry that is kept accurate as connections churn.

Because the live path is lossy, correctness comes from the durable path: every message gets a per-conversation **sequence number** in the message store; clients track the last sequence they have seen; on reconnect, or when they notice a gap, they fetch the missing

range over HTTPS. Live delivery is an optimization of latency; the store guarantees completeness. This is the same at-least-once-plus-deduplication pattern as §30.8.

FORMULA

Fan-out load

$$D = \mu \times \bar{r}$$

Symbol	Meaning	Units
D	Message deliveries written to sockets	deliveries/second
μ	Messages published	messages/second
$\bar{r}$	Average number of *online* recipients per message	recipients/message

WORKED EXAMPLE

Worked example — Fan-out for a team chat product.

At peak, users send $\mu = 50,000$ messages/s; the average channel has 40 members, 25 % online, so $\bar{r} = 10$ and $D = 500,000$ deliveries/s — about 13,900 socket writes/s per gateway across 36 gateways. But one announcement channel with 200,000 online members turns a single message into 200,000 deliveries. Large channels need posting rate limits and delivery once per *gateway* (each gateway then fans out locally), so the backplane carries 36 copies rather than 200,000.

9.9.4 Sticky routing and session resumption

A WebSocket is sticky by construction for its lifetime. The question is what happens on *reconnect*:

- **Stateless reconnect (preferred).** Any gateway can accept any user; everything needed to resume — subscriptions, last-seen sequence numbers — is rebuilt from the client's handshake and the shared registry. Load balancing is then simple least-connections.
- **Sticky reconnect.** The load balancer returns a user to the same gateway (consistent hashing on user ID or an affinity cookie, §19.6) so a per-connection buffer can be resumed without a store query — cheaper in the common case, but it breaks whenever the fleet resizes and concentrates hot users.

Long-polling and SSE fallbacks *require* stickiness, or shared state, because consecutive HTTP requests of one logical session must find the same buffer (§9.4).

9.9.5 Presence with heartbeats

Presence — the green dot — answers "is this user online right now?". The naïve design writes `online` on connect and `offline` on disconnect; it fails because disconnections are often silent (§9.6.5) and gateways crash without cleaning up. Robust presence uses **leases**:

1. On connect and on each heartbeat (every h = 30 s), the gateway writes `presence:user42 = gateway-7` with a TTL of about $3h$ = 90 s.
2. If heartbeats stop, the key expires and the user becomes offline within at most 90 s — no explicit cleanup needed after a crash.
3. A user with several devices is online if any device's lease is alive.
4. Status changes (online → offline, active → idle) are published to interested watchers through the backplane.

To cut write load, gateways refresh *batched* leases (one pipeline per second per gateway) or refresh a per-gateway liveness key and record users per gateway, so a dead gateway expires all its users at once.

> WORKED EXAMPLE
>
> **Worked example — Presence load for 10 million online users.**
>
> 1. Lease refresh writes with $h = 30$ s: $10,000,000/30 \approx 333,000$ writes/s — a sharded Redis cluster is required (several shards at an assumed 100,000+ simple operations/s each), or the per-gateway lease design above, which needs only 36 writes/s plus membership changes.
> 2. Status-change fan-out: if each user changes status every 10 minutes on average and 50 online contacts watch each user, $10,000,000 \times (1/600) \times 50 \approx 833,000$ presence deliveries/s — more than the chat messages themselves.
>
> **Engineering implication.** Presence is often the most expensive real-time feature. Common mitigations: deliver presence only for users currently visible on the watcher's screen (subscribe on view), coalesce rapid flaps (offline-then-online within a few seconds), and do not show live presence for very large groups.

9.9.6 Reconnect storms and jittered backoff

When a gateway dies, a load balancer fails over or a region recovers, hundreds of thousands of clients lose their connections at once. If all reconnect immediately, surviving gateways face a spike of TLS handshakes, the auth service a spike of token checks, and the message store a spike of resync queries; they time out, clients retry, and the storm sustains itself — the **thundering herd**. The fix is exponential backoff with **jitter** (§22.12, [Brooker 2015]).

FORMULA

Reconnect arrival rate with uniform jitter

$$\lambda_{\text{reconnect}} \approx \frac{n_{\text{lost}}}{W}$$

Symbol	Meaning	Units
$\lambda_{\text{reconnect}}$	Peak reconnect (handshake) rate	connections/second
n_{lost}	Connections dropped by the failure	connections
W	Width of the random delay window for the first reconnect attempt	seconds

WORKED EXAMPLE

Worked example — One gateway of 36 fails.

1. $n_{\text{lost}} = 278,000$ connections (from §9.9.2).
2. No jitter, everyone retries within about 1 s: $\lambda \approx 278,000$ handshakes/s, about 7,900 per surviving gateway, plus 278,000 auth checks/s and 278,000 resync queries/s — likely to overload auth and the store.
3. Uniform jitter over $W = 30$ s: $\lambda \approx 9,300$/s fleet-wide, about 265 per gateway — comfortably absorbed.
4. A simulation of 500,000 clients confirms the arithmetic: all in one second without jitter; a peak of about 16,900 per one-second bucket with a 30 s uniform window (expected $500,000/30 \approx 16,700$).

Engineering implication. Jitter turns a spike into a plateau. Add server-side protection too: a token-bucket admission limit on new handshakes per gateway, close code 1013 (“try again later”) with a server-suggested delay, and resumable sessions so a reconnect costs a delta fetch rather than a full resync.

```
        import random

        def full_jitter_delay(attempt: int, base: float = 1.0, cap: float = 60.0) ->
float:
            """'Full jitter': uniform in [0, min(cap, base * 2**attempt)] seconds."""
            return random.uniform(0, min(cap, base * (2 ** attempt)))

        # illustrative client loop
        # attempt = 0
        # while not connected:
        #     await asyncio.sleep(full_jitter_delay(attempt)); attempt += 1
        #     connected = await try_connect()      # reset attempt = 0 after a stable
minute
```

What to notice: clients that failed together spread out immediately and back off further if the outage persists; `cap` bounds the wait; reset the attempt counter only after a connection has stayed healthy for a while, or a server that accepts and immediately drops connections causes a tight retry loop.

9.9.7 Graceful drain on deploy

Deploying a gateway restarts the process that owns its connections. Doing it abruptly is a self-inflicted reconnect storm. A graceful **drain**:

1. **Stop new connections.** Fail the gateway's readiness check or deregister it from the load balancer; existing connections stay open.
2. **Close gradually.** Over a drain window D (for example, 5 minutes), close connections at a steady rate n/D — 278,000 / 300 s ≈ 930 per second — using close code 1012 (service restart) or 1001 (going away), or send an application "please reconnect" message with a randomized delay hint.
3. **Clients reconnect with jitter** and land on other gateways, because the load balancer no longer routes to this one.
4. **Clean up and exit.** Unsubscribe from the backplane, release presence leases, flush metrics, exit.
5. **Orchestrator settings.** Kubernetes gives a pod 30 seconds by default (`terminationGracePeriodSeconds`) between `SIGTERM` and `SIGKILL`; gateways need this raised to cover D, plus a `preStop` hook that starts the drain (§42.7).

Rolling 36 servers in batches of three (one per zone) with a 5-minute drain takes $12 \times 5 = 60$ minutes — another reason to keep business logic out of the gateway and deploy it rarely.

Failure scenarios

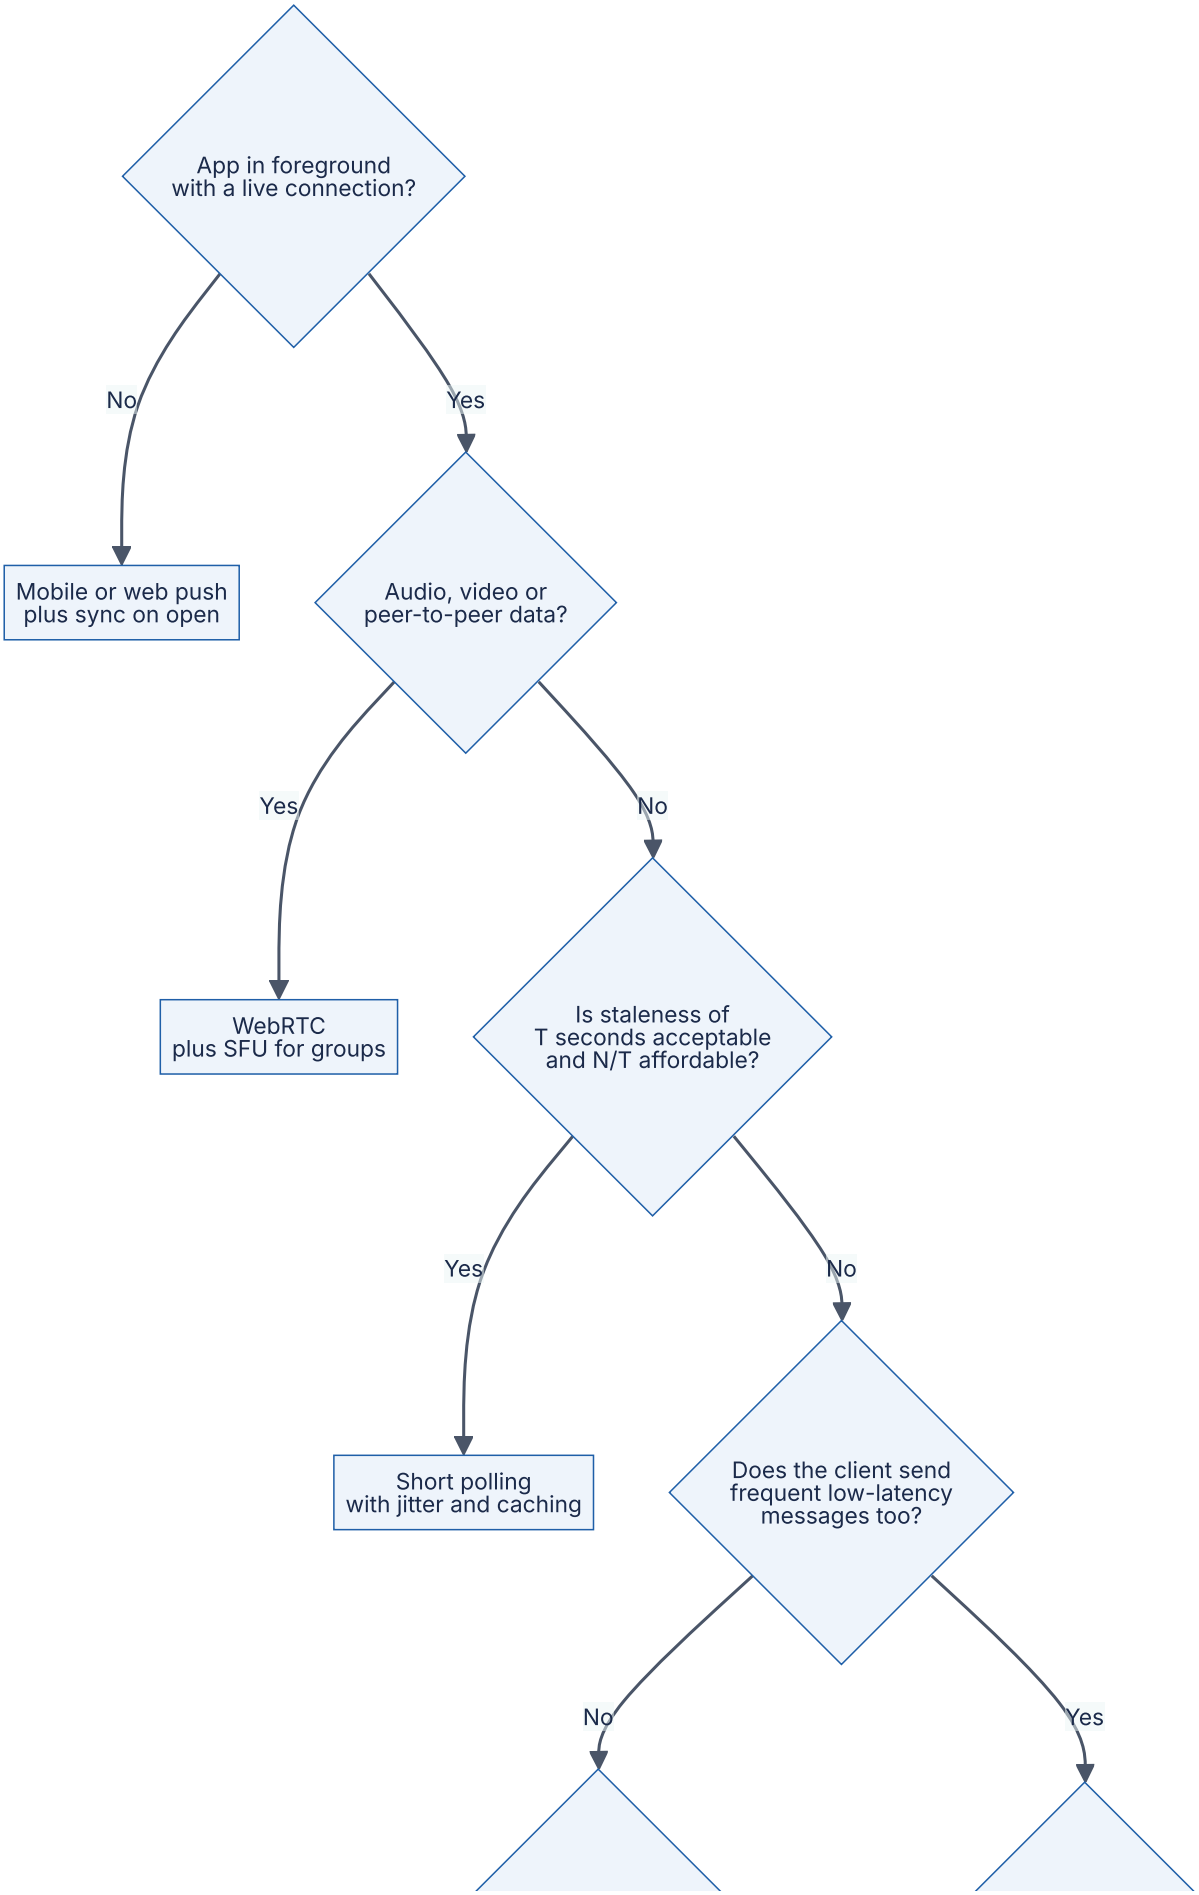
Table 9.13 — Connection-fleet failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Reconnect storm takes down auth	Mass disconnect, synchronized retries	Handshake rate and auth latency spike together	Admission control, 1013 with delay	Jittered backoff; cached token validation at gateway
New gateways sit idle after scale-out	Connections only rebalance on reconnect	Connection-count skew across gateways	Shed a few % of connections from hot gateways	Least-connections LB; periodic gentle rebalancing
Messages lost during backplane blip	Redis Pub/Sub is at-most-once	Clients detect sequence gaps	Client fetches missing range	Sequence numbers + durable store as source of truth
Users shown online for hours	Presence written on connect, never expired	Online count exceeds connection count	Expire stale entries	Lease with TTL refreshed by heartbeat

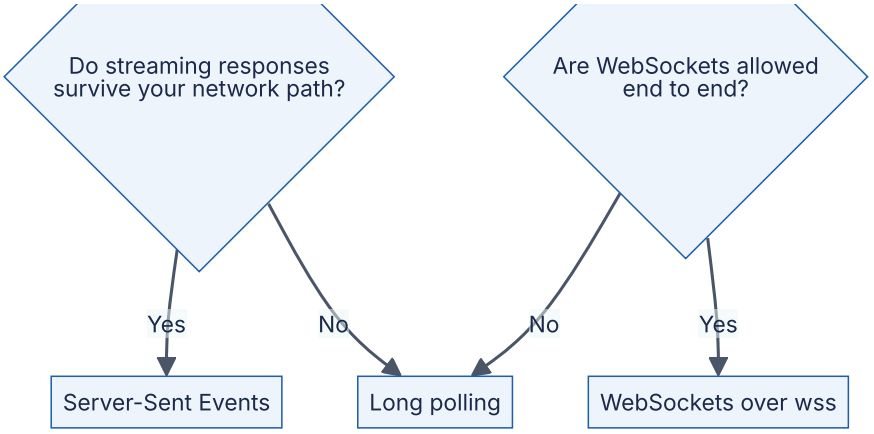
9.10 Choosing a real-time technique

No technique is best; each answers a different question. Work through the requirements in this order: *Is the app even running? Which direction does data flow? How fresh must it be? Is it media? What does the network allow?*

Figure 9.10 — Decision flowchart for choosing a real-time technique.



App in foreground with a live connection?
No
Yes
Mobile or web push plus sync on open
Audio, video or peer-to-peer data?
Yes
No
WebRTC plus SFU for groups
Is staleness of T seconds acceptable and N/T affordable?
Yes
No
Short polling with jitter and caching
Does the client send frequent low-latency messages too?
No
Yes



Reading the diagram. Diamonds are requirement questions; rectangles are recommended techniques. Only platform push can reach a suspended mobile app, so that split comes first; media goes to WebRTC regardless. For ordinary data, the cheapest technique that meets the freshness requirement wins; long polling is the fallback for hostile networks. Real systems combine branches: a chat app uses WebSockets in the foreground, push in the background, HTTPS for history and WebRTC for calls.

Table 9.14 — Real-time techniques compared.

Aspect	Short polling	Long polling	SSE	WebSockets	WebRTC	Mobile push
What it is	Periodic HTTP requests	Held HTTP request	Streamed HTTP response	Upgraded full-duplex TCP	P2P UDP media/data	OS-level provider delivery
Direction	Client pulls	Server → client	Server → client	Both	Both, peer to peer	Server → device
Latency	≈ T/2	≈ 1 RTT	≈ ½ RTT	≈ ½ RTT	Lowest; UDP	Seconds to never
Overhead per message	Full HTTP request	Full HTTP request	~10–50 bytes	2–14 bytes	RTP/SRTP headers	Provider API call
Server state	None	Parked request	Open stream	Open connection	Signaling + TURN/SFU	Token store
Infrastructure friendliness	Excellent	Good (timeouts)	Good (buffering)	Needs Upgrade + timeouts	NAT traversal, TURN	Provider-dependent
Resumption	Cursor	Cursor	Built in (`Last-Event-ID`)	Build your own	ICE restart	Collapse + sync
Operational complexity	Low	Medium	Medium	High	Very high	Medium
Cost driver	*N*/*T* requests	Concurrent connections	Concurrent connections	Concurrent connections + fan-out	TURN/SFU bandwidth	Send volume + return traffic
Use cases	Dashboards, job status	Fallback transport	Feeds, notifications, LLM token streams	Chat, collaboration, games, trading	Calls, screen share, P2P files	Background alerts
Choose when	Rare updates, few clients	Streaming blocked	One-way, HTTP-native	Two-way, high frequency	Real-time media	App not running

RECOMMENDATION

Default choices for common products. Notifications badge on a website: SSE (or short polling at 30–60 s if traffic is small). Chat and collaborative editing: WebSockets in the foreground, mobile push in the background, HTTPS sync for history. Live sports scores or stock tickers for millions of viewers: SSE or WebSockets fed from a CDN or edge fan-out tier, with “latest value wins” coalescing. Video meetings: WebRTC with an SFU, WebSockets for signaling. Ride-hailing driver location to a rider: WebSockets or SSE while the app is open, push for “driver arrived” when it is not.

INTERVIEW TIP

In an interview, state the requirement that drives the choice (“updates are server-to-client only and must survive reconnects, so SSE with `Last-Event-ID`”), then immediately address the scale consequence: how many concurrent connections, how many gateways, how messages reach the right gateway, and what happens on reconnect. Interviewers care far more about the connection-management design (§9.9) than about the name of the protocol.

9.11 Summary and revision notes

SUMMARY

- HTTP is client-initiated; every technique in this chapter is a way for the server to speak first, trading freshness against connection cost and infrastructure complexity.
- **Short polling:** $R = N/T$; average delay $T/2$; with rare events nearly every request is wasted ($P_{\text{empty}} = e^{-\lambda T}$). Fine for few clients or slow-changing data; jitter the timers.
- **Long polling:** the server holds the request until data or a hold timeout (keep it below every intermediary's idle timeout, e.g. 25–30 s); cursors prevent loss in the gap between polls; cost moves from requests to concurrent connections. Comet (2006) and RFC 6202 document it.
- **SSE:** one streamed `text/event-stream` response; fields `data`, `event`, `id`, `retry`, comments for heartbeats; browsers reconnect and send `Last-Event-ID`; server-to-client only; text only; prefer HTTP/2 to escape the ~6 connections-per-origin limit; disable proxy buffering.
- **WebSockets (RFC 6455):** HTTP/1.1 `Upgrade` handshake with `Sec-WebSocket-Accept` = base64(SHA-1(key + GUID)); frames with 2–14 byte headers; opcodes text, binary, continuation, close, ping, pong; client frames masked to protect intermediaries; heartbeats below idle timeouts; close codes guide reconnection; check `Origin`; bound send queues and disconnect slow consumers.
- **WebRTC:** signaling (yours) + ICE with STUN (discover public address) and TURN (relay fallback) + DTLS-SRTP media; mesh for ≤ 4, SFU for most group calls, MCU for weak or legacy clients.
- **Mobile push:** one OS-managed connection to APNs/FCM; best effort; APNs keeps only the latest notification per app when offline, FCM up to 100 messages and 4 collapse keys; 4 KB payloads; prune tokens on 410/404; push is a tickle — sync from your API with a cursor.
- **At scale:** thin, rarely deployed connection gateways; size by memory *and* blast radius *and* zone failure (10 M connections × 40 KB ≈ 400 GB; 36 servers of 64 GB in the worked example); route through a pub/sub backplane or connection registry; make the durable store with sequence numbers the source of truth; presence as TTL leases refreshed by heartbeats; jittered reconnects ($\lambda \approx n/W$); drain gradually on deploy.

9.12 Knowledge checkpoint

1. A site has 400,000 tabs open, each polling every 4 s. What request rate reaches the servers?

2. Why does long polling need a cursor, and what goes wrong without one?
3. Why should a long-poll hold timeout be 25–30 s rather than 120 s?
4. Name the four SSE fields and the purpose of a line that starts with a colon.
5. What header does a browser send when an `EventSource` reconnects, and what must the server do with it?
6. Why does SSE over HTTP/1.1 cause problems for users with many tabs, and how does HTTP/2 change this?
7. Compute `Sec-WebSocket-Accept` conceptually: what inputs and which functions?
8. What are the header sizes of an unmasked 100-byte frame and a masked 1,000-byte frame?
9. Why are client-to-server WebSocket frames masked and server-to-client frames not?
10. What is the difference between close codes 1000, 1001, 1006 and 1008?
11. Why can't browser JavaScript rely on WebSocket Ping frames for its own liveness detection?
12. What role do STUN and TURN each play in ICE, and which one carries media?
13. In a 5-person SFU call at 2 Mbit/s per stream, what is each participant's upload and full-quality download?
14. What does APNs do with notifications sent while a device is offline? What does FCM do?
15. Using the formula in §9.9.2, how many gateways are needed for 3 M connections with a 300 k per-server ceiling across 3 zones that must survive one zone failure?
16. Why are presence systems built on TTL leases rather than explicit "offline" writes?

Answers

1. $R = 400,000/4 = 100,000$ requests/s.
2. After each response there is a gap of about one round trip with no outstanding request; events in that gap would be lost unless the next request asks for "everything after cursor c" from a server-side buffer. The cursor also lets the client discard duplicates.
3. Proxies and load balancers commonly close idle requests at 60 s (for example, ALB and NGINX defaults); a hold longer than the smallest idle timeout produces errors instead of clean empty responses.
4. `data`, `event`, `id`, `retry`. A line starting with `:` is a comment, ignored by the client and used as a heartbeat to keep intermediaries from timing out the stream.
5. `Last-Event-ID`, containing the last `id:` received; the server replays events after it from a buffer (or signals a full resync if the buffer no longer reaches back that far).
6. Each SSE stream occupies one of roughly six HTTP/1.1 connections per origin shared across all tabs, so further tabs' requests stall. Over HTTP/2 streams are multiplexed on one connection, limited only by the negotiated maximum concurrent streams (commonly 100+).
7. Concatenate the client's `Sec-WebSocket-Key` with the fixed GUID `258EAFA5-E914-47DA-95CA-C5AB0DC85B11`, take SHA-1, base64-encode the 20-byte digest.

8. Unmasked 100 bytes: 2-byte header. Masked 1,000 bytes: 2 + 2 (extended length) + 4 (key) = 8 bytes.
9. Masking with an unpredictable key prevents a malicious script from choosing the exact bytes on the wire and thereby confusing intermediaries (cache poisoning). The attacker controls only browser (upstream) data, so only client frames are masked.
10. 1000 normal closure (done; do not auto-reconnect); 1001 going away (server shutdown or navigation; reconnect with jitter); 1006 abnormal closure, never sent, reported locally when TCP died without a Close frame; 1008 policy violation (for example auth failure or slow consumer).
11. The browser `WebSocket` API exposes no method to send Pings or observe Pongs; browsers answer server Pings automatically. Client-side liveness requires an application-level heartbeat message.
12. STUN tells a peer the public address and port its NAT presents (server-reflexive candidate); TURN allocates a relay address and forwards traffic when no direct path works. Only TURN carries media.
13. Upload 2 Mbit/s (more with simulcast); download $(5-1)\times 2 = 8$ Mbit/s.
14. APNs stores only the most recent notification per app and discards older ones. FCM stores up to 100 non-collapsible messages (beyond that it drops them all and signals the app to sync) and at most four collapse keys; both drop messages past their expiry/TTL.
15. Per zone $\lceil 3,000,000/(2\times 300,000)\rceil = 5$; total $3\times 5 = 15$ servers, plus deploy/surge headroom (for example 18).
16. Disconnections are often silent and gateways can crash; a lease that must be refreshed by heartbeats expires automatically, so presence converges to correct without relying on cleanup code that may never run.

9.13 Interview questions

Basic

Q1. What is the difference between short polling, long polling and WebSockets?

Answer. Short polling sends a request every T seconds and gets an immediate (often empty) answer: simple, stateless, average delay $T/2$, cost N/T requests/s. Long polling sends a request that the server holds until data arrives or a timeout fires, then the client re-requests: near-instant delivery over plain HTTP, but a full HTTP exchange per message and one held connection per client. WebSockets upgrade one HTTP/1.1 connection into a persistent full-duplex channel with 2–14 bytes of framing per message: lowest overhead and bidirectional, but stateful, requiring heartbeats, reconnection logic and proxy/load-balancer configuration.

Q2. When would you choose Server-Sent Events over WebSockets?

Answer. When data flows only from server to client (notifications, feeds, live scores, LLM token streams) and you want to stay on plain HTTP. SSE gets HTTP/2 multiplexing, standard authentication, cookies and observability for free; browsers reconnect automatically and resume with `Last-Event-ID`. Choose WebSockets when the client also sends frequent low-latency messages or when you need binary frames.

Intermediate

Q3. Users report that WebSocket connections drop every 60 seconds in production but not locally. Diagnose.

Answer. Exactly-periodic drops point to an idle timeout on an intermediary — commonly a load balancer or reverse proxy with a 60 s default — closing connections that carried no traffic. Confirm by correlating close times with connection-open times and checking close codes (1006 on the client indicates TCP loss without a Close frame). Fix by sending server Pings (or application heartbeats) every 20–30 s, below the smallest idle timeout, and optionally raising the timeout on WebSocket routes. Also verify that the proxy forwards `Upgrade` / `Connection` correctly and that heartbeats are not suppressed by client backgrounding on mobile.

Q4. Design delivery of a chat message to recipients connected to different gateway servers.

Answer. The sender’s gateway forwards the message to a chat service, which assigns a per-conversation sequence number and persists it (source of truth). The service then publishes to the conversation’s topic on a pub/sub backplane (for example, Redis sharded pub/sub); every gateway with at least one local member is subscribed and writes the message to its local sockets. Recipients without a live connection get an APNs/FCM push with a collapse key. Because the backplane is at-most-once, clients track the last sequence number seen and fetch missing ranges over HTTPS on reconnect or gap detection; deduplicate by sequence number. Discuss large-room fan-out (deliver once per gateway, rate limits) and backpressure (bounded per-connection queues).

Advanced

Q5. Size a gateway fleet for 10 million concurrent connections and explain how you would deploy it without disrupting users.

Answer. Measure memory per idle TLS WebSocket (assume 40 KB) → 400 GB total. On 64 GB servers with 50 % budgeted, memory allows 800 k per server, but cap at a blast-radius limit such as 500 k. To survive losing one of three zones, each zone needs $\lceil 10\text{M}/(2\times 500\text{k})\rceil = 10$ servers → 30, plus deploy/surge headroom → 36 (≈ 278 k each, ≈ 11

GB). Raise file-descriptor limits to ~1 M. Heartbeats at 25 s → 400 k pings/s fleet-wide. For deploys: keep the gateway thin so it rarely changes; drain one server per zone at a time — remove from the load balancer, close connections gradually over ~5 minutes with code 1012, clients reconnect with full-jitter backoff, then exit; raise `terminationGracePeriodSeconds` accordingly. Protect dependencies with admission control on handshakes and cached token validation.

Q6. A gateway crash causes a cascading outage of your auth service. What happened and how do you prevent it?

Answer. A reconnect storm: hundreds of thousands of clients reconnected within a second, each requiring a TLS handshake and a token validation; the auth service saturated, handshakes timed out, clients retried immediately, and the load became self-sustaining — possibly spreading to other gateways and the message store via resync queries. Prevention: client-side exponential backoff with full jitter (spreading n reconnects over a window W gives $\lambda \approx n/W$); server-side admission control (token bucket on new handshakes, close 1013 with a retry hint); validate signed tokens locally at the gateway instead of calling auth on every connect; resumable sessions so a reconnect costs a small delta fetch; smaller per-gateway connection counts to limit blast radius; load-test failure of a gateway at peak.

9.14 Practical exercises

Exercise 9.1 — SSE endpoint with resumption. Run the standard-library SSE server from §9.5. (a) Connect with `curl -N http://127.0.0.1:8080/events`, disconnect after five events, and reconnect with `-H "Last-Event-ID: 5"`; confirm no events are lost or duplicated. (b) Write a small HTML page using `EventSource` and watch the browser reconnect automatically when you restart the server. (c) Replace the in-memory `HISTORY` with a Redis Stream (`XADD` / `XRANGE`) so two server processes behind a proxy can both resume a client. (d) Put NGINX in front with default settings and observe buffering; then fix it with `proxy_buffering off`.

Exercise 9.2 — WebSocket chat server with heartbeats and backpressure. The following server uses the `websockets` library (`pip install "websockets>=13"`; tested with version 17.3 on Python 3.13). It supports rooms, server Pings every 20 s, a maximum message size, and a bounded outbox per client that disconnects slow consumers with close code 1008.

```
        """Room-based WebSocket chat server with heartbeats and slow-consumer protec-
tion."""
        import asyncio
        import json

        from websockets.asyncio.server import serve, ServerConnection
        from websockets.exceptions import ConnectionClosed

        OUTBOX_LIMIT = 100                          # max queued messages per client
        rooms: dict[str, set["Client"]] = {}

        class Client:
            def __init__(self, ws: ServerConnection, room: str, name: str):
                self.ws, self.room, self.name = ws, room, name
                self.outbox: asyncio.Queue[str] = asyncio.Queue(maxsize=OUTBOX_LIMIT)

            def offer(self, message: str) -> None:
                """Non-blocking enqueue; a full outbox means a slow consumer."""
                try:
                    self.outbox.put_nowait(message)
                except asyncio.QueueFull:
                    # Policy: disconnect slow consumers rather than buffer without
limit.
                    asyncio.ensure_future(self.ws.close(code=1008, reason="slow con-
sumer"))

            async def writer(self) -> None:
                while True:
                    message = await self.outbox.get()
                    await self.ws.send(message)    # awaits if the TCP send buffer is
full

        def publish(room: str, sender: str, text: str) -> None:
            message = json.dumps({"room": room, "from": sender, "text": text})
            for client in list(rooms.get(room, ())):
                client.offer(message)

        async def handler(ws: ServerConnection) -> None:
            # First message must be a join: {"room": "...", "name": "..."}
            try:
                hello = json.loads(await asyncio.wait_for(ws.recv(), timeout=10))
                room, name = str(hello["room"]), str(hello["name"])
            except (asyncio.TimeoutError, ValueError, KeyError, TypeError):
                await ws.close(code=1008, reason="expected join message")
                return

            client = Client(ws, room, name)
            rooms.setdefault(room, set()).add(client)
            writer_task = asyncio.create_task(client.writer())
            publish(room, "system", f"{name} joined")
            try:
                async for raw in ws:                        # reader loop
                    if isinstance(raw, str) and len(raw) <= 4096:
                        publish(room, name, raw)
            except ConnectionClosed:
                pass
```

```
            finally:
                writer_task.cancel()
                rooms[room].discard(client)
                if not rooms[room]:
                    del rooms[room]
                publish(room, "system", f"{name} left")

        async def main() -> None:
            # Ping every 20 s; close if no Pong within 20 s (detects dead TCP peers).
            async with serve(handler, "127.0.0.1", 8765,
                             ping_interval=20, ping_timeout=20,
                             max_size=64 * 1024) as server:
                await server.serve_forever()

        if __name__ == "__main__":
            asyncio.run(main())
```

What to notice:

- Each connection has two tasks: the handler's reader loop and a writer draining a bounded queue. Fan-out (`publish`) never awaits, so one slow socket cannot stall delivery to the rest of the room.
- When a client's outbox fills, the server closes it with 1008; in testing, a client that stopped reading while another flooded the room was disconnected with `1008 slow consumer` while the server stayed healthy.
- The `finally` block is the cleanup path from Figure 9.5: unsubscribe and announce departure regardless of how the connection ended.
- `max_size` bounds memory per inbound message (oversized messages are closed with 1009).

Tasks: (a) write a client with `websockets.asyncio.client.connect` that joins a room and prints messages; (b) add per-room sequence numbers and a `{"type":"resume","after":N}` message backed by a bounded history; (c) run two server processes and connect them with Redis Pub/Sub so rooms span processes; (d) add a client reconnect loop using `full_jitter_delay` from §9.9.6 and kill the server to watch the reconnect spread.

Exercise 9.3 — Measure memory per connection. Using Exercise 9.2's server, open 10,000 idle connections from a load generator (raise `ulimit -n` first), record the server's resident memory before and after, and compute KB per connection. Repeat with `wss://` (TLS) and compare against Table 9.12.

Exercise 9.4 — Capacity spreadsheet. Implement the formulas from §9.3, §9.4 and §9.9 in a script that takes N, T, λ, m, M, f, Z and c_{blast} and prints request rates, gateway counts, memory, heartbeat rate and reconnect-storm peak for a given jitter window.

9.15 Design challenges

1. **Live sports scores for 20 million viewers.** Scores change a few times per minute; viewers must see updates within 2 seconds. Compare short polling through a CDN (cacheable responses, $T = 2$ s) with SSE through an edge fan-out tier. Estimate request rate, connection count and egress for each, and decide.
2. **Collaborative document editor.** Up to 50 concurrent editors per document, 10 keystroke operations per second per editor, cursors and presence shown live. Design the gateway routing (all editors of a document on one node, or a backplane?), ordering (per-document sequence numbers), backpressure for cursor updates (coalesce), and what happens when the node holding a document fails.
3. **Ride-hailing driver tracking.** 1 million active drivers send GPS every 4 s; riders watch their assigned driver while the app is open and receive “driver arrived” when it is not. Choose techniques for each direction, size the ingest and fan-out, and design behavior when the rider’s phone loses connectivity for 30 s.

9.17 Open verification items

- APNs: exact current wording that only the latest notification per app is stored for offline devices; `apns-collapse-id` 64-byte limit; VoIP payload 5 KB; guidance of “two or three” background pushes per hour (Apple docs not fetched directly in this session).
- FCM: default/maximum TTL of 4 weeks (28 days) and 4 KB payload limit (firebase.google.com was unreachable from the authoring environment; limits on 100 stored messages, four collapse keys and 270-day token expiry were confirmed via search snippets of the official pages only).
- SSE: confirm current WHATWG text that non-200 responses “fail the connection” (no auto-reconnect) and the default reconnection time wording.
- Default idle timeouts (AWS ALB 60 s, NGINX `proxy_read_timeout` 60 s) and Kubernetes `terminationGracePeriodSeconds` 30 s — stable for years but flagged “as of 2024”.
- Authors of RFC 8489 and RFC 8656 reference entries; exact URL of Russell 2006 post.
- Per-connection memory figures in Table 9.12 are Illustrative and should be replaced with measured values (Exercise 9.3).
- Runnable programs should also be copied to `code/ch09/` per style guide §8 (not done; out of this author’s file scope).

Chapter 10 — Security Fundamentals for System Designers

> **Level:** 2 · **Track:** Shared · **Estimated reading time:** 5 h

Every system you design will be attacked. Not “might be”: a service with a public IP address receives automated scanning traffic within minutes of going online, and any system that stores money, personal data or compute capacity is worth an attacker’s time. Security is therefore not a feature you add at the end. It is a property of the architecture, in the same way that availability and latency are, and the cheapest time to get it right is when the boxes and arrows are still on the whiteboard.

This chapter gives you the vocabulary and mental models a system designer needs: finding threats systematically, choosing cryptographic building blocks, storing passwords and secrets, encrypting data with managed keys, limiting the blast radius of a breach, surviving denial-of-service attacks and keeping records an intruder cannot quietly rewrite. The focus is defensive and architectural. Chapter 50 builds on it with identity architecture, supply-chain security and privacy engineering.

10.1 Learning objectives

After this chapter you should be able to:

- Draw a data-flow diagram for a system, mark its trust boundaries and enumerate threats with STRIDE.
- Choose the correct cryptographic primitive (hash, MAC, symmetric encryption, asymmetric encryption, signature, key exchange) for a stated security goal and explain what it does *not* guarantee.
- Explain how a browser decides to trust a TLS certificate, and design certificate issuance and rotation for internal services.
- Store passwords with Argon2id, scrypt or bcrypt, choose cost parameters, and compute an attacker’s expected brute-force cost.
- Map each OWASP Top 10 (2021) category to an architectural control.
- Design secrets management with a vault, short-lived credentials and automated rotation.
- Explain envelope encryption with a key management service (KMS) and draw its sequence diagram.

- Contrast perimeter security with zero trust, and explain mTLS, least privilege and network segmentation.
- Classify DDoS attacks as volumetric, protocol or application-layer and place mitigations at the right layer.
- Design a tamper-evident audit log.
- Apply a security checklist to any system design.

10.2 Prerequisites

- TCP, UDP and the OSI layers — §7.3, §7.7, §7.8 (DDoS attacks target specific layers).
- TLS 1.3 and HTTPS — §7.10 (this chapter explains the cryptography and certificates underneath it).
- Firewalls and security groups — §7.14 (the starting point for network segmentation).
- Authentication, authorization, sessions, JWT and OAuth 2.0 — §8.10–§8.14 (we assume you know what a session token is).
- Powers of two and logarithms — §4.3, §4.4 (key sizes and brute-force estimates are exponential).
- Probability essentials — §4.6 (collision and risk estimates).

10.3 Threat modeling

10.3.1 What “secure” means: security goals

DEFINITION

Definition — Security property. A statement about what must remain true about a system even when an adversary is actively trying to violate it. The classic triad is **confidentiality** (only authorized parties can read data), **integrity** (data and behavior cannot be changed without detection) and **availability** (authorized parties can use the system when they need it), often abbreviated **CIA**. System designers add **authentication** (knowing who is acting), **authorization** (deciding what that actor may do) and **non-repudiation** (an actor cannot credibly deny an action they took).

First-principles explanation

Think about a house. Confidentiality is curtains: people outside cannot see your belongings. Integrity is a tamper seal on the medicine cabinet: you may not stop someone opening it, but you will know if they did. Availability is being able to get into your own home: a burglar who glues your lock shut has harmed you without stealing anything.
Authentication is the doorman recognizing your face; authorization is the rule that your

face opens the front door but not the neighbor's flat. Non-repudiation is the signed visitor's book: a visitor cannot later claim they were never there.

"Is this system secure?" has no answer on its own. The only answerable question is "secure against *whom*, protecting *what*, with respect to *which* property?" A public weather website needs integrity and availability but almost no confidentiality. A password database needs all three, and confidentiality failures there are catastrophic. Threat modeling is the discipline of asking these questions systematically instead of by intuition.

10.3.2 Assets, adversaries and trust boundaries

> DEFINITION
>
> **Definition — Threat model.** A structured description of a system, the **assets** in it that are worth protecting, the **adversaries** who might attack it and their capabilities, the **threats** (ways a security property could be violated), and the **mitigations** chosen for each threat [Shostack 2014].

> DEFINITION
>
> **Definition — Trust boundary.** A line in a system where the level of trust changes: data or requests crossing it come from a party that the receiving side does not fully control or trust. Examples: the internet-to-load-balancer edge, the browser-to-server connection, a service calling a third-party API, a tenant's code running on shared infrastructure.

Assets are the things an attacker wants or the things you cannot afford to lose: user credentials, payment data, personal data, signing keys, the ability to send email from your domain, compute capacity (attackers mine cryptocurrency on stolen cloud accounts), and your reputation. Rank them: a leaked public product catalog is embarrassing; leaked password hashes or private keys are a crisis.

Adversaries range from automated opportunists (bots scanning the whole internet for default passwords and known vulnerabilities), through targeted external attackers who study *your* system and phish *your* employees, malicious or compromised **insiders** who already hold legitimate credentials, and supply-chain attackers who compromise a library or vendor you depend on, up to well-resourced state actors. Every internet-facing design must handle the first three. The insider is the one beginners forget, and the reason zero trust (§10.10) and audit logging (§10.12) exist.

Trust boundaries are where attacks happen. Inside a single process, data you created yourself can be trusted; the moment data crosses a boundary, it must be **authenticated**

(who sent it?), **authorized** (are they allowed?) and **validated** (is it well-formed?). Almost every vulnerability class in §10.7 is a failure to do one of these three things at a boundary.

10.3.3 Data-flow diagrams

How it works internally

A **data-flow diagram (DFD)** is the standard picture for threat modeling. It uses only four element types, plus boundaries:

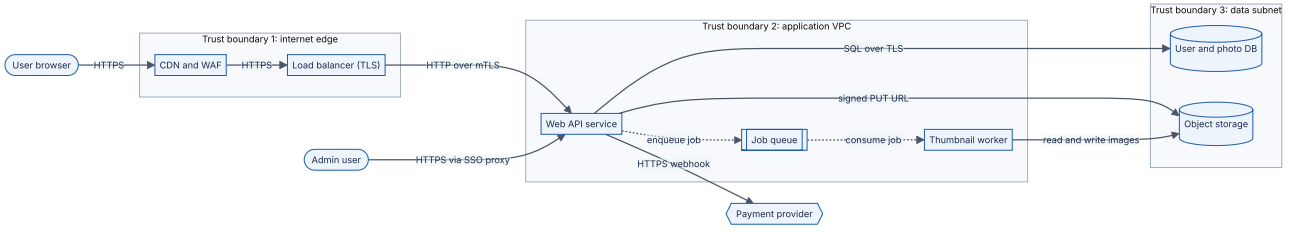
1. **External entity** — something outside your control that sends or receives data (a user, a partner API).
2. **Process** — code that transforms data (a web server, a worker).
3. **Data store** — where data rests (a database, a bucket, a cache, a log).
4. **Data flow** — an arrow showing data moving between the above, labeled with what moves and over which protocol.
5. **Trust boundary** — a dashed box or line where trust changes.

The rules are deliberately simple so that every engineer on a team can draw one in ten minutes. The value is not the drawing; it is that each arrow crossing a boundary becomes a question: *how is this authenticated, authorized, validated and protected in transit?*

Shostack frames the whole exercise as four questions [Shostack 2014]: **What are we working on?** (draw the DFD) · **What can go wrong?** (apply STRIDE) · **What are we going to do about it?** (choose mitigations) · **Did we do a good job?** (review and test).

Architecture diagram

Figure 10.1 — Data-flow diagram of a photo-sharing web application with trust boundaries.



Reading the diagram. Two external entities (the user's browser and an administrator) and one external system (a payment provider, hexagon) sit outside every boundary. Trust boundary 1 is the internet edge: the CDN with a web application firewall (WAF) and the TLS-terminating load balancer are the first components that see untrusted traffic, so they carry rate limiting and coarse filtering. Trust boundary 2 is the application network: the web API is the only process that authenticates users and authorizes actions; it talks to the load balancer over mutual TLS. Solid arrows are synchronous request/response flows; the

dotted arrows to and from the job queue are asynchronous — the thumbnail worker processes uploads later, so a failure there delays thumbnails but does not break uploads. Trust boundary 3 contains the storage: the database and object store accept connections only from the application subnet. Notice where the risky crossings are: every arrow from `U`, `ADM` and `PAY` crosses at least one boundary, and the worker parses user-uploaded image files, which is a classic place for parser vulnerabilities. Scaling options (more web replicas, more workers) do not change the boundaries, but each new data store or third-party integration adds a new arrow that must be modeled.

10.3.4 STRIDE

DEFINITION

Definition — STRIDE. A mnemonic for six threat categories, developed at Microsoft in 1999 by Loren Kohnfelder and Praerit Garg and popularized by Shostack [Shostack 2014]: **S**poofing, **T**ampering, **R**epudiation, **I**nformation disclosure, **D**enial of service and **E**levation of privilege. Each category is the violation of one security property.

Table 10.1 — STRIDE categories, the property each violates, and typical mitigations.

Threat	Violates	Plain-language question	Typical mitigations
Spoofing	Authentication	Can someone pretend to be another user or service?	Strong authentication, MFA, mTLS, signed tokens
Tampering	Integrity	Can someone change data in transit or at rest?	TLS, MACs, signatures, AEAD encryption, DB permissions
Repudiation	Non-repudiation	Can someone deny doing something?	Audit logs, signatures, tamper-evident storage
Information disclosure	Confidentiality	Can someone read what they should not?	Encryption, access control, data minimization
Denial of service	Availability	Can someone stop legitimate use?	Rate limits, quotas, autoscaling, DDoS protection
Elevation of privilege	Authorization	Can someone gain rights they were not granted?	Least privilege, authorization checks on every request, sandboxing

You apply STRIDE **per element** of the DFD: for each process, data store and flow, walk through the six letters and ask whether the threat applies. Not every letter applies to every element type: an external entity can be spoofed but cannot be “tampered with” by you; a data flow can be tampered with, disclosed or flooded. This mechanical walk-

through is what makes STRIDE useful — it stops you from fixating on the one threat you happened to think of first.

10.3.5 Worked example: STRIDE on the photo-sharing application

WORKED EXAMPLE

Worked example — STRIDE pass over Figure 10.1.

Step 1 — Assets. User credentials and session tokens; private photos; payment tokens returned by the provider; admin capabilities (delete any account); the database administrator credentials; the TLS private keys.

Step 2 — Walk each boundary-crossing element. The table below shows a representative (not exhaustive) result.

Step 3 — Rank. Score each threat for likelihood and impact on a 1–3 scale (see the risk-score formula below) and fix high scores first.

Step 4 — Record. The result is a short table in the design document, owned by the team, revisited whenever the DFD changes.

Table 10.2 — STRIDE threats for the photo-sharing application (excerpt).

#	Element	STRIDE	Threat	Mitigation	L × I
T1	User → Web API	S	Credential stuffing with passwords leaked from other sites	Rate limit per account and IP; breached-password check; MFA; Argon2id storage	3 × 3 = 9
T2	Web API	E	User changes `photo_id` in URL and reads another user's private photo (IDOR)	Object-level authorization check on every read, enforced in a shared data-access layer	3 × 3 = 9
T3	Web API → Object store	I	Bucket accidentally made public	Block public access at account level; serve via short-lived signed URLs	2 × 3 = 6
T4	Thumbnail worker	E	Malicious image exploits image-parsing library, attacker runs code in worker	Sandbox worker (no network, minimal IAM role), patch libraries, separate account	2 × 3 = 6
T5	Payment webhook	S	Attacker forges "payment succeeded" webhook	Verify provider's HMAC signature and timestamp (§10.4.6)	2 × 3 = 6
T6	Admin → Web API	R	Admin deletes an account and later denies it	Append-only, tamper-evident audit log of admin actions (§10.12)	1 × 2 = 2
T7	Upload endpoint	D	Attacker uploads thousands of 1 GB files	Size limits, per-user quotas, rate limits	2 × 2 = 4
T8	Web API → DB	T	SQL injection modifies rows	Parameterized queries; DB user without DDL rights	2 × 3 = 6

Look at what the exercise produced: eight concrete, testable requirements, most of which are architectural (where the authorization check lives, which account the worker runs in, how the bucket is exposed) rather than "write secure code". That is the point of threat modeling for a system designer.

Mathematical foundations

FORMULA

Qualitative risk score

$$R = L \times I$$

Symbol	Meaning	Units
R	Risk score used to rank threats	dimensionless (1–9 on a 3-point scale)
L	Likelihood that the threat is exploited within the planning horizon (1 = unlikely, 2 = plausible, 3 = expected)	ordinal score
I	Impact if exploited (1 = minor, 2 = serious, 3 = severe: data breach, financial loss, regulatory)	ordinal score

WORKED EXAMPLE

Worked example — Ranking T1 against T6. Credential stuffing (T1) is *expected* for any consumer login page, because attackers replay billions of leaked username–password pairs automatically: $L = 3$. Its impact is account takeover and private-photo exposure: $I = 3$. So $R = 3 \times 3 = 9$. Admin repudiation (T6) requires a malicious administrator ($L = 1$) and its impact is a dispute rather than a breach ($I = 2$): $R = 2$. *Interpretation:* fix T1 in the first release; T6 can follow. *Engineering implication:* the score is ordinal, not a probability — do not multiply it by dollar figures or average it across threats. Its only job is to order the work and make the reasoning visible to reviewers.

Advantages, disadvantages and alternatives

STRIDE is easy to teach, systematic and tied to properties, which makes it ideal for design reviews. Its weaknesses: it can produce long lists of low-value threats, it does not rank risk by itself, and it focuses on technical threats more than abuse of legitimate features (spam, fraud, harassment). Alternatives include **attack trees** (a root goal such as “read another user’s photo” decomposed into AND/OR subgoals — good for deep analysis of one critical asset), **PASTA** (a seven-stage risk-centric process), **LINDDUN** (privacy threats) and **kill-chain** analysis (focused on detection and response). Many teams use STRIDE for breadth and attack trees for the top two or three risks.

Failure scenarios

Table 10.3 — Threat-modeling failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Threat model is stale	Architecture changed, DFD did not	New data store or vendor absent from DFD in review	Re-run STRIDE on changed elements	Make DFD update a checklist item for design changes
Threat model is a document nobody reads	Produced for compliance, not engineering	Mitigations not traced to tickets/tests	Convert each mitigation to a tracked task	Keep it short; review it in design review
Insider threats ignored	"Everything inside the VPC is trusted" assumption	Red-team exercise with internal credentials	Add authorization and audit inside the network	Include insider row in adversary list

Common misconceptions

COMMON MISTAKE

"We use HTTPS, so we are secure." TLS protects data *in transit* between two endpoints. It does nothing about a logged-in user requesting someone else's data (T2), a forged webhook (T5) or SQL injection (T8). Most real breaches happen through authenticated, encrypted connections.

10.4 Cryptography essentials

Cryptography is the toolbox that turns security goals into mathematics. As a system designer you will almost never implement a cryptographic algorithm, but you will constantly *choose* one, and choosing the wrong primitive for a goal (encrypting when you needed to authenticate, hashing when you needed a secret key) is one of the most common design errors. This section explains each primitive by analogy, then by mechanism, then with the numbers that tell you how strong it is.

Table 10.4 — Which primitive achieves which goal.

Goal	Primitive	Needs a key?	Typical algorithm (as of 2026)	Analogy
Detect accidental or malicious change, given a trusted reference value	Cryptographic hash	No	SHA-256, SHA-3, BLAKE2/3	Fingerprint
Prove a message came from someone holding a shared secret, unchanged	MAC	Shared secret	HMAC-SHA-256	Wax seal pressed with a ring both parties own
Keep data secret *and* detect tampering, between parties sharing a key	Authenticated (AEAD) symmetric encryption	Shared secret	AES-256-GCM, ChaCha20-Poly1305	Locked box with a tamper seal
Let anyone send you a secret without a pre-shared key	Asymmetric encryption / KEM	Public + private key	RSA-OAEP, ECIES, ML-KEM	Padlock you hand out open; only you hold its key
Agree on a shared secret over a public channel	Key exchange	Ephemeral key pairs	ECDHE (X25519, P-256)	Mixing paint colors (see §10.4.4)
Prove to *anyone* that a specific key holder approved a message	Digital signature	Private key signs, public key verifies	Ed25519, ECDSA P-256, RSA-PSS	Notarized handwritten signature
Produce unpredictable keys, nonces, tokens	CSPRNG	Seeded by OS	`/dev/urandom`, `getrandom()`, `secrets`	Fair dice nobody can watch

10.4.1 Hash functions

DEFINITION

Definition — Cryptographic hash function. A deterministic function H that maps an input of any length to a fixed-length output (the **digest**), such that it is computationally infeasible to (1) find an input that hashes to a given digest (**preimage resistance**), (2) given one input, find a different input with the same digest (**second-preimage resistance**), and (3) find any two distinct inputs with the same digest (**collision resistance**).

First-principles explanation

A hash is a fingerprint. You cannot reconstruct a person from a fingerprint, two people practically never share one, and the tiniest change in the person (a cut on the finger) changes the print. SHA-256 takes a 4 GB disk image or the single letter “a” and produces 256 bits; flip one input bit and roughly half of the output bits flip (the **avalanche effect**).

Hashes give you integrity *only if the reference digest itself is trustworthy*. If an attacker can change a download *and* the digest published next to it, the hash proves nothing. That is why hashes are combined with keys (MACs) or signatures, and why a plain hash is never a password-storage scheme on its own (§10.6).

How it works internally

SHA-2 hashes pad the input, split it into 512-bit (SHA-256) blocks and mix each block into a running internal state with a **compression function** (the **Merkle–Damgård construction**); the final state is the digest. A side effect is the **length-extension property**: given $H(m)$ and the length of m, anyone can compute $H(m \parallel \text{padding} \parallel x)$ without knowing m. That is harmless for fingerprints but fatal if you build a MAC as $H(\text{key} \parallel \text{message})$ — the reason HMAC exists (§10.4.6). SHA-3 uses a different “sponge” construction without this property.

MD5 and SHA-1 are broken for collision resistance: practical collisions were published for MD5 in 2004 and for SHA-1 in 2017 (the “SHAttered” attack). Do not use them for any security purpose.

Mathematical foundations

FORMULA

Birthday bound for hash collisions

$$P_{\text{collision}} \approx \frac{k^2}{2^{n+1}}$$

Symbol	Meaning	Units
k	Number of distinct inputs hashed	count
n	Digest length	bits
$P_{\text{collision}}$	Probability that at least two of the k digests are equal (valid while $P \ll 1$)	probability

Consequence: an n-bit hash offers about $n/2$ bits of collision resistance, because P approaches $1/2$ when $k \approx 2^{n/2}$.

WORKED EXAMPLE

Worked example — Is a 64-bit truncated hash safe as a content ID? Suppose a storage service names objects by the first 64 bits of their SHA-256 digest and stores $k = 10^{10}$ objects (ten billion).

1. $k^2 = 10^{20}$.
2. $2^{65} \approx 3.69 \times 10^{19}$.
3. $P \approx 10^{20} / 3.69 \times 10^{19} \approx 2.7$ — the approximation has broken down because P is not small; in reality a collision is all but certain.

With the full 256-bit digest: $P \approx 10^{20} / 2^{257} \approx 10^{20} / 2.3 \times 10^{77} \approx 4 \times 10^{-58}$.

Interpretation: 64 bits feels large, but birthday collisions arrive at around $2^{32} \approx 4.3$ billion items. *Engineering implication:* if an adversary benefits from a collision (deduplication, content addressing, signatures), use at least 256-bit digests; truncate only for non-adversarial uses such as cache sharding.

10.4.2 Symmetric encryption and AES-GCM

DEFINITION

Definition — Symmetric encryption. Encryption in which the same secret key is used to encrypt and decrypt. A **block cipher** such as AES (Advanced Encryption Standard) encrypts fixed 128-bit blocks under a 128-, 192- or 256-bit key; a **mode of operation** turns the block cipher into a scheme for messages of any length.

DEFINITION

Definition — Authenticated encryption with associated data (AEAD). A symmetric scheme that provides confidentiality for the plaintext *and* integrity for both the ciphertext and optional unencrypted **associated data** (AAD), producing an authentication **tag** that decryption checks before releasing any plaintext. AES-GCM and ChaCha20-Poly1305 are AEAD schemes.

First-principles explanation

Symmetric encryption is a lockbox where sender and receiver hold copies of the same key. It is extremely fast: modern CPUs have AES instructions (AES-NI on x86, equivalent extensions on ARM) that encrypt at multiple gigabytes per second per core, which is why every bulk-data protocol — TLS records, disk encryption, database encryption — uses symmetric ciphers for the data itself. The hard part is not encrypting; it is getting the

same key to both parties securely and keeping it secret, which the rest of this chapter addresses.

An *unauthenticated* mode such as AES-CBC or AES-CTR hides the content but does not detect changes. An attacker who flips bit 7 of a CTR ciphertext flips bit 7 of the plaintext — turning “pay $100” into “pay $900” without knowing the key. AEAD adds the tamper seal: any change to ciphertext, tag, nonce or associated data makes decryption fail.

How it works internally

AES-GCM (Galois/Counter Mode, NIST SP 800-38D):

1. Take a key K and a 96-bit **nonce** (number used once) N.
2. Generate a keystream by encrypting the counter values $N \| 2, N \| 3, \ldots$ with AES; XOR it with the plaintext to get ciphertext (counter mode).
3. Compute a 128-bit tag over the AAD and ciphertext using GHASH, a polynomial hash keyed by a value derived from K, and mask it with the encryption of $N \| 1$.
4. Output (nonce, ciphertext, tag). Decryption recomputes the tag and rejects mismatches before returning plaintext.

The single most important rule: **never reuse a nonce with the same key.** A repeated nonce produces the same keystream, so XOR of two ciphertexts reveals the XOR of the two plaintexts, and it also leaks enough to forge tags. Use a 96-bit random nonce per message, or a counter that is guaranteed never to repeat, and rotate keys before the nonce collision probability becomes meaningful.

FORMULA

Random-nonce collision probability for AES-GCM

$$P_{\text{reuse}} \approx \frac{q^2}{2^{97}}$$

Symbol	Meaning	Units
q	Number of messages encrypted under one key with random 96-bit nonces	messages
P_{reuse}	Probability that any two of them share a nonce (birthday bound with $n = 96$)	probability

WORKED EXAMPLE

Worked example — How many messages per key? NIST SP 800-38D caps random-nonce GCM at 2^{32} invocations per key. Check the risk: $q = 2^{32}$ gives $q^2 = 2^{64}$, so $P \approx 2^{64}/2^{97} = 2^{-33} \approx 1.2 \times 10^{-10}$. A service encrypting 50,000 messages per second reaches $2^{32} \approx 4.3 \times 10^9$ messages in $4.3 \times 10^9 / 5 \times 10^4 \approx 86,000$ s, about one day. *Engineering implication:* a high-throughput service must rotate data keys at least daily, or use per-object keys (envelope encryption, §10.9), or a nonce-misuse-resistant mode such as AES-GCM-SIV, or a scheme with larger nonces (XChaCha20-Poly1305 uses 192-bit nonces).

The associated data is a powerful design tool. If you encrypt a user's tax ID in row 42 of the `users` table and put `table=users;id=42` in the AAD, an attacker with database write access cannot copy that ciphertext into row 43 — decryption would fail because the context differs. The runnable example in §10.4.8 demonstrates exactly this.

10.4.3 Asymmetric cryptography: RSA and elliptic curves

DEFINITION

Definition — Asymmetric (public-key) cryptography. Cryptography using a mathematically linked **key pair**: a **public key** that can be shared with anyone and a **private key** kept secret by its owner. What one key does, only the other can undo or verify. Security rests on problems believed hard to invert: factoring large integers (RSA) or computing discrete logarithms on elliptic curves (ECC).

First-principles explanation

Picture a padlock factory. You manufacture thousands of open padlocks, all of which only your key opens, and leave them in a bowl on the street. Anyone can put a message in a box, snap one of your padlocks shut, and mail it to you; nobody, including the sender, can reopen it — only you. The open padlocks are your public key; your key is the private key. Asymmetric cryptography solves the problem symmetric encryption cannot: two parties who have never met can communicate securely, provided the sender knows the padlock really is yours (that is what certificates in §10.5 establish).

The price is speed and size. An RSA-2048 private-key operation costs on the order of a millisecond of CPU, thousands of times more than encrypting a short message with AES. So real systems use asymmetric cryptography only to establish or protect a symmetric key and to sign things, never for bulk data. This combination is called **hybrid encryption**.

How it works internally

- **RSA**: pick two large random primes p and q; the public key is $(n = pq, e)$, the private key is d with $ed \equiv 1 \pmod{(p-1)(q-1)}$. Encryption is $c = m^e \bmod n$, decryption $m = c^d \bmod n$. Breaking it requires factoring n. RSA must always be used with a padding scheme (OAEP for encryption, PSS for signatures); "textbook RSA" is insecure.
- **Elliptic-curve cryptography (ECC)**: the private key is a random integer a; the public key is the point $A = a \cdot G$ obtained by "adding" a fixed base point G on a curve to itself a times. Recovering a from A (the elliptic-curve discrete logarithm problem) is believed to be infeasible. ECC achieves the same security as RSA with much smaller keys and faster operations, which is why TLS 1.3 deployments overwhelmingly use X25519 and P-256.

Table 10.5 — Approximate equivalent security strengths (NIST SP 800-57 Part 1).

Security strength (bits)	Symmetric	RSA modulus	Elliptic curve key	Hash for collision resistance	Status
112	3-key 3DES (legacy)	2048	224	SHA-224	Minimum acceptable today
128	AES-128	3072	256 (P-256, X25519, Ed25519)	SHA-256	Recommended default
192	AES-192	7680	384 (P-384)	SHA-384	High assurance
256	AES-256	15360	512+ (P-521)	SHA-512	Long-term / post-quantum margin for symmetric

"128-bit security" means the best known attack takes about 2^{128} operations. At 10^{18} operations per second (far beyond all computers on Earth combined) that is $3.4 \times 10^{38} / 10^{18} = 3.4 \times 10^{20}$ s, about 10^{13} years.

WARNING / TRADE-OFF

Quantum computers and "harvest now, decrypt later." A large fault-tolerant quantum computer running Shor's algorithm would break RSA and ECC; Grover's algorithm only roughly halves symmetric strength, leaving AES-256 a large margin. No such machine exists as of 2026, but recorded traffic could be decrypted later. NIST published post-quantum standards in August 2024 — FIPS 203 (ML-KEM), FIPS 204 (ML-DSA) and FIPS 205 (SLH-DSA) — and TLS libraries have begun deploying hybrid X25519 + ML-KEM key exchange. Design for **crypto agility** (configurable algorithms) and prefer AES-256 for long-lived data.

10.4.4 Key exchange and forward secrecy

First-principles explanation

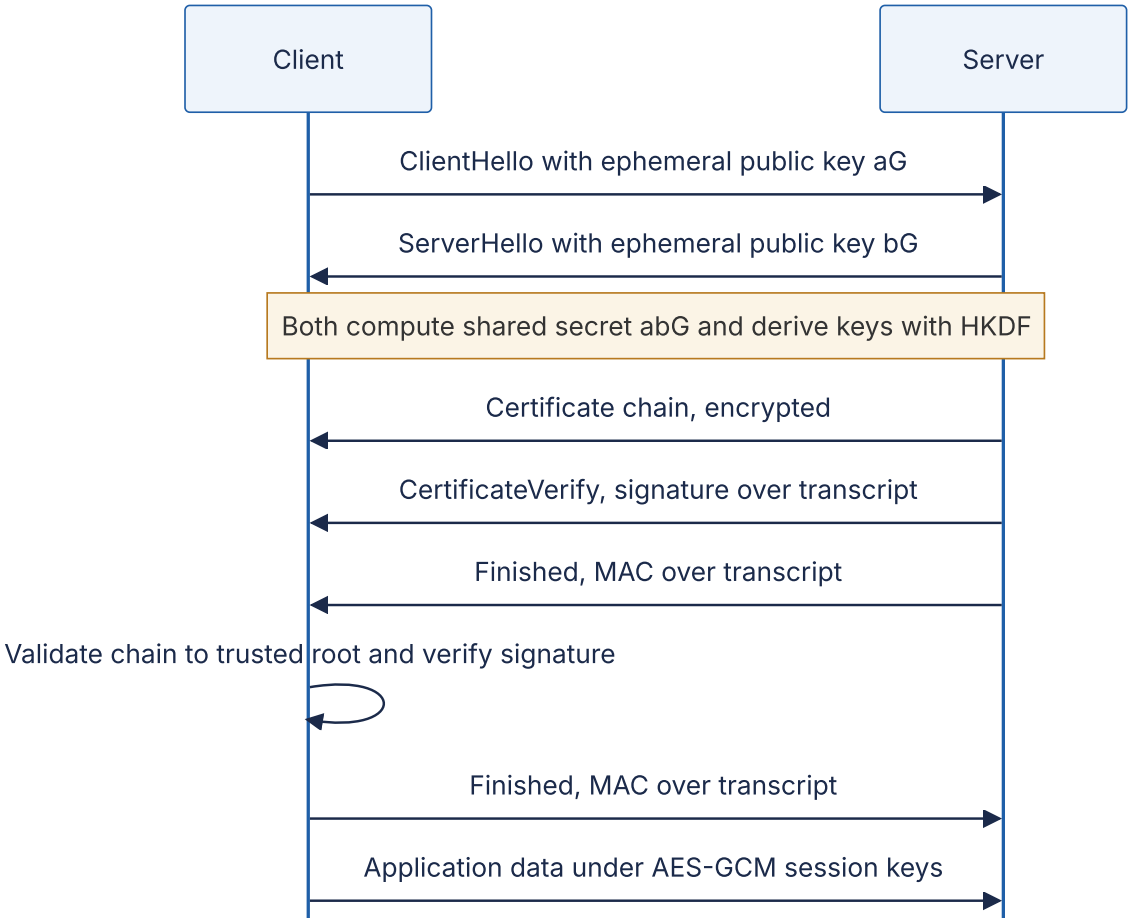
The classic analogy for **Diffie–Hellman key exchange** uses paint. Alice and Bob publicly agree on a common color, yellow. Alice secretly picks red, Bob secretly picks blue. Alice mixes yellow + red and sends the result (orange) across the open channel; Bob mixes yellow + blue and sends green. Alice adds her secret red to Bob's green; Bob adds his secret blue to Alice's orange. Both end up with the same yellow + red + blue brown. An eavesdropper saw yellow, orange and green but cannot "unmix" paint to recover red or blue.

In the elliptic-curve version (ECDH), Alice's secret is a, her public value aG; Bob's are b and bG; both compute the shared point abG. The shared secret is then fed through a **key-derivation function** such as HKDF to produce symmetric session keys.

> DEFINITION
>
> **Definition — Forward secrecy.** A property of a key-exchange protocol whereby compromise of a party's long-term private key does not reveal session keys from past sessions. It is achieved by using fresh **ephemeral** key pairs for every session (the "E" in ECDHE) and deleting them afterward.

Why it matters: before TLS 1.3, many servers used RSA key transport, where the client encrypted the session secret with the server's long-term RSA public key. Anyone who recorded traffic and later stole that one private key could decrypt *years* of recorded sessions. TLS 1.3 removed RSA key transport entirely; every full handshake uses ephemeral (EC)DHE, and the server's long-term key is used only to *sign* the handshake, proving its identity.

Figure 10.2 — Simplified TLS 1.3 handshake: ephemeral key exchange plus signature.



Reading the diagram. All messages flow synchronously over one TCP (or QUIC) connection, and the full handshake completes in one round trip before application data flows (round-trip costs and 0-RTT resumption are covered in §7.10). The ephemeral public values travel in the clear; the shared secret never crosses the network. From the ServerHello onward, everything is encrypted with keys derived from that secret, including the certificate (hiding which certificate the server uses from passive observers). The server proves it owns the certificate's private key by **signing** the handshake transcript (CertificateVerify); the client validates the certificate chain (§10.5). The Finished messages are MACs over everything exchanged so far, so a man-in-the-middle who altered any earlier message is detected. Failure points: an expired or untrusted certificate (handshake aborts), a client and server with no common cipher suite, or clock skew on the client breaking validity checks.

10.4.5 Digital signatures

DEFINITION

Definition — Digital signature. A scheme with three algorithms: key generation, **sign** (using the private key, produces a signature over a message) and **verify** (using the public key, checks a signature against a message). A valid signature shows that the message was approved by the holder of the private key and has not changed since. Because verification needs only the public key, *anyone* can verify, which provides non-repudiation.

Signatures are the notary of cryptography. They secure software updates (the update client holds the vendor's public key and refuses unsigned binaries), container images, JWTs signed with RS256 or ES256 (§8.13), certificates themselves, Git commits and the TLS handshake. In practice you sign a *hash* of the message: the signing algorithm hashes internally, so signing a 2 GB file costs one SHA-256 pass plus one fast private-key operation.

Prefer **Ed25519** (fast, deterministic, small 64-byte signatures, few ways to misuse) or **ECDSA P-256** where compliance requires NIST curves. ECDSA is fragile when the per-signature random value repeats or is biased: in 2010 researchers extracted Sony's PlayStation 3 code-signing key because the same random value was reused for every signature. Ed25519 derives this value deterministically, eliminating the failure mode.

10.4.6 Message authentication codes and HMAC

DEFINITION

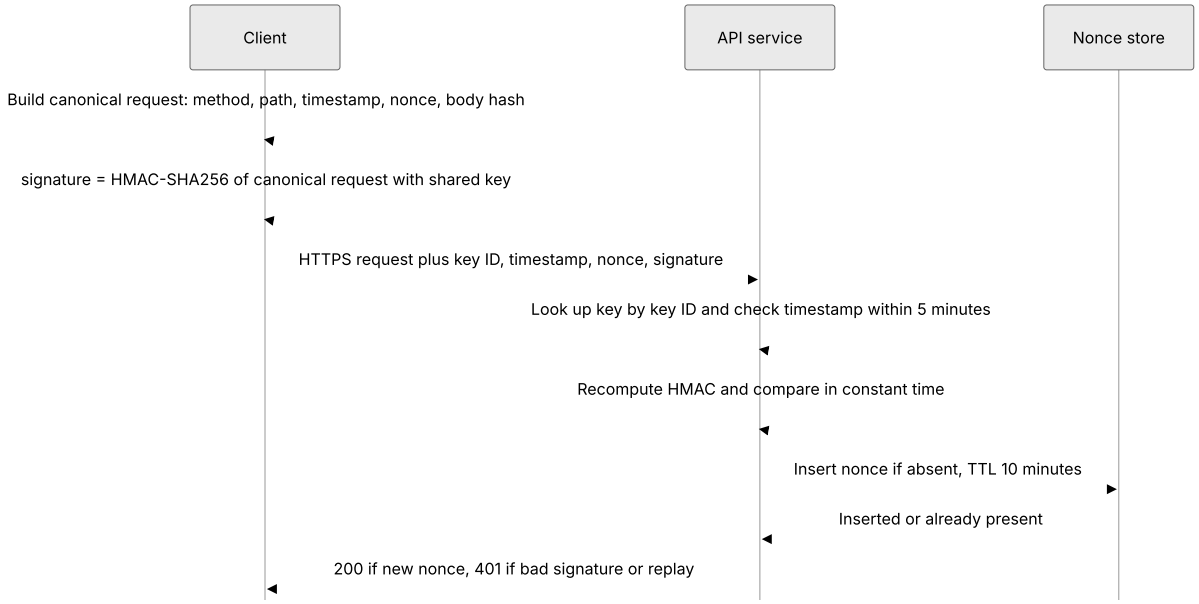
Definition — Message authentication code (MAC). A short tag computed from a message and a secret key, $t = \mathrm{MAC}_K(m)$, such that without K it is infeasible to produce a valid tag for any new message. **HMAC** is the standard construction from a hash function: $\mathrm{HMAC}_K(m) = H((K \oplus \mathrm{opad}) \parallel H((K \oplus \mathrm{ipad}) \parallel m))$ [Krawczyk et al. 1997].

A MAC is a wax seal pressed with a ring that both parties own. The receiver, holding the same ring, can tell the letter is genuine and unopened. But because both own the ring, a third party cannot tell *which* of them sealed it — so MACs provide integrity and authenticity between the two key holders, but **not** non-repudiation. That is the essential difference from a signature, and the reason payment providers sign webhooks with an HMAC (they only need you to know it came from them) while software vendors sign releases with asymmetric signatures (millions of verifiers who must not be able to forge).

HMAC's nested structure defeats the length-extension attack described in §10.4.1. It is also fast (two hash computations) and needs only a shared key, which makes it the stan-

dard tool for **request signing**: AWS Signature Version 4, Stripe and GitHub webhook signatures and many internal service-to-service schemes use HMAC-SHA-256.

Figure 10.3 — HMAC request signing with replay protection.



Reading the diagram. The client and API service share a secret key identified by a key ID (so keys can be rotated: during rotation the server accepts both the old and new key IDs). The client signs a **canonical** representation — a byte-exact serialization of every field the server will act on — because if a field is not covered (say, the HTTP method), an attacker can change it without invalidating the signature. The timestamp bounds how long a captured request remains useful; the nonce store (in production a shared cache such as Redis with a TTL slightly longer than twice the allowed skew) rejects exact replays inside that window. The signature comparison must be constant-time to avoid leaking, byte by byte, how much of a forged signature was correct. All calls are synchronous; the nonce store is the only shared state and a single point of failure — if it is unavailable, the service must choose between failing closed (reject requests) and failing open (accept possible replays), a decision that belongs in the design document.

Code example: HMAC request signing

```
        """HMAC-SHA256 request signing and verification with replay protection."""
        import hashlib
        import hmac
        import secrets
        import time

        MAX_SKEW_SECONDS = 300          # accept requests at most 5 minutes old/new

        def canonical_request(method: str, path: str, timestamp: str,
                              nonce: str, body: bytes) -> bytes:
            body_hash = hashlib.sha256(body).hexdigest()
            # Every field the server relies on must be covered by the signature.
            return "\n".join([method.upper(), path, timestamp, nonce,
body_hash]).encode()

        def sign(key: bytes, method: str, path: str, body: bytes) -> dict:
            ts = str(int(time.time()))
            nonce = secrets.token_hex(16)
            mac = hmac.new(key, canonical_request(method, path, ts, nonce, body),
                           hashlib.sha256).hexdigest()
            return {"X-Key-Id": "client-42", "X-Timestamp": ts,
                    "X-Nonce": nonce, "X-Signature": mac}

        class Verifier:
            def __init__(self, keys: dict[str, bytes]):
                self.keys = keys
                self.seen_nonces: dict[str, int] = {}    # production: shared store with
TTL

            def verify(self, method: str, path: str, body: bytes, headers: dict) ->
bool:
                key = self.keys.get(headers.get("X-Key-Id", ""))
                if key is None:
                    return False
                ts = int(headers["X-Timestamp"])
                now = int(time.time())
                if abs(now - ts) > MAX_SKEW_SECONDS:
                    return False                                    # stale or future
                expected = hmac.new(key, canonical_request(method, path, headers["X-
Timestamp"],
                                                           headers["X-Nonce"], body),
                                    hashlib.sha256).hexdigest()
                if not hmac.compare_digest(expected, headers["X-Signature"]):
                    return False                                    # forged or tampered
                # Expire old nonces, then reject a nonce we have already seen (replay).
                self.seen_nonces = {n: t for n, t in self.seen_nonces.items()
                                    if now - t <= 2 * MAX_SKEW_SECONDS}
                if headers["X-Nonce"] in self.seen_nonces:
                    return False
                self.seen_nonces[headers["X-Nonce"]] = ts
                return True
```

Tested with Python 3.13: a correctly signed request verifies; replaying it, altering one byte of the body, or signing with a different key all return `False`.

What to notice:

- `hmac.compare_digest` compares in constant time; `==` returns early at the first differing byte and can leak timing information.
- The body is covered via its SHA-256 hash, and the method and path are included, so neither can be swapped.
- The order of checks matters: the nonce is recorded only *after* the signature verifies, so an attacker cannot fill the nonce store with garbage that blocks legitimate nonces.
- The in-memory `seen_nonces` dictionary works for one process only; with several API replicas, use a shared store with an atomic "set if absent" operation (for example Redis `SET key value NX EX 600`).

10.4.7 Randomness

Every key, nonce, salt, session token and password-reset link depends on unpredictable random numbers. General-purpose generators (`random` in Python, `Math.random()` in JavaScript, `rand()` in C) are designed for simulations: they are fast and statistically uniform but **predictable** — observing a few hundred outputs of Python's Mersenne Twister lets an attacker compute all future outputs. Security code must use a **cryptographically secure pseudo-random number generator (CSPRNG)** seeded from the operating system's entropy pool: `secrets` or `os.urandom` in Python, `crypto.getRandomValues` in browsers, `SecureRandom` in Java, `crypto/rand` in Go.

FORMULA

Entropy of a uniformly random secret

$$H = L \cdot \log_2 N$$

Symbol	Meaning	Units
H	Entropy: the number of bits an attacker must effectively guess	bits
L	Length of the secret	symbols
N	Number of equally likely choices per symbol	symbols

Valid only when every symbol is chosen independently and uniformly at random — true for machine-generated tokens, false for human-chosen passwords.

WORKED EXAMPLE

Worked example — How long should a session token be?
`secrets.token_urlsafe(32)` draws 32 random bytes ($N = 256$, $L = 32$): $H = 32 \times 8 = 256$ bits. An attacker making 10^6 guesses per second for a year (3.15×10^{13} guesses) against 10^8 live sessions succeeds with probability about $3.15 \times 10^{13} \times 10^8 / 2^{256} \approx 3 \times 10^{-56}$.
Engineering implication: 128 bits of CSPRNG output is already ample; the realistic risk is tokens leaking through logs, URLs and referrer headers, not guessing.

10.4.8 Don’t roll your own crypto

“Don’t roll your own crypto” does not only mean “don’t invent a cipher”. It means: do not assemble primitives into your own protocol or storage format when a vetted, high-level construction exists. The canonical failures are all compositions of *correct* primitives: encrypting without authenticating (bit-flipping attacks), MAC-then-encrypt with distinguishable padding errors (padding-oracle attacks against CBC), `SHA256(key || msg)` as a MAC (length extension), reused GCM nonces, comparing MACs with `==` (timing attacks), and ECB mode, which encrypts identical blocks to identical ciphertext so that patterns in an image remain visible. Ferguson, Schneier and Kohno make the case that most cryptographic failures in practice are engineering failures in how primitives are combined and keys are handled, not breaks of the primitives themselves [Ferguson et al. 2010].

RECOMMENDATION

Practical rule set. (1) Use TLS 1.3 for data in transit — do not design a transport protocol. (2) Use a high-level library API (libsodium/NaCl `secretbox`, Google Tink, or the `cryptography` package’s AEAD classes) that chooses nonces, modes and tag checks for you. (3) Use a managed KMS for key storage and envelope encryption (§10.9). (4) Use a password-hashing function, not a hash (§10.6). (5) Use your platform’s JWT/OAuth libraries, pinned to an explicit algorithm allow-list. (6) Have a cryptographer review any design where you still feel you need to combine primitives.

Code example: AEAD, signatures and key agreement

```
        """AES-256-GCM with associated data, Ed25519 signatures and X25519 key agree-
ment."""
        import os
        from cryptography.exceptions import InvalidSignature, InvalidTag
        from cryptography.hazmat.primitives import hashes
        from cryptography.hazmat.primitives.asymmetric.ed25519 import Ed25519PrivateKey
        from cryptography.hazmat.primitives.asymmetric.x25519 import X25519PrivateKey
        from cryptography.hazmat.primitives.ciphers.aead import AESGCM
        from cryptography.hazmat.primitives.kdf.hkdf import HKDF

        # --- 1. Authenticated symmetric encryption: AES-256-GCM ---
        key = AESGCM.generate_key(bit_length=256)
        aead = AESGCM(key)
        nonce = os.urandom(12)                        # 96-bit nonce; NEVER reuse with
same key
        aad = b"user_id=42;table=payments"            # authenticated but not encrypted
        ct = aead.encrypt(nonce, b"card ending 4242", aad)
        print("ciphertext+tag bytes:", len(ct))       # plaintext length + 16-byte tag
        print("decrypted:", aead.decrypt(nonce, ct, aad))
        try:
            aead.decrypt(nonce, ct, b"user_id=43;table=payments")   # wrong context
        except InvalidTag:
            print("AAD mismatch -> InvalidTag (ciphertext cannot be moved to another
row)")
        tampered = bytearray(ct); tampered[0] ^= 1
        try:
            aead.decrypt(nonce, bytes(tampered), aad)
        except InvalidTag:
            print("bit flip -> InvalidTag")

        # --- 2. Digital signatures: Ed25519 ---
        signing_key = Ed25519PrivateKey.generate()
        verify_key = signing_key.public_key()
        release = b"release v2.4.1 sha256=9f86d08..."
        sig = signing_key.sign(release)
        print("signature bytes:", len(sig))
        verify_key.verify(sig, release)               # raises if invalid
        try:
            verify_key.verify(sig, release + b"!")
        except InvalidSignature:
            print("modified message -> InvalidSignature")

        # --- 3. Key agreement: X25519 + HKDF ---
        alice, bob = X25519PrivateKey.generate(), X25519PrivateKey.generate()
        shared_a = alice.exchange(bob.public_key())  # only public keys cross the net-
work
        shared_b = bob.exchange(alice.public_key())
        assert shared_a == shared_b
        session_key = HKDF(algorithm=hashes.SHA256(), length=32, salt=None,
                           info=b"example-protocol v1 session key").derive(shared_a)
        print("both sides derived the same 256-bit session key:", session_key.hex()
[:16], "...")
```

Tested with `cryptography` 50.0.1: decryption succeeds with the right AAD; a changed AAD or a single flipped ciphertext bit raises `InvalidTag`; a modified release string raises `InvalidSignature`; both X25519 parties derive the same key.

What to notice:

- The 16-byte plaintext became 32 bytes: GCM ciphertext is the same length as the plaintext plus a 16-byte tag. The 12-byte nonce must be stored alongside it (it is not secret).
- Decryption fails *loudly* on any tampering or context mismatch; there is no way to obtain partially decrypted garbage.
- The raw X25519 output is never used directly as a key; HKDF with a protocol-specific `info` string turns it into a uniformly random key bound to its purpose.

Table 10.6 — Hash vs MAC vs signature vs encryption.

	Hash	MAC (HMAC)	Digital signature	AEAD encryption
Confidentiality	No	No	No	Yes
Integrity	Only against a trusted digest	Yes	Yes	Yes
Authenticity	No	Yes, among key holders	Yes, publicly verifiable	Yes, among key holders
Non-repudiation	No	No	Yes	No
Key	None	Shared secret	Private / public pair	Shared secret
Speed	GB/s	GB/s	~10^4–10^5 signatures/s per core (Ed25519)	GB/s with AES-NI
Typical use	Checksums, content addressing, Merkle trees	Webhooks, API request signing, cookies	Software updates, certificates, JWT (RS/ES), audit anchors	Data at rest and in transit

Common misconceptions

COMMON MISTAKE

"Encoding, hashing and encryption are interchangeable." Base64 is an *encoding*: reversible by anyone, provides no security. A hash is one-way and keyless: anyone can compute it, so it cannot keep a low-entropy value (a phone number, a password) secret — an attacker hashes every candidate. Encryption is reversible *with the key*. Kubernetes Secrets stored as base64 in etcd without encryption at rest are, from a security standpoint, plaintext.

10.5 PKI and certificates

DEFINITION

Definition — Public key infrastructure (PKI). The set of roles, policies and systems that bind public keys to identities. A **certificate** (X.509) is a document stating "this public key belongs to this name (for example `api.example.com`), valid from date A to date B", signed by a **certificate authority (CA)**. A client trusts a certificate if it can build a **chain** of valid signatures from it to a **root CA** certificate in its local **trust store**.

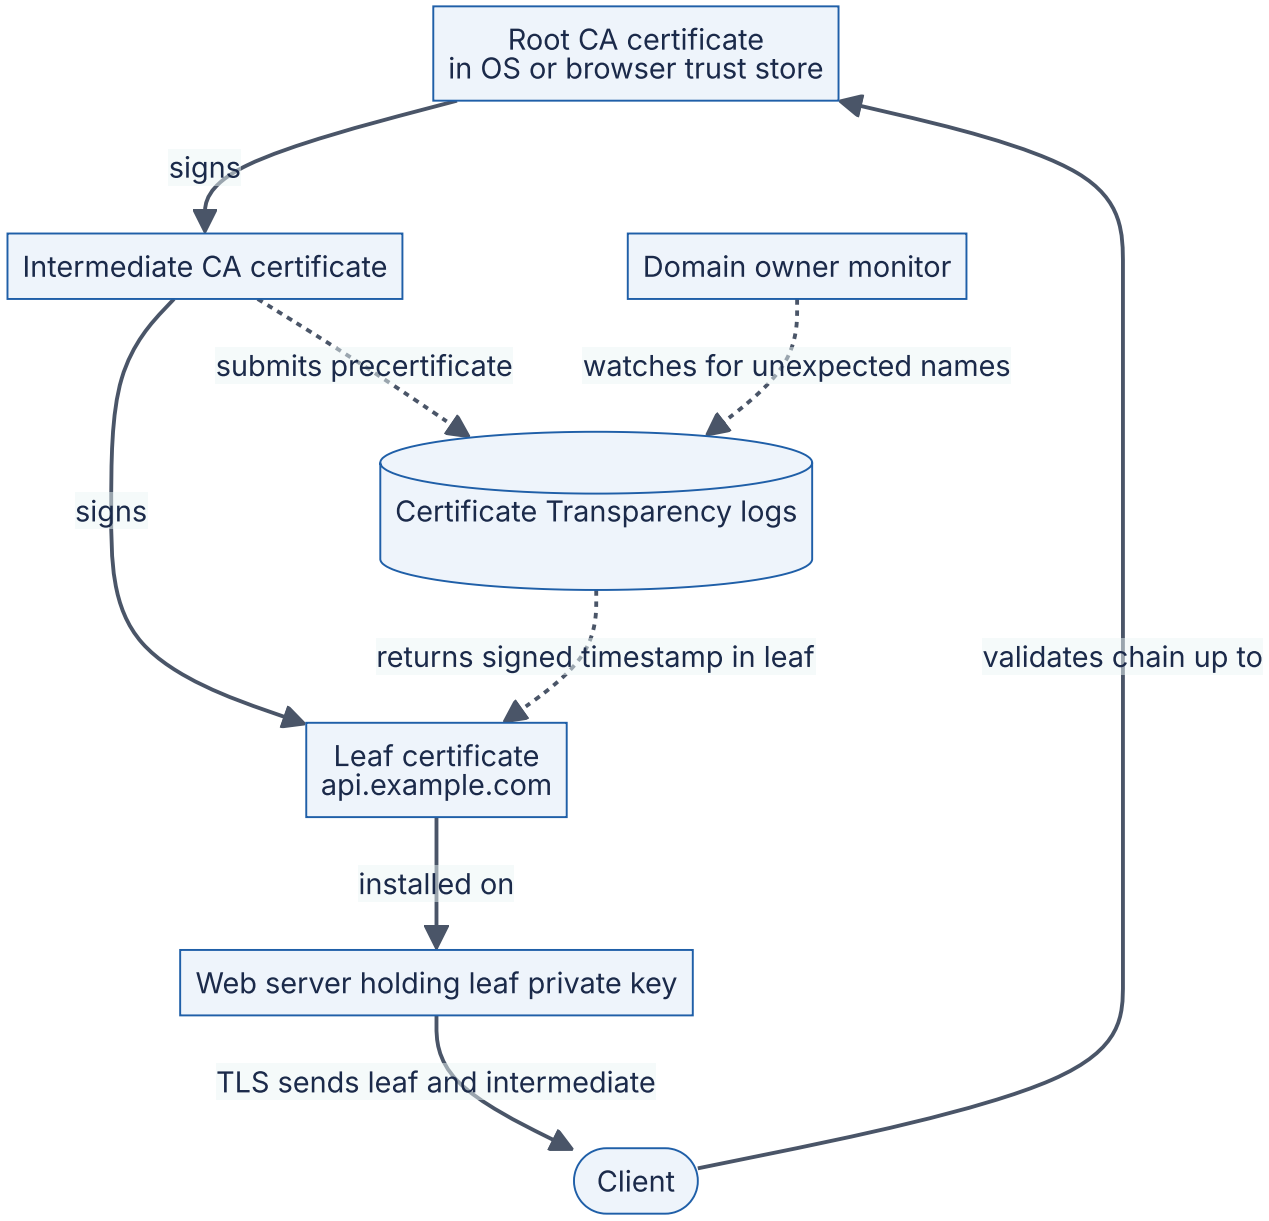
First-principles explanation

Asymmetric cryptography lets anyone lock a box with your padlock — but how does a stranger know the padlock in the bowl is *yours* and not one an impostor swapped in? A passport solves the same problem for people: a government you already trust vouches for the link between a photo and a name. A CA is that government for public keys. Your browser or operating system ships with roughly a hundred-odd root CA certificates (the exact number varies by vendor), and it trusts any certificate that chains back to one of them.

How it works internally

1. The server operator generates a key pair and sends the CA a **certificate signing request** containing the public key and the domain name.
2. The CA verifies control of the domain — for automated CAs, via the **ACME** protocol (RFC 8555): placing a token at a well-known HTTP path or in a DNS TXT record.
3. The CA signs a certificate using an **intermediate CA** key. Root keys are kept offline in hardware security modules and only sign intermediates, so a root key is used a few times per decade.
4. In the TLS handshake the server sends its **leaf** certificate plus intermediates. The client checks each signature up to a trusted root, the validity dates, the domain name, key-usage constraints and revocation status.

Figure 10.4 — Certificate chain of trust and Certificate Transparency.



Reading the diagram. Solid arrows show the signing hierarchy and the synchronous TLS path: the root signs the intermediate, the intermediate signs the leaf, and the server presents leaf plus intermediate to the client, which already holds the root. Dotted arrows show the asynchronous transparency path: before issuance the CA submits a precertificate to public append-only logs and embeds the logs' signed timestamps in the final certificate; browsers that enforce CT reject publicly trusted certificates without them. A domain owner's monitor watches the logs and alerts on any certificate for its names it did not request. Failure points: an expired leaf or intermediate (the most common certificate outage), a server that forgets to send the intermediate (works in some clients, fails in others), and a compromised or misbehaving CA — the reason CT exists.

Revocation — withdrawing a certificate before expiry because its key leaked — works poorly in practice: revocation lists grow large, online status checks (OCSP) add latency and leak browsing history, and clients usually "soft-fail" when the responder is unreach-

able. The industry's answer is shorter lifetimes. Let's Encrypt has issued 90-day certificates since 2015 to force automation, and in 2025 the CA/Browser Forum voted to shrink the maximum lifetime of publicly trusted TLS certificates in stages, reaching 47 days by 2029 (as of 2026; check the current Baseline Requirements).

DEFINITION

Definition — Certificate Transparency (CT). A system of public, append-only, Merkle-tree-based logs into which CAs record every certificate they issue, so that mis-issued certificates become publicly detectable [RFC 6962].

INDUSTRY EXAMPLE

DigiNotar (2011). Attackers compromised the Dutch CA DigiNotar and issued hundreds of fraudulent certificates, including one for `*.google.com` that was used to intercept traffic of users in Iran. Browsers removed DigiNotar from their trust stores and the company went bankrupt within weeks. The incident directly motivated Certificate Transparency: had CT existed, Google's monitors would have seen the rogue certificate within hours of issuance. *Evidence: Secondary* — [Fox-IT 2012]

Certificate rotation for internal services

For service-to-service mTLS (§10.10) you run a private CA (cloud private CA services, HashiCorp Vault's PKI engine, or a service mesh's built-in CA). The design rules: issue **short-lived** certificates (hours to days); rotate automatically well before expiry (renew at about two-thirds of lifetime); have services reload certificates without restarting; alert on any certificate with less than, say, 25% of its lifetime remaining; and treat the CA's private key as the most sensitive key in the company (store it in an HSM or KMS).

Table 10.7 — Certificate failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Expired certificate outage	Manual renewal forgotten; long lifetime meant the process was never exercised	Synthetic TLS probes; expiry metrics	Emergency renewal and deploy	Automated issuance (ACME), short lifetimes, expiry alerts
Private key leak	Key in a repo, image or backup	Secret scanning; CT monitor shows unexpected certs	Revoke, reissue, rotate	Keys generated on host or in KMS/HSM, never copied
Rogue certificate for your domain	Compromised or careless CA	CT log monitoring	Request revocation; report to browser vendors	CAA DNS records restricting which CAs may issue

10.6 Password storage

10.6.1 Why passwords need special treatment

First-principles explanation

Suppose you run a coat check. You could keep each customer's ticket number in a ledger, but if the ledger is stolen, the thief can claim every coat. Better: keep only a "fingerprint" of each ticket, so a stolen ledger is useless — *unless* the tickets are so predictable that the thief can fingerprint every possible ticket and match them. Human passwords are predictable tickets: "Summer2024!" and its millions of cousins appear in every attacker's wordlist.

The design goal therefore is: **assume the password database will one day be stolen** (via SQL injection, a leaked backup or an insider), and make each password as expensive as possible to recover from what was stolen. Three techniques combine to achieve this.

1. **Hash, don't encrypt.** The server never needs the password back; it only needs to check a candidate. A one-way function means there is no decryption key to steal.
2. **Salt.** A **salt** is a unique random value (at least 16 bytes) stored next to each hash and mixed into it. Without salts, identical passwords produce identical hashes, so one computation cracks every user with "123456", and attackers can use precomputed **rainbow tables**. With salts, every guess must be computed separately per user.
3. **Slow, memory-hard hashing.** SHA-256 is designed to be fast; a single high-end GPU computes on the order of 10^{10} SHA-256 hashes per second (order-of-magnitude figure as of 2024). A **password-hashing function** (bcrypt, scrypt, Argon2id) is deliberately slow and, for scrypt and Argon2, **memory-hard**: each guess needs tens of megabytes of RAM, which defeats the massive parallelism of GPUs and custom chips.

Optionally add a **pepper**: a secret key, stored outside the database (in a KMS or HSM), applied as an HMAC before or after hashing. A database-only leak then yields hashes that cannot be attacked at all without also stealing the pepper. NIST SP 800-63B recommends this additional keyed step.

INDUSTRY EXAMPLE

LinkedIn (2012). About 6.5 million LinkedIn password hashes were posted publicly in 2012; they were unsalted SHA-1 hashes, and a large fraction were cracked within days. In 2016 a much larger dataset from the same breach (reported at over 100 million accounts) surfaced. The lesson is both technical (fast, unsalted hashes) and architectural (credential reuse turns one site's breach into credential stuffing against every other site — threat T1 in Table 10.2). *Evidence: Secondary* — widely reported in the technology press, 2012 and 2016.

10.6.2 Algorithms and cost parameters

Table 10.8 — Password-hashing functions compared (parameters per [OWASP Password Storage Cheat Sheet], as of 2026).

	Argon2id	scrypt	bcrypt	PBKDF2-HMAC-SHA-256
What it is	Winner of the 2015 Password Hashing Competition, RFC 9106	Memory-hard KDF, RFC 7914	Blowfish-based adaptive hash (1999)	Iterated HMAC, NIST-approved
Cost knobs	memory m, iterations t, parallelism p	N (CPU/memory), r (block size), p	work factor (cost c ⇒ 2^c rounds)	iteration count
Memory-hard	Yes	Yes	No (4 KiB)	No
OWASP minimum	m = 19 MiB, t = 2, p = 1	$N = 2^{17}$, r = 8, p = 1	cost ≥ 10	≥ 600,000 iterations
Gotchas	Library support varies	Memory = $128 \cdot N \cdot r$ bytes (128 MiB at OWASP minimum)	Truncates input at 72 bytes	GPU-friendly; use only when FIPS-140 is required
Choose when	Default for new systems	Argon2id unavailable	Legacy systems, wide library support	Compliance mandates FIPS

RFC 9106 also gives two general-purpose Argon2id recommendations: $t = 1$, $p = 4$, $m = 2$ GiB where memory allows, or $t = 3$, $p = 4$, $m = 64$ MiB otherwise [RFC 9106]. The OWASP minimums are lower because login servers must handle many concurrent hashes.

Choosing cost parameters is a capacity-planning decision. Pick the most expensive setting that keeps a single hash at roughly 50–500 ms on your production hardware and that your login fleet can afford at peak. If peak login rate is 200 per second and one hash costs 100 ms of one core and 64 MiB, you need about $200 \times 0.1 = 20$ cores and 20×64 MiB ≈ 1.3 GiB of RAM dedicated to hashing — plus headroom, because an attacker can make login attempts to burn your CPU (rate-limit the endpoint). Store the algorithm and parameters with each hash so you can raise them later and **rehash on next successful login**.

Mathematical foundations

FORMULA

Expected offline brute-force time

$$T = \frac{S}{2 \cdot R \cdot G}$$

Symbol	Meaning	Units
T	Expected time to find one password (average: half the space)	seconds
S	Size of the search space: N^L for random passwords, or the size of the attacker's ranked wordlist up to the target	candidates
R	Guesses per second per attacking device for this hash function and cost	guesses/s/device
G	Number of attacking devices (GPUs)	devices

Salting means T is paid **per user**; without salts, one pass covers all users.

WORKED EXAMPLE

Worked example — Fast hash vs slow hash. A user picks a random 8-character password from the 95 printable ASCII characters.

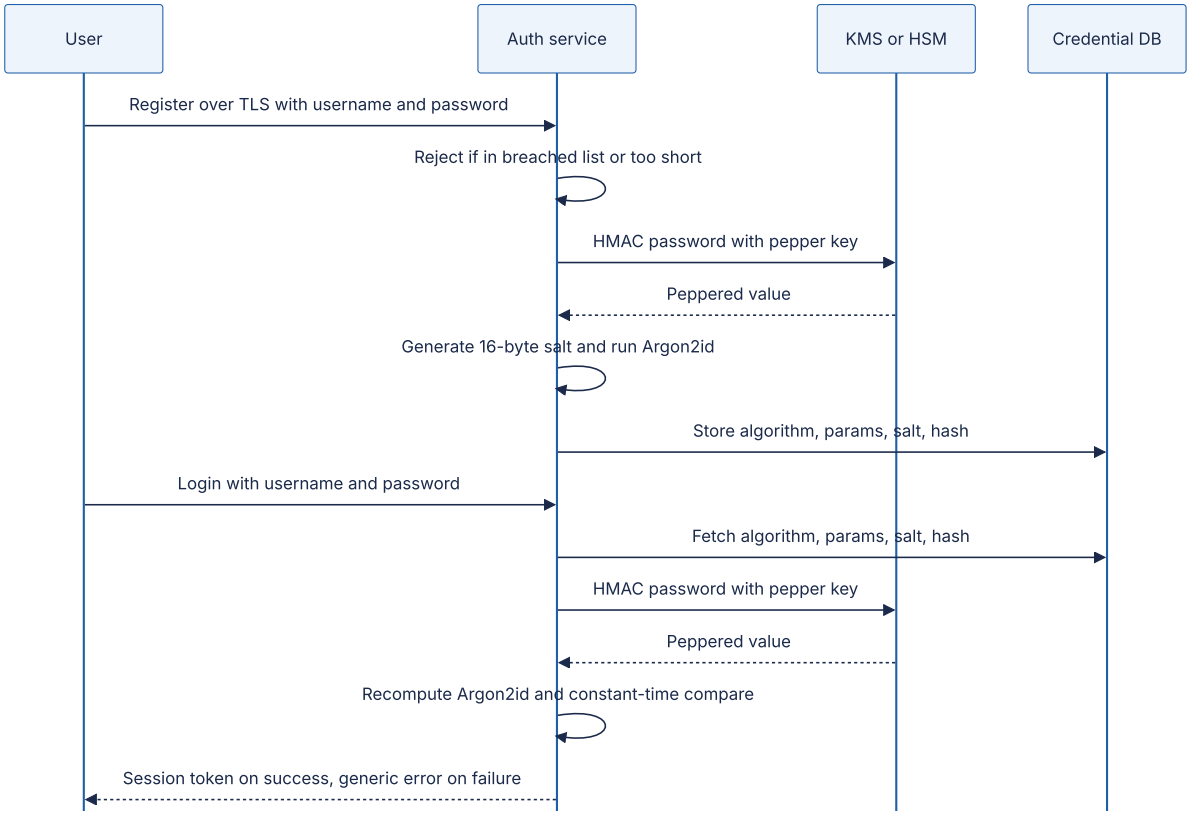
1. Search space: $S = 95^8 \approx 6.63 \times 10^{15}$ (entropy $8 \log_2 95 \approx 52.6$ bits).
2. *Salted SHA-256,* $R \approx 10^{10}$ /s, $G = 10$ GPUs: $T = 6.63 \times 10^{15} / (2 \times 10^{11}) \approx 3.3 \times 10^4$ s $\approx$ **9 hours**.
3. *Argon2id or bcrypt tuned to ~100 ms on a server core*. An attacker's GPU is far less advantaged on memory-hard functions; assume an optimistic $R \approx 10^4$ /s per device: $T = 6.63 \times 10^{15} / (2 \times 10^5) \approx 3.3 \times 10^{10}$ s $\approx$ **1,050 years** per password.
4. A 12-character random password ($S = 95^{12} \approx 5.4 \times 10^{23}$) against the same slow hash: $\approx 2.7 \times 10^{18}$ s, about 8.6×10^{10} years.

Interpretation: the slow hash multiplies the attacker's cost by 10^6; length multiplies it exponentially. *But* human passwords are not random: "Summer2024!" appears near the top of real wordlists, so S for it is perhaps 10^6, and even at 10^4 guesses/s it falls in under a minute. *Engineering implication:* slow hashing protects the middle of the distribution; protecting the weakest passwords requires refusing them at registration (breached-password lists) and adding MFA.

NIST guidance. NIST SP 800-63B, revised as SP 800-63B-4 (final in 2025), reverses several folk rules: do **not** impose composition rules (“one uppercase, one symbol”), do **not** force periodic password changes without evidence of compromise, **do** check new passwords against lists of breached and commonly used passwords, allow at least 64 characters and all printable characters including spaces, and require a minimum length — 15 characters when the password is the only authentication factor, 8 when it is part of multi-factor authentication [NIST SP 800-63B-4].

Architecture diagram

Figure 10.5 — Registration and login with salted Argon2id and a pepper.



Reading the diagram. All calls are synchronous. The password exists in plaintext only in memory of the auth service, briefly. The pepper key never leaves the KMS or HSM; the service sends it data to MAC (some designs instead load the pepper into service memory at startup, trading isolation for one fewer network call per login). The credential database stores only the self-describing record — for example `argon2id$m=19456,t=2,p=1$<salt>$<hash>` — so a stolen database alone is not enough to start guessing. The failure response is deliberately generic (“invalid username or password”) and takes the same time for unknown users to avoid revealing which accounts exist. Scaling: the Argon2id step dominates CPU and memory, so login capacity scales with auth-service replicas; rate limiting per account and per IP sits in front of it.

Code example

```
        """Password hashing with scrypt (standard library) and Argon2id (cryptography >=
44)."""
        import base64
        import hashlib
        import hmac
        import os
        import time

        # ---------- scrypt (stdlib) ----------
        SCRYPT_N, SCRYPT_R, SCRYPT_P = 2**17, 8, 1   # OWASP minimum: N=2^17, r=8, p=1
        SCRYPT_MAXMEM = 256 * 1024 * 1024            # memory needed is ~128*N*r = 128
MiB

        def b64(b: bytes) -> str:
            return base64.b64encode(b).decode().rstrip("=")

        def unb64(s: str) -> bytes:
            return base64.b64decode(s + "=" * (-len(s) % 4))

        def scrypt_hash(password: str) -> str:
            salt = os.urandom(16)                                  # unique per pass-
word
            dk = hashlib.scrypt(password.encode("utf-8"), salt=salt,
                                n=SCRYPT_N, r=SCRYPT_R, p=SCRYPT_P,
                                maxmem=SCRYPT_MAXMEM, dklen=32)
            # Store algorithm, parameters, salt and hash together so they can evolve.
            return f"scrypt${SCRYPT_N}${SCRYPT_R}${SCRYPT_P}${b64(salt)}${b64(dk)}"

        def scrypt_verify(password: str, stored: str) -> bool:

            salt = os.urandom(16)
            kdf = Argon2id(salt=salt, length=32, iterations=ARGON_T,
                           lanes=ARGON_P, memory_cost=ARGON_M_KIB)
```

```
            tag = kdf.derive(password.encode("utf-8"))
            return f"argon2id${ARGON_M_KIB}${ARGON_T}${ARGON_P}${b64(salt)}${b64(tag)}"

        def argon2id_verify(password: str, stored: str) -> bool:
            alg, m, t, p, salt_s, tag_s = stored.split("$")
            if alg != "argon2id":
                raise ValueError("unknown algorithm")
            kdf = Argon2id(salt=unb64(salt_s), length=32, iterations=int(t),
                           lanes=int(p), memory_cost=int(m))
            try:
                kdf.verify(password.encode("utf-8"), unb64(tag_s))  # constant-time in-
side
                return True
            except InvalidKey:
                return False
```

Tested with Python 3.13 and `cryptography` 50.0.1 on a cloud VM: one scrypt hash at OWASP-minimum settings took about 400 ms, one Argon2id hash about 33 ms; correct passwords verify, a one-letter change fails, and hashing the same password twice gives different strings.

What to notice:

- `hashlib.scrypt` refuses to use more than 32 MiB by default; `maxmem` must be raised for $N = 2^{17}$, $r = 8$ (128 MiB).
- The stored string is self-describing (algorithm, parameters, salt, hash), which is what makes `needs_rehash` and gradual parameter upgrades possible. Production code should prefer the standard PHC string format produced by maintained libraries such as `argon2-cffi`.
- ~33 ms for Argon2id at OWASP-minimum settings is a floor; raise m or t until the cost reaches your latency and capacity budget.

> COMMON MISTAKE
>
> **“Encrypting passwords is safer than hashing them.”** Encryption is reversible, so whoever obtains the key — an attacker with application-server access, a rogue administrator — recovers every password at once. Systems should never need to recover a user’s password; if a product requirement says “email users their password”, the requirement is wrong.

10.7 The OWASP Top 10 in architectural terms

DEFINITION

Definition — OWASP Top 10. A consensus ranking of the most critical web application security risk categories, published by the Open Worldwide Application Security Project from vulnerability data contributed by testing organizations plus a community survey. This section uses the **2021 edition** [OWASP 2021]. A 2025 edition has since been published; it keeps broken access control at #1, folds SSRF into it, and adds categories for software supply-chain failures and mishandling of exceptional conditions, so the architectural controls below remain applicable.

The Top 10 is often taught as a list of coding bugs. For a system designer, each category is better read as a *missing architectural control*: something that should exist once, centrally, rather than being re-implemented correctly by every developer on every endpoint.

Table 10.9 — OWASP Top 10 (2021) mapped to architectural controls.

ID	Category	What goes wrong	Architectural control
A01	Broken Access Control	Users act outside their permissions: IDOR, missing function-level checks, CORS misconfiguration	Deny by default; central policy engine or authorization middleware; object-level checks in the data-access layer; tenant ID derived from the token, never from the request body
A02	Cryptographic Failures	Sensitive data unencrypted or protected with weak/misused crypto	TLS everywhere; KMS-managed keys; AEAD; data classification deciding what is encrypted (§10.9)
A03	Injection	Untrusted data interpreted as code: SQL, NoSQL, OS command, LDAP; cross-site scripting is included here in 2021	Parameterized queries/ORMs; no shell invocation with user input; context-aware output encoding; Content Security Policy
A04	Insecure Design	Missing or ineffective security controls by design, not by implementation	Threat modeling (§10.3); abuse-case requirements; rate limits and business-logic limits designed in
A05	Security Misconfiguration	Default credentials, verbose errors, open buckets, unnecessary features enabled	Infrastructure as code with policy checks; hardened base images; configuration drift detection
A06	Vulnerable and Outdated Components	Known-vulnerable libraries, frameworks, OS packages	Software bill of materials (SBOM); dependency scanning in CI; patch SLAs; automated update PRs
A07	Identification and Authentication Failures	Credential stuffing, weak session handling, missing MFA	Central identity provider; MFA; rate limiting; secure session tokens (§10.4.7)
A08	Software and Data Integrity Failures	Unsigned updates, compromised CI/CD, insecure deserialization	Signed artifacts and provenance; protected build pipeline; no deserialization of untrusted native objects
A09	Security Logging and Monitoring Failures	Breaches go undetected for months	Central, tamper-evident audit logs (§10.12); alerting on security events
A10	Server-Side Request Forgery (SSRF)	Server fetches an attacker-chosen URL, reaching internal services	Egress allow-lists via a dedicated fetch proxy; block metadata and private ranges; IMDSv2-style token-protected metadata

10.7.1 Broken access control (A01)

Broken access control is #1 because authorization is the one control that cannot be bolted on by infrastructure: only the application knows that photo 9001 belongs to user 42. The classic form is the **insecure direct object reference (IDOR)**: `GET /api/photos/9001` returns the photo to anyone authenticated, because the handler checks *that* the user is logged in but not *whether* they own photo 9001.

Architectural patterns that make the correct behavior the default:

- **Deny by default.** A new endpoint without an explicit policy rejects all requests.
- **Centralize decisions.** Route every authorization question through one library or service (a policy engine such as Open Policy Agent, or a relationship-based system modeled on Google's Zanzibar — §8.12), so the rules are written and reviewed once.
- **Push checks to the data layer.** Repository methods take the caller's identity and add `WHERE owner_id = :caller` (or tenant filters) automatically; database row-level security can enforce the same rule underneath.
- **Use unguessable identifiers as defense in depth, not as the control.** Random UUIDs make enumeration harder but are not authorization; IDs leak through URLs, logs and shares.

10.7.2 Injection (A03)

Injection happens when data and code share a channel. A query built as `"SELECT * FROM users WHERE name = '" + name + "'"` lets an attacker supply `' OR '1'='1` and change the query's *structure*. **Parameterized queries** separate the channels: the query text is sent to the database with placeholders, and values are sent separately, so a value can never become syntax.

```
        import sqlite3
        db = sqlite3.connect(":memory:")
        db.execute("CREATE TABLE users (name TEXT, email TEXT)")
        db.execute("INSERT INTO users VALUES ('alice', 'a@example.com')")
        attacker_input = "x' OR '1'='1"
        # Vulnerable (illustrative, never do this): f"... WHERE name =
'{attacker_input}'"
        rows = db.execute("SELECT email FROM users WHERE name = ?",
(attacker_input,)).fetchall()
        print(rows)   # [] -- the input is treated purely as a value
```

What to notice: the `?` placeholder is bound by the driver; no escaping function is needed or involved. The architectural layer of defense is to give the application's database user only the rights it needs (no `DROP`, no access to other schemas), so a missed injection cannot become a full compromise.

10.7.3 Server-side request forgery (A10)

Many features make the server fetch a URL the user supplied: link previews, webhooks, “import from URL”, PDF rendering. If the server can reach internal addresses, the attacker can make it fetch `http://169.254.169.254/` (the cloud instance-metadata endpoint that hands out the instance’s IAM credentials), `http://localhost:8080/admin` or internal databases’ HTTP interfaces.

> INDUSTRY EXAMPLE
>
> **Capital One (2019).** An attacker exploited a misconfigured web application firewall to make requests to the AWS instance-metadata service, obtained temporary credentials for the instance’s IAM role, and used that role’s overly broad permissions to copy data on roughly 100 million credit-card applicants from S3. Two architectural failures compounded: an SSRF path to metadata, and a role with far more S3 access than the WAF needed. Later that year AWS introduced IMDSv2, which requires a session token obtained via an HTTP `PUT`, defeating most simple SSRF requests. *Evidence: Secondary* — public court filings and widespread reporting; [AWS Docs: IMDSv2].

Defense in depth for SSRF: (1) route all user-driven outbound fetches through a dedicated **egress proxy** in its own network segment with no route to internal ranges; (2) validate URLs (scheme, port, resolved IP) and **pin** the validated IP for the connection, otherwise **DNS rebinding** — a hostname that resolves to a public IP at check time and a private IP at fetch time — bypasses the check; (3) disable redirects or re-validate each hop; (4) require IMDSv2 and give instance roles least privilege.

```
        """Defense-in-depth check for user-supplied URLs fetched by a server (SSRF)."""
        import ipaddress
        import socket
        from urllib.parse import urlsplit

        ALLOWED_SCHEMES = {"https"}
        ALLOWED_PORTS = {443}

        def resolve_and_check(url: str) -> list[str]:
            parts = urlsplit(url)
            if parts.scheme not in ALLOWED_SCHEMES:
                raise ValueError(f"scheme {parts.scheme!r} not allowed")
            port = parts.port or 443
            if port not in ALLOWED_PORTS or not parts.hostname:
                raise ValueError("port or host not allowed")
            infos = socket.getaddrinfo(parts.hostname, port, proto=socket.IPPROTO_TCP)
            addrs = sorted({info[4][0] for info in infos})
            for a in addrs:
                ip = ipaddress.ip_address(a)
                if not ip.is_global:   # rejects private, loopback, link-local
(169.254.169.254), etc.
                    raise ValueError(f"{parts.hostname} resolves to non-public {ip}")
            # Caller must connect to one of THESE addresses (pin them) to avoid DNS re-
binding.
            return addrs
```

Tested results: `http://example.com/` is denied (scheme), `https://127.0.0.1/admin`, `https://169.254.169.254/latest/meta-data/`, `https://10.0.0.5:443/` and `https://[::1]/` are denied (non-public address), and `https://localhost:8443/` is denied (port). What to notice: the check uses *every* resolved address, not just the first, and `ip.is_global` covers private, loopback, link-local and other reserved ranges for both IPv4 and IPv6. Application-level validation is the inner layer; the network-level egress proxy is the layer that still holds when a developer forgets to call this function.

> COMMON MISTAKE
>
> **“A WAF fixes the OWASP Top 10.”** A web application firewall blocks known attack *patterns* at the edge and buys time for patching. It cannot know who owns photo 9001 (A01), cannot fix insecure design (A04), and can itself be a component with an SSRF flaw, as the Capital One case shows. Treat the WAF as one layer, not the control.

10.8 Secrets management

DEFINITION

Definition — Secret. Any value that grants access and must be kept confidential: database passwords, API keys, OAuth client secrets, TLS and signing private keys, encryption keys, webhook HMAC keys. **Secrets management** is the practice of storing, distributing, rotating, auditing and revoking secrets so that they are available to the workloads that need them and to nobody else.

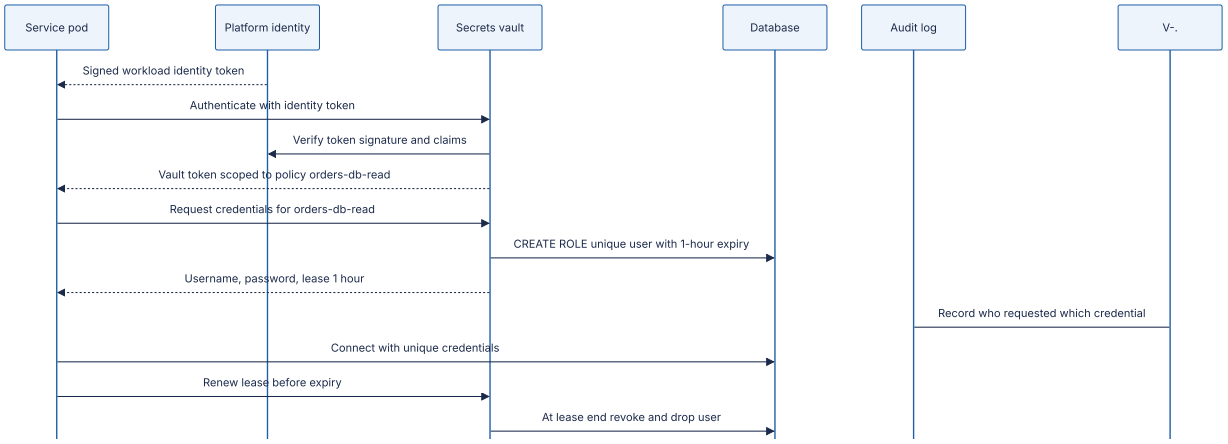
First-principles explanation

In an office, physical keys drift: copies are cut for contractors, left in drawers, never returned. Eventually nobody knows who can open the server room. Software secrets drift the same way and faster: a database password gets pasted into a configuration file, committed to Git, baked into a container image, printed in a debug log, copied into a CI variable and a teammate's laptop. Each copy is a place it can leak from, and a secret that has existed unchanged for three years has had three years to leak.

The progression of maturity is:

1. **Hard-coded** in source — anyone with repository access has production access, forever (Git history keeps it).
2. **Environment variables / config files** injected at deploy time — out of source, but static, widely copied, visible in crash dumps.
3. **Central vault** — a secrets manager (HashiCorp Vault, AWS Secrets Manager, Google Secret Manager, Azure Key Vault) stores secrets encrypted, releases them only to authenticated workloads, logs every read and supports rotation.
4. **Dynamic, short-lived credentials** — the vault *creates* a unique credential per workload on demand with a lease (say one hour) and revokes it at expiry.
5. **Identity-based ("secretless")** — workloads authenticate with a platform-attested identity (cloud IAM role, Kubernetes service-account token, SPIFFE ID) and receive short-lived tokens; there is no long-lived secret to leak.

Figure 10.6 — A workload obtaining dynamic database credentials from a vault.



Reading the diagram. The pod starts with no secret at all: the platform (for example Kubernetes or a cloud provider) gives it a signed identity token describing which service it is. The vault verifies that token and maps the identity to a policy. Instead of returning a shared password, the vault connects to the database with its own administrative credential and creates a unique, time-limited database user. The workload receives credentials it alone holds; the vault records the issuance asynchronously in an audit log (dotted arrow). Leases are renewed while the pod lives; when the pod dies the lease expires and the vault drops the user. Failure points: the vault is now a critical dependency — if it is unavailable, new pods cannot get credentials, so vaults are run as replicated clusters (Vault uses Raft consensus, §26.7) and clients cache credentials for their lease. Scaling: one credential per pod means the database must tolerate many distinct users; for very large fleets, issue per-service rather than per-pod credentials.

FORMULA

Credential misuse window

$$W = \begin{cases} T_{\text{detect}} + T_{\text{rotate}} & \text{long-lived credential} \\ \min\left(T_{\text{TTL}},\ T_{\text{detect}} + T_{\text{revoke}}\right) & \text{short-lived credential} \end{cases}$$

Symbol	Meaning	Units
W	Time during which a leaked credential remains usable	hours
T_{detect}	Time from leak to detection	hours
$T_{\text{rotate}}, T_{\text{revoke}}$	Time to rotate or revoke after detection	hours
T_{TTL}	Lifetime of a short-lived credential	hours

WORKED EXAMPLE

Worked example — Static key vs one-hour credential. Industry breach studies commonly report detection times measured in months; assume $T_{\text{detect}} = 200$ days $= 4,800$ h and $T_{\text{rotate}} = 24$ h. A static API key leaked to a public repository is usable for $W = 4,824$ h. A one-hour dynamic credential leaked in the same way is usable for at most $W = \min(1, 4,824) = 1$ h. *Interpretation:* short lifetimes shrink the window by more than three orders of magnitude *without* requiring detection to improve. *Engineering implication:* invest first in making credentials short-lived and automatically renewed; detection and response remain necessary for the vault and identity provider themselves.

Rotation must be designed, not improvised. A safe rotation for a static secret uses **two valid versions**: (1) create the new secret and register it with the receiving side, which now accepts both; (2) roll out the new secret to all callers; (3) verify no traffic uses the old one (metrics per key ID); (4) revoke the old one. This is why key IDs appear in the HMAC design of Figure 10.3. Complement rotation with **secret scanning** in repositories and CI, pre-commit hooks, and an incident runbook that answers "this key leaked — what do we do in the next 15 minutes?"

WARNING / TRADE-OFF

Kubernetes Secrets are not encrypted by default. They are base64-encoded objects in etcd; anyone with etcd access or broad RBAC `get secrets` permission can read them. Enable encryption at rest for etcd with a KMS provider, restrict RBAC, and prefer mounting secrets from an external vault (§42.11).

10.9 Encryption at rest and in transit, KMS and envelope encryption

10.9.1 In transit and at rest

Encryption in transit protects data moving over a network from eavesdropping and tampering. The rule is simple: TLS 1.2 or later (prefer 1.3) on *every* hop, including internal ones — between load balancer and service, service and database, service and cache. "The internal network is trusted" is exactly the perimeter assumption that zero trust (§10.10) rejects.

Encryption at rest protects stored data from someone who obtains the storage medium or a copy of it. It is applied at different layers, and the layer determines *which* attacker it stops.

Table 10.10 — Layers of encryption at rest and what each protects against.

Layer	Example	Protects against	Does **not** protect against	Cost
Full-disk / volume	Cloud volume encryption, LUKS	Stolen disks, discarded hardware	Anyone who can query the running system	Near-zero; usually default
Storage service	S3 SSE-KMS, managed DB storage encryption	Above, plus snapshots/backups copied without key permission	Application or DB credentials compromise	Low; KMS call costs
Database (TDE)	Transparent data encryption	Stolen DB files and backups	SQL injection, compromised DB user	Low
Application / field-level	App encrypts SSN column with a KMS-managed key before writing	DB admins, SQL injection reading raw columns, backup leaks	Compromise of the application with decrypt permission	Higher: no querying on ciphertext, key plumbing
Client-side / end-to-end	Messaging apps, client-encrypted backups	The service operator itself	Compromised client device	Highest: server cannot read or index data

The key insight: lower layers are cheap and defeat *physical* and *backup* threats; higher layers are expensive and defeat *logical* threats from people and processes with access to the running system. Most designs use volume or service encryption everywhere, and field-level encryption for a small set of highly sensitive fields (government IDs, health data, payment details).

10.9.2 Key management services and envelope encryption

DEFINITION

Definition — Key management service (KMS). A managed service, backed by hardware security modules (HSMs), that generates and stores **key-encryption keys (KEKs)** that never leave it in plaintext, performs cryptographic operations with them on request, enforces access policies on every use and logs every call. Examples: AWS KMS, Google Cloud KMS, Azure Key Vault, HashiCorp Vault's Transit engine.

DEFINITION

Definition — Envelope encryption. Encrypting data with a **data-encryption key (DEK)** generated for that data, then encrypting ("wrapping") the DEK with a KEK held in a KMS, and storing the wrapped DEK alongside the ciphertext [AWS Docs: KMS concepts].

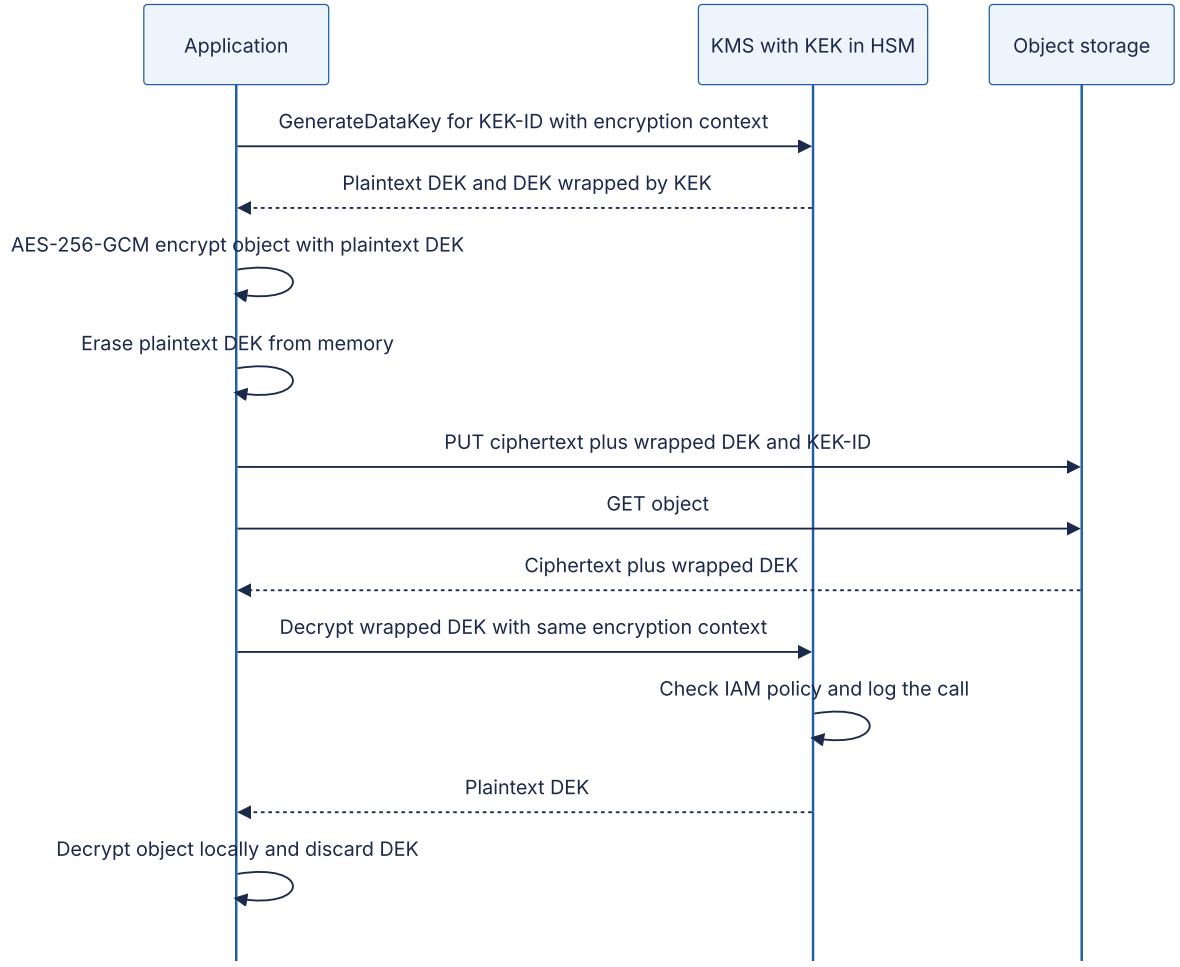
First-principles explanation

A hotel does not give each guest the master key. Each room has its own key (the DEK); the room keys are kept in a safe at the front desk, and only the manager has the key to the safe (the KEK in the KMS). Losing one room key affects one room; changing the safe's lock does not require changing every room's lock.

Why does this exist?

Three problems with sending all data to the KMS directly: (1) **size** — KMS encrypt APIs accept only small payloads (AWS KMS `Encrypt` takes at most 4,096 bytes of plaintext); (2) **latency and throughput** — every encryption would cost a network round trip and count against request quotas; (3) **blast radius** — one key encrypting everything means one leak exposes everything. Envelope encryption sends only 32-byte keys to the KMS and encrypts the bulk data locally at memory speed.

Figure 10.7 — Envelope encryption: write and read paths.



Reading the diagram. All calls are synchronous. On the write path the application asks the KMS for a fresh DEK; the KMS returns it twice — in plaintext for immediate use, and wrapped under the KEK for storage. The object is encrypted locally and stored with its

wrapped DEK, so the storage system holds only ciphertext. On the read path the application sends the small wrapped DEK to the KMS; the KMS enforces the access policy *at decrypt time* and writes an audit record, which means “who read this data” becomes visible in KMS logs even if storage access logging is off. The **encryption context** (non-secret key–value pairs such as tenant and object name) is bound to the wrapped DEK as associated data; a wrapped DEK copied onto another tenant’s object fails to unwrap. Failure points: KMS unavailability blocks all reads and writes of new objects (mitigate with regional KMS keys, retries and, carefully, short-lived DEK caching); a deleted KEK makes all data under it unrecoverable (KMS services enforce deletion waiting periods for this reason). Scaling: KMS calls grow with the number of objects, not their size.

Code example: envelope encryption with a simulated KMS

```
        """Envelope encryption with a simulated KMS (the KEK never leaves the 'KMS')."""
        import json
        import os
        from dataclasses import dataclass
        from cryptography.hazmat.primitives.ciphers.aead import AESGCM

        class FakeKMS:
            """Stands in for AWS KMS / Cloud KMS / Vault Transit. Holds KEKs inter-
nally."""
            def __init__(self):
                self._keks = {"kek-2026-10": AESGCM.generate_key(bit_length=256)}
                self.current = "kek-2026-10"

            def generate_data_key(self, context: dict) -> tuple[bytes, dict]:
                dek = AESGCM.generate_key(bit_length=256)            # fresh DEK per ob-
ject
                nonce = os.urandom(12)
                aad = json.dumps(context, sort_keys=True).encode()   # "encryption con-
text"
                wrapped = AESGCM(self._keks[self.current]).encrypt(nonce, dek, aad)
                return dek, {"kek_id": self.current, "nonce": nonce.hex(), "wrapped":
wrapped.hex()}

            def decrypt_data_key(self, blob: dict, context: dict) -> bytes:
                aad = json.dumps(context, sort_keys=True).encode()
                return AESGCM(self._keks[blob["kek_id"]]).decrypt(
                    bytes.fromhex(blob["nonce"]), bytes.fromhex(blob["wrapped"]), aad)

            def rotate(self) -> None:
                new_id = f"kek-{len(self._keks) + 1}"
                self._keks[new_id] = AESGCM.generate_key(bit_length=256)
                self.current = new_id                                 # old KEKs kept
for decrypt

            def rewrap(self, blob: dict, context: dict) -> dict:
                """Re-encrypt a DEK under the current KEK without touching the data."""
                dek = self.decrypt_data_key(blob, context)
                nonce = os.urandom(12)
                aad = json.dumps(context, sort_keys=True).encode()
                return {"kek_id": self.current, "nonce": nonce.hex(),
                        "wrapped": AESGCM(self._keks[self.current]).encrypt(nonce, dek,
aad).hex()}

        @dataclass
        class EncryptedObject:
            wrapped_dek: dict
            nonce: bytes
            ciphertext: bytes

        def encrypt_object(kms: FakeKMS, plaintext: bytes, context: dict) ->
EncryptedObject:
            dek, wrapped = kms.generate_data_key(context)             # 1 KMS call per
object
            nonce = os.urandom(12)
```

```
            ct = AESGCM(dek).encrypt(nonce, plaintext, None)          # bulk data en-
crypted locally
            del dek                                                   # drop plaintext
DEK ASAP
            return EncryptedObject(wrapped, nonce, ct)

        def decrypt_object(kms: FakeKMS, obj: EncryptedObject, context: dict) -> bytes:
            dek = kms.decrypt_data_key(obj.wrapped_dek, context)
            return AESGCM(dek).decrypt(obj.nonce, obj.ciphertext, None)

        if __name__ == "__main__":
            kms = FakeKMS()
            ctx = {"tenant": "acme", "object": "invoices/2026-10.pdf"}
            data = os.urandom(5_000_000)                              # 5 MB document
            obj = encrypt_object(kms, data, ctx)
            assert decrypt_object(kms, obj, ctx) == data
            print("round trip OK; wrapped DEK is",
len(bytes.fromhex(obj.wrapped_dek["wrapped"])), "bytes")

            kms.rotate()
            obj.wrapped_dek = kms.rewrap(obj.wrapped_dek, ctx)        # rotate KEK: re-
wrap ~60 bytes,
            assert decrypt_object(kms, obj, ctx) == data              # not re-encrypt 5
MB
            print("after KEK rotation, DEK now wrapped by", obj.wrapped_dek["kek_id"])

            try:
                decrypt_object(kms, obj, {"tenant": "evil", "object": "invoices/2026-
10.pdf"})
            except Exception as e:
                print("wrong encryption context ->", type(e).__name__)
```

Output (tested):

```
round trip OK; wrapped DEK is 48 bytes
after KEK rotation, DEK now wrapped by kek-2
wrong encryption context -> InvalidTag
```

What to notice:

- **Rotation is cheap.** Rotating the KEK means rewrapping a 48-byte wrapped DEK per object, not re-encrypting 5 MB of data. Managed KMS services go further: automatic rotation keeps old key versions for decryption, so existing wrapped DEKs remain valid without any rewrap.
- **Crypto-shredding.** Deleting a tenant's KEK (or an object's DEK) renders the data permanently unreadable, including every backup copy — a practical way to honor deletion requests in systems with immutable backups.
- **Context binding.** The encryption context is authenticated, so a confused-deputy bug that passes the wrong tenant fails closed.

- `del dek` only removes the Python reference; Python cannot guarantee the bytes are wiped from memory. Production envelope encryption should use a maintained SDK (for example the AWS Encryption SDK or Google Tink), which also defines a standard on-disk message format.

FORMULA

KMS request rate under envelope encryption

$$Q_{\text{KMS}} = \frac{\lambda_{\text{obj}}}{B}$$

Symbol	Meaning	Units
Q_{KMS}	KMS requests generated	requests/s
λ_{obj}	Rate of objects (or records) encrypted or decrypted	objects/s
B	Objects protected per KMS call (1 for a DEK per object; larger with DEK caching or per-batch keys)	objects/request

WORKED EXAMPLE

Worked example — Sizing KMS usage. An ingestion service writes $\lambda = 20,000$ records per second. With one DEK per record ($B = 1$), it would send 20,000 KMS requests per second — likely above a default per-account quota (AWS KMS cryptographic-operation quotas are in the thousands to tens of thousands of requests per second depending on region and key type, as of 2026) and costly at roughly $0.03 per 10,000 requests: $20,000 \times 86,400/10,000 \times \$0.03 \approx \$5,184$ per day. If each of 40 ingestion nodes instead generates a DEK once per minute and uses it for a batch of records (storing the wrapped DEK once per batch), then $Q = 40/60 \approx 0.67$ requests per second, about $0.17 per day. *Interpretation:* DEK granularity is a trade-off between cost/throughput and blast radius: a per-minute DEK exposes at most one minute of one node's records if leaked from memory. *Engineering implication:* choose per-object DEKs for large or individually deletable objects, and time- or count-bounded cached DEKs for high-rate small records — and keep under the GCM per-key message limit from §10.4.2.

10.10 Network security, zero trust and mTLS

10.10.1 From the castle to zero trust

The traditional **perimeter model** is a castle with a moat: a firewall at the edge, a VPN for remote workers, and implicit trust for anything inside. Its failure mode is total. Once an attacker is inside — through a phished laptop, a vulnerable VPN appliance or a compromised internal service — they can reach everything, a technique called **lateral movement**. Most large breaches are a small initial foothold followed by weeks of lateral movement.

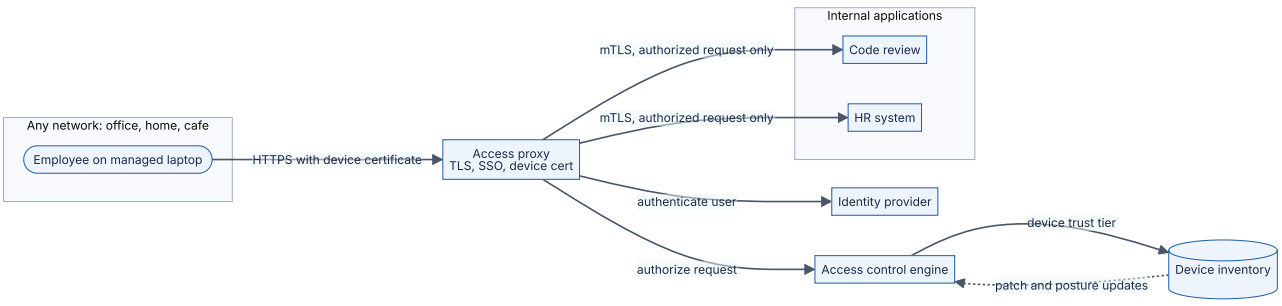
DEFINITION

Definition — Zero trust. A security model in which network location confers no trust: every request is authenticated, authorized and encrypted based on the identity of the user, the device and the workload, plus contextual signals, regardless of where it originates. NIST SP 800-207 describes it as moving defenses "from static, network-based perimeters to focus on users, assets, and resources" [NIST SP 800-207].

INDUSTRY EXAMPLE

Google BeyondCorp. After the 2009 "Operation Aurora" intrusions, Google began moving its corporate applications off the privileged internal network. In BeyondCorp, as described by Ward and Beyer, employee devices sit on an *unprivileged* network even inside Google offices; every request to an internal application goes through an internet-facing **access proxy**; access decisions are made per request by an **access control engine** using the user's identity and group membership, a **device inventory** with per-device certificates, and a computed **trust tier** for the device (patch level, management state). Remote and in-office access become identical, and the VPN is retired. Follow-up papers describe the multi-year migration and the access-proxy design. *Evidence: Primary* — [Ward & Beyer 2014]; [Osborn et al. 2016]

Figure 10.8 — Zero-trust access in the style of BeyondCorp.



Reading the diagram. The employee's location is irrelevant: the office network has no special privileges. Every request reaches the access proxy over HTTPS, presenting a device certificate (identifying the machine) and a single-sign-on session (identifying the person). The proxy asks the identity provider to authenticate the user and the access control engine to authorize *this request to this application*, using group membership and the device's current trust tier from the inventory (fed asynchronously by device-management data). Only authorized requests are forwarded, over mTLS, to applications that accept connections from the proxy alone. Failure points: the proxy and access engine become critical, highly available infrastructure; an over-permissive policy reproduces the old flat network. Scaling: the proxy is a stateless, horizontally scaled L7 tier (§19.3).

10.10.2 Mutual TLS and workload identity

Ordinary TLS authenticates only the server. **Mutual TLS (mTLS)** has *both* sides present certificates and prove possession of the private key, so a service knows cryptographically which workload is calling it — not merely which IP address, which can be spoofed or reused. In practice mTLS between services is provided by a **service mesh** sidecar or proxy (§34.10) that obtains short-lived certificates automatically. The **SPIFFE** standard defines a portable workload identity such as `spiffe://example.org/ns/payments/sa/api` carried in an X.509 certificate (an SVID), so authorization policies can be written as "only `orders` may call `payments` `POST /charge`", independent of IP addresses.

10.10.3 Least privilege and segmentation

Least privilege grants every user, service and credential the minimum permissions needed for its task, for the minimum time [Adkins et al. 2020]. In practice: one IAM role per service, not a shared "app" role; read-only database users for read-only services; no standing production admin access (engineers request time-boxed, approved, logged elevation — "just-in-time access"); and periodic review that removes unused permissions (cloud providers report "last used" data for this).

Segmentation limits blast radius at the network layer: separate VPCs or accounts for production and non-production; subnets for edge, application and data tiers with security groups allowing only the required flows (the boundaries in Figure 10.1); Kubernetes NetworkPolicies that default-deny pod-to-pod traffic; and dedicated egress paths. **Microsegmentation** pushes this down to per-workload policies. Zero trust does not abolish network controls — it stops *relying* on them. Defense in depth means an attacker must defeat identity, authorization, network policy and monitoring, not just one.

Table 10.11 — Perimeter model vs zero trust.

	Perimeter (“castle and moat”)	Zero trust
What it is	Trust based on network location	Trust based on verified identity and context per request
How it works	Edge firewall, VPN, flat internal network	Identity-aware proxies, mTLS, per-request policy
Advantages	Simple; works with legacy apps	Limits lateral movement; uniform remote access
Disadvantages	One breach exposes everything	Requires strong identity, device inventory, mature tooling
Operational complexity	Low initially, high after incidents	High upfront; policy management is ongoing
Choose when	Never as the only control	Default target architecture for new systems

10.11 DDoS basics

DEFINITION

Definition — Distributed denial of service (DDoS). An attack that makes a service unavailable by overwhelming some finite resource — network bandwidth, packet-processing capacity, connection-state tables, or application CPU, memory and database capacity — with traffic from many sources at once, typically a **botnet** of compromised devices or abused open servers.

First-principles explanation

Imagine a restaurant. A volumetric attack is a crowd so large it blocks the street, so no customer reaches the door. A protocol attack is a crowd that walks in, occupies every table, and orders nothing. An application-layer attack is a crowd of well-dressed customers each ordering the single dish that takes the kitchen an hour to cook. Each needs a different defense, applied at a different place.

Table 10.12 — DDoS attack classes.

	Volumetric	Protocol (state exhaustion)	Application layer (L7)
Target resource	Link bandwidth	Connection tables in fire-walls, load balancers, servers	Application CPU, DB, cache, downstream APIs
Examples	UDP floods; reflection/amplification via DNS, NTP, memcached	SYN floods, fragmented-packet floods	HTTP floods on expensive endpoints; HTTP/2 Rapid Reset
Measured in	Bits per second (Gbps–Tbps)	Packets per second	Requests per second
Looks like	Obviously abnormal traffic	Half-open connections	Legitimate-looking requests
Primary defense	Upstream capacity: any-cast scrubbing networks, CDN	SYN cookies, stateless edge proxies, scrubbing	WAF rules, rate limits, bot detection, caching, au-toscaling, load shedding

Reflection and amplification are what make volumetric attacks cheap. The attacker sends small UDP requests to thousands of open servers with the *victim's* IP address forged as the source; each server sends its (much larger) reply to the victim.

FORMULA

Amplified attack bandwidth

$$B_{\text{victim}} = B_{\text{attacker}} \times A$$

Symbol	Meaning	Units
B_{victim}	Traffic arriving at the victim	bits/s
B_{attacker}	Spoofed request traffic the at-tacker sends	bits/s
A	Bandwidth amplification factor of the abused protocol (response bytes / request bytes)	dimensionless

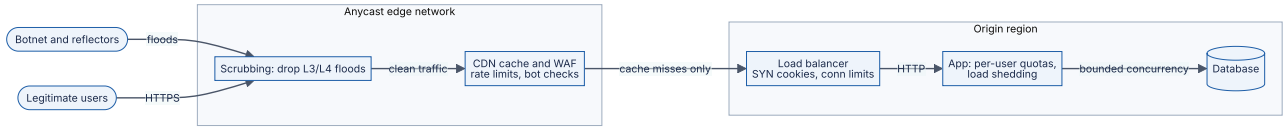
WORKED EXAMPLE

Worked example — DNS amplification. US-CERT lists DNS amplification factors of roughly 28–54 [US-CERT TA14-017A]. An attacker with 2 Gbps of spoofing capacity and $A = 50$ produces $B = 2 \times 50 = 100$ Gbps at the victim. A single origin data center with a 10 Gbps uplink is saturated tenfold; nothing the origin does locally helps, because the link is full before packets reach any server. *Engineering implication:* volumetric defense must happen **upstream**, in networks whose capacity exceeds the attack — anycast CDNs and scrubbing services that advertise your IP prefixes from many locations and absorb the flood across their global capacity.

INDUSTRY EXAMPLE

GitHub memcached attack (2018) and HTTP/2 Rapid Reset (2023). On 28 February 2018 GitHub received a 1.35 Tbps memcached-reflection attack; memcached servers exposed on UDP can amplify requests by factors in the tens of thousands. GitHub routed traffic to its DDoS-mitigation provider and the attack was mitigated within about ten minutes. In 2023 the “HTTP/2 Rapid Reset” technique (CVE-2023-44487) — opening and immediately canceling streams on a single connection — produced application-layer floods that Google reported peaking at about 398 million requests per second. *Evidence: Primary* — [GitHub 2018]; [Google Cloud 2023]

Figure 10.9 — DDoS mitigation in layers.



Reading the diagram. Traffic flows left to right through successively narrower and more expensive layers. The anycast edge, spread across many locations, absorbs volumetric and protocol floods (the scrubbing stage) because its aggregate capacity is far larger than any single origin’s. The CDN serves cacheable content without touching the origin and applies L7 controls: WAF rules, per-IP and per-session rate limits, and bot challenges. The origin should accept traffic only from the edge (allow-list the CDN’s ranges or use authenticated origin pulls), otherwise attackers bypass the edge by hitting the origin IP directly. Inside, the load balancer defends connection state, and the application enforces per-user quotas and sheds load (§22.9) so that the database — the scarcest resource — sees bounded concurrency. Scaling: autoscaling helps against L7 floods only up to your budget; an attacker’s marginal cost per request is usually lower than yours, so the main lever is making requests cheap (caching) or refusing them early.

RECOMMENDATION

Design rules. Put every public endpoint behind an anycast CDN or DDoS-protection service; hide origin IPs; cache aggressively; make expensive endpoints (search, report generation, login) authenticated and rate-limited; set timeouts and bounded queues everywhere (§22.11); know in advance who you call and what you toggle during an attack (a runbook, rehearsed).

10.12 Audit logging and tamper evidence

DEFINITION

Definition — Audit log. An append-only record of security-relevant events — who (actor), did what (action), to which resource, when, from where, and with what result — retained so that actions can be investigated and attributed. A log is **tamper-evident** if any modification, deletion or reordering of past entries can be detected.

First-principles explanation

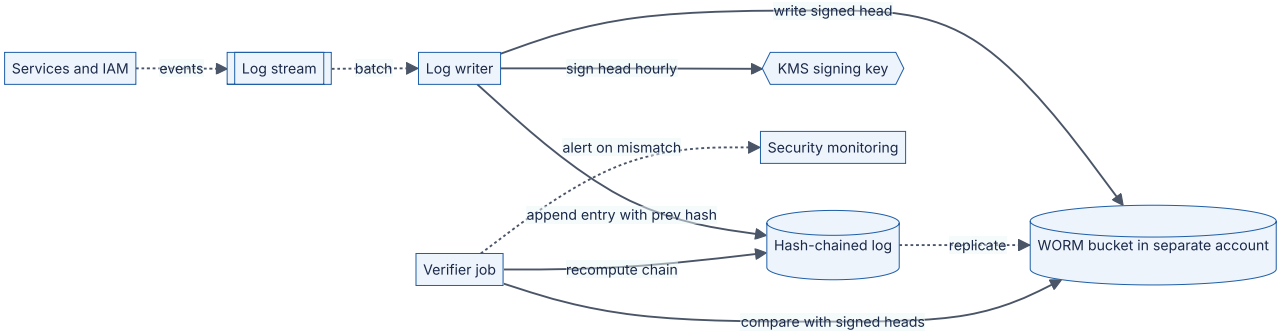
An audit log is a bank's bound, page-numbered ledger written in ink: you can add lines but cannot tear out a page or erase a line without it being obvious. Application debug logs are the opposite — a whiteboard. Attackers who gain privileged access routinely delete or edit logs to hide their tracks, and malicious insiders are precisely the people with access to logs. So audit logs must be designed so that the people being audited cannot rewrite them.

What to log. Authentication events (success, failure, MFA changes), authorization failures, privilege and role changes, access to sensitive data (reads, exports), administrative and configuration changes, key and secret usage (KMS logs this for you), and security-control changes (disabling logging is itself an event). Each entry: timestamp (UTC, synchronized clock), actor identity (user and workload), source (IP, device), action, resource, result, and a request or trace ID. **What not to log:** passwords, session tokens, full card numbers, secret values, or more personal data than necessary — the log becomes a sensitive data store itself.

How tamper evidence works. Each entry includes the hash of the previous entry, forming a **hash chain**: $h_i = H(h_{i-1} \parallel e_i)$. Changing any past entry changes its hash and breaks every link after it. A chain alone is not enough — whoever can write the log can recompute the whole chain — so the latest hash (the **head**) is periodically **anchored** somewhere the writer cannot alter: signed by a key in a KMS, written to a separate account's write-once (WORM) storage, or published to an external transparency log. Schneier and Kelsey described keyed hash-chain audit logs in 1999; Crosby and Wallach later showed

how Merkle-tree structures make such logs efficiently verifiable — the same idea behind Certificate Transparency (§10.5) [Schneier & Kelsey 1999; Crosby & Wallach 2009].

Figure 10.10 — Tamper-evident audit logging pipeline.



Reading the diagram. Services emit events asynchronously to a stream (dotted arrows), so logging never blocks user requests — at the cost that events can be delayed; the stream must be durable so events are not lost. A single writer appends each event with the previous entry's hash. Every hour it asks the KMS to sign the current head (the signing key is usable only by the writer's role and never leaves the KMS) and stores signed heads and log replicas in a WORM bucket in a separate account with object lock, so even production administrators cannot delete them before retention expires. An independent verifier recomputes the chain and compares it with the signed heads, alerting the security team on any mismatch. Failure points: the writer is a bottleneck and single point of ordering (partition the chain per service or per tenant to scale); clock skew complicates ordering (use the chain order, not timestamps, as the authority).

```
        """Tamper-evident audit log: each entry commits to the previous one (hash
chain)."""
        import hashlib
        import hmac
        import json

        GENESIS = "0" * 64

        def entry_hash(prev_hash: str, event: dict) -> str:
            payload = json.dumps(event, sort_keys=True, separators=(",", ":")).encode()
            return hashlib.sha256(prev_hash.encode() + payload).hexdigest()

        class AuditLog:
            def __init__(self):
                self.entries: list[dict] = []

            def append(self, event: dict) -> str:
                prev = self.entries[-1]["hash"] if self.entries else GENESIS
                h = entry_hash(prev, event)
                self.entries.append({"event": event, "prev": prev, "hash": h})
                return h                        # publish/anchor this "head" externally

            def verify(self, anchored_head: str | None = None) -> int | None:
                """Return index of first bad entry, or None if the chain is intact."""
                prev = GENESIS
                for i, e in enumerate(self.entries):
                    if e["prev"] != prev or not hmac.compare_digest(e["hash"],
entry_hash(prev, e["event"])):
                        return i
                    prev = e["hash"]
                if anchored_head is not None and prev != anchored_head:
                    return len(self.entries)   # tail truncated or rewritten
                return None
```

Tested: an intact chain verifies; editing the `resource` field of entry 1 makes `verify` return index 1; deleting the last entry is caught only when the verifier is given the previously anchored head.

What to notice: canonical JSON (`sort_keys`, fixed separators) makes the hash reproducible; truncation is detectable *only* because the verifier holds an anchored head from outside the log; and in production the anchor is signed and stored where the writer cannot overwrite it.

INDUSTRY EXAMPLE

AWS CloudTrail log file integrity validation. CloudTrail delivers hourly digest files that contain the SHA-256 hashes of the log files delivered in that hour, are signed with an RSA key held by AWS, and include the signature of the previous digest — a signed hash chain. Customers verify with a CLI command and are advised to store logs in a separate account with S3 Object Lock. *Evidence: Primary* — [AWS Docs: CloudTrail log file integrity validation]

10.13 A security checklist for every design

Use this table in every design document and design review — and in interviews, where spending two minutes on it distinguishes senior candidates.

Table 10.13 — Security checklist for every design.

Area	Question to answer in the design	Default good answer	Section
Threat model	What are the assets, adversaries and trust boundaries? Top 3 threats?	DFD with boundaries; STRIDE table; owners for mitigations	§10.3
Authentication	How is every user and every service identified?	Central IdP, MFA for humans; mTLS or signed tokens for services	§10.10, §8.11
Authorization	Where is each access decision made? Default?	Deny by default; central policy; object-level checks in data layer	§10.7.1
Input handling	What untrusted input crosses boundaries, and how is it validated?	Schema validation; parameterized queries; output encoding; SSRF egress proxy	§10.7
Data in transit	Is every hop encrypted, including internal ones?	TLS 1.3 everywhere; mTLS between services	§10.4.4, §10.10
Data at rest	What is sensitive? At which layer is it encrypted? Who can decrypt?	Volume encryption everywhere; KMS envelope/field encryption for sensitive fields	§10.9
Keys and secrets	Where do secrets live? Lifetime? Rotation?	Vault or KMS; short-lived dynamic credentials; no secrets in code or images	§10.8
Passwords	If you store them, how?	Argon2id (or scrypt/bcrypt), unique salt, optional pepper, breached-list check	§10.6
Least privilege	What is the minimum each component can do? Blast radius if compromised?	Per-service roles; segmented networks; no standing admin access	§10.10.3
Availability under attack	What happens under a 100× traffic flood?	CDN/anycast, rate limits, quotas, load shedding, hidden origin	§10.11
Logging and detection	Can you reconstruct who did what? Can logs be altered?	Structured audit log; tamper-evident; separate account; alerts	§10.12
Supply chain	How do dependencies and builds stay trustworthy?	Pinned dependencies, scanning, signed artifacts, protected CI	§10.7, Ch 50
Incident response	Who is paged, what is revoked, how do you rotate everything?	Runbooks; tested key rotation; backups that attackers cannot delete	§39.12
Privacy and retention	Do you need this data? For how long?	Collect minimum; retention limits; crypto-shredding for deletion	§10.9, Ch 50

10.14 Summary and revision notes

SUMMARY

- Security is a property of the architecture. Ask “against whom, protecting what, for which property (CIA, authentication, authorization, non-repudiation)?”
- Threat modeling: draw a DFD, mark trust boundaries, walk STRIDE per element, rank with likelihood × impact, and turn mitigations into tracked requirements. Most mitigations are architectural.
- Pick primitives by goal: hash (fingerprint, no key), MAC (shared-key authenticity), AEAD such as AES-GCM (secrecy + integrity), asymmetric encryption/KEM (no pre-shared key), signatures (publicly verifiable, non-repudiation), ECDHE (key agreement with forward secrecy), CSPRNG (all randomness).
- Never reuse a GCM nonce with the same key; never use `H(key‖msg)` as a MAC; never compare MACs with `==`; never use MD5/SHA-1 for security; use high-level libraries.
- PKI binds keys to names through CA signatures; Certificate Transparency makes mis-issuance detectable; short-lived, automatically rotated certificates beat revocation.
- Passwords: Argon2id (OWASP minimum m = 19 MiB, t = 2, p = 1), scrypt or bcrypt; unique salt; optional pepper in a KMS; store parameters; rehash on login; check breached lists; MFA. Expected cracking time $T = S/(2RG)$.
- OWASP Top 10 categories are missing central controls: deny-by-default authorization, parameterized queries, egress proxies against SSRF, signed artifacts, audit logging.
- Secrets: vault, short-lived dynamic credentials, workload identity, two-version rotation, secret scanning. Misuse window shrinks from months to the TTL.
- Encrypt in transit everywhere (TLS 1.3, mTLS). At rest, the layer decides which attacker you stop. Envelope encryption: DEK encrypts data locally, KMS-held KEK wraps the DEK; cheap rotation, auditable decrypts, crypto-shredding.
- Zero trust: no trust from network location; per-request authentication and authorization of user, device and workload (BeyondCorp, NIST SP 800-207), plus least privilege and segmentation for defense in depth.
- DDoS: volumetric (bandwidth, absorb upstream), protocol (state, SYN cookies/stateless edge), application (requests, rate limits, caching, shedding). Amplification $B_{\text{victim}} = B_{\text{attacker}} \times A$.
- Audit logs: who/what/which/when/where/result, no secrets; hash-chained, anchored heads signed and stored in WORM storage outside the writer’s control.

10.15 Knowledge checkpoint

1. Which STRIDE category does each of the following violate: (a) a forged webhook, (b) an admin denying a deletion, (c) reading another user's invoice by changing an ID?
2. Why is SHA-256(key ‖ message) not a safe MAC, and what does HMAC change?
3. What happens if AES-GCM encrypts two messages with the same key and nonce?
4. What is the purpose of associated data (AAD) in an AEAD scheme? Give a database example.
5. Why does TLS 1.3 use ephemeral Diffie–Hellman rather than RSA key transport?
6. A MAC and a signature both detect tampering. Which one provides non-repudiation, and why?
7. What problem does Certificate Transparency solve that the CA chain alone does not?
8. Name three reasons salts are required in password storage.
9. Compute the entropy of a 10-character password chosen uniformly from 62 alphanumeric characters.
10. Give two architectural controls for SSRF beyond URL validation.
11. Classify: SYN flood, DNS amplification, HTTP flood on `/search`.
12. Why must the head of a hash-chained audit log be anchored outside the log?

Answers

1. a. Spoofing; (b) Repudiation; (c) Elevation of privilege (an authorization failure — an IDOR; it also causes information disclosure).
2. SHA-256 is vulnerable to length extension: from the tag of `key‖m`, an attacker can compute a valid tag for `key‖m‖padding‖x` without the key. HMAC's nested two-pass construction with inner and outer padded keys prevents this.
3. The same keystream is used twice, so XORing the ciphertexts reveals the XOR of the plaintexts, and the authentication key can be recovered, enabling forgeries. Confidentiality and integrity both fail.
4. AAD is authenticated but not encrypted; it binds ciphertext to its context. Putting `table=users;id=42` in the AAD prevents an attacker with DB write access from moving that ciphertext to row 43.
5. Forward secrecy: ephemeral keys are discarded after each session, so stealing the server's long-term key later does not decrypt recorded traffic. The long-term key only signs.
6. The signature. A MAC key is shared by both parties, so either could have produced the tag; only the private-key holder can produce a signature, and anyone can verify it.
7. It detects a trusted CA issuing a certificate for your domain to someone else (compromise or error). The chain only shows *some* trusted CA signed it; CT logs make every issuance public so domain owners can notice.

8. Identical passwords no longer have identical hashes; precomputed (rainbow) tables become useless; attackers must attack each user separately, multiplying cost by the number of users.
9. $H = 10 \times \log_2 62 \approx 10 \times 5.954 = 59.5$ bits.
10. A dedicated egress proxy in a network segment without routes to internal ranges; blocking or token-protecting the metadata service (IMDSv2); least-privilege instance roles; pinning resolved IPs and disabling redirects.
11. SYN flood: protocol (state exhaustion). DNS amplification: volumetric. HTTP flood on `/search`: application layer.
12. Anyone who can write the log can recompute the entire chain after editing it. A head signed by a separate key and stored in WORM storage the writer cannot modify fixes a point the rewritten chain will not match.

10.16 Interview questions

Basic

Q1. How should a web application store user passwords? Answer. Never in plaintext or reversibly encrypted. Hash each password with a slow, memory-hard password-hashing function — Argon2id by default (at least m = 19 MiB, t = 2, p = 1 per OWASP), otherwise scrypt or bcrypt — with a unique random salt of at least 16 bytes. Store algorithm and parameters with the hash so you can raise cost later and rehash on next login. Optionally apply a pepper (a secret key in a KMS/HSM) so a database-only leak is not attackable. Compare in constant time, rate-limit login, check new passwords against breached lists, and offer MFA. Size the login fleet for the hashing cost.

Q2. What is the difference between encryption, hashing and signing? Answer. Encryption provides confidentiality and is reversible with a key. Hashing is a keyless one-way fingerprint for integrity against a trusted reference. Signing uses a private key to produce a tag anyone can verify with the public key, providing integrity, authenticity and non-repudiation. A MAC is the shared-key analog of a signature without non-repudiation. AEAD encryption combines confidentiality with integrity.

Intermediate

Q3. Design encryption for a multi-tenant document store where each tenant's data must be deletable on request, including from backups. Answer. Use envelope encryption with a per-tenant KEK in a KMS and a per-document DEK. Each document is encrypted locally with AES-256-GCM under its DEK; the wrapped DEK and KEK ID are stored with it, and the encryption context includes tenant ID and document ID. IAM policy on each KEK allows decrypt only by the service's role, and KMS logs every decrypt for audit. To delete a tenant, schedule deletion of its KEK: all its DEKs, and therefore all copies

of its documents including immutable backups, become unreadable (crypto-shredding). Discuss KMS quotas (DEK per document is fine for large documents; batch keys for tiny records), KMS availability as a dependency, regional keys for residency, and the waiting period that protects against accidental KEK deletion.

Q4. A partner sends you webhooks. How do you make sure they are genuine and not replayed? Answer. Share a high-entropy secret per partner (with a key ID for rotation). The partner computes HMAC-SHA-256 over a canonical string of timestamp, a unique event ID or nonce, and the raw body. You verify by recomputing over the raw bytes, comparing in constant time, rejecting timestamps outside a ±5-minute window and rejecting event IDs already seen (a shared store with TTL just longer than the window). Process idempotently by event ID (§22.15), since retries are legitimate. Support two active keys during rotation. Use TLS for confidentiality; HMAC provides authenticity.

Advanced

Q5. Your company runs 400 microservices on a flat internal network with shared database passwords in environment variables. Propose a two-year security roadmap. Answer. Start with visibility: inventory services and data flows, threat-model the most sensitive data stores, centralize tamper-evident audit logging. Phase 1 (0–6 months): move secrets into a vault and rotate all of them (assume compromise); add secret scanning; one IAM role and one database user per service. Phase 2 (6–12 months): issue short-lived SPIFFE-style workload certificates via a mesh or library; enable mTLS in permissive then strict mode; move databases to dynamic credentials. Phase 3 (12–24 months): default-deny network policies, per-service authorization policies, an identity-aware proxy for internal tools, just-in-time admin access. Measure progress (share of traffic on mTLS, secrets older than 30 days, wildcard permissions), roll out with dashboards and per-phase rollback switches. Trade-offs: mesh latency and operational load, database connection limits with per-workload users, and the need for owned, reviewed policies.

Q6. How would you design an audit logging system for a bank that regulators and internal investigators must be able to trust, even against a malicious administrator? Answer. Define the event schema (actor, workload, action, resource, result, source, trace ID) and emit from every service through a durable stream so logging does not block requests. A writer service builds per-partition hash chains; hourly it signs each chain head using a KMS key restricted to the writer role and writes signed heads plus log segments to WORM storage (object lock in compliance mode) in a separate account administered by a different team. An independent verifier recomputes chains and compares with signed heads; mismatches alert security operations. Separate duties: no single administrator controls the production account, the log account and the KMS key policy. Index a copy in a SIEM for search, treating the SIEM as derived and untrusted. Address clock sync, retention (years, per regulation), personal data minimization, and Merkle-tree structures if third parties need efficient inclusion proofs.

10.17 Practical exercises

1. **Password hashing benchmark.** Run the code in §10.6.2. Increase Argon2id memory to 64 MiB and t to 3 and measure latency. Compute how many cores you would need for 500 logins per second at peak with 50% headroom.
2. **HMAC request signing.** Extend the code in §10.4.6 to support two active keys per client, and write a test proving that removing the HTTP method from the canonical string lets an attacker turn a signed `GET` into a `DELETE`.
3. **Envelope encryption.** Extend the `FakeKMS` example in §10.9.2 with a per-tenant KEK and a `delete_tenant` operation. Show that encrypted objects for a deleted tenant can no longer be decrypted while other tenants are unaffected. Then replace `FakeKMS` with a real KMS client in a sandbox account if you have one.
4. **Brute-force calculator.** Write a function that takes alphabet size, length, guesses per second and number of GPUs and prints expected time. Use it to compare a 4-word and a 6-word Diceware passphrase (7,776 words) against bcrypt and against unsalted SHA-256.
5. **Tamper-evident log.** Modify the audit log in §10.12 so that every 100 entries the head is signed with an Ed25519 key (§10.4.8). Write a verifier that accepts only chains whose signed heads verify.
6. **Threat model.** Draw a DFD for a URL shortener (§52.4) with trust boundaries and produce a STRIDE table with at least eight threats ranked by $L \times I$.

10.18 Design challenges

1. **Secure file-sharing link service.** Users share files by link; links can expire and be revoked; recipients may be anonymous. Design storage encryption, link-token generation (entropy and length), revocation, download rate limiting and audit logging. Identify where signed URLs, HMAC and envelope encryption each fit.
2. **Zero-trust migration for an admin console.** A company's internal admin console is reachable over VPN by 300 support agents and offers "view any customer" functionality. Redesign access with an identity-aware proxy, device posture, just-in-time elevation for sensitive actions and an audit trail that customers can be shown. State the failure mode if the identity provider is down.
3. **DDoS-resilient public API.** A public API serves 20,000 RPS normally, with an expensive search endpoint costing 50 ms of database time per request. Design layered defenses for a 1 Tbps volumetric attack and for a 2 million RPS application-layer flood from residential IPs. Quantify how much the cache hit ratio and per-key rate limits reduce database load.

Part III — Data Systems

Chapter 11 — Relational Databases

> **Level:** 1–2 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Almost every system you will design has a relational database somewhere in it. The orders in a shop, the balances in a bank, the users of a social network and the configuration of a cloud platform usually live in PostgreSQL, MySQL or a database that speaks their SQL dialect. Relational databases have been the default for fifty years because they solve three hard problems at once: they let you describe *what* data you want without saying *how* to fetch it, they keep data correct while thousands of clients change it concurrently, and they keep committed data safe through crashes.

This chapter explains how they do it, using one running example: the order system of an online shop. You will learn to model its data, index it, read query plans, choose isolation levels and avoid costly concurrency bugs. On-disk internals (write-ahead logging, buffer pools, LSM trees) are covered in Chapter 13, replication and sharding in Chapter 14, and distributed transactions in Chapter 28.

11.1 Learning objectives

After this chapter you should be able to:

- Explain the relational model and choose primary keys (natural or surrogate) and foreign keys.
- Normalize a schema to BCNF using functional dependencies, and justify each deliberate denormalization.
- Write inner, outer, semi- and anti-joins, and estimate the I/O cost of nested-loop, hash and sort-merge joins.
- Design clustered, secondary, composite, covering and partial indexes for a stated query workload.
- Compute B+ tree height and I/Os per lookup from page size, key size and row count.
- Read a PostgreSQL `EXPLAIN (ANALYZE, BUFFERS)` plan and diagnose a cardinality misestimate.
- Define ACID precisely and distinguish ACID consistency from consistency in distributed systems.
- Reproduce dirty reads, non-repeatable reads, phantoms, lost updates and write skew, and state which isolation level prevents each in PostgreSQL and MySQL.

- Explain MVCC in PostgreSQL (tuple versions, `xmin`/`xmax`, VACUUM) and InnoDB (undo logs, purge).
- Explain two-phase locking, gap locks and deadlock detection, and avoid deadlocks and hot-row contention.
- Produce an end-to-end schema, DDL and queries for an e-commerce order system.

11.2 Prerequisites

- Logarithms and B-tree fan-out — §4.4 (index height is a logarithm with a large base).
- Storage devices and latency numbers — §5.6, §4.17 (a random SSD read costs ~100 µs; RAM ~100 ns).
- Page cache and `fsync` — §6.6, §6.14 (durability depends on forcing the log to disk).
- Race conditions, mutexes and deadlock — §6.9–§6.11 (database locking applies the same ideas to rows).
- Keyset pagination — §8.6.5 (we reuse it in the order-history query).
- Idempotency keys — §8.6.3 and §22.15 (the order API must be safe to retry).

11.3 The relational model: tables, rows and columns

11.3.1 Relations, tuples and attributes

> DEFINITION
>
> **Definition — Relation.** A **relation** is a named set of **tuples** that share the same **attributes**. Each attribute has a name and a **domain** (the set of allowed values, such as 64-bit integers). In SQL a relation is a **table**, a tuple is a **row** and an attribute is a **column**. The relation's name and attributes together form its **schema**; the set of rows at a moment is its **instance**.

First-principles explanation

A table looks like a spreadsheet, but three differences matter. A relation is a *set*: rows have no inherent order and are identified by their values (a key), never by "row 17". Every column has a fixed type, enforced on every write. And relationships are expressed by *values*: an order row stores the customer's ID, not a pointer. These properties let the query optimizer rearrange *how* a question is answered without changing the answer.

Why does this exist?

Before 1970, hierarchical (IBM IMS) and network (CODASYL) databases linked records by physical pointers, and programs *navigated* them: "go to customer 42, follow the first-

order pointer…". Reorganizing storage broke the programs. Codd's paper "A Relational Model of Data for Large Shared Data Banks" proposed that users should see only relations, and that access paths should be the database's private business [Codd 1970]. This **physical data independence** is why you can add an index to a production table today and every existing query keeps working, only faster.

How it works internally

1. You state *what* you want in SQL, a declarative language first built at IBM for System R.
2. The database translates it into **relational algebra**: selection σ (filter rows), projection π (choose columns), join ⋈, union, difference and aggregation.
3. Algebraic equivalences ("filter before joining", "join A with B before C") let the optimizer generate equivalent plans and pick the cheapest (§11.10).
4. The executor runs that plan against physical structures (heap files, B+ trees) that the query never mentions (§11.9).

NULL and three-valued logic

SQL adds **NULL**, meaning "unknown or not applicable". Any comparison with NULL yields UNKNOWN, not TRUE or FALSE, and `WHERE` keeps only rows whose condition is TRUE.

> COMMON MISTAKE
>
> **Mistake — `WHERE coupon_code <> 'SPRING'` returns orders without a coupon.** It does not: for rows where `coupon_code` is NULL, the comparison is UNKNOWN and the row is dropped. Write `WHERE coupon_code IS DISTINCT FROM 'SPRING'` (PostgreSQL, SQLite) or add `OR coupon_code IS NULL`. Likewise `NOT IN (subquery)` returns no rows if the subquery yields a single NULL; prefer `NOT EXISTS`.

11.4 Keys: primary, foreign, natural and surrogate

11.4.1 Superkeys, candidate keys and primary keys

DEFINITION

Definition — Keys. A **superkey** is a set of columns whose values are unique across all rows. A **candidate key** is a minimal superkey: remove any column and it stops being unique. The **primary key** is the candidate key chosen as the row's main identifier; it must be unique and NOT NULL. Other candidate keys are enforced with `UNIQUE` constraints. A **foreign key** is a column (or set) in one table whose values must match a key of another table, a rule called **referential integrity**.

In the shop, `customers` has two candidate keys: `customer_id` and `email`. We choose `customer_id` as the primary key and declare `email` `UNIQUE`. `orders.customer_id` is a foreign key to `customers.customer_id`: the database rejects an order for a customer that does not exist, and rejects deleting a customer who still has orders unless you specify otherwise.

The **referential action** says what happens to child rows when a parent is deleted: `NO ACTION` / `RESTRICT` (reject; the default), `CASCADE`, `SET NULL` or `SET DEFAULT`. Use `CASCADE` for true ownership (an order owns its items) and the default for independent entities (deactivate products rather than delete them).

Code example

```
        import sqlite3

        db = sqlite3.connect(":memory:")
        db.executescript("""
        PRAGMA foreign_keys = ON;            -- SQLite enforces FKs only when this is
set
        CREATE TABLE customers (customer_id INTEGER PRIMARY KEY, email TEXT NOT NULL
UNIQUE);
        CREATE TABLE orders (
          order_id    INTEGER PRIMARY KEY,
          customer_id INTEGER NOT NULL REFERENCES customers (customer_id)
        );
        INSERT INTO customers VALUES (1, 'ana@example.com');
        INSERT INTO orders VALUES (100, 1);
        """)
        for sql in ["INSERT INTO orders VALUES (101, 99)",                    # no cus-
tomer 99
                    "INSERT INTO customers VALUES (2, 'ana@example.com')",   # duplicate
candidate key
                    "DELETE FROM customers WHERE customer_id = 1"]:          # still has
an order
            try:
                db.execute(sql)
            except sqlite3.IntegrityError as e:
                print(f"{sql[:40]:<42} -> {e}")
```

What to notice:

- All three statements fail with `IntegrityError`: the database, not application code, guards the invariants. Output: `FOREIGN KEY constraint failed`, `UNIQUE constraint failed: customers.email`, `FOREIGN KEY constraint failed`.
- SQLite enforces foreign keys only after `PRAGMA foreign_keys = ON`, per connection. PostgreSQL and MySQL (InnoDB) always enforce them.
- Foreign-key checks cost an index lookup on the parent for every child insert. PostgreSQL does **not** automatically index the *child* column (`orders.customer_id`); without that index, deleting a customer scans the whole `orders` table. Index foreign-key columns you join or delete through.

11.4.2 Natural versus surrogate keys

DEFINITION

Definition — Natural and surrogate keys. A **natural key** is a candidate key with business meaning (email address, ISBN, country code). A **surrogate key** is a meaningless value generated by the system (an auto-increment integer, a UUID) whose only job is identification.

Business identifiers change (people change email addresses; product codes are reissued), and every foreign key that copied the old value must change too. Surrogate keys never change, are compact and make joins cheap. The common rule: a surrogate primary key, plus a `UNIQUE` constraint on the natural key. Natural keys suit small, stable code tables (ISO country or currency codes).

The *kind* of surrogate matters for B+ tree indexes (§11.8). Sequential integers always insert at the right-most leaf, so pages fill completely and stay hot in cache. Random UUIDv4 values insert into a random leaf, causing page splits, half-empty pages and a working set as large as the whole index. Time-ordered identifiers (UUIDv7, Snowflake-style IDs; §17.10) keep the insert locality of integers while being globally unique without a central counter.

Table 11.1 — Choosing a primary key.

Key type	Size	Insert locality in B+ tree	Globally unique	Leaks information	Choose when
Natural key (email, SKU)	Variable	Random	Within domain	Yes (it is data)	Small stable code tables
`bigint` identity / auto-increment	8 bytes	Sequential (excellent)	Per table only	Row count, growth rate	Single database, default choice
UUIDv4	16 bytes	Random (poor)	Yes	No	IDs generated offline by clients; small tables
UUIDv7 / Snowflake-style	16 / 8 bytes	Roughly sequential	Yes	Creation time	Many writers or shards (§17.10)

INDUSTRY EXAMPLE

Instagram — sharded PostgreSQL with time-ordered 64-bit IDs. Instagram described generating primary keys inside PostgreSQL with a function that packs 41 bits of milliseconds since a custom epoch, 13 bits of logical shard ID and 10 bits of a per-shard sequence. IDs sort by time (good B+ tree locality, cheap “newest first” queries), fit in a `bigint`, and need no central ID service. The trade-off is that IDs reveal creation time and that the bit budget caps per-shard throughput at 1,024 IDs per millisecond. *Evidence: Primary* — [Instagram Engineering 2012]

COMMON MISTAKE

Mistake — “UUIDs are slow, never use them.” The cost is randomness, not size. A UUIDv4 primary key in InnoDB, where the primary key *is* the storage order (§11.7), scatters inserts across the whole table; a UUIDv7 key does not.

11.5 Normalization and denormalization

11.5.1 Redundancy and the three anomalies

First-principles explanation

Imagine the shop's first version kept one spreadsheet row per order line, with the customer's email and the product's name copied into every row. When Ana changes her email, 40 rows must change; miss one and the database holds two "truths". Normalization's goal is that **every fact is stored exactly once**.

Redundant designs suffer three **anomalies**:

1. **Update anomaly** — changing one fact requires changing many rows; a partial update leaves contradictions.
2. **Insert anomaly** — you cannot record a fact without an unrelated one: a new product cannot be stored until somebody orders it.
3. **Delete anomaly** — deleting one fact destroys another: canceling and purging the only order of a product loses the product's name and price.

DEFINITION

Definition — Functional dependency. In a relation R, the functional dependency $X \to Y$ holds if any two rows that agree on the columns X also agree on the columns Y. X is the **determinant**. Example: `product_id → product_name` because one product ID always has one name.

11.5.2 The normal forms

DEFINITION

Definition — Normal forms (1NF to BCNF). 1NF: every column holds a single atomic value (no lists or repeating groups). **2NF:** 1NF, and no non-key column depends on only *part* of a composite candidate key. **3NF:** 2NF, and no non-key column depends on another non-key column (no transitive dependency); formally, for every non-trivial $X \to A$, either X is a superkey or A is part of some candidate key. **BCNF (Boyce–Codd normal form):** for every non-trivial $X \to A$, X is a superkey. BCNF removes 3NF's exception for key columns.

Kent's one-line summary of 2NF and 3NF is that every non-key column must provide a fact about "the key, the whole key, and nothing but the key" [Kent 1983]. Higher forms (4NF, 5NF) deal with multi-valued and join dependencies and rarely matter in application design.

Table 11.2 — Normal forms at a glance.

Form	Forbids	Typical symptom	Fix
1NF	Lists or repeating groups in a column	`items = 'MUG-1x2; TEE-1x1'`	One row per item
2NF	Dependency on part of a composite key	Product name repeated on every order line	Move to a table keyed by the part
3NF	Non-key → non-key dependency	Customer email repeated on every order	Move to a table keyed by the determinant
BCNF	Any determinant that is not a superkey	Overlapping candidate keys (see below)	Split on the offending dependency

11.5.3 Worked decomposition: from a flat export to BCNF

WORKED EXAMPLE

Worked example — Normalizing the shop's order export. The legacy export has one row per order line:

`order_lines_flat(order_id, order_date, customer_id, customer_email, customer_city, product_id, product_name, list_price_cents, quantity, unit_price_cents)`

Step 1 — 1NF. An even older format stored all items of an order in one text cell. Splitting that cell into one row per product makes every value atomic, giving the table above.

Step 2 — List the functional dependencies. From the business rules: - FD1: `order_id → order_date, customer_id` - FD2: `customer_id → customer_email, customer_city` - FD3: `customer_email → customer_id` (emails are unique) - FD4: `product_id → product_name, list_price_cents` - FD5: `order_id, product_id → quantity, unit_price_cents` (one line per product per order)

The only candidate key is `{order_id, product_id}`: together they determine every column, and neither does alone.

Step 3 — 2NF. FD1 and FD4 have determinants that are *part* of the key, so `order_date`, the customer columns and the product columns depend on part of the key. Split each partial dependency into its own table: `- orders_wide(order_id, order_date, customer_id, customer_email, customer_city) - products(product_id, product_name, list_price_cents) - order_lines(order_id, product_id, quantity, unit_price_cents)`

Step 4 — 3NF. In `orders_wide`, `order_id → customer_id → customer_email, customer_city` is a transitive dependency. Split on FD2: `- orders(order_id, order_date, customer_id) - customers(customer_id, customer_email, customer_city)`

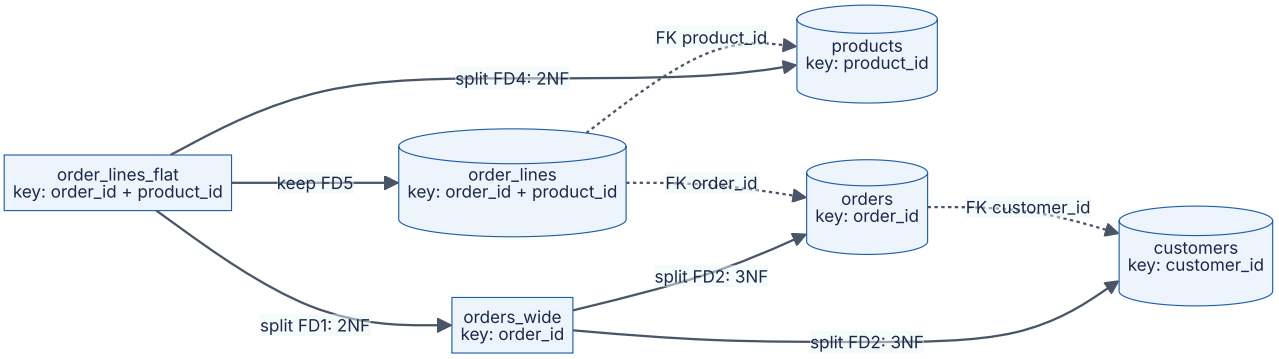
Step 5 — BCNF check. In `customers`, the determinants are `customer_id` and `customer_email`, both candidate keys. In every other table the only determinant is the primary key. All five tables are in BCNF.

Step 6 — Lossless-join check. A split of R into R_1 and R_2 is **lossless** (joining them back reproduces exactly the original rows, no more, no fewer) if the shared columns form a key of at least one side. Each split above shares a column that is a key of one side (`order_id`, `product_id`, `customer_id`), so joining the five tables reproduces the export exactly.

Interpretation. Ana's email is now stored once, products exist without orders, and deleting an order never loses product data. **Engineering implication.** Notice that

> `unit_price_cents` stayed in `order_lines` while `list_price_cents` moved to `products`. They are different facts: the price *charged* on that day versus the price *today*. Copying the price into the order line is not redundancy; it is history, and dropping it would make every past invoice change whenever marketing changes a price.

Figure 11.1 — Decomposing the flat order export into BCNF tables.



Reading the diagram. The rectangle on the left is the unnormalized input, middle rectangles are intermediate tables and cylinders are the final BCNF tables. Solid arrows are decomposition steps labeled with the dependency that justified them; dotted arrows are the foreign keys that make the decomposition lossless. These are join paths, not runtime flows, so there is no synchronous or asynchronous traffic here. The risk a decomposition introduces is a lost dependency (§11.5.4); the scaling cost is one more join per extra table, which denormalization later buys back.

11.5.4 When BCNF and 3NF disagree

Most 3NF schemas are already in BCNF; the exception needs overlapping candidate keys. Suppose each delivery depot is run by one carrier (`depot → carrier`) and each carrier serves a postal code from one depot (`postal_code, carrier → depot`). In `coverage(postal_code, carrier, depot)` the candidate keys are `{postal_code, carrier}` and `{postal_code, depot}`, so `depot → carrier` violates BCNF but not 3NF (`carrier` is part of a key). Splitting into `depots(depot, carrier)` and `coverage(postal_code, depot)` reaches BCNF but `postal_code, carrier → depot` can no longer be enforced by a unique constraint. BCNF decomposition is always lossless but not always **dependency-preserving**; 3NF can always achieve both [Ramakrishnan and Gehrke 2003].

11.5.5 Denormalization

DEFINITION

Definition — Denormalization. Deliberately storing a fact more than once, or storing a derived value, to make important reads cheaper, while accepting the cost of keeping the copies consistent.

Normalization optimizes for correct, cheap writes; some read paths (a product page with its review count, a revenue dashboard) would then need large joins or aggregations on every request. Common forms of denormalization:

1. **Stored aggregates** — `orders.total_cents`, `products.review_count`, updated in the same transaction as the rows they summarize.
2. **Copied columns** — `order_lines.product_name` kept so invoices render without a join (and, like the unit price, it is also a historical fact).
3. **Materialized views** — a stored query result, refreshed periodically (`REFRESH MATERIALIZED VIEW CONCURRENTLY` in PostgreSQL).
4. **Read models outside the database** — caches (Chapter 20), search indexes (Chapter 16) or CQRS projections fed by change data capture (§32.4, §32.6). These are updated asynchronously and are therefore eventually consistent.

RECOMMENDATION

Recommendation — Normalize the source of truth; denormalize with an owner. Add a redundant copy only for a measured read problem, and name what keeps it consistent: the same transaction, a trigger, or an asynchronous pipeline (eventually consistent, needs a reconciliation job). A copy with no owner will drift.

Table 11.3 — Failure scenarios in schema design.

What goes wrong	Why	Detection	Recovery	Prevention
Two customers rows with the same email	Natural key not declared `UNIQUE`	Duplicate-detection query; login bugs	Merge rows, repoint FKs	`UNIQUE` on every candidate key
Denormalized total disagrees with items	Update path forgot the aggregate	Nightly reconciliation query	Recompute from source rows	Update in the same transaction; reconciliation job
Old invoices change when prices change	Price stored only in `products`	Customer complaints, audit	Restore from backups or logs	Store price-at-purchase in `order_lines`
Orphaned order lines	No FK constraint	Anti-join `NOT EXISTS` check	Delete or repair orphans	Declare FKs; `ON DELETE CASCADE` for owned rows

11.6 SQL and joins

11.6.1 SQL as a declarative language

> DEFINITION
>
> **Definition — SQL.** The Structured Query Language, standardized by ANSI/ISO, with sublanguages for defining schema (DDL: `CREATE`, `ALTER`, `DROP`), manipulating data (DML: `SELECT`, `INSERT`, `UPDATE`, `DELETE`) and controlling transactions (`BEGIN`, `COMMIT`, `ROLLBACK`). Every major database implements the core standard plus its own dialect.

A `SELECT` is evaluated, logically, in the order `FROM`/`JOIN` → `WHERE` → `GROUP BY` → `HAVING` → `SELECT` → `ORDER BY` → `LIMIT`, which is why a `SELECT` alias cannot be used in `WHERE`. The physical execution order may differ (a filter pushed below a join) as long as the result is identical.

11.6.2 Join types

A **join** combines rows from two tables that satisfy a condition. Using the shop tables:

```
        -- Inner join: orders with their customer (orders without a customer cannot ex-
ist: FK)
        SELECT o.order_id, c.email, o.total_cents
        FROM orders o
        JOIN customers c ON c.customer_id = o.customer_id;

        -- Left outer join: every customer, with order count (0 for customers who never
ordered)
        SELECT c.customer_id, c.email, COUNT(o.order_id) AS orders
        FROM customers c
        LEFT JOIN orders o ON o.customer_id = c.customer_id
        GROUP BY c.customer_id, c.email;

        -- Semi-join: customers who bought product 42 (each customer once, however many
orders)
        SELECT c.email FROM customers c
        WHERE EXISTS (SELECT 1 FROM orders o JOIN order_items i ON i.order_id =
o.order_id
                      WHERE o.customer_id = c.customer_id AND i.product_id = 42);

        -- Anti-join: customers with no orders at all
        SELECT c.email FROM customers c
        WHERE NOT EXISTS (SELECT 1 FROM orders o WHERE o.customer_id = c.customer_id);
```

What to notice:

- `COUNT(o.order_id)` counts non-NULL values, so customers with no orders get 0; `COUNT(*)` would wrongly give 1, because the outer join produces one row padded

with NULLs.
- `EXISTS` expresses "at least one match" without duplicating the customer per matching row; a plain join followed by `DISTINCT` gives the same answer with more work.
- A `RIGHT JOIN` is a left join with the tables swapped; a `FULL OUTER JOIN` keeps unmatched rows from both sides. All four statements run unchanged in SQLite and PostgreSQL.

11.6.3 Join algorithms

The SQL says *what* to join; the database picks *how*. There are three families, and every relational engine uses some of them [Ramakrishnan and Gehrke 2003; Graefe 1993].

First-principles explanation

To match 1,000 wedding guests to their table assignments, you could read the whole assignment list once per guest (**nested loop**), file the assignments on cards by surname and look each guest up (**hash join**), or sort both lists and walk them together (**sort-merge join**). The fastest choice depends on list sizes, existing order and desk space (memory).

How it works internally

1. **Nested-loop join (NLJ).** For each row of the *outer* input, scan the *inner* input and emit matching pairs. **Block NLJ** reads the outer side in memory-sized chunks so the inner side is scanned once per chunk instead of once per row. **Index NLJ** replaces the inner scan with an index lookup: for each outer row, descend the inner table's B+ tree on the join column. Index NLJ is the best algorithm when the outer side is small, which is the case for most OLTP queries ("this customer's orders").
2. **Hash join.** *Build* phase: read the smaller input and insert each row into an in-memory hash table keyed on the join column. *Probe* phase: stream the larger input and look up each row's key. It needs an equality condition. If the build side does not fit in memory, both inputs are first **partitioned** by a hash of the key into spill files on disk so that each partition pair fits (the **Grace hash join**).
3. **Sort-merge join.** Sort both inputs on the join key (or read them in order from an index), then advance two cursors in step, emitting matches. It handles equality and also benefits range conditions; it is attractive when inputs are already sorted or when the output must be sorted anyway.

```
        from collections import defaultdict

        customers = [(1, "Berlin"), (2, "Austin"), (3, "Pune")]           #
(customer_id, city)
        orders = [(10, 1, 2500), (11, 3, 900), (12, 1, 4100), (13, 4, 50)]  # (order_id,
customer_id, total)

        def nested_loop_join(outer, inner, okey, ikey):
            for o in outer:                       # for every outer row ...
                for i in inner:                   # ... scan the whole inner input
                    if o[okey] == i[ikey]:
                        yield o + i

        def hash_join(build, probe, bkey, pkey):
            table = defaultdict(list)
            for b in build:                       # build phase: hash the smaller input
                table[b[bkey]].append(b)
            for p in probe:                       # probe phase: one lookup per probe row
                for b in table.get(p[pkey], ()):
                    yield b + p

        def sort_merge_join(left, right, lkey, rkey):
            left, right = sorted(left, key=lambda r: r[lkey]), sorted(right, key=lambda
r: r[rkey])
            i = j = 0
            while i < len(left) and j < len(right):
                lv, rv = left[i][lkey], right[j][rkey]
                if lv < rv:
                    i += 1
                elif lv > rv:
                    j += 1
                else:                             # emit every pair in the matching
groups
                    j_end = j
                    while j_end < len(right) and right[j_end][rkey] == lv:
                        j_end += 1
                    while i < len(left) and left[i][lkey] == lv:
                        for r in right[j:j_end]:
                            yield left[i] + r
                        i += 1
                    j = j_end

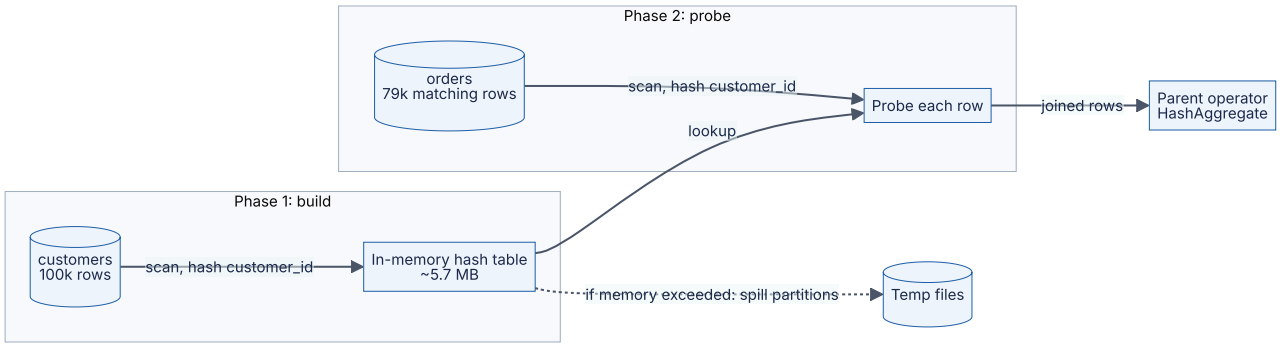
        for name, rows in [("nested loop", nested_loop_join(customers, orders, 0, 1)),
                           ("hash", hash_join(customers, orders, 0, 1)),
                           ("sort-merge", sort_merge_join(customers, orders, 0, 1))]:
            print(f"{name:<12}", sorted(rows, key=lambda r: r[2]))
```

What to notice:

- All three print the same three rows: Berlin with orders 10 and 12, Pune with order 11. Order 13 (customer 4) has no match and disappears, as an inner join requires.
- The nested loop performs $3 \times 4 = 12$ comparisons; the hash join performs 3 inserts and 4 probes. With a million rows on each side, that difference is 10^{12} versus 2×10^{6}

operations.

Figure 11.2 — Hash join: build on the smaller input, probe with the larger.



Reading the diagram. Cylinders are tables or temporary files; rectangles are in-memory operator state; every solid arrow is a synchronous in-process data flow. The build phase must finish before probing starts (blocking), while the probe phase passes each `orders` row upward immediately (pipelined). The dotted arrow is the degradation path: if the hash table exceeds the memory budget (`work_mem` in PostgreSQL), both inputs are partitioned to disk and re-read. Sizes come from the real plan in §11.10. Scaling: more memory, an earlier filter on the build side, or parallel probe workers.

Mathematical foundations

The classic way to compare join algorithms counts **page I/Os**, because on a disk-resident database they dominate [Ramakrishnan and Gehrke 2003]. Let the outer relation R have M pages and the inner relation S have N pages.

FORMULA

I/O cost of join algorithms

$$C_{\text{tuple NLJ}} = M + p_R \cdot M \cdot N \qquad C_{\text{block NLJ}} = M + \lceil \frac{M}{B-2} \rceil N$$

$$C_{\text{index NLJ}} = M + p_R \cdot M \cdot c_{\text{idx}} \qquad C_{\text{Grace hash}} \approx 3(M+N) \qquad C_{\text{sort-merge}} \approx 3(M+N) \text{ to } 5(M+N)$$

Symbol	Meaning	Units
M, N	Pages in the outer relation R and inner relation S	pages
p_R	Rows per page of R	rows/page
B	Buffer pages available to the join (one for output, one for the inner scan)	pages
c_{idx}	Page reads to find matching inner rows through an index (descent plus row fetch)	pages/row
C	Total page reads and writes	page I/Os

The hash and sort-merge figures assume enough memory to finish in two passes (roughly $B > \sqrt{\min(M,N)}$ for hash, $B > \sqrt{\max(M,N)}$ for sort); with fewer buffers, more passes are needed. If the build side fits entirely in memory, a hash join reads each input once: $M + N$.

WORKED EXAMPLE

Worked example — Joining `orders` with `order_items`. The PostgreSQL tables of §11.10 have $M = 15,385$ pages for `orders` (1,000,000 rows, so $p_R = 65$) and $N = 18,383$ pages for `order_items` (2,500,000 rows), with 8 KiB pages. Assume $B = 1,002$ buffer pages (about 8 MiB).

1. Tuple NLJ: $15,385 + 65 \times 15,385 \times 18,383 = 15,385 + 1.84 \times 10^{10} \approx 1.8 \times 10^{10}$ I/Os. At 100 µs per random read that is 1.8×10^{6} s, about 21 days.
2. Block NLJ: $\lceil 15,385/1,000 \rceil = 16$ chunks; $15,385 + 16 \times 18,383 = 309,513$ I/Os, about 31 s at 100 µs each (much less with sequential reads).
3. Grace hash join: $3 \times (15,385 + 18,383) = 101,304$ I/Os, about 10 s; if `orders` fits in memory, $33,768$ I/Os.
4. Index NLJ for **one customer's** 10 orders: the outer side is 10 rows; each needs about 4 page reads in the `order_items` primary-key index plus heap: roughly $10 \times 4 = 40$ I/Os, about 4 ms cold and well under 1 ms when cached (the real plan in §11.10 took 0.43 ms).

Interpretation. For a whole-table join, the naive nested loop is impossible, block NLJ is tolerable and the hash join wins. For a selective OLTP query, the index nested loop wins by four orders of magnitude, because it touches only the rows it needs.
Engineering implication. There is no universally best join algorithm; the optimizer must know *how many rows* each side produces, which is why cardinality estimation (§11.10) decides performance.

Table 11.4 — Join algorithms compared.

Algorithm	Join conditions	Memory	Best when	Weakness
Nested loop (block)	Any	Small	Tiny inputs; non-equality conditions	Quadratic on large inputs
Index nested loop	Equality or range on indexed inner column	Small	Small outer side, indexed inner (OLTP)	Random I/O per outer row if outer is large
Hash join	Equality only	Build side (spills if needed)	Large unsorted inputs, analytics	Blocking build; spills when memory is short
Sort-merge join	Equality (and some ranges)	Sort buffers	Inputs already sorted or output needs sorting	Sorting cost if inputs are unsorted

As of 2026, PostgreSQL implements all three. MySQL implements nested-loop variants (including batched key access) and, since 8.0.18, hash joins; it has no sort-merge join [MySQL Docs: Hash Join].

11.7 Indexes

11.7.1 What an index is

DEFINITION

Definition — Index. A secondary data structure, kept in sync with a table by the database, that maps values of one or more **key columns** to the locations of the rows holding them, so that rows can be found without scanning the whole table. Most relational indexes are B+ trees (§11.8); others include hash, GiST, GIN and BRIN indexes in PostgreSQL and full-text and spatial indexes in MySQL.

First-principles explanation

A book's index finds "isolation levels" without reading 900 pages because it is sorted, small and points to page numbers. It must be updated when the book changes, takes paper, and is useless for a word on every page ("the"). Database indexes behave the same way: fast for selective conditions, extra work on every write, extra storage, no help when a query needs much of the table.

Why does this exist?

Without an index, `SELECT * FROM orders WHERE customer_id = 4242` read all 15,385 pages of the table and took 70 ms to find 10 rows (§11.10). With an index it read 16 pages and took 0.14 ms.

11.7.2 Clustered and secondary indexes

DEFINITION

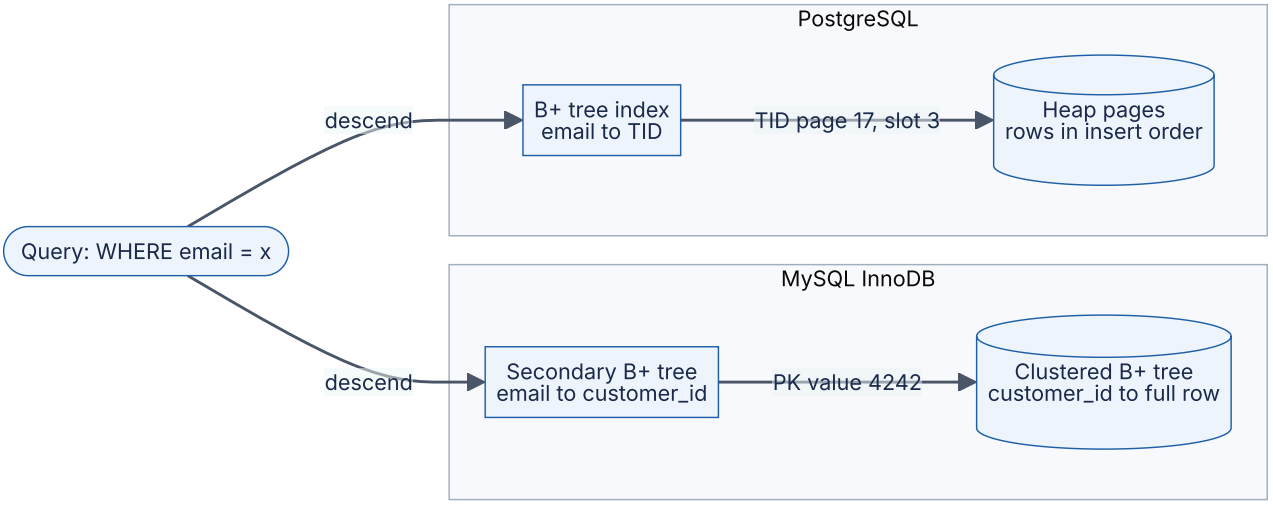
Definition — Clustered and secondary index. In a **clustered index** (an index-organized table), the leaf level of the index *is* the table: rows are stored in key order inside the index's leaf pages. A table can have at most one. A **secondary index** stores, for each key, a pointer to the row; the table can have many.

The two most popular open-source databases make opposite choices:

- **InnoDB (MySQL)** stores every table as a B+ tree clustered on the primary key. If you declare none, it uses the first `UNIQUE NOT NULL` index, or else generates a hidden 6-byte row ID. Secondary index leaves store the indexed columns plus the *primary-key value*. A secondary lookup therefore descends two trees: the secondary index to find the primary key, then the clustered index to find the row [MySQL Docs: Clustered and Secondary Indexes].

- **PostgreSQL** stores rows in an unordered **heap** file. Every index, including the primary key, is secondary; its leaves store a **TID** (tuple identifier: page number and slot), so a lookup descends one tree and then reads one heap page. The `CLUSTER` command reorders the heap once, but later inserts are not kept in order.

Figure 11.3 — Secondary-index lookup paths in InnoDB and PostgreSQL.



Reading the diagram. The same query descends two storage designs; all arrows are synchronous reads inside one database process. InnoDB's secondary index yields a primary-key *value*, which drives a second descent of the clustered index; PostgreSQL's index yields a physical TID, followed by one heap-page read. The logical pointer survives row moves, so clustered-index splits never touch secondary indexes; the physical pointer is cheaper to follow but must be updated in every index when an update moves a row (§11.14). Failure point: a long InnoDB primary key is copied into every secondary index. Scaling: keep InnoDB keys short and monotonic; leave free space in PostgreSQL heap pages (`fillfactor`).

11.7.3 Composite indexes and the leftmost-prefix rule

A **composite index** on `(customer_id, created_at)` sorts entries by `customer_id`, and within equal `customer_id` by `created_at`, like a phone book sorted by surname and then first name. You can use it to find everyone named "Rao" (leftmost column), or "Rao, Priya" (both columns), but not everyone named "Priya": those entries are scattered across the whole book. This is the **leftmost-prefix rule**: a B+ tree index can seek on a prefix of its columns, with equality on all but possibly the last column used, which may be a range.

The index on `(customer_id, created_at)` serves:

- `WHERE customer_id = ?`
- `WHERE customer_id = ? AND created_at >= ?`

- `WHERE customer_id = ? ORDER BY created_at DESC LIMIT 20` (no sort needed: entries are already in order)

and does *not* efficiently serve `WHERE created_at >= ?`. Some engines can **skip-scan** (seek once per distinct leading value), which helps only when the leading column has few distinct values: MySQL since 8.0.13, and PostgreSQL from version 18 (as of 2026).

> RECOMMENDATION
>
> **Recommendation — Column order in composite indexes.** Put columns compared with equality first, then the column used for a range or `ORDER BY`. Selectivity of the leading column matters less than whether queries can use the prefix at all. One well-ordered composite index often replaces two or three single-column indexes.

11.7.4 Covering, partial and expression indexes

- A **covering index** contains every column a query needs, so it can be answered from the index alone (an **index-only scan**). PostgreSQL 11+ adds payload columns with `INCLUDE`; InnoDB secondary indexes always cover the primary key. PostgreSQL still visits heap pages not marked all-visible in the **visibility map**, which VACUUM maintains (§11.14).
- A **partial index** indexes only rows matching a predicate: `CREATE INDEX ... ON orders (created_at) WHERE status = 'pending'`. If 1% of orders are pending, the index is 1% of the size. PostgreSQL and SQLite support partial indexes; MySQL does not (as of 8.4).
- An **expression index** indexes a computed value such as `lower(email)` (MySQL 8.0.13+: functional key parts).

```
        import sqlite3

        db = sqlite3.connect(":memory:")
        db.executescript("""
        CREATE TABLE orders (
          order_id    INTEGER PRIMARY KEY,          -- rowid alias: the table's clus-
tered key
          customer_id INTEGER NOT NULL,
          status      TEXT    NOT NULL,
          total_cents INTEGER NOT NULL,
          created_at  TEXT    NOT NULL
        );
        CREATE INDEX orders_cust_created ON orders (customer_id, created_at);
        CREATE INDEX orders_pending ON orders (created_at) WHERE status = 'pending';
        """)
        db.executemany(
            "INSERT INTO orders (customer_id, status, total_cents, created_at) VALUES
(?,?,?,?)",
            [(i % 1000, "pending" if i % 100 == 0 else "shipped", i, f"2026-10-{1 + i %
28:02d}")
             for i in range(50_000)])

        queries = {
            "both columns":        "SELECT * FROM orders WHERE customer_id = 7 AND
created_at >= '2026-10-15'",
            "leftmost column only": "SELECT * FROM orders WHERE customer_id = 7",
            "second column only":  "SELECT * FROM orders WHERE created_at >= '2026-10-
15'",
            "covering":            "SELECT created_at FROM orders WHERE customer_id =
7",
            "partial index":       "SELECT order_id FROM orders WHERE status = 'pending'
AND created_at < '2026-10-03'",
        }
        for label, sql in queries.items():
            plan = db.execute("EXPLAIN QUERY PLAN " + sql).fetchall()
            print(f"{label:<21} -> {plan[0][3]}")
```

Output (SQLite 3.45):

```
both columns          -> SEARCH orders USING INDEX orders_cust_created (customer_id=?
AND created_at>?)
leftmost column only  -> SEARCH orders USING INDEX orders_cust_created (customer_id=?)
second column only    -> SCAN orders
covering              -> SEARCH orders USING COVERING INDEX orders_cust_created
(customer_id=?)
partial index         -> SEARCH orders USING COVERING INDEX orders_pending
(created_at<?)
```

What to notice:

- `SEARCH` means an index seek; `SCAN` means reading the whole table. Filtering on the second column alone falls back to a scan: the leftmost-prefix rule in action.

- The covering query asks only for `created_at`, which is in the index, so the table is never read.
- The partial-index query is covering too, because SQLite stores the rowid (`order_id`) in every index entry, just as InnoDB stores the primary key.

11.7.5 When an index does not help

Mathematical foundations

An index lookup through a secondary index costs roughly one *random* page read per matching row (when the rows are scattered across the table), while a full scan costs one *sequential* page read per table page. Above some fraction of matching rows, the scan wins.

FORMULA

Break-even selectivity for a secondary-index scan

$$s^{*} = \frac{P \cdot c_{\text{seq}}}{n \cdot c_{\text{rand}}}$$

Symbol	Meaning	Units
s^{*}	Fraction of rows matched above which a full scan is cheaper	dimensionless
P	Pages in the table	pages
n	Rows in the table	rows
c_{seq}	Cost of a sequential page read	cost units/page
c_{rand}	Cost of a random page read	cost units/page

WORKED EXAMPLE

Worked example — When does PostgreSQL stop using the index on `orders`? $P = 15,385$ pages, $n = 1,000,000$ rows, and PostgreSQL's default cost parameters are `seq_page_cost` $= 1$ and `random_page_cost` $= 4$.

1. Full scan cost: $15,385 \times 1 = 15,385$ units.
2. Index cost for fraction s: $s \times 10^6 \times 4$ units (ignoring the small index-page cost).
3. Break-even: $s^* = 15,385/(4 \times 10^6) = 0.0038$, about 0.4% of rows, or 3,800 rows.

Interpretation. A query matching 10 rows uses the index; one matching 50% of rows (`customer_id > 50000` in §11.10) is planned as a sequential scan, which is exactly what PostgreSQL chose. **Engineering implication.** Indexes serve *selective* predicates. PostgreSQL softens the cliff with **bitmap scans**, which collect matching TIDs, sort them by page and read each heap page once; and correlation statistics lower the estimated cost when the table is physically ordered by the indexed column. On SSDs, many teams lower `random_page_cost` to about 1.1–2 because random and sequential reads cost nearly the same.

Table 11.5 — Index variants.

Variant	What it stores	Speeds up	Costs	Engine support
Clustered (primary)	Full rows in key order	PK lookups and PK range scans	Wide secondary indexes (InnoDB)	InnoDB, SQL Server, SQLite rowid tables
Secondary	Key + row pointer (TID or PK)	Selective lookups on other columns	One extra structure to update per write	All
Composite	Several columns, lexicographic order	Prefix equality + range/sort	Useless without the leading column	All
Covering / `INCLUDE`	Extra payload columns	Index-only scans	Larger index	PostgreSQL 11+, SQL Server; InnoDB via PK
Partial	Only rows matching a predicate	Queries on a small, hot subset	Query must imply the predicate	PostgreSQL, SQLite (not MySQL)
Expression / functional	Computed values	Queries on the same expression	Expression evaluated on write	PostgreSQL, MySQL 8.0.13+, SQLite

COMMON MISTAKE

Mistake — "Add an index on every column to be safe." A table with eight indexes turns one row insert into nine B+ tree insertions, inflates storage and the buffer pool's working set, and in PostgreSQL prevents heap-only-tuple updates of indexed columns (§11.14). Index the queries you run; drop indexes whose `pg_stat_user_indexes.idx_scan` stays at zero.

COMMON MISTAKE

Mistake — Wrapping the indexed column in a function. `WHERE date(created_at) = '2026-10-30'` cannot use an index on `created_at`, because the index is sorted by `created_at`, not by `date(created_at)`. Rewrite as a range: `WHERE created_at >= '2026-10-30' AND created_at < '2026-10-31'`. The same applies to implicit type casts, such as comparing a text column with a number in MySQL.

11.8 B-trees and B+ trees

11.8.1 Structure and operations

DEFINITION

Definition — B-tree and B+ tree. A **B-tree** is a balanced search tree whose nodes are disk pages holding many sorted keys; every leaf is at the same depth, and nodes split and merge to stay between half-full and full [Bayer and McCreight 1972]. A **B+ tree** is the variant used by almost every relational database: internal nodes hold only separator keys and child pointers, all keys and values (or row pointers) live in the leaves, and leaves are linked to their siblings so range scans can walk sideways [Comer 1979; Petrov 2019].

Why does this exist?

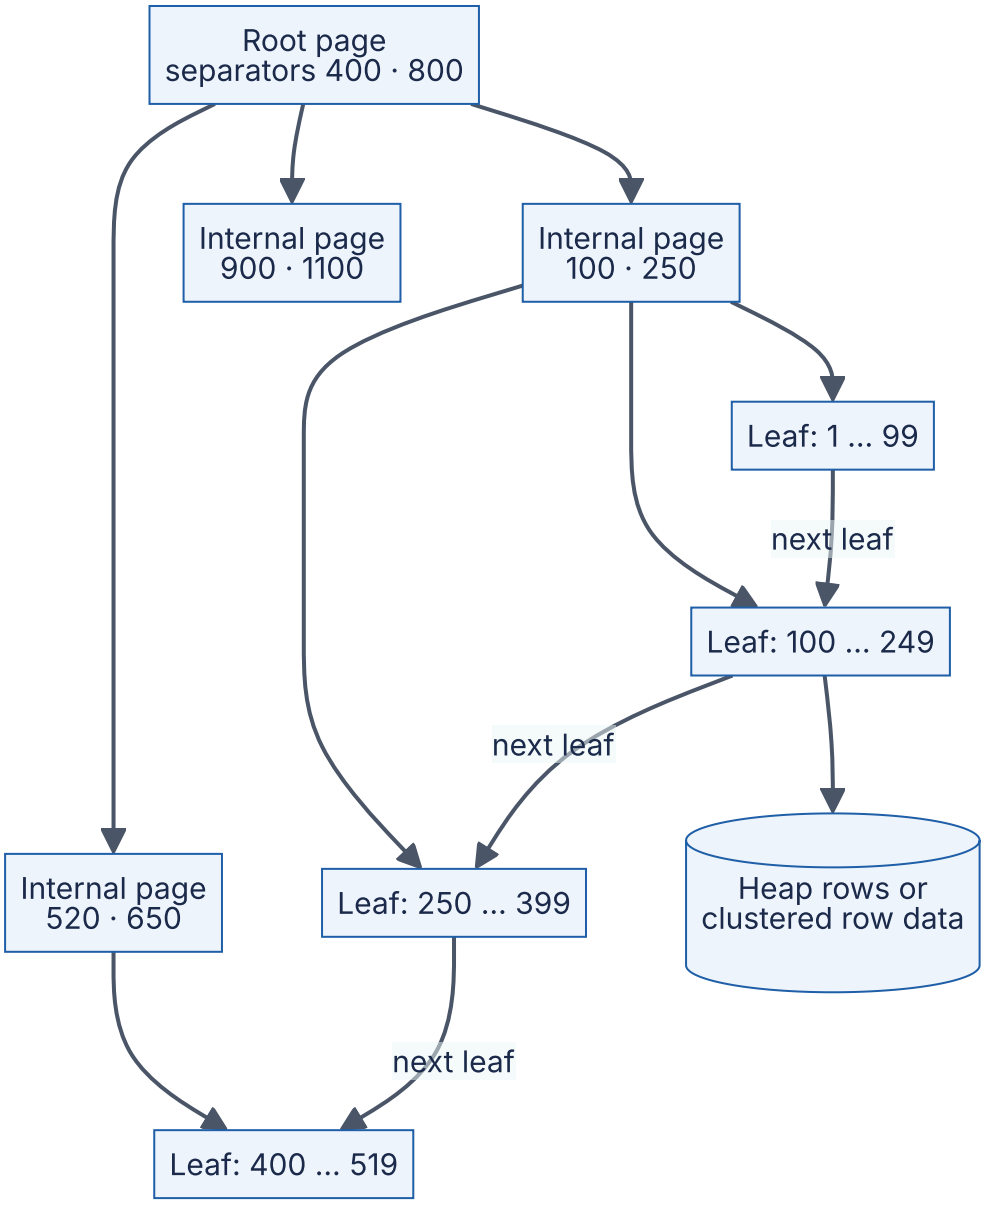
A binary search tree needs about 30 levels for a billion keys (§4.4.2): 30 dependent disk reads. The B-tree makes each node one page holding hundreds of keys, so the tree is wide and shallow. Keeping values only in leaves (the B+ variant) makes internal nodes denser, so more of the tree fits in memory, and sibling links turn range predicates into a sequential walk.

How it works internally

1. **Search.** Start at the root page. Binary-search its separator keys in memory to choose a child pointer. Repeat until a leaf; binary-search the leaf.
2. **Range scan.** Search for the lower bound, then follow leaf sibling links until the upper bound.
3. **Insert.** Search for the target leaf and insert the key in order. If the leaf overflows, **split** it into two half-full leaves and insert a separator key into the parent; if the parent overflows, split it too. A split of the root creates a new root, which is the only way the tree grows taller, so all leaves stay at the same depth.
4. **Delete.** Remove the key; if a node becomes too empty, borrow from or merge with a sibling (many engines merge lazily or not at all, leaving reclaimable space).

5. **Concurrency and crash safety.** Splits modify several pages, so engines latch pages briefly and log every change in the write-ahead log; PostgreSQL uses Lehman and Yao's right-links so readers never block on a concurrent split [Lehman and Yao 1981]. Details are in §13.5–§13.6.

Figure 11.4 — A B+ tree on `order_id` with three levels.



Reading the diagram. Each rectangle is one fixed-size page (8 KiB in PostgreSQL, 16 KiB in InnoDB). A search follows child pointers synchronously, one page per level: for `order_id` 180 the root goes left (180 < 400) and the internal page picks the second leaf. The "next leaf" arrows are sibling links that range scans walk. The cylinder is the storage boundary below the leaves: a heap row (PostgreSQL) or the row itself (InnoDB clustered index). Failure points: a split changes several pages atomically, hence WAL logging

(§13.5), and a cold cache makes every level an I/O. Scaling: multiplying the data by the fan-out adds one level.

11.8.2 Fan-out, height and I/Os per lookup

§4.4.3 derived $h = \lceil \log_f n \rceil$ for a tree whose leaves hold one key each. In a real B+ tree each leaf holds L entries, so only the internal levels need the logarithm.

FORMULA

Height of a B+ tree with L entries per leaf

$$h = 1 + \left\lceil \log_f \left\lceil \frac{n}{L} \right\rceil \right\rceil, \qquad f = \left\lfloor \frac{u \cdot P}{e_{\text{int}}} \right\rfloor, \qquad L = \left\lfloor \frac{u \cdot P}{e_{\text{leaf}}} \right\rfloor$$

Symbol	Meaning	Units
h	Levels from root to leaf (page reads per lookup with a cold cache)	levels
n	Entries (rows) indexed	rows
P	Page size	bytes
u	Average fraction of each page holding entries (fill factor minus headers)	dimensionless
e_{int}	Bytes per internal entry (separator key + child pointer + overhead)	bytes
e_{leaf}	Bytes per leaf entry (full row for a clustered index; key + pointer for a secondary index)	bytes
f	Fan-out of internal pages	children/page
L	Entries per leaf page	entries/page

WORKED EXAMPLE

Worked example — A billion-row `orders` table in InnoDB with 16 KiB pages. Assume $u = 0.8$, a `bigint` primary key with 16-byte internal entries (as in §4.4.3), and 200-byte rows.

1. Usable bytes per page: $0.8 \times 16,384 = 13,107$ bytes.
2. Fan-out: $f = \lfloor 13,107/16 \rfloor = 819$. Rows per leaf: $L = \lfloor 13,107/200 \rfloor = 65$.
3. Leaf pages: $\lceil 10^9/65 \rceil = 15,384,616$ (about 235 GiB of row data).
4. Internal levels: $\lceil 15,384,616/819 \rceil = 18,785$ pages, then $\lceil 18,785/819 \rceil = 23$, then 1 root. Check with the formula: $\log_{819}(15,384,616) = 16.55/6.71 = 2.47$, rounded up to 3, plus the leaf level: $h = 4$.
5. Memory for all internal pages: $(1 + 23 + 18,785) \times 16$ KiB $= 18,809 \times 16$ KiB ≈ 294 MiB.
6. A secondary index on `customer_id` (8-byte key + 8-byte primary key per leaf entry, $L = 819$) has $\lceil 10^9/819 \rceil = 1,221,002$ leaves (about 18.6 GiB), then 1,491, 2 and 1 pages: also 4 levels, with only 23 MiB of internal pages.

I/Os per lookup:

- Cold cache: 4 page reads for a primary-key lookup.
- Internal pages cached (294 MiB is trivial for a database server): **1 random read** per primary-key lookup, about 0.1 ms on NVMe (§4.17).
- Secondary-index lookup in InnoDB: 1 read for the secondary leaf + 1 for the clustered leaf = **2 reads**. In PostgreSQL: index leaf + heap page = 2 reads, similarly.

Interpretation. A billion rows cost only one more level than a million rows (a million rows needs $1 + \lceil \log_{819} 15,385 \rceil = 3$ levels). **Engineering implication.** Index lookups stay fast at any table size you will meet in one database; what grows is the *leaf* working set. If the hot rows' leaves (here up to 235 GiB) do not fit in the buffer pool, every lookup pays a real I/O, and that, not tree height, is the scaling limit. Wide keys shrink f and L; random keys spread the hot set across all leaves.

```
        import math

        def bplus_tree(n_rows, page_bytes=16 * 1024, fill=0.8, internal_entry=16,
leaf_entry=200):
            """Return (fan-out, entries per leaf, pages per level from root to
leaves)."""
            usable = page_bytes * fill
            fanout = int(usable // internal_entry)          # child pointers per inter-
nal page
            per_leaf = int(usable // leaf_entry)            # entries per leaf page
            levels = [math.ceil(n_rows / per_leaf)]         # leaf level first
            while levels[-1] > 1:
                levels.append(math.ceil(levels[-1] / fanout))
            return fanout, per_leaf, levels[::-1]

        for label, leaf_entry in [("clustered, 200-byte rows", 200), ("secondary, 8-byte
key + 8-byte PK", 16)]:
            f, L, pages = bplus_tree(10**9, leaf_entry=leaf_entry)
            internal_mib = sum(pages[:-1]) * 16 / 1024
            leaf_gib = pages[-1] * 16 / 1024**2
            print(f"{label}: fan-out={f}, entries/leaf={L}, height={len(pages)}")
            print(f"  pages per level (root..leaf) = {pages}")
            print(f"  internal levels = {internal_mib:,.0f} MiB, leaf level =
{leaf_gib:,.1f} GiB")
```

What to notice:

- Output: the clustered tree has pages per level `[1, 23, 18785, 15384616]` and the secondary tree `[1, 2, 1491, 1221002]`; both have height 4, matching the hand calculation.
- Change `leaf_entry` to 1,000 (wide rows) and the leaf level grows fivefold while the height stays 4: width costs memory before it costs levels.

> COMMON MISTAKE
>
> **Mistake — "B-tree and B+ tree are the same thing."** In a classic B-tree, values can live in internal nodes, so a range scan must move up and down the tree. Database "B-tree" indexes are B+ trees (PostgreSQL's `btree`, InnoDB's indexes): values only in leaves, leaves linked. In interviews, say "B+ tree" and explain the leaf links.

11.9 Query execution and plans

11.9.1 From SQL text to rows

Every statement passes through the same pipeline:

1. **Parse** — check syntax and build a parse tree.

2. **Analyze and rewrite** — resolve table and column names against the catalog, check permissions, expand views, and apply rewrite rules (for example, flattening a sub-query into a join).
3. **Plan (optimize)** — enumerate alternative physical plans, estimate the cost of each using table statistics, and choose the cheapest (§11.10).
4. **Execute** — run the plan's operators against the storage engine, which reads pages through the buffer pool (§13.4).

11.9.2 The Volcano (iterator) model

> DEFINITION
>
> **Definition — Volcano (iterator) model.** An execution model in which a query plan is a tree of operators, each implementing the same interface — `open()`, `next()` and `close()` — and each `next()` call pulls one row from the operator's children on demand [Graefe 1994].

First-principles explanation

In a kitchen line, the waiter asks plating for the next dish, plating asks the grill, the grill asks the fridge; nobody cooks a thousand steaks in advance. This **pull model** lets operators compose freely, keeps memory small for streaming operators, and lets a `LIMIT 20` stop the scans below after 20 rows.

Sort, hash aggregation and the build side of a hash join cannot emit a row until they have consumed all input. These **blocking** operators need memory proportional to their input and spill to disk when it runs out; in `EXPLAIN`, their startup cost is close to their total cost.

```
        class Operator:
            """Volcano iterator: every operator exposes open(), next() and close()."""
            def open(self): pass
            def next(self): raise NotImplementedError   # returns one row, or None when
exhausted
            def close(self): pass

        class SeqScan(Operator):
            def __init__(self, rows): self.rows = rows
            def open(self): self.pos = 0
            def next(self):
                if self.pos == len(self.rows): return None
                self.pos += 1
                return self.rows[self.pos - 1]

        class Filter(Operator):
            def __init__(self, child, pred): self.child, self.pred = child, pred
            def open(self): self.child.open()
            def next(self):
                while (row := self.child.next()) is not None:
                    if self.pred(row): return row
                return None
            def close(self): self.child.close()

        class HashJoin(Operator):
            def __init__(self, build, probe, bkey, pkey):
                self.build, self.probe, self.bkey, self.pkey = build, probe, bkey, pkey
            def open(self):                       # blocking: consumes the whole build
side
                self.table, self.pending = {}, []
                self.build.open()
                while (b := self.build.next()) is not None:
                    self.table.setdefault(b[self.bkey], []).append(b)
                self.build.close()
                self.probe.open()
            def next(self):                       # pipelined: one probe row at a time
                while not self.pending:
                    p = self.probe.next()
                    if p is None: return None
                    self.pending = [b + p for b in self.table.get(p[self.pkey], [])]
                return self.pending.pop()
            def close(self): self.probe.close()

        class Project(Operator):
            def __init__(self, child, cols): self.child, self.cols = child, cols
            def open(self): self.child.open()
            def next(self):
                row = self.child.next()
                return None if row is None else tuple(row[c] for c in self.cols)
            def close(self): self.child.close()

        class Limit(Operator):
            def __init__(self, child, n): self.child, self.n = child, n
            def open(self): self.child.open(); self.seen = 0
            def next(self):
                if self.seen == self.n: return None   # stop pulling: the scan below
```

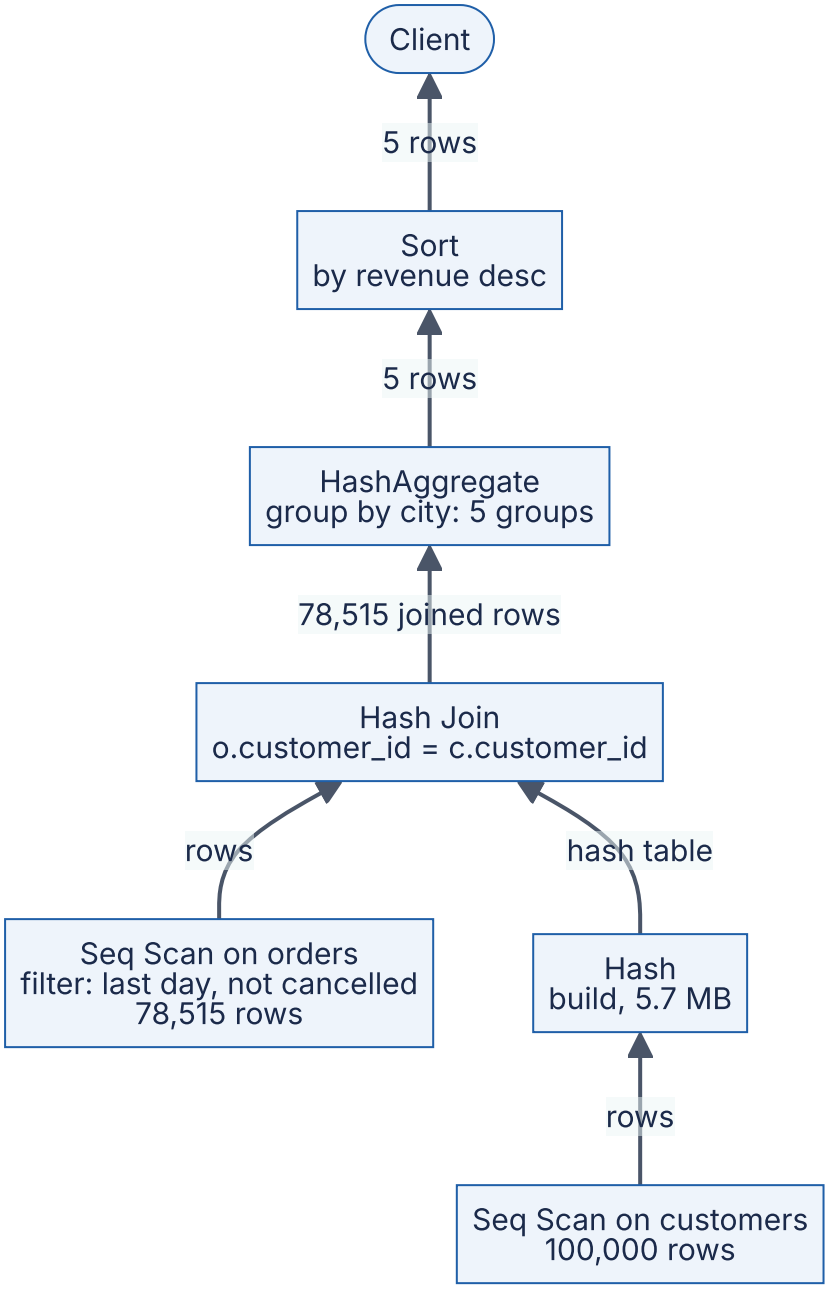
```
never finishes
                self.seen += 1
                return self.child.next()
            def close(self): self.child.close()

        # SELECT c.city, o.total FROM customers c JOIN orders o ON c.id = o.customer_id
        # WHERE o.total > 1000 LIMIT 2
        customers = [(1, "Berlin"), (2, "Austin"), (3, "Pune")]
        orders = [(10, 1, 2500), (11, 3, 900), (12, 1, 4100), (13, 2, 1800)]
        plan = Limit(Project(HashJoin(SeqScan(customers),
                                      Filter(SeqScan(orders), lambda r: r[2] > 1000), 0,
1),
                             cols=[1, 4]), 2)
        plan.open()
        while (row := plan.next()) is not None:
            print(row)
        plan.close()
```

What to notice:

- The output is `('Berlin', 2500)` and `('Berlin', 4100)`. Order 13 (Austin, 1800) also qualifies but is never produced: `Limit` stopped pulling after two rows, so the orders scan stopped early.
- `HashJoin.open()` drains its build child completely (blocking); `next()` handles one probe row at a time (pipelined).
- Every row costs several virtual function calls. Modern analytic engines reduce that overhead with **vectorized** execution (each `next()` returns a batch of about a thousand values) [Boncz et al. 2005] or by **compiling** the plan into machine code [Neumann 2011]. PostgreSQL remains a Volcano-style executor, with optional JIT compilation of expressions.

Figure 11.5 — The executed plan tree for “revenue by city over the last day”.



Reading the diagram. This is the real plan PostgreSQL 16 chose for the revenue query of §11.10, drawn bottom-up: rows flow upward while `next()` calls flow down, all synchronously inside one backend process. The scans are the storage boundary; `Hash`, `HashAggregate` and `Sort` are blocking and spill to temporary files if they exceed `work_mem`. The main failure point is a misestimated row count, which can make this plan win when an index-driven plan would be better. Scaling: an index on `orders(created_at)` would replace the million-row scan, and parallel workers could split it.

11.10 Query optimization

11.10.1 The cost-based optimizer

DEFINITION

Definition — Cost-based optimizer. The component that enumerates equivalent physical plans for a query (access paths, join orders, join algorithms), estimates each plan's cost from **statistics** about the data using a **cost model**, and returns the plan with the lowest estimated cost.

The design dates from IBM's System R. Selinger and colleagues introduced the three ideas every optimizer still uses: estimate the **selectivity** of each predicate from catalog statistics; cost plans in a weighted mix of page I/O and CPU; and find the best join order by **dynamic programming**, building the best plan for every subset of tables from the best plans of smaller subsets, while remembering plans that produce **interesting orders** (sorted output that a later merge join or `ORDER BY` can reuse) [Selinger et al. 1979].

Mathematical foundations

FORMULA

Size of the join-order search space

$$N_{\text{left-deep}} = n! \qquad N_{\text{bushy}} = \frac{(2(n-1))!}{(n-1)!} \qquad W_{\text{DP}} \approx n \cdot 2^{n-1}$$

Symbol	Meaning	Units
n	Number of tables joined	tables
$N_{\text{left-deep}}$	Join orders where every join's inner input is a base table	plans
N_{bushy}	All binary join trees, including joins of two intermediate results	plans
W_{DP}	Approximate subproblems examined by Selinger-style dynamic programming over left-deep plans	subproblems

WORKED EXAMPLE

Worked example — Ten tables. For $n = 10$: left-deep orders $10! = 3,628,800$; bushy trees $18!/9! \approx 1.76 \times 10^{10}$; dynamic programming examines about $10 \times 2^9 = 5,120$ subset extensions. **Interpretation.** Dynamic programming makes ten-way joins tractable, but 2^n still explodes: at $n = 20$ it is about 10 million. **Engineering implication.** PostgreSQL switches to a genetic (randomized) search at 12 `FROM` items by default (`geqo_threshold`), and stops reordering explicit joins beyond 8 (`join_collapse_limit`); very wide joins generated by ORMs or reporting tools can therefore get poor plans.

11.10.2 Cost model and statistics in PostgreSQL

PostgreSQL's costs are in arbitrary units anchored on one sequential page read. The defaults (verified on PostgreSQL 16) are `seq_page_cost` = 1, `random_page_cost` = 4, `cpu_tuple_cost` = 0.01, `cpu_index_tuple_cost` = 0.005 and `cpu_operator_cost` = 0.0025 [PostgreSQL Docs: Using EXPLAIN].

FORMULA

Cost of a sequential scan with one filter (PostgreSQL)

$$C_{\text{seq}} = P \cdot c_{\text{seq}} + n \cdot c_{\text{tuple}} + n \cdot k \cdot c_{\text{op}}$$

Symbol	Meaning	Units
P	Heap pages (`pg_class.relpages`)	pages
n	Rows (`pg_class.reltuples`)	rows
k	Operators evaluated per row in the filter	operators
c_{seq}, c_{tuple}, c_{op}	`seq_page_cost`, `cpu_tuple_cost`, `cpu_operator_cost`	cost units

To estimate how many rows survive a filter, the planner uses per-column statistics collected by `ANALYZE` from a random sample (visible in `pg_stats`): the number of distinct values, the **most common values** with their frequencies, a histogram of the rest, the null fraction and the physical **correlation** between column order and heap order.

FORMULA

Cardinality estimate under the independence assumption

$$\hat{r} = n \cdot \prod_{i=1}^{k} s_i, \qquad s_i \approx \text{freq}(v_i) \text{ or } \frac{1}{d_i}$$

Symbol	Meaning	Units
$\hat{r}$	Estimated rows satisfying all k predicates	rows
n	Rows in the table	rows
s_i	Selectivity of predicate i (fraction of rows passing it)	dimensionless
$\text{freq}(v_i)$	Sampled frequency of value v_i if it is a most-common value	dimensionless
d_i	Number of distinct values in the column	values

WORKED EXAMPLE

Worked example — Checking the planner's arithmetic on real plans. On the 1,000,000-row `orders` table (15,385 pages):

1. `EXPLAIN SELECT * FROM orders WHERE customer_id = 4242` reported `cost=0.00..27885.00`. By the formula: $15,385 \times 1 + 10^6 \times 0.01 + 10^6 \times 1 \times 0.0025 = 15,385 + 10,000 + 2,500 = 27,885$. Exact match.
2. Its row estimate was 10: with 100,000 distinct customers, $s = 1/100,000$ and $\hat{r} = 10^6/10^5 = 10$. Actual: 10.
3. Now a table `addr` of 1,000,000 rows where `city` determines `country` (every Pune row is in India). Each column has 5 values at about 20% each. For `WHERE city = 'Pune' AND country = 'IN'` the independence assumption gives $\hat{r} = 10^6 \times 0.2 \times 0.2 = 40,000$. PostgreSQL estimated 39,960; the actual count was 200,000, an underestimate of 5×.

Interpretation. The formulas are simple and exact for single predicates on well-sampled columns; the error comes from *correlation*, which the independence assumption ignores. **Engineering implication.** Errors multiply through joins: an estimate that is 5× too low feeding a join whose own estimate is 5× too low is 25× off, which is enough to choose a nested loop over a million rows. For correlated columns, PostgreSQL 10+ supports extended statistics: after `CREATE STATISTICS addr_city_country (dependencies) ON city, country FROM addr; ANALYZE addr;` the estimate became 198,500.

INDUSTRY EXAMPLE

Research evidence — How good are query optimizers? Leis and colleagues built the Join Order Benchmark on the real IMDB dataset (queries with many joins over correlated data) and measured PostgreSQL and several commercial systems. Cardinality estimates were routinely wrong by orders of magnitude, errors grew with the number of joins, and estimation errors mattered far more for plan quality than the cost model did [Leis et al. 2015]. *Evidence: Primary* — [Leis et al. 2015]

11.10.3 Reading EXPLAIN and EXPLAIN ANALYZE

`EXPLAIN` shows the chosen plan with estimates; `EXPLAIN ANALYZE` actually runs the query and adds measured times and row counts; `BUFFERS` adds page counts. (MySQL 8.0.18+ has `EXPLAIN ANALYZE` with a different format.) The following is real PostgreSQL 16 output for the order-history query after creating an index on `orders (customer_id, created_at DESC)`, with parallel query disabled for readability:

```
Limit  (cost=44.03..44.05 rows=10 width=32) (actual time=0.110..0.112 rows=10 loops=1)
  Buffers: shared hit=3 read=13
  ->  Sort  (cost=44.03..44.05 rows=10 width=32) (actual time=0.109..0.110 rows=10
loops=1)
        Sort Key: created_at DESC
        Sort Method: quicksort  Memory: 25kB
        ->  Bitmap Heap Scan on orders  (cost=4.50..43.86 rows=10 width=32) (actual
time=0.042..0.099 rows=10 loops=1)
              Recheck Cond: (customer_id = 4242)
              Heap Blocks: exact=10
              ->  Bitmap Index Scan on orders_customer_created_idx  (cost=0.00..4.50
rows=10 width=0) (actual time=0.028..0.028 rows=10 loops=1)
                    Index Cond: (customer_id = 4242)
Planning Time: 0.219 ms
Execution Time: 0.135 ms
```

How to read it:

1. Read from the most indented node outward: the bitmap index scan finds 10 TIDs, the heap scan fetches 10 pages, the sort orders them, the limit returns them.
2. `cost=startup..total` and `rows` are estimates; `actual time=first..last` is in milliseconds *per loop* (multiply by `loops`).
3. **Compare estimated and actual `rows` at every node.** A gap above about 10× points to stale statistics (`ANALYZE`), correlated columns (`CREATE STATISTICS`) or an unestimatable predicate (functions, casts).
4. `Buffers: shared hit=3 read=13`: 3 pages from the buffer pool, 13 from the OS or disk.

With only 10 orders per customer, sorting 10 rows was estimated cheaper than walking the index in `created_at` order; for a customer with thousands of orders the plan switches to an index scan that needs no sort.

WARNING / TRADE-OFF

Warning — `EXPLAIN ANALYZE` executes the statement. For `INSERT`, `UPDATE` or `DELETE`, wrap it: `BEGIN; EXPLAIN ANALYZE UPDATE ...; ROLLBACK;`. Also remember that the first run may read from disk and the second from cache; compare `Buffers` before comparing times.

Table 11.6 — Failure scenarios in query planning.

What goes wrong	Why	Detection	Recovery	Prevention
Query suddenly 100× slower after a data load	Stale statistics; plan flipped	`pg_stat_statements` latency jump; estimate vs actual gap	`ANALYZE` the table	Autovacuum/analyze tuning; analyze after bulk loads
Nested loop over millions of rows	Underestimated cardinality from correlated predicates	`rows=` estimate far below actual	Extended statistics; rewrite query	`CREATE STATISTICS` on correlated columns
Index ignored	Function or cast on column; low selectivity	`Seq Scan` with selective filter	Expression index or rewritten predicate	Code review of predicates
Hash join or sort spills to disk	Memory budget too small for build side	`Batches: >1`, `Sort Method: external merge`	Raise `work_mem` for that session	Filter earlier; size memory per query

11.11 Transactions

11.11.1 Commit, rollback and savepoints

DEFINITION

Definition — Transaction. A sequence of reads and writes that the database treats as one logical unit: either all of its effects become permanent together (**commit**) or none of them do (**abort** or **rollback**), and concurrently running transactions are isolated from each other's intermediate states.

First-principles explanation

Moving money between two accounts is two writes: debit one, credit the other. If the server crashes between them, or a constraint fails on the second, money is created or destroyed. Without transactions, every application would need its own crash-recovery and

concurrency logic for every multi-step operation, and most would get it wrong. A transaction lets you write the steps as if nothing else were happening and nothing could fail, and makes the database responsible for the rest [Gray and Reuter 1993].

How it works internally

1. `BEGIN` starts a transaction (many drivers start one implicitly; with **autocommit**, every statement is its own transaction).
2. Each write is recorded in the write-ahead log and applied to pages in memory; concurrency control (MVCC and locks, §11.14–§11.15) decides what other transactions may see and do.
3. `COMMIT` forces the log records to durable storage, then makes the changes visible. `ROLLBACK`, an error or a crash before the commit record is durable undoes them.
4. `SAVEPOINT name` / `ROLLBACK TO name` undo part of a transaction without abandoning it.

```
        import sqlite3

        db = sqlite3.connect(":memory:")
        db.executescript("""
        CREATE TABLE accounts (
          account_id    INTEGER PRIMARY KEY,
          balance_cents INTEGER NOT NULL CHECK (balance_cents >= 0)   -- invariant: no
overdraft
        );
        INSERT INTO accounts VALUES (1, 10000), (2, 0);
        """)

        def transfer(src, dst, cents):
            try:
                with db:                                    # BEGIN; ... COMMIT (or
ROLLBACK on error)
                    db.execute("UPDATE accounts SET balance_cents = balance_cents + ? "
                               "WHERE account_id = ?", (cents, dst))          # credit
first, on purpose
                    db.execute("UPDATE accounts SET balance_cents = balance_cents - ? "
                               "WHERE account_id = ?", (cents, src))          # may vio-
late the CHECK
                return "committed"
            except sqlite3.IntegrityError as e:
                return f"rolled back ({e})"

        print(transfer(1, 2, 7000), db.execute("SELECT * FROM accounts").fetchall())
        print(transfer(1, 2, 7000), db.execute("SELECT * FROM accounts").fetchall())
```

What to notice:

- Output: `committed [(1, 3000), (2, 7000)]`, then `rolled back (CHECK constraint failed: balance_cents >= 0) [(1, 3000), (2, 7000)]`. The second transfer's credit had already been applied when the debit failed, yet it vanished: atomicity.

- The invariant lives in the schema (`CHECK`), so no code path can violate it, including ones written next year.

WARNING / TRADE-OFF

Warning — Keep transactions short, and never wait on the network inside one. An open transaction holds row locks and pins old row versions (§11.14). Do slow external work, such as payment calls, before or after the transaction, and make it idempotent (§22.15).

11.12 ACID

DEFINITION

Definition — ACID. The four guarantees of a database transaction, named by Härder and Reuter [Härder and Reuter 1983]: **Atomicity** — all of a transaction's writes take effect, or none do. **Consistency** — a transaction takes the database from one state satisfying all declared invariants (constraints) to another. **Isolation** — concurrently executing transactions do not see each other's partial effects; at the strongest level, the outcome equals some serial execution. **Durability** — once a commit is acknowledged, its effects survive crashes.

How each is implemented:

- **Atomicity** — undo information (InnoDB undo records; in PostgreSQL, uncommitted versions are never marked visible).
- **Consistency** — constraints (`PRIMARY KEY`, `UNIQUE`, `FOREIGN KEY`, `CHECK`, `NOT NULL`). Invariants the schema cannot express ("at least one doctor on call") are the application's job, helped by isolation.
- **Isolation** — MVCC and locking (§11.13–§11.15).
- **Durability** — **write-ahead logging**: the commit record is flushed with `fsync` before "committed" is returned, with many commits sharing one flush (**group commit**). `synchronous_commit = off` (PostgreSQL) or `innodb_flush_log_at_trx_commit = 2` trade recent commits for throughput (§13.5). Surviving machine loss needs replication (Chapter 14).

11.12.1 The "C" in ACID is not the "C" in CAP

The word *consistency* is used for at least three unrelated ideas. Mixing them up is a classic interview mistake.

Table 11.7 — Three meanings of "consistency".

Term	Question it answers	Scope	Where in this book
ACID consistency	Do committed states satisfy the declared invariants?	One database, constraints	§11.12
Strong consistency (linearizability), the “C” in CAP	Does every read see the latest completed write, as if there were one copy?	Replicated data	§25.3, §25.8
Eventual consistency	Will replicas converge if writes stop?	Replicated data	§25.7

A single PostgreSQL server is ACID-consistent and, for reads on that server, linearizable. Add an asynchronous read replica and a client can commit a write on the primary and then read the old value from the replica: the system is still ACID at the primary, but reads are no longer linearizable (§14.4). Kleppmann notes that the C in ACID is really a property of the application’s use of transactions, not something the database provides by itself [Kleppmann 2017].

11.13 Isolation levels and anomalies

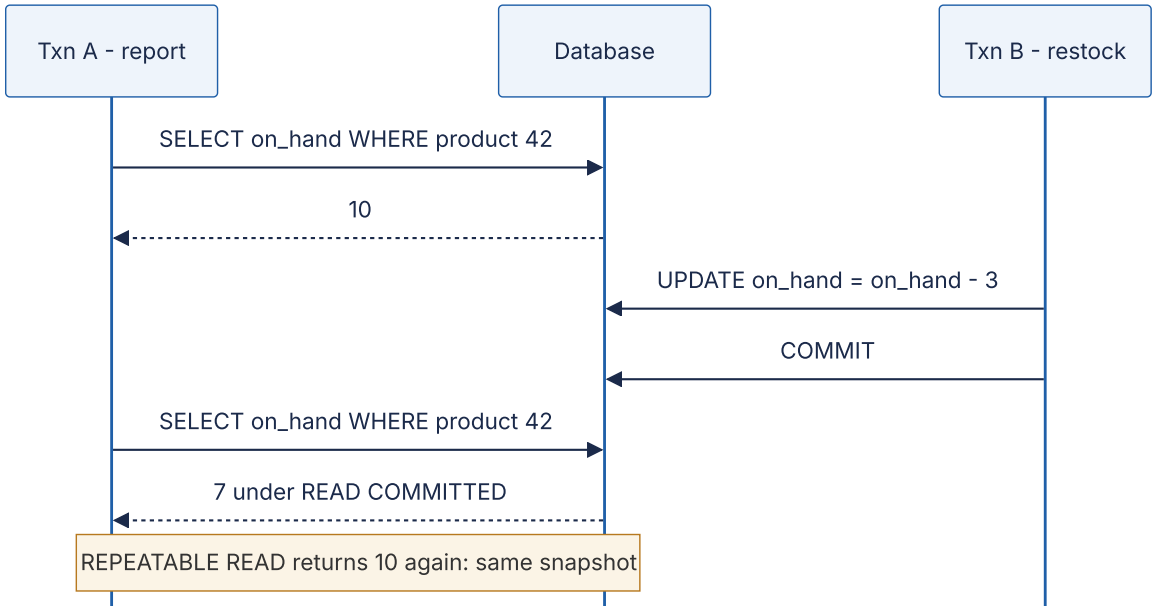
11.13.1 The anomalies

Perfect isolation, called **serializability**, means the result of running transactions concurrently equals the result of running them one at a time in *some* order. It costs throughput, so databases offer weaker **isolation levels** that permit specific **anomalies**. Berenson and colleagues showed that the SQL standard’s definitions were ambiguous and cataloged the anomalies precisely [Berenson et al. 1995]:

DEFINITION

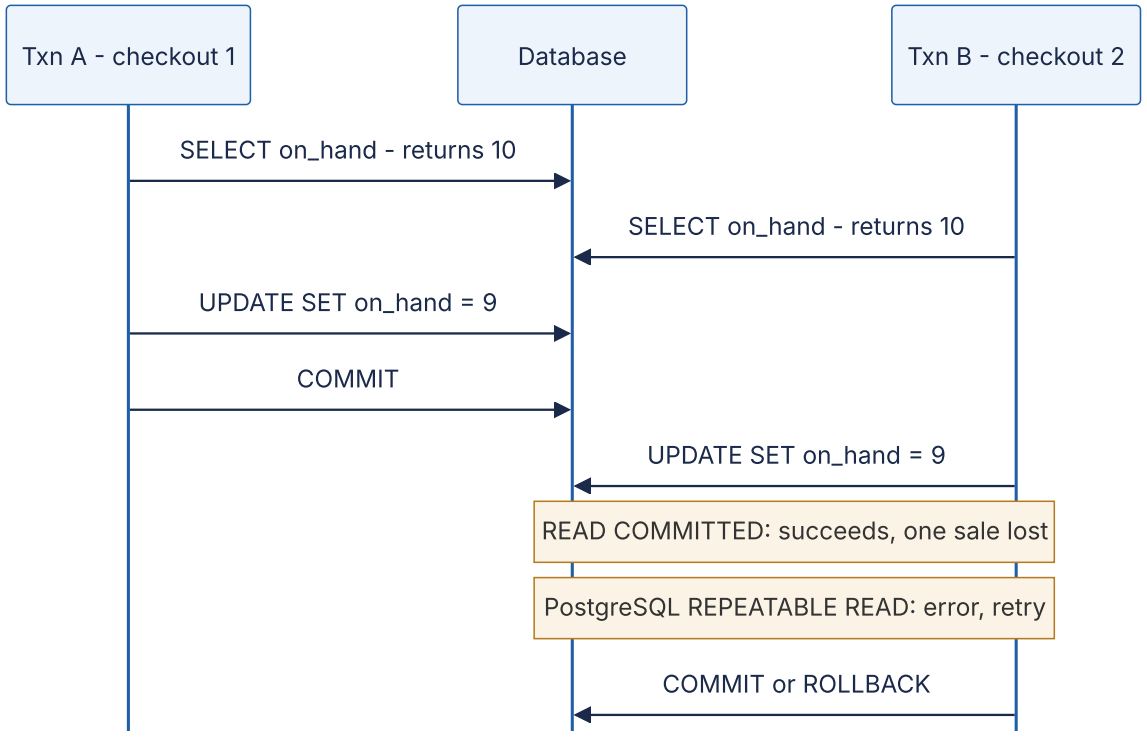
Definition — Isolation anomalies. Dirty write: a transaction overwrites another’s uncommitted write. **Dirty read:** a transaction reads another’s uncommitted write (which may later roll back). **Non-repeatable (fuzzy) read:** a transaction reads a row twice and sees different committed values because another transaction updated it in between. **Phantom:** a transaction runs the same *predicate* query twice (`WHERE status = 'pending'`) and gets a different set of rows because another transaction inserted or deleted matching rows. **Lost update:** two transactions read the same value, both compute a new value from it and write; the second write silently overwrites the first. **Read skew:** a transaction sees part of another transaction’s effects (reads account A before a transfer commits and account B after it). **Write skew:** two transactions read an overlapping set of rows, each checks an invariant, then each writes a *different* row; each write is valid alone but together they violate the invariant.

Figure 11.6 — Non-repeatable read under READ COMMITTED.



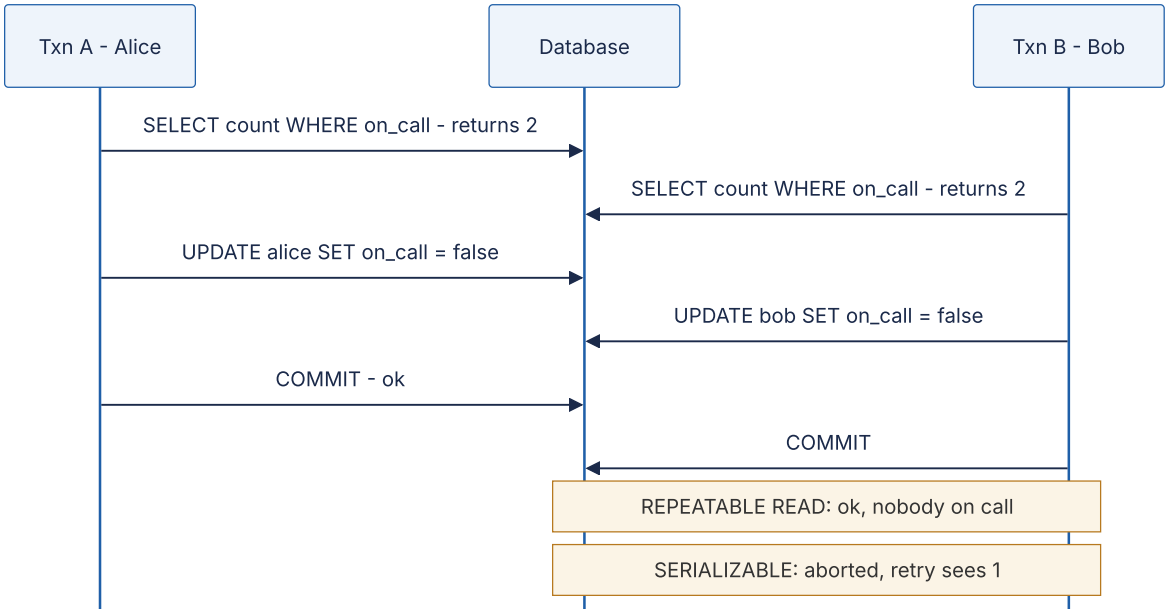
Reading the diagram. Two clients on separate connections send synchronous SQL; time runs downward. Under READ COMMITTED each *statement* takes a new snapshot, so A's second read sees B's committed change; under PostgreSQL REPEATABLE READ the *transaction* keeps its first snapshot and sees 10 twice. Both outcomes were reproduced on PostgreSQL 16. Both row versions exist inside the database at once (§11.14); the failure is any logic in A that combines the two reads, such as a report whose totals do not add up.

Figure 11.7 — Lost update from an application-side read-modify-write.



Reading the diagram. Each checkout reads 10 and writes the literal 9 computed *in the application*. Under READ COMMITTED (and MySQL REPEATABLE READ) B silently overwrites A: two units sold, one decremented. Under PostgreSQL REPEATABLE READ, B's `UPDATE` fails with `could not serialize access due to concurrent update` and B must retry. The fix at any level is to let the database do the arithmetic, `UPDATE inventory SET on_hand = on_hand - 1 WHERE product_id = 42 AND on_hand >= 1`, or to lock first with `SELECT ... FOR UPDATE`, or to check a version (§11.15.3).

Figure 11.8 — Write skew: both doctors go off call.



Reading the diagram. The invariant "at least one doctor on call" is checked by a read and protected by nothing: the transactions write *different* rows, so neither snapshot isolation nor row locks see a conflict, and both commit at REPEATABLE READ. PostgreSQL SERIALIZABLE tracks what each transaction *read*, detects the dangerous dependency pattern and aborts one with `could not serialize access due to read/write dependencies among transactions`; its retry sees one doctor on call. In the shop the same pattern double-redeems a limited coupon. Below SERIALIZABLE, materialize the conflict by locking a shared row with `FOR UPDATE`.

11.13.2 The standard levels and what databases actually do

Table 11.8 — ANSI SQL isolation levels as defined by the three phenomena.

Level	Dirty read	Non-repeatable read	Phantom
READ UNCOMMITTED	Possible	Possible	Possible
READ COMMITTED	Prevented	Possible	Possible
REPEATABLE READ	Prevented	Prevented	Possible
SERIALIZABLE	Prevented	Prevented	Prevented

Berenson and colleagues pointed out that this table misses lost update, read skew and write skew, and that **snapshot isolation** (each transaction reads from a consistent snapshot taken at its start, and a transaction aborts if it tries to write a row that another transaction changed after its snapshot) fits nowhere: it prevents all three standard phenomena yet permits write skew, so it is not serializable [Berenson et al. 1995]. Real databases implement the levels differently, so the level *name* tells you little; check the behavior.

Table 11.9 — Anomalies permitted in practice (PostgreSQL 16, MySQL 8.0 InnoDB).

Anomaly	PG READ COMMITTED (default)	PG REPEATABLE READ (snapshot isolation)	PG SERIALIZABLE (SSI)	MySQL READ COMMITTED	MySQL REPEATABLE READ (default)	MySQL SERIALIZABLE
Dirty read	No	No	No	No	No	No
Non-repeatable read	Yes	No	No	Yes	No	No
Phantom	Yes	No	No	Yes	No for plain reads	No
Lost update	Yes	No (error)	No	Yes	**Yes**	No
Read skew	Yes	No	No	Yes	No	No
Write skew	Yes	Yes	No	Yes	Yes	No

Key facts behind the table:

- **PostgreSQL** accepts `READ UNCOMMITTED` but runs it as READ COMMITTED. REPEATABLE READ is snapshot isolation. SERIALIZABLE (since 9.1) is **Serializable Snapshot Isolation (SSI)**: snapshot isolation plus tracking of read–write dependencies, aborting a transaction when a cycle is possible [Cahill et al. 2008; Ports and Grittner 2012]. It takes no extra blocking locks, but applications must retry on serialization failures (SQLSTATE `40001`).
- **MySQL InnoDB** defaults to REPEATABLE READ. Plain `SELECT`s read a snapshot, but `UPDATE`, `DELETE` and locking reads (`SELECT ... FOR UPDATE`) read the *latest committed* row and do not check whether it changed since the snapshot, which is why

lost updates and write skew get through. Locking reads take next-key locks that block phantom inserts (§11.15). SERIALIZABLE converts plain `SELECT`s into `SELECT ... FOR SHARE` when autocommit is off, i.e., two-phase locking [MySQL Docs: Transaction Isolation Levels].

- Kleppmann's Hermitage project collects independent tests of these behaviors [Kleppmann 2014].

The following program reproduced two rows of Table 11.9 against PostgreSQL 16:

```
        # PostgreSQL-specific: needs a running PostgreSQL and `pip install psycopg2-
binary`.
        import psycopg2

        DSN = "dbname=shop user=postgres host=localhost"   # adjust to your server

        def session(level):
            conn = psycopg2.connect(DSN)
            conn.set_session(isolation_level=level)
            return conn, conn.cursor()

        def reset():
            conn = psycopg2.connect(DSN); conn.autocommit = True
            conn.cursor().execute("""
                DROP TABLE IF EXISTS stock, doctors;
                CREATE TABLE stock (product_id int PRIMARY KEY, on_hand int NOT NULL);
                INSERT INTO stock VALUES (42, 10);
                CREATE TABLE doctors (name text PRIMARY KEY, on_call bool NOT NULL);
                INSERT INTO doctors VALUES ('alice', true), ('bob', true);""")
            conn.close()

        def try_commit(conn):
            try:
                conn.commit(); return "commit"
            except psycopg2.Error as e:
                conn.rollback(); return "abort: " + e.pgerror.splitlines()[0]

        def lost_update(level):           # read-modify-write computed in the applica-
tion
            reset(); (a, ca), (b, cb) = session(level), session(level)
            ca.execute("SELECT on_hand FROM stock WHERE product_id = 42"); va =
ca.fetchone()[0]
            cb.execute("SELECT on_hand FROM stock WHERE product_id = 42"); vb =
cb.fetchone()[0]
            ca.execute("UPDATE stock SET on_hand = %s WHERE product_id = 42", (va -
1,)); a.commit()
            try:
                cb.execute("UPDATE stock SET on_hand = %s WHERE product_id = 42", (vb -
1,))
                result = try_commit(b)
            except psycopg2.Error as e:
                b.rollback(); result = "abort: " + e.pgerror.splitlines()[0]
            print(f"lost update, {level}: B {result}")

        def write_skew(level):            # invariant: at least one doctor on call
            reset(); (a, ca), (b, cb) = session(level), session(level)
            for cur, me in ((ca, "alice"), (cb, "bob")):
                cur.execute("SELECT count(*) FROM doctors WHERE on_call")
                if cur.fetchone()[0] >= 2:
                    cur.execute("UPDATE doctors SET on_call = false WHERE name = %s",
(me,))
            print(f"write skew, {level}: A {try_commit(a)}; B {try_commit(b)}")

        for level in ("READ COMMITTED", "REPEATABLE READ"):
            lost_update(level)
```

```
        for level in ("REPEATABLE READ", "SERIALIZABLE"):
            write_skew(level)
```

Output on PostgreSQL 16.15:

```
lost update, READ COMMITTED: B commit
lost update, REPEATABLE READ: B abort: ERROR:  could not serialize access due to concur-
rent update
write skew, REPEATABLE READ: A commit; B commit
write skew, SERIALIZABLE: A commit; B abort: ERROR:  could not serialize access due to
read/write dependencies among transactions
```

What to notice:

- Two sessions are interleaved by hand in one thread; nothing blocks, because PostgreSQL readers never wait for writers.
- At REPEATABLE READ and SERIALIZABLE, an abort is *normal* behavior, not a bug. Production code wraps such transactions in a retry loop with a bounded number of attempts.

RECOMMENDATION

Recommendation — Choosing an isolation level. Default to READ COMMITTED (PostgreSQL) and make every read-modify-write atomic in SQL (`SET x = x - 1 WHERE ... AND x >= 1`) or explicitly locked (`FOR UPDATE`). Use SERIALIZABLE, with retries, for transactions that check an invariant across several rows and then write. In MySQL, do not assume REPEATABLE READ protects read-modify-write cycles; use locking reads.

11.14 Multi-version concurrency control (MVCC)

11.14.1 The idea

DEFINITION

Definition — MVCC. A concurrency-control technique in which a write creates a new **version** of a row instead of overwriting it in place, and each transaction reads the versions visible in its **snapshot**: the set of transactions that had committed when the snapshot was taken. Readers therefore never block writers and writers never block readers; only writers of the same row wait for each other.

First-principles explanation

A library keeps every edition of a reference book; a reader arriving at 10:00 gets the edition current at 10:00, even if a new one is shelved at 10:05. Editors never wait for readers. The costs are shelf space and a librarian who discards editions nobody can still be reading. PostgreSQL and InnoDB differ in *where* they keep old editions and *who* discards them.

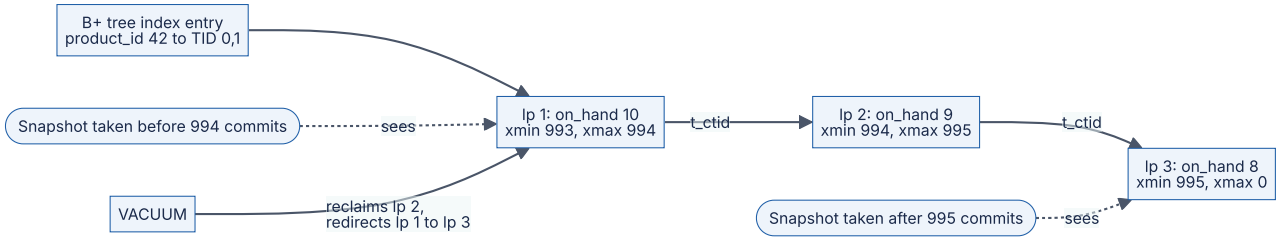
11.14.2 PostgreSQL: versions in the heap, cleaned by VACUUM

Each heap tuple carries a header with `xmin` (the ID of the transaction that created this version), `xmax` (the ID of the transaction that deleted or replaced it, or 0) and `ctid` (the location of this version, or of its successor). An `UPDATE` sets `xmax` on the old version and inserts a complete new version. A snapshot records the oldest still-running transaction ID, the next unassigned ID and the list of IDs in progress; a version is visible if its `xmin` committed before the snapshot and its `xmax` is empty, aborted or not yet visible to the snapshot [PostgreSQL Docs: Concurrency Control].

Real output from PostgreSQL 16 after inserting a stock row and updating it twice (the `pageinspect` extension shows raw page contents):

```
        INSERT INTO stock VALUES (42, 10);                          -- transaction 993
        UPDATE stock SET on_hand = 9 WHERE product_id = 42;         -- transaction 994
        UPDATE stock SET on_hand = 8 WHERE product_id = 42;         -- transaction 995
        SELECT xmin, xmax, ctid, * FROM stock;                      -- only the visible
version
        --  xmin | xmax | ctid  | product_id | on_hand
        --   995 |    0 | (0,3) |         42 |       8
        SELECT lp, t_xmin, t_xmax, t_ctid FROM heap_page_items(get_raw_page('stock',
0));
        --  lp | t_xmin | t_xmax | t_ctid
        --   1 |    993 |    994 | (0,2)
        --   2 |    994 |    995 | (0,3)
        --   3 |    995 |      0 | (0,3)
```

Figure 11.9 — PostgreSQL version chain for product 42.



Reading the diagram. All three versions sit in heap page 0. The updates changed no indexed column and the page had room, so they were **heap-only tuple (HOT)** updates: the index still points to line pointer 1 and readers follow `t_ctid` links to the version their

snapshot can see (dotted arrows show visibility, not messages). On the real page, VACUUM turned line pointer 1 into a redirect to 3 and freed 2. Failure point: a long-running transaction pins an old snapshot, so VACUUM cannot clean dead versions in any table and tables bloat. Scaling: an update that changes an indexed column or finds the page full is not HOT, and every index gets a new entry.

VACUUM (run automatically by **autovacuum**) removes dead versions, records free space for reuse, updates the **visibility map** that index-only scans rely on (§11.7.4), and **freezes** old tuples. Freezing matters because transaction IDs are 32-bit counters compared with wrap-around arithmetic: only about 2^{31} IDs are "in the past" at any moment. A tuple must be frozen (marked as visible to everyone) before its `xmin` becomes 2 billion transactions old, or it would appear to be in the future [PostgreSQL Docs: Routine Vacuuming].

FORMULA

Time until transaction-ID wraparound

$$T_{\text{wrap}} = \frac{2^{31} - A}{\lambda_{\text{xid}}}$$

Symbol	Meaning	Units
T_{wrap}	Time until PostgreSQL must stop assigning transaction IDs	seconds
A	Current age of the oldest unfrozen transaction ID in the database	transactions
λ_{xid}	Rate of transactions that write (read-only transactions consume no ID)	transactions/second

WORKED EXAMPLE

Worked example — How long can freezing be blocked? A shop database commits $\lambda_{xid} = 5,000$ writing transactions per second. Autovacuum normally forces an anti-wraparound vacuum once a table's oldest ID reaches `autovacuum_freeze_max_age` = 200 million (the default).

1. Time to reach the forced-vacuum threshold from zero: $2 \times 10^8 / 5,000 = 40,000$ s, about 11 hours.
2. Suppose a forgotten idle transaction blocks freezing at age $A = 2 \times 10^8$. Remaining headroom: $2^{31} - 2 \times 10^8 = 2,147,483,648 - 200,000,000 \approx 1.95 \times 10^9$.
3. $T_{wrap} = 1.95 \times 10^9 / 5,000 = 389,497$ s, about 4.5 days.

Interpretation. A busy database burns through its safety margin in days, not years. As it approaches the limit PostgreSQL emits warnings and eventually refuses new writing transactions until a vacuum completes. **Engineering implication.** Alert on `age(datfrozenxid)` and on transactions open longer than a few minutes (`pg_stat_activity.xact_start`), and never leave sessions "idle in transaction" (`idle_in_transaction_session_timeout`).

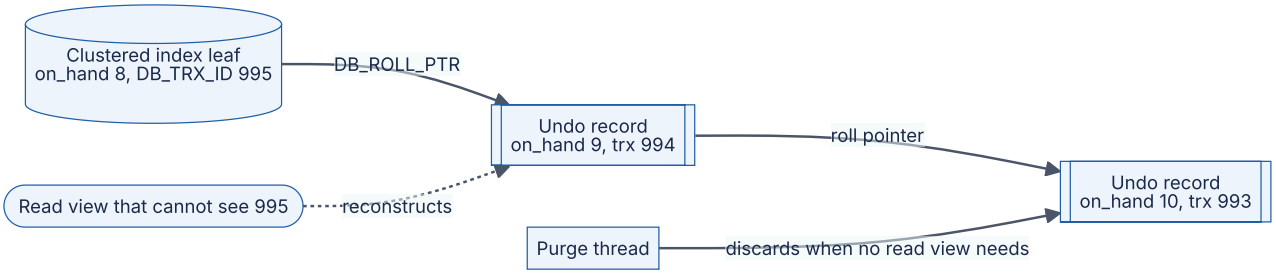
INDUSTRY EXAMPLE

Sentry — transaction ID wraparound outage. Sentry published a postmortem of an outage in which its PostgreSQL database stopped accepting writes to prevent transaction ID wraparound, and service returned only after vacuuming. The lesson: in PostgreSQL, vacuum is part of the write path's capacity budget, not optional maintenance. *Evidence: Primary* — [Sentry 2015]

11.14.3 InnoDB: update in place, old versions in the undo log

InnoDB updates the row *in place* in the clustered index and writes the *previous* values to an **undo log** record. Each clustered-index record has hidden columns `DB_TRX_ID` (the last transaction to modify it, 6 bytes) and `DB_ROLL_PTR` (a pointer to the undo record holding the previous version, 7 bytes). A consistent read creates a **read view** (the set of transactions it must not see); if the current row is too new, InnoDB follows the roll pointers backwards, reconstructing older versions until it reaches a visible one. A background **purge** thread discards undo records no read view needs; the backlog appears as the **history list length** in `SHOW ENGINE INNODB STATUS` [MySQL Docs: InnoDB Multi-Versioning].

Figure 11.10 — InnoDB current row and undo chain for product 42.



Reading the diagram. The cylinder is the one current version in the clustered index; the subroutine shapes are undo records, linked newest to oldest. A reader whose read view excludes transaction 995 applies undo backwards until it reaches a visible version (dotted arrow: a visibility decision). Purge is asynchronous background work. Failure point: a long transaction blocks purge, the history list grows and hot-row reads walk ever-longer chains. Scaling benefit: updates do not bloat the table, and secondary indexes change only when their columns change.

Table 11.10 — MVCC in PostgreSQL and InnoDB.

Aspect	PostgreSQL	MySQL InnoDB
Where old versions live	In the table heap, next to current ones	In undo logs, outside the table
What an update writes	A complete new tuple (and index entries unless HOT)	In-place change plus an undo record
Version metadata	`xmin`, `xmax`, `ctid` in each tuple header	`DB_TRX_ID`, `DB_ROLL_PTR` hidden columns
Reading an old version	Scan to the visible tuple; cheap	Reconstruct by applying undo; cost grows with chain length
Garbage collection	VACUUM / autovacuum; must also freeze XIDs	Purge threads
Rollback cost	Nearly free (versions never become visible)	Must apply undo to restore rows
Symptom of a long transaction	Table and index bloat; wraparound risk	Growing history list; slower reads

11.15 Locking

11.15.1 Two-phase locking and lock granularity

DEFINITION

Definition — Two-phase locking (2PL). A protocol in which each transaction acquires locks (shared **S** for reading, exclusive **X** for writing) before accessing data and, once it releases any lock, acquires no new ones: a *growing* phase followed by a *shrinking* phase. **Strict 2PL** holds all X locks until commit or abort. Any schedule produced by 2PL is serializable [Eswaran et al. 1976].

S locks are compatible with each other; X locks conflict with everything. MVCC databases lock mainly for *writes*: two updates of one row serialize on its row lock, while plain reads take no row locks. Granularities:

- **Row locks** — taken by `UPDATE`, `DELETE` and explicit `SELECT ... FOR UPDATE` / `FOR SHARE`. PostgreSQL also has weaker `FOR NO KEY UPDATE` and `FOR KEY SHARE` modes so that foreign-key checks do not block updates of non-key columns.
- **Table locks** — PostgreSQL has eight table-lock modes from `ACCESS SHARE` (taken by every `SELECT`) to `ACCESS EXCLUSIVE` (taken by most `ALTER TABLE` forms) [PostgreSQL Docs: Explicit Locking]. InnoDB uses **intention locks** (IS, IX) on the table to signal row locks below.
- **Gap and next-key locks (InnoDB)** — at REPEATABLE READ, a locking read or update over a range locks the index records it scans *and the gaps between them* (a **next-key lock** is a record lock plus the gap before it). This blocks inserts into the range, preventing phantoms, at the price of extra blocking [MySQL Docs: InnoDB Locking]. READ COMMITTED disables most gap locking.

`SELECT ... FOR UPDATE SKIP LOCKED` (PostgreSQL 9.5+, MySQL 8.0+) lets many workers pull different rows from a job table without blocking on each other, a common way to build a simple, transactional work queue.

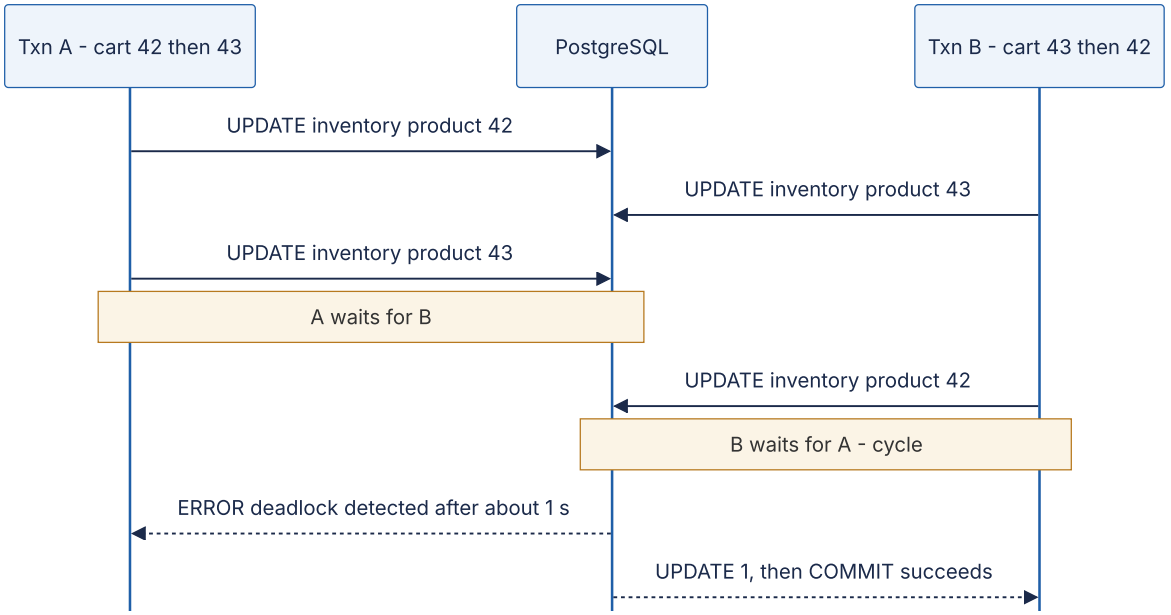
WARNING / TRADE-OFF

Warning — A schema change can stop all traffic. `ALTER TABLE orders ADD COLUMN ...` needs PostgreSQL's `ACCESS EXCLUSIVE` lock for at least a moment. If a long report query holds `ACCESS SHARE`, the `ALTER` waits, and every new query on `orders` queues *behind the waiting* `ALTER`. Set `lock_timeout` (for example 2 s) on migrations and retry; use online schema-change tools for MySQL (such as GitHub's gh-ost [GitHub gh-ost]).

11.15.2 Deadlocks

A **deadlock** occurs when transactions wait for each other's locks in a cycle (§6.11). Databases detect cycles in the **wait-for graph** and abort one transaction, the **victim**. PostgreSQL checks for a cycle after a waiter has been blocked for `deadlock_timeout` (default 1 s); InnoDB detects them immediately by default (`innodb_deadlock_detect`), and otherwise relies on `innodb_lock_wait_timeout` (default 50 s) [MySQL Docs: Deadlock Detection].

Figure 11.11 — A deadlock between two checkouts, as reproduced on PostgreSQL 16.



Reading the diagram. Each checkout updates inventory rows in cart order with synchronous, blocking statements. A holds 42 and waits for 43; B holds 43 and waits for 42: a cycle in the wait-for graph. After A had waited `deadlock_timeout`, PostgreSQL aborted it with `deadlock detected` (SQLSTATE `40P01`) and B's update proceeded. The cost is a retried transaction and up to a second of latency, and deadlocks become more frequent as concurrency grows. **Prevention:** acquire locks in a canonical order, for example by sorting cart lines by `product_id`, as the code in §11.17 does.

11.15.3 Hot rows and optimistic concurrency

FORMULA

Throughput ceiling of a single hot row

$$X_{\max} = \frac{1}{t_{\text{hold}}}$$

Symbol	Meaning	Units
$X_{\max}$	Maximum transactions per second that can update the same row	transactions/second
t_{hold}	Time each transaction holds the row's X lock (from its update to commit)	seconds

WORKED EXAMPLE

Worked example — A flash sale on one product. Each checkout updates the product's `inventory` row, then (wrongly) calls a payment provider inside the transaction before committing.

1. With a 200 ms payment call inside the transaction: $X_{\max} = 1/0.2 = 5$ checkouts per second, however many servers you add.
2. Payment moved outside the transaction; update and commit take 2 ms including a commit flush and one network round trip: $X_{\max} = 1/0.002 = 500$ per second.
3. Stock split into 10 bucket rows (each holding a tenth of the units, chosen at random per checkout): about $10 \times 500 = 5,000$ per second.

Interpretation. Lock hold time, not CPU, bounds a hot row: this is Little's Law (§4.11) applied to a lock with capacity one. **Engineering implication.** Keep slow work out of transactions, update hot rows last (just before commit) so the lock is held briefly, and split hot counters when one row cannot keep up.

When conflicts are rare, **optimistic concurrency control** avoids holding locks across user think time: write only if the row's version is unchanged since you read it.

```
        import sqlite3

        db = sqlite3.connect(":memory:")
        db.executescript("""
        CREATE TABLE products (
          product_id  INTEGER PRIMARY KEY,
          description TEXT    NOT NULL,
          version     INTEGER NOT NULL DEFAULT 1
        );
        INSERT INTO products (product_id, description) VALUES (7, 'Blue mug');
        """)

        def save(product_id, new_description, version_read):
            """Optimistic concurrency control: the write succeeds only if nobody wrote
since we read."""
            with db:
                cur = db.execute(
                    "UPDATE products SET description = ?, version = version + 1 "
                    "WHERE product_id = ? AND version = ?",
                    (new_description, product_id, version_read))
            return cur.rowcount == 1          # 0 rows updated means a concurrent edit
won

        # Two editors load the same row (version 1), then both try to save.
        _, _, v_alice = db.execute("SELECT * FROM products WHERE product_id =
7").fetchone()
        _, _, v_bob = db.execute("SELECT * FROM products WHERE product_id =
7").fetchone()
        print("alice saved:", save(7, "Blue ceramic mug", v_alice))
        print("bob saved:  ", save(7, "Navy mug", v_bob))       # rejected: must re-read
and retry
        print(db.execute("SELECT * FROM products").fetchall())
```

What to notice:

- Output: Alice's save returns `True`, Bob's `False`, and the row is `(7, 'Blue ceramic mug', 2)`: Bob's stale edit is rejected instead of silently overwriting Alice's (a lost update prevented without locks).
- The check-and-write is one atomic `UPDATE`; HTTP APIs expose the same idea with `ETag` and `If-Match` headers.

11.16 PostgreSQL versus MySQL

11.16.1 Comparison

Both are mature, open-source ACID databases that handle most transactional workloads well; the differences decide edge cases, operations and ecosystem fit.

Table 11.11 — PostgreSQL and MySQL (InnoDB) compared, as of PostgreSQL 16–18 and MySQL 8.0–8.4.

Row	PostgreSQL	MySQL (InnoDB)
What it is	Extensible object-relational database; PostgreSQL License	Relational database; GPLv2 community edition plus commercial editions (Oracle)
How it works	Heap tables, all indexes secondary (TID pointers); MVCC versions in heap; VACUUM; process per connection; 8 KiB pages	Index-organized tables clustered on PK; secondary indexes store PK; MVCC via undo logs; purge; thread per connection; 16 KiB pages
Advantages	Rich SQL (CTEs, window functions, `JSONB`, partial/expression indexes, GIN/GiST/BRIN), transactional DDL, SSI serializable, extensions (PostGIS, pgvector)	Fast PK lookups and PK range scans, compact secondary-index updates, mature replication tooling, very wide hosting and operator familiarity
Disadvantages	Vacuum tuning and XID wraparound; non-HOT updates touch every index; connections are costly (needs a pooler, §14.13)	No partial indexes; DDL not transactional (atomic since 8.0, but commits implicitly); REPEATABLE READ allows lost updates; gap-lock surprises
Performance	Strong on complex queries, joins and analytics-style SQL; good write throughput when HOT applies	Strong on simple PK-centric OLTP and high connection counts; secondary lookups cost two tree descents
Operational complexity	Autovacuum, bloat and freeze monitoring; major-version upgrades via `pg_upgrade` or logical replication	Purge lag and undo growth; online schema change tools for large tables
Cost	Free; managed offerings on all major clouds	Free community edition; managed offerings on all major clouds; commercial support from Oracle
Use cases	Complex domains, geospatial, JSON-heavy data, mixed OLTP and reporting	High-volume web OLTP with simple access patterns; large existing MySQL ecosystems
Choose when	You need advanced SQL, data types, extensions or serializable isolation	Your team and tooling know MySQL, or the workload is dominated by PK access and you rely on its replication ecosystem

Table 11.12 — Defaults and behaviors that change application code.

Behavior	PostgreSQL	MySQL InnoDB
Default isolation level	READ COMMITTED	REPEATABLE READ
Serializable implementation	SSI (optimistic, aborts)	2PL with shared locks (blocking)
Phantom protection at REPEATABLE READ	Snapshot	Snapshot for reads; next-key locks for locking reads
Join algorithms	Nested loop, hash, merge	Nested loop, hash (8.0.18+)
Partial indexes	Yes	No
`INCLUDE` covering columns	Yes (11+)	Implicit PK only
Deadlock detection	After `deadlock_timeout` (1 s)	Immediate by default

INDUSTRY EXAMPLE

Uber — moving a core datastore from PostgreSQL to MySQL (2016). Uber's engineering blog attributed the move to PostgreSQL's physical design at its scale: non-HOT updates write new entries in every index (write amplification), physical WAL replication shipped those amplified changes across data centers, and MVCC on replicas interacted badly with long queries. InnoDB's PK-pointer secondary indexes and row-based replication fit its write pattern better. PostgreSQL practitioners responded with mitigations (HOT-friendly schemas, `fillfactor`, logical replication). The lesson is to match storage design to workload. *Evidence: Primary* — [Klitzke 2016]

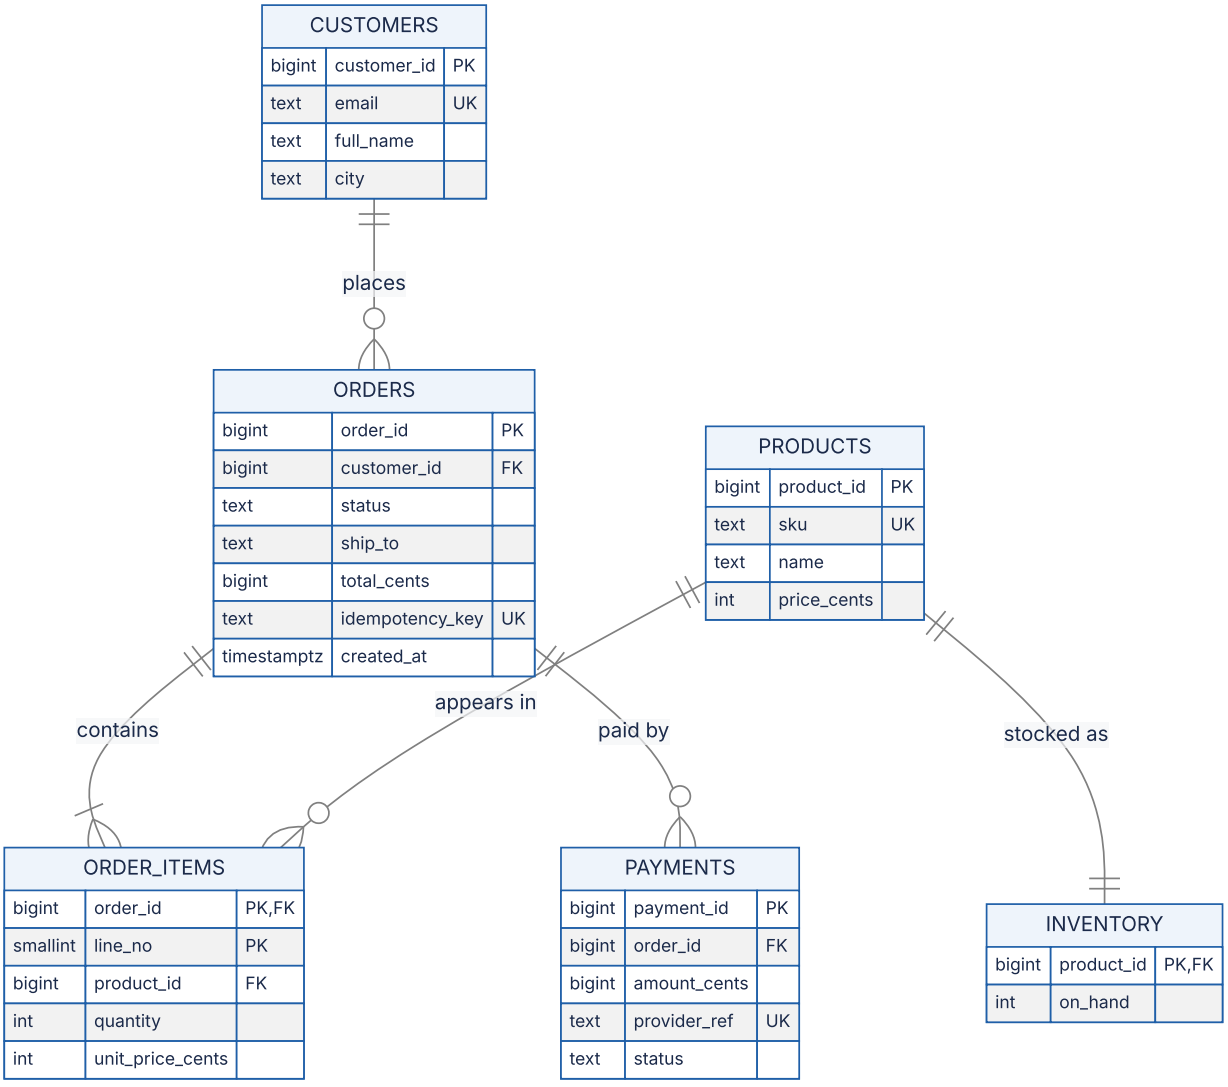
11.17 Data modeling for a real application

11.17.1 Requirements to schema

The order service must reserve stock and create an order atomically, never oversell, accept retries without duplicates, record payments, show order history newest first and report best sellers. We model it in five steps:

1. **Entities and relationships** from nouns and verbs: customers *place* orders; orders *contain* items; items *reference* products; products *have* inventory; orders are *paid by* payments.
2. **Keys**: `bigint` identity surrogates; natural keys (`email`, `sku`, `provider_ref`, `idempotency_key`) as `UNIQUE`.
3. **Normalize** to BCNF (§11.5), keeping historical facts (`unit_price_cents`, `ship_to`) on the order.
4. **Invariants as constraints**: `CHECK (on_hand >= 0)` makes overselling impossible.
5. **Indexes from queries**: one per access path, and no others.

Figure 11.12 — Entity-relationship diagram of the order system.



Reading the diagram. Each box is a table with key markers (PK, FK, UK); crow's-foot lines give cardinality: a customer places zero or more orders, an order has one or more items, a product has exactly one inventory row, an order has zero or more payment attempts. Every line is a foreign key enforced synchronously inside one database, the single storage boundary. Failure points are rows many transactions touch: the `inventory` rows of popular products (§11.15.3). Scaling: read replicas for history and reports (§14.3), then partitioning orders and items by `customer_id` (§14.7).

11.17.2 DDL (PostgreSQL)

The following DDL was run on PostgreSQL 16:

```
        CREATE TABLE customers (
          customer_id  bigint GENERATED ALWAYS AS IDENTITY PRIMARY KEY,
          email        text NOT NULL UNIQUE,
          full_name    text NOT NULL,
          city         text NOT NULL,
          created_at   timestamptz NOT NULL DEFAULT now()
        );
        CREATE TABLE products (
          product_id   bigint GENERATED ALWAYS AS IDENTITY PRIMARY KEY,
          sku          text NOT NULL UNIQUE,
          name         text NOT NULL,
          price_cents  integer NOT NULL CHECK (price_cents >= 0)
        );
        CREATE TABLE inventory (
          product_id   bigint PRIMARY KEY REFERENCES products,
          on_hand      integer NOT NULL CHECK (on_hand >= 0)
        );
        CREATE TABLE orders (
          order_id         bigint GENERATED ALWAYS AS IDENTITY PRIMARY KEY,
          customer_id      bigint NOT NULL REFERENCES customers,
          status           text NOT NULL DEFAULT 'pending'
                           CHECK (status IN ('pending','paid','shipped','cancelled')),
          ship_to          text NOT NULL,
          total_cents      bigint NOT NULL CHECK (total_cents >= 0),
          idempotency_key  text NOT NULL UNIQUE,
          created_at       timestamptz NOT NULL DEFAULT now()
        );
        CREATE TABLE order_items (
          order_id          bigint NOT NULL REFERENCES orders ON DELETE CASCADE,
          line_no           smallint NOT NULL,
          product_id        bigint NOT NULL REFERENCES products,
          quantity          integer NOT NULL CHECK (quantity > 0),
          unit_price_cents  integer NOT NULL CHECK (unit_price_cents >= 0),
          PRIMARY KEY (order_id, line_no)
        );
        CREATE TABLE payments (
          payment_id    bigint GENERATED ALWAYS AS IDENTITY PRIMARY KEY,
          order_id      bigint NOT NULL REFERENCES orders,
          amount_cents  bigint NOT NULL CHECK (amount_cents > 0),
          provider_ref  text UNIQUE,
          status        text NOT NULL CHECK (status IN
('authorized','captured','failed','refunded')),
          created_at    timestamptz NOT NULL DEFAULT now()
        );
        -- One index per access path
        CREATE INDEX orders_customer_created_idx ON orders (customer_id, created_at
DESC, order_id DESC); -- history
        CREATE INDEX order_items_product_idx     ON order_items (product_id);       --
FK checks, sales by product
        CREATE INDEX payments_order_idx          ON payments (order_id);            --
payments of an order
        CREATE INDEX orders_pending_created_idx  ON orders (created_at) WHERE status =
'pending'; -- sweeper
```

What to notice:

- Money is stored as integer cents (or `numeric`), never floating point. Timestamps use `timestamptz`.
- `order_items` has a composite primary key `(order_id, line_no)`: its leading column serves "items of this order" and the foreign-key check, so no separate index on `order_items.order_id` is needed.
- `total_cents` is a stored aggregate (a denormalization, §11.5.5) written in the same transaction as the items; it is also the amount charged, a fact worth keeping.
- `status` uses `CHECK` rather than a separate lookup table or PostgreSQL `ENUM` type; adding a status later is a one-line constraint change.

11.17.3 The place-order transaction and core queries

The order service runs this transaction (shown with literal values; the application binds parameters). The decrements are atomic conditional updates, sorted by `product_id` to avoid deadlocks; the idempotency key makes retries safe (§22.15):

```
        BEGIN;
        INSERT INTO orders (customer_id, ship_to, total_cents, idempotency_key)
        VALUES (1, '1 Main St', 0, '7f1c9a52-key')
        ON CONFLICT (idempotency_key) DO NOTHING
        RETURNING order_id;                      -- no row returned: a retry; fetch and
return the existing order
        UPDATE inventory SET on_hand = on_hand - 2 WHERE product_id = 1 AND on_hand >=
2;  -- expect 1 row
        UPDATE inventory SET on_hand = on_hand - 1 WHERE product_id = 2 AND on_hand >=
1;  -- 0 rows: out of stock, ROLLBACK
        INSERT INTO order_items (order_id, line_no, product_id, quantity,
unit_price_cents)
        SELECT 1, row_number() OVER (ORDER BY v.product_id), v.product_id, v.qty,
p.price_cents
        FROM (VALUES (1, 2), (2, 1)) AS v(product_id, qty) JOIN products p USING
(product_id);
        UPDATE orders SET total_cents = (SELECT sum(quantity * unit_price_cents)
                                         FROM order_items WHERE order_id = 1)
        WHERE order_id = 1;
        COMMIT;
```

The complete model also runs on SQLite through Python's standard library; this script creates the schema, places an order, retries it with the same idempotency key, attempts an order that would oversell, and runs the history, best-seller and anti-join queries:

```
        """E-commerce order schema and queries (Section 11.17), runnable with Python's
sqlite3.
        The PostgreSQL DDL in the chapter differs only in types (bigint identity, times-
tamptz)."""
        import sqlite3

        SCHEMA = """
        PRAGMA foreign_keys = ON;
        CREATE TABLE customers (
          customer_id INTEGER PRIMARY KEY,
          email       TEXT NOT NULL UNIQUE,
          full_name   TEXT NOT NULL,
          city        TEXT NOT NULL,
          created_at  TEXT NOT NULL DEFAULT CURRENT_TIMESTAMP
        );
        CREATE TABLE products (
          product_id  INTEGER PRIMARY KEY,
          sku         TEXT NOT NULL UNIQUE,
          name        TEXT NOT NULL,
          price_cents INTEGER NOT NULL CHECK (price_cents >= 0)
        );
        CREATE TABLE inventory (
          product_id INTEGER PRIMARY KEY REFERENCES products,
          on_hand    INTEGER NOT NULL CHECK (on_hand >= 0)
        );

        print("plan:", db.execute("EXPLAIN QUERY PLAN " + ORDER_HISTORY,
                                  {"cid": 1, "after_created": "9999", "after_id":
0}).fetchall()[0][3])
        try:
            db.execute("INSERT INTO orders (customer_id, ship_to, idempotency_key)
VALUES (99, 'x', 'k')")
        except sqlite3.IntegrityError as e:
            print("foreign key enforced:", e)
```

What to notice:

- Output: the retry returns the same order (1); the oversell attempt raises `OutOfStock` for product 3 and leaves inventory at `[(1, 3), (2, 4), (3, 5)]`. Product 1 had already been decremented (lines are processed in `product_id` order) when product 3 failed, and the rollback restored it. Only one order exists, with total 4,900 cents.
- The history query uses a keyset cursor (§8.6.5); the first page passes a cursor greater than any real value. Its plan is `SEARCH orders USING INDEX orders_customer_created (customer_id=? AND created_at<?)`: the composite index serves both the filter and the sort.

- Best sellers: `TEE-1` (2,500 cents) then `MUG-1` (2,400 cents); the anti-join finds `bo@example.com`, who never ordered.

Table 11.13 — Failure scenarios in the order system.

What goes wrong	Why	Detection	Recovery	Prevention
Overselling	Read-then-write stock check in the application	Negative-stock or oversold reports	Cancel and refund	Conditional `UPDATE ... AND on_hand >= q` plus `CHECK (on_hand >= 0)`
Duplicate orders on client retry	Timeout after commit; client retries	Two orders with identical items seconds apart	Refund duplicate	`UNIQUE` idempotency key; `ON CONFLICT DO NOTHING`
Deadlocks at peak	Carts lock inventory rows in different orders	`deadlock detected` errors in logs	Automatic retry	Sort lines by `product_id` before updating
Checkout stalls during a sale	Payment call inside the transaction holds a hot row lock	Lock waits in `pg_stat_activity`; p99 latency	Kill long transactions	Pay outside the transaction; short transactions; split hot counters
Order history slows over time	Missing or wrong composite index; offset pagination	`EXPLAIN` shows sort or scan	Add index	Index `(customer_id, created_at DESC, order_id DESC)`; keyset pagination

11.18 Summary and revision notes

SUMMARY

- Relations are typed sets related by values; physical data independence lets the database choose access paths [Codd 1970].
- Use surrogate primary keys, `UNIQUE` natural keys and foreign keys; index the child columns you join or delete through.
- Normalize the source of truth to 3NF/BCNF on functional dependencies, with lossless splits; denormalize only for measured reads, with a named consistency mechanism. Prices at purchase time are history, not redundancy.
- Join algorithms: index nested loop for small outer inputs (OLTP), hash join for large unsorted equality joins, sort-merge when inputs are sorted. The right choice depends on row counts, so cardinality estimation drives performance.
- Composite indexes follow the leftmost-prefix rule (equality columns first, then range/sort). Covering indexes avoid table reads; partial indexes index only hot subsets. A secondary index pays off only below a break-even selectivity, about 0.4% of rows in our example.
- A B+ tree with 16 KiB pages indexes 10^9 rows in 4 levels; with internal pages cached, a lookup costs about one random I/O (two for an InnoDB secondary index). The leaf working set, not height, limits scale.
- Plans are trees of Volcano iterators; blocking operators need memory and can spill. In `EXPLAIN ANALYZE`, compare estimated and actual rows at each node.
- ACID: atomicity (undo), consistency (constraints), isolation (concurrency control), durability (WAL + fsync, §13.5). ACID consistency is unrelated to linearizability or CAP consistency.
- Isolation-level names differ by database. PostgreSQL: READ COMMITTED default, REPEATABLE READ = snapshot isolation (prevents lost update by aborting, allows write skew), SERIALIZABLE = SSI. MySQL: REPEATABLE READ default, allows lost updates and write skew for read-modify-write cycles.
- MVCC keeps old versions so readers never block writers: PostgreSQL in the heap (VACUUM, freezing, wraparound), InnoDB in undo logs (purge). Long-running transactions hurt both.
- Writers still lock rows (strict 2PL for writes); InnoDB adds gap/next-key locks. Avoid deadlocks with a canonical lock order; a hot row's throughput is at most $1/t_{\text{hold}}$, so keep slow work out of transactions.

11.19 Knowledge checkpoint

1. Why does `WHERE coupon_code <> 'SPRING'` not return rows where `coupon_code` is NULL?

2. A table `enrollment(student_id, course_id, course_title, grade)` has key `(student_id, course_id)`. Which normal form does it violate, and how do you fix it?
3. Why is storing `unit_price_cents` in `order_items` not a normalization violation?
4. Estimate the I/O cost of a block nested-loop join with $M = 1,000$, $N = 5,000$ and $B = 102$ buffer pages.
5. Which of these queries can use an index on `(customer_id, created_at)`: (a) `customer_id = 5`, (b) `created_at > X`, (c) `customer_id = 5 ORDER BY created_at`?
6. How many levels does a B+ tree need for 10^8 rows with $f = 500$ and $L = 100$?
7. What makes an operator "blocking" in the Volcano model? Name three.
8. Distinguish the C in ACID from the C in CAP.
9. Which anomaly does PostgreSQL REPEATABLE READ allow that SERIALIZABLE prevents? Give an example.
10. Does MySQL InnoDB REPEATABLE READ prevent lost updates from `SELECT` then `UPDATE ... SET x = <computed value>`?
11. Why does a long-running idle transaction cause table bloat in PostgreSQL?
12. A transaction holds a hot row's lock for 10 ms. What is the maximum update rate on that row?

Answers

1. Comparisons with NULL evaluate to UNKNOWN, and `WHERE` keeps only TRUE rows. Use `IS DISTINCT FROM` or add `OR coupon_code IS NULL`.
2. 2NF: `course_title` depends only on `course_id`, part of the key. Move it to `courses(course_id, course_title)`.
3. It records the price charged at purchase time, a different fact from the product's current price; it is determined by the order line, not by `product_id`.
4. $1,000 + \lceil 1,000/100 \rceil \times 5,000 = 1,000 + 50,000 = 51,000$ I/Os.
5. a. and (c). (b) cannot seek because `created_at` is not a leftmost prefix (only a full index scan or skip scan is possible).
6. Leaves: $10^8/100 = 10^6$. $\lceil \log_{500} 10^6 \rceil = \lceil 2.22 \rceil = 3$. Height $= 1 + 3 = 4$.
7. It must consume all input before producing its first output row: sort, hash aggregate, hash-join build side (also materialize).
8. ACID consistency: transactions preserve declared invariants in one database. CAP consistency: linearizability, i.e., every read of replicated data sees the latest completed write.
9. Write skew. Two doctors each check that two are on call and each sets themselves off call; both commit under REPEATABLE READ.
10. No. The `UPDATE` reads the latest committed row without checking it against the snapshot. Use `SELECT ... FOR UPDATE`, an atomic `SET x = x - 1`, or a version check.
11. Its snapshot may still need old row versions, so VACUUM cannot remove any version that became dead after the snapshot was taken, in any table.
12. $1/0.010 = 100$ updates per second.

11.20 Interview questions

Basic

Q1. What is a database index, and what does it cost? Answer. A sorted structure, usually a B+ tree, mapping key values to row locations, so a selective lookup costs a few page reads instead of a full scan (about 4 levels at 10^9 rows, roughly 1 I/O with internal pages cached). Costs: every write to indexed columns updates the index, extra storage and memory, and no benefit for low-selectivity predicates. Index the real workload: composite indexes with the leftmost-prefix rule, covering indexes for hot paths, drop unused ones.

Q2. Explain ACID with an example. Answer. Transferring $70 from A to B: atomicity, both debit and credit happen or neither; consistency, declared invariants (no negative balance, valid references) hold after commit; isolation, a concurrent report never sees money in flight; durability, once "committed" is returned a crash cannot lose it, because the WAL was flushed. Note that ACID consistency differs from distributed "strong consistency".

Intermediate

Q3. Two users buy the last unit of a product at the same moment. How do you guarantee you do not oversell? Answer. Make check and decrement one atomic statement, `UPDATE inventory SET on_hand = on_hand - 1 WHERE product_id = ? AND on_hand >= 1`, treat 0 rows updated as out of stock, and back it with `CHECK (on_hand >= 0)`. The row lock serializes the updates; the second finds 0. Alternatives: `SELECT ... FOR UPDATE`, or SERIALIZABLE with retries. Application read-modify-write loses updates at READ COMMITTED and at MySQL REPEATABLE READ. For a flash sale, discuss hot-row throughput ($1/t_{\text{hold}}$), payment outside the transaction and stock buckets.

Q4. A query that took 5 ms now takes 4 s after a large data import. How do you investigate? Answer. Capture `EXPLAIN (ANALYZE, BUFFERS)` and find nodes where estimated and actual rows differ by an order of magnitude; after an import, stale statistics are likely, so run `ANALYZE`. If correlated predicates keep estimates wrong, add extended statistics. Check for unusable indexes (functions, casts), spills (`external merge`, `Batches > 1`) and cold caches (`Buffers read`). Then guard with analyze settings and `pg_stat_statements` monitoring.

Advanced

Q5. Compare PostgreSQL's and InnoDB's MVCC, and explain how each fails under a long-running analytics query on the primary. Answer. PostgreSQL writes a new heap tuple per update (`xmin` / `xmax`), adds index entries for non-HOT updates, and relies

on VACUUM to remove dead versions and freeze XIDs. InnoDB updates in place, keeps prior versions in undo logs and purges them in the background. A multi-hour query holds an old snapshot: in PostgreSQL, VACUUM cannot remove newer dead versions, so hot tables bloat, index-only scans degrade and freezing stalls; in InnoDB, purge stalls, the history list grows and hot-row reads walk longer undo chains. Mitigations: run analytics on a replica or warehouse, set statement and idle-in-transaction timeouts, monitor `age(datfrozenxid)` and history list length.

Q6. Design the concurrency control for an "at least one admin per organization" rule. Answer. This is write skew: each demotion checks a count, then writes a different row. Options: (1) SERIALIZABLE (PostgreSQL SSI) with a retry loop; simplest, with occasional aborts. (2) Materialize the conflict: `SELECT ... FROM organizations WHERE org_id = ? FOR UPDATE` before counting, so changes in one organization serialize; works at READ COMMITTED and in MySQL. (3) A stored `admin_count` with `CHECK (admin_count >= 1)` updated in the same transaction. REPEATABLE READ alone is insufficient in both databases; across shards the invariant needs a single owner (Chapter 28).

11.21 Practical exercises

1. Load the §11.17 schema into PostgreSQL with one million orders (use `generate_series`). Run the order-history query before and after creating `orders_customer_created_idx` with `EXPLAIN (ANALYZE, BUFFERS)`; record pages read and time.
2. Reproduce the correlated-columns misestimate of §11.10 and fix it with `CREATE STATISTICS`. Then build a three-table join where the misestimate changes the join algorithm.
3. Run the isolation program of §11.13 at all four PostgreSQL levels and, if you have MySQL, adapt it to MySQL 8; fill in Table 11.9 from your own results.
4. Install `pageinspect`, update one row 10 times with and without an index on the updated column, and observe HOT chains, `n_tup_hot_upd` and the effect of `VACUUM`.
5. Write a load test with 50 concurrent clients buying from 5 products in random cart order. Count deadlocks, then sort cart lines by `product_id` and count again.

11.22 Design challenges

1. **Seat reservation.** Model a cinema with seats, showings and bookings so that a seat can never be double-booked, even under concurrent requests and client retries. Choose constraints, isolation level and indexes, and justify each.
2. **Ledger.** Design a double-entry ledger (accounts, journal entries, postings) in which every entry balances to zero and balances can be read in O(1). Decide what is normalized, what is a stored aggregate, and how the aggregate stays correct.

3. **Multi-tenant SaaS schema.** One PostgreSQL cluster hosts 5,000 tenants of very different sizes. Compare a shared schema with a `tenant_id` column, schema-per-tenant and database-per-tenant on index design, isolation, migrations and noisy neighbors; prepare the move of large tenants to shards (Chapter 14).

11.24 Open verification items

- PostgreSQL 18 B-tree skip scan (stated as available from version 18, released 2025) and MySQL 8.4 still lacking partial indexes: confirm against current release notes.

- Sentry 2015 wraparound postmortem: title, date and details are from memory; confirm URL and wording.
- Uber 2016 blog post URL (moved from eng.uber.com); Instagram 2012 post URL.
- Exact PostgreSQL 16 thresholds for wraparound warnings and write refusal (stated qualitatively here).
- Claim that MySQL 8.0/8.4 has no sort-merge join.

Chapter 12 — NoSQL Databases

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3.5 h

Chapter 11 described the relational database: one general-purpose model that can answer almost any question you think of later. That generality assumes the data fits on one primary node, the schema is known up front, and joins are cheap because both tables share a disk. In the mid-2000s several companies hit all three limits at once and built databases that dropped some relational guarantees in exchange for the property they needed most. The industry later grouped them under one awkward label, **NoSQL**.

Think of a city's storage options. A relational database is a well-run library: everything cataloged, cross-referenced and lendable under strict rules, but there is one building and one front desk. A **key-value store** is a wall of numbered lockers: you can find locker 4,711 instantly, but you cannot ask "which lockers contain umbrellas?". A **document database** is a filing cabinet in which each folder holds everything about one customer. A **wide-column store** is a warehouse whose aisles are sorted by a label you choose, so a forklift can sweep one aisle end to end. A **graph database** is a map of who knows whom, in which walking from one person to a friend is a single step. A **time-series database** is a weather station's logbook, written strictly in time order and summarized as it ages. Each is better than the library at one kind of question. This chapter teaches which question each family answers, how, and how to choose.

12.1 Learning objectives

After this chapter you should be able to:

- Explain the pressures that produced NoSQL and the 2006–2010 papers that defined it.
- Describe the data model, internals and failure modes of key-value, document, wide-column, graph and time-series databases.
- Design a DynamoDB single-table schema from access patterns, and compute its capacity units and billing break-even.
- Model a Cassandra table query-first and size its partitions with the documented formula.
- Choose between embedding and referencing in MongoDB and order compound indexes by the equality–sort–range rule.

- Explain when index-free adjacency beats joins, and size a time-series store using Gorilla compression and downsampling.
- Apply a selection flowchart and design a polyglot-persistence architecture, accounting for its operational cost.

12.2 Prerequisites

- Relational model, joins, B-tree indexes and ACID — §11.3–§11.12 (NoSQL is defined by what it removes).
- Range and hash partitioning — §14.6 (every family here is partitioned).
- Latency numbers — §4.17 (why single-partition reads are fast and scatter-gather is not).
- Serialization formats — §8.9 (documents are serialized objects).
- Back-of-the-envelope estimation — §2.11.

Several topics appear here only in summary because another chapter owns them: log-structured merge trees (Chapter 13), replication and consistent hashing (Chapter 14, §14.8), quorums (§27.8), and consistency models (Chapter 25).

12.3 Why NoSQL emerged

12.3.1 Three pressures on the relational database

> DEFINITION
>
> **Definition — NoSQL database.** A database that does not use the relational table-and-join model as its primary data model and typically trades some combination of cross-record transactions, ad-hoc querying and fixed schemas for horizontal scale-out, flexible schemas or availability during failures. The name is usually read as “not only SQL”; it describes a movement, not a specification.

First-principles explanation

A single relational server is a kitchen with one head chef: orders are consistent because one person sees everything. A stadium caterer serving 100,000 meals an hour must open many kitchens, and then “consistent at every instant” requires the kitchens to phone each other before every plate leaves — over phone lines that sometimes go down. NoSQL systems are the designs that accept many kitchens as the starting point.

Why does this exist?

Three pressures arrived together between roughly 2004 and 2010:

1. **Scale-out.** Data and traffic outgrew the largest single server; commodity servers were cheap, very large ones were not. A relational database can be sharded by hand (§14.7), but cross-partition joins and transactions become slow or unavailable and the application inherits the routing logic. If most requests touch one entity, why not partition by that entity natively?
2. **Schema flexibility.** Product teams changed their data shape weekly, and `ALTER TABLE` on a multi-terabyte table in 2008-era MySQL could lock or rewrite it for hours. Self-describing records let each record carry its own shape.
3. **Availability.** During a network partition a replicated system must either reject some requests or accept writes that may conflict — the trade-off formalized as the CAP theorem [Brewer 2000; Gilbert & Lynch 2002] and treated in §25.8. Several NoSQL systems chose to stay writable, because a failed "add to cart" loses money.

A fourth argument came from researchers: Stonebraker and Çetintemel argued that "one size fits all" was over and that specialized engines would beat a general row store by an order of magnitude on their own workloads [Stonebraker & Çetintemel 2005; Stonebraker et al. 2007]. NoSQL is one branch of that specialization.

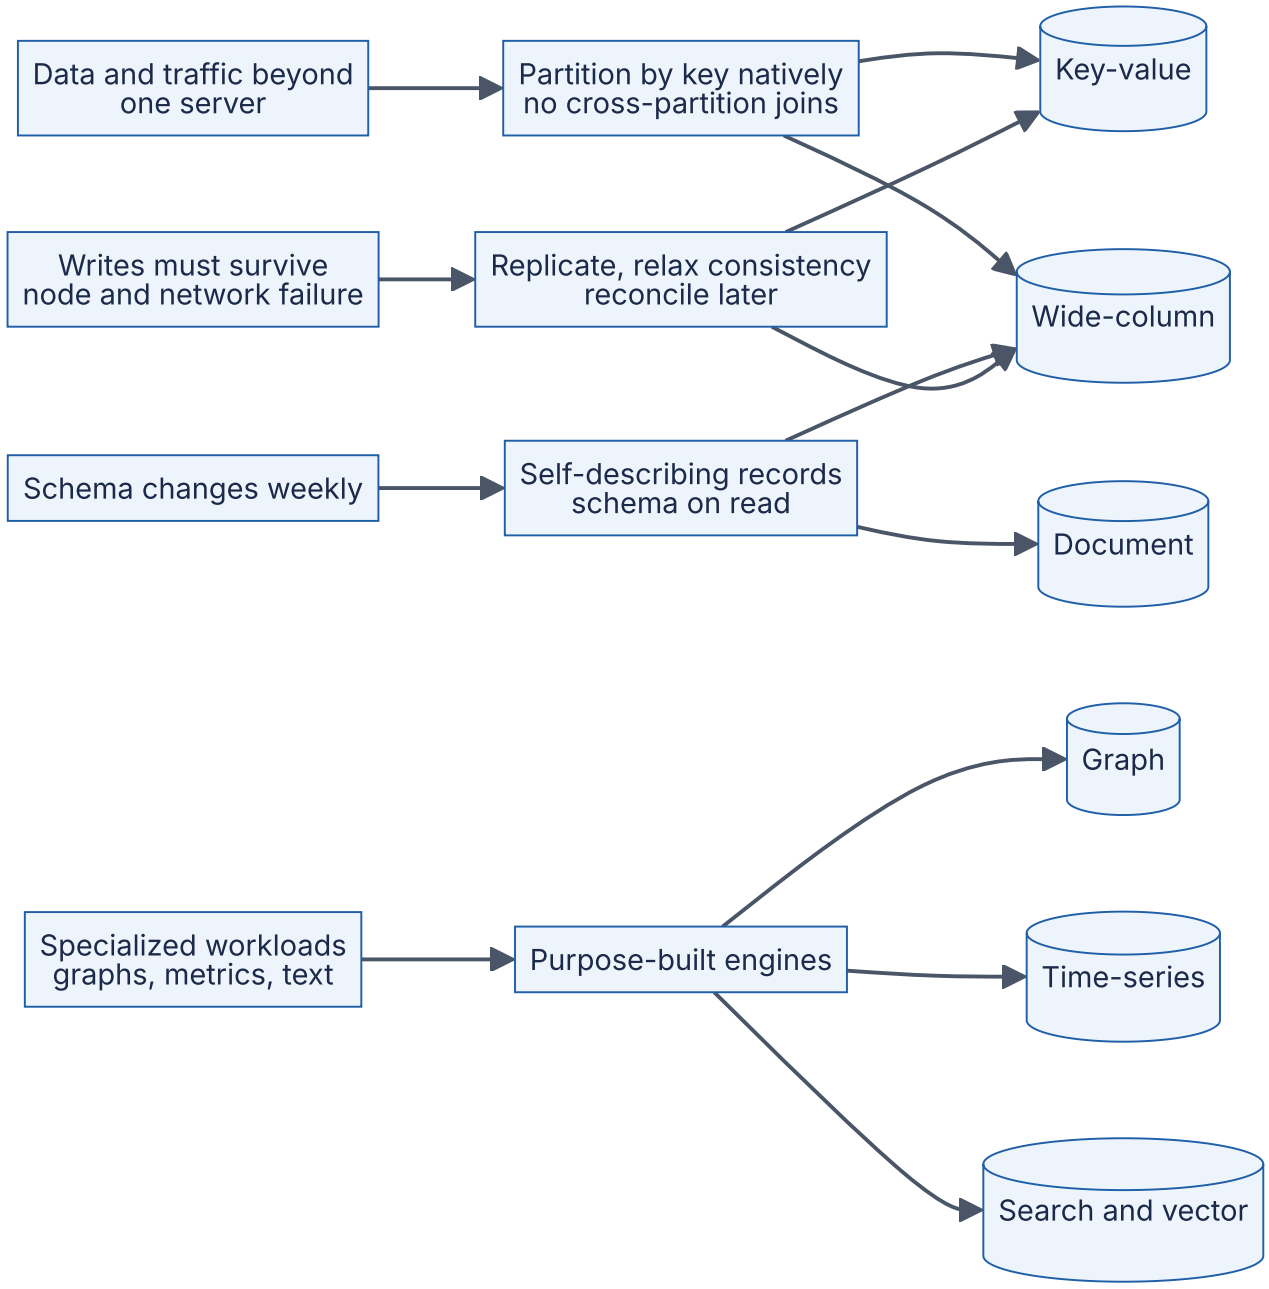
12.3.2 The papers that defined the movement

Four publications supplied most of the ideas that later products copied:

- **Bigtable** (Google, OSDI 2006) — "a sparse, distributed, persistent multidimensional sorted map" indexed by row key, column key and timestamp, stored as immutable files on GFS [Chang et al. 2006]. It is the ancestor of HBase, Cassandra's storage model and Google Cloud Bigtable.
- **Dynamo** (Amazon, SOSP 2007) — an "always writeable" key-value store for the shopping cart, combining consistent hashing, replication across N nodes, sloppy quorums, hinted handoff, vector clocks and Merkle-tree anti-entropy [DeCandia et al. 2007]. Its ideas live on in Cassandra, Riak and Voldemort; Amazon's managed DynamoDB service shares the name and lessons but a different, leader-based design [Elhemali et al. 2022].
- **PNUTS** (Yahoo!, VLDB 2008) — geographically replicated tables with per-record timeline consistency [Cooper et al. 2008].
- **Cassandra** (Facebook, LADIS 2009; SIGOPS OSR 2010) — Dynamo's distribution design married to Bigtable's data model, built for Facebook's inbox search [Lakshman & Malik 2010].

Open-source projects followed: CouchDB (2005), HBase (2008), MongoDB and Redis (2009). The label came from a 2009 San Francisco meetup on distributed, non-relational databases organized by Johan Oskarsson, who needed a Twitter hashtag [Sadalage & Fowler 2012].

Figure 12.1 — Forces that produced NoSQL and the design responses.



Reading the diagram. Pressures (left) led to design responses (middle), embodied by database families (cylinders); arrows mean “led to”, not data flow. One family can answer several pressures: wide-column stores partition natively, tolerate sparse schemas and, in Cassandra’s case, stay writable during failures. The bottom row is the “one size does not fit all” argument: graphs, metrics and text differ so much from row lookups that a specialized layout wins. There are no storage boundaries or failure paths here; each family’s failure modes appear in its own section.

12.3.3 What was given up, and what came back

Early systems typically gave up **joins** (the application stores data pre-joined), **multi-record transactions** (atomicity only within one key, row or document) and **ad-hoc**

queries (you query by designed keys, or scan). Many defaulted to **eventual consistency** — replicas converge if writes stop (§25.7).

The pendulum then swung back: MongoDB 4.0 and DynamoDB added transactions in 2018, Cassandra added Paxos-based lightweight transactions, and the **NewSQL** systems of §12.11 showed that scalable, strongly consistent SQL is possible at a latency cost. The useful question today is "which data model and consistency guarantees fit this access pattern?" — answered in §12.12.

KEY CONCEPT

Key insight — Aggregate orientation. Key-value, document and wide-column databases store an **aggregate** — related data read and written as a unit, such as an order with its line items — under one key, and atomicity, partitioning and replication happen per aggregate [Sadalage & Fowler 2012]. When access patterns follow aggregates these stores scale linearly; slicing across aggregates in unforeseen ways calls for a relational model. Graph databases are relationship-oriented instead.

COMMON MISTAKE

"NoSQL means no schema." The schema still exists, in the code that reads the data: **schema-on-read** rather than the relational **schema-on-write** [Kleppmann 2017, ch. 2]. Evolving records become easy, but every reader must handle every historical shape, so mature deployments add validation (MongoDB's `$jsonSchema`, typed CQL tables).

COMMON MISTAKE

"NoSQL is faster than SQL." A cached PostgreSQL key lookup takes tens of microseconds, like a NoSQL lookup. NoSQL systems keep latency *flat* as data grows, by partitioning and by making expensive operations (joins, scans) impossible or explicit.

12.4 Key-value stores

12.4.1 The key-value model

DEFINITION

Definition — Key-value store. A database whose primary interface is `get(key)`, `put(key, value)` and `delete(key)`, where the value is opaque to the database or has a small set of built-in types. The key alone determines where the value lives.

First-principles explanation

A coat check is a key-value store: hand over a coat, get ticket 217, later exchange 217 for the coat. The attendant never looks in the pockets, which is why it is fast and why you cannot ask “which coats have gloves?”. Because the ticket alone says which rack holds the coat, you can add racks and attendants who never talk to each other.

Why does this exist?

Many hot paths are pure lookups by identifier: session by ID, cart by user, rate-limit counter by API key. For these, a query planner and joins are overhead. Removing them makes partitioning trivial — `hash(key) mod P`, or consistent hashing (§14.8) — and keeps latency flat at any scale. **In-memory stores** such as Redis and Memcached give sub-millisecond latency and usually hold caches or ephemeral state (§20.6); **durable distributed key-value databases** such as DynamoDB, Riak and FoundationDB persist across replicas and act as a system of record.

12.4.2 Redis: a data-structure server

Redis values are typed data structures, and commands execute one at a time on a main thread, so each command — `INCR`, `ZADD` — is atomic without locks.

Table 12.1 — Redis value types and what they are for.

Type	Example command	Typical use
String	`SET session:9f3 "{...}" EX 1800`	Cached objects, sessions with TTL
Hash	`HSET user:42 name Ana plan pro`	Small objects with fields
Set	`SADD online:room7 u42`	Membership, deduplication
Sorted set	`ZINCRBY leaderboard 15 u42`	Leaderboards, rate-limit windows, priority queues
Stream	`XADD events * type click`	Append-only event log with consumer groups

Durability is optional: **RDB** snapshots write point-in-time files; the **AOF** (append-only file) logs every write and can `fsync` every second, bounding loss to about one second. Redis Cluster splits keys into 16,384 hash slots across primaries with asynchronous replicas, so an acknowledged write can be lost on failover. Licensing has shifted (as of 2026): Redis moved to source-available licenses in 2024, the Linux Foundation’s **Valkey** fork followed, and Redis 8 added an AGPLv3 option [Redis Docs].

WARNING / TRADE-OFF

Redis as a primary database. Using Redis as the only copy of business-critical data means accepting asynchronous-replication loss windows, RAM-bounded capacity (tens of times more per GB than SSD) and restore time proportional to dataset size. Decide deliberately.

12.4.3 DynamoDB: the key-value and sort-key model

DynamoDB, Amazon's managed service, is the clearest example of a durable key-value model designed for predictable latency at any scale [Elhemali et al. 2022; AWS Docs: DynamoDB].

DEFINITION

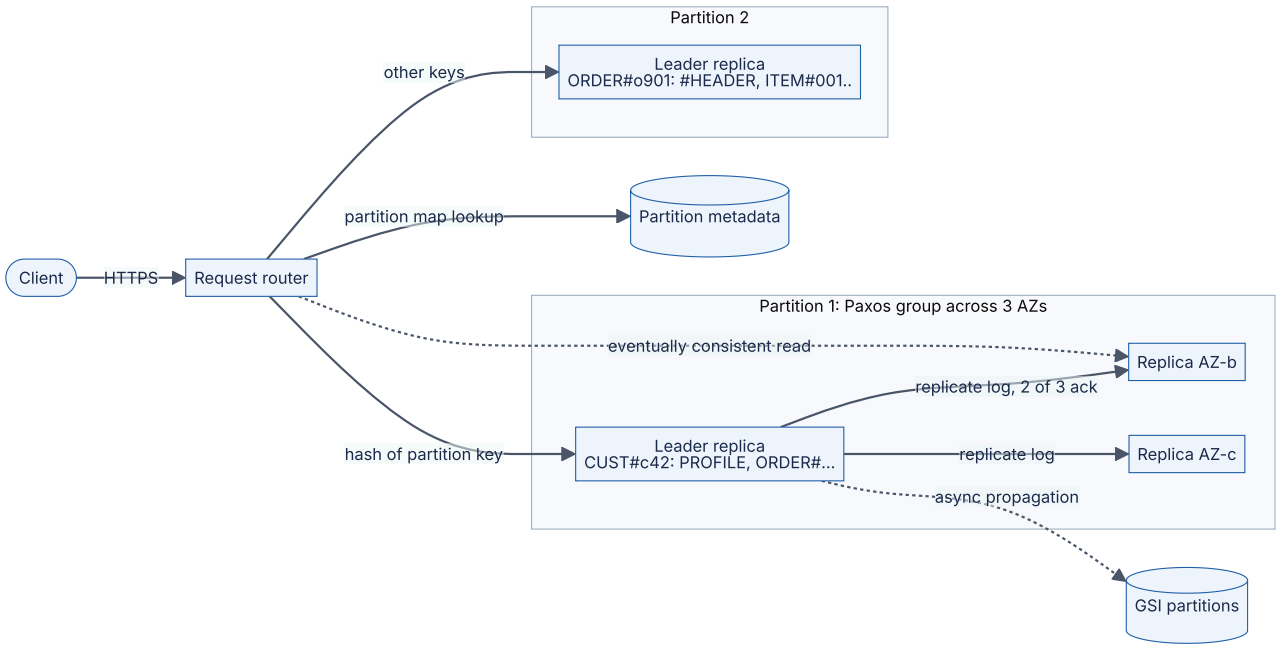
Definition — Partition key, sort key and item collection. In DynamoDB every **item** (a record of up to 400 KB, as of 2026) has a primary key made of a **partition key** and, optionally, a **sort key**. DynamoDB hashes the partition key to choose the storage partition. All items sharing a partition key form an **item collection**, stored together and ordered by sort key, so a single **Query** can return a contiguous, sorted range of them.

How it works internally

1. A client sends `PutItem`, `GetItem` or `Query` over HTTPS to stateless **request routers**, which authenticate it and hash the partition key against a cached partition map.
2. Each partition is replicated across three Availability Zones as a **Multi-Paxos** group; only the leader accepts writes and serves strongly consistent reads [Elhemali et al. 2022].
3. The leader appends a write to its write-ahead log and acknowledges once two of three replicas have persisted it. Each replica stores a B-tree plus the log.
4. An **eventually consistent read** (the default) may go to any replica and miss a just-acknowledged write; a **strongly consistent read** goes to the leader and costs twice as much.
5. Partitions that grow too large or hot are split; **adaptive capacity** shifts throughput toward hot partitions.

Every request touches one partition (or one item collection), so latency does not grow with table size.

Figure 12.2 — DynamoDB data model and request path.



Reading the diagram. Stateless request routers receive HTTPS requests and route by the hash of the partition key — never the sort key; inside a partition, item collections are kept in sort-key order. Writes are acknowledged synchronously once two of three replicas in different Availability Zones have logged them; eventually consistent reads may go to any replica (dotted). Global secondary indexes are separate partitions fed asynchronously, so GSI reads are always eventually consistent. Failure points: losing a replica is invisible; losing a leader triggers a seconds-long election for that partition only. Scaling is by partition splits, invisible to clients.

Secondary indexes: LSI and GSI

To query by anything other than the primary key you declare an index, which DynamoDB maintains on every write.

Table 12.2 — Local versus global secondary indexes (limits as of 2026).

Property	Local secondary index (LSI)	Global secondary index (GSI)
Key	Same partition key, different sort key	Any attribute(s) as new partition and sort key
When created	Only at table creation	Any time
Limit per table	5	20 by default (adjustable quota)
Consistency	Strong or eventual	Eventual only
Throughput	Shares the table's	Its own; throttling can back-pressure table writes
Size constraint	Item collection ≤ 10 GB	None beyond table limits

A **sparse index** includes only items that have the index key attribute; **index overloading** stores several entity types in one GSI under generic attribute names such as `GSI1PK`.

12.4.4 Single-table design: a worked access-pattern example

Relational design normalizes first and writes queries later. In DynamoDB you list every **access pattern** first, then design keys so each pattern is one `GetItem` or `Query`. With no joins, entities read together share an item collection, often in one table per service — **single-table design** [DeBrie 2020; AWS Docs: DynamoDB]. Consider an order service:

Table 12.3 — Access patterns and the operation that serves each.

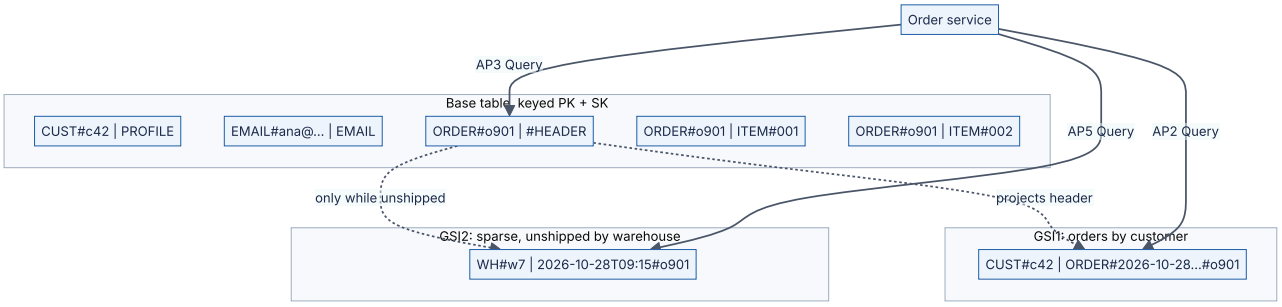
#	Access pattern	Operation
AP1	Get a customer's profile	`GetItem PK=CUST#c42, SK=PROFILE`
AP2	List a customer's orders, newest first	`Query GSI1 PK=CUST#c42, SK begins_with ORDER#`, descending
AP3	Get one order with all its line items	`Query PK=ORDER#o901` (strongly consistent)
AP4	Find a customer by e-mail; keep e-mail unique	`GetItem PK=EMAIL#ana@example.com`
AP5	List a warehouse's unshipped orders, oldest first	`Query GSI2 PK=WH#w7` (sparse)

Table 12.4 — Item layout in the single table.

PK	SK	GSI1PK / GSI1SK	GSI2PK / GSI2SK	Other attributes
`CUST#c42`	`PROFILE`	—	—	name, e-mail, address
`EMAIL#ana@example.com`	`EMAIL`	—	—	customerId
`ORDER#o901`	`#HEADER`	`CUST#c42` / `ORDER#2026-10-28T09:15#o901`	`WH#w7` / `2026-10-28T09:15#o901`	status, total
`ORDER#o901`	`ITEM#001`	—	—	sku, qty, price
`ORDER#o901`	`ITEM#002`	—	—	sku, qty, price

In this design AP3 is one Query (the header sorts first because `#` precedes letters in byte order); AP2's ISO-8601 sort keys make lexical order equal time order; AP4 doubles as a uniqueness constraint, because sign-up writes the profile and `EMAIL#` item in one `TransactWriteItems` call conditioned on `attribute_not_exists(PK)`; and AP5 is sparse — shipping an order removes `GSI2PK`, dropping it from GSI2.

Figure 12.3 — Single-table design with two global secondary indexes.



Reading the diagram. The order service issues synchronous Queries (solid) against the base table or an index, each touching one partition key. Dotted arrows are asynchronous index propagation: a header write is copied into GSI1, and into GSI2 only while it carries the warehouse attribute. Each GSI is a separate storage boundary with its own partitions and capacity. Failure points: a throttled GSI slows base-table writes, and GSI reads can briefly miss a new order. Scaling: every pattern stays one partition-local request regardless of customer count.

Code example

This runnable program imitates the key model so you can experiment without an AWS account.

```
        """A toy single-table store that mimics DynamoDB's key model:
        hash(partition key) -> partition; items sorted by sort key inside it;
        global secondary indexes maintained from attributes on each item."""
        import bisect
        import hashlib
        from collections import defaultdict

        class Table:
            def __init__(self, partitions=4, gsis=()):
                self.partitions = [defaultdict(list) for _ in range(partitions)]
                self.gsis = {name: Table(partitions) for name in gsis}   # name -> index
table

            def _part(self, pk):
                h = int(hashlib.md5(pk.encode()).hexdigest(), 16)
                return self.partitions[h % len(self.partitions)]

            def put(self, item):
                rows = self._part(item["PK"])[item["PK"]]          # the item collection
                keys = [r["SK"] for r in rows]
                i = bisect.bisect_left(keys, item["SK"])
                if i < len(rows) and rows[i]["SK"] == item["SK"]:
                    rows[i] = item                                   # overwrite same
key
                else:
                    rows.insert(i, item)                             # keep sorted by SK
                for name, index in self.gsis.items():                # sparse: only if
keys present
                    if f"{name}PK" in item:
                        index.put({**item, "PK": item[f"{name}PK"], "SK": item[f"
{name}SK"]})

            def query(self, pk, sk_prefix="", newest_first=False):
                rows = [r for r in self._part(pk).get(pk, []) if
r["SK"].startswith(sk_prefix)]
                return rows[::-1] if newest_first else rows

        t = Table(gsis=("GSI1", "GSI2"))
        t.put({"PK": "CUST#c42", "SK": "PROFILE", "name": "Ana", "email":
"ana@example.com"})
        t.put({"PK": "EMAIL#ana@example.com", "SK": "EMAIL", "customer": "c42"})
        for oid, ts, wh in [("o900", "2026-10-21T08:02", None), ("o901", "2026-10-
28T09:15", "WH#w7")]:
            header = {"PK": f"ORDER#{oid}", "SK": "#HEADER", "total": 59.0,
                      "GSI1PK": "CUST#c42", "GSI1SK": f"ORDER#{ts}#{oid}"}
            if wh:                                       # only unshipped orders enter GSI2
                header |= {"GSI2PK": wh, "GSI2SK": f"{ts}#{oid}"}
            t.put(header)
            for n in (1, 2):
                t.put({"PK": f"ORDER#{oid}", "SK": f"ITEM#{n:03d}", "sku": f"SKU-{n}",
"qty": n})

        print("AP1 profile:  ", t.query("CUST#c42", "PROFILE")[0]["name"])
        print("AP2 orders:   ", [r["SK"] for r in t.gsis["GSI1"].query("CUST#c42",
"ORDER#", newest_first=True)])
        print("AP3 order:    ", [r["SK"] for r in t.query("ORDER#o901")])
```

```
        print("AP4 by email: ", t.query("EMAIL#ana@example.com")[0]["customer"])
        print("AP5 to ship:  ", [r["SK"] for r in t.gsis["GSI2"].query("WH#w7")])
```

Output (Python 3.10+):

```
AP1 profile:   Ana
AP2 orders:    ['ORDER#2026-10-28T09:15#o901', 'ORDER#2026-10-21T08:02#o900']
AP3 order:     ['#HEADER', 'ITEM#001', 'ITEM#002']
AP4 by email:  c42
AP5 to ship:   ['2026-10-28T09:15#o901']
```

What to notice:

- `_part` hashes only the partition key, which is why a Query must name exactly one.
- `bisect` keeps item collections sorted, so sort-key prefix and range conditions are contiguous reads.
- `put` skips an index when its key is absent — that is all a sparse index is; order `o900` never enters GSI2.
- Real GSIs update asynchronously and allow duplicate keys; the toy does neither.

12.4.5 Capacity: read and write units

DynamoDB meters throughput in units. One **write capacity unit (WCU)** is one write per second of an item up to 1 KB; one **read capacity unit (RCU)** is one strongly consistent read per second of up to 4 KB, or two eventually consistent reads (as of 2026) [AWS Docs: DynamoDB]. Sizes are rounded *up*: a GetItem rounds each item, but a Query sums the sizes of all returned items before rounding.

FORMULA

DynamoDB capacity units

$$\text{WCU} = \sum_{\text{write types}} r_w \times \lceil \frac{s_w}{1\,\text{KB}} \rceil \times t_w \qquad \text{RCU} = \sum_{\text{read types}} r_r \times \lceil \frac{s_r}{4\,\text{KB}} \rceil \times c_r$$

Symbol	Meaning	Units
r_w, r_r	Rate of a given write or read type, including index writes	operations/second
s_w	Size of the item written (for a GSI, the projected size)	KB
s_r	Item size for GetItem; total returned size for Query	KB
t_w	1 for standard writes, 2 for transactional writes	dimensionless
c_r	0.5 eventually consistent, 1 strongly consistent, 2 transactional	dimensionless

WORKED EXAMPLE

Worked example — Sizing the order table at peak.

Peak load: 1,000 orders/s placed. Each order writes a 1.5 KB header and three 0.6 KB line items. GSI1 projects the whole header (1.5 KB); GSI2 projects keys only (under 1 KB). Reads: 10,000 order-detail lookups/s (AP3), eventually consistent, each returning 1.5 + 3 × 0.6 = 3.3 KB.

1. Header $1,000 \times \lceil 1.5 \rceil = 2,000$ WCU; line items $3,000 \times \lceil 0.6 \rceil = 3,000$ WCU.
2. GSI1 header copy $1,000 \times 2 = 2,000$ WCU; GSI2 copy $1,000 \times 1 = 1,000$ WCU.
3. Total $8,000$ WCU, of which 3,000 (37.5 %) is index maintenance.
4. Query reads: $\lceil 3.3/4 \rceil = 1$ unit × 0.5 → $10,000 \times 0.5 = 5,000$ RCU.
5. Four GetItem calls instead round each item: $10,000 \times 4 \times 0.5 = 20,000$ RCU.

Interpretation. Co-locating items cut read cost by 75 %; index maintenance is over a third of the write bill.

Engineering implication. Project only needed attributes into indexes, keep items small, read related items with one Query — and check the per-partition ceiling of 3,000 RCU and 1,000 WCU (as of 2026). A warehouse receiving over about 1,000 orders/s would throttle its single `WH#w7` GSI2 key whatever the table capacity, so shard it as `WH#w7#0` … `WH#w7#9` and query all ten.

Billing is **provisioned** (per WCU-hour and RCU-hour) or **on-demand** (per request unit used); the choice reduces to one ratio.

FORMULA

On-demand versus provisioned break-even utilization

$$u^* = \frac{p_{\text{prov}}/3600}{p_{\text{od}}}$$

Symbol	Meaning	Units
u^*	Average utilization of provisioned capacity above which provisioned is cheaper	fraction (0–1)
p_{prov}	Price of one provisioned capacity unit for one hour	USD per unit-hour
p_{od}	Price of one on-demand request unit	USD per request unit

WORKED EXAMPLE

Worked example — Which billing mode for the order table?

Assume us-east-1 list prices as of 2026 (verify before use): provisioned \$0.00065 per WCU-hour and \$0.00013 per RCU-hour; on-demand \$0.625 per million write request units and \$0.125 per million read request units.

1. Writes: $u^* = (0.00065/3600)/(0.625 \times 10^{-6}) = 1.806 \times 10^{-7}/6.25 \times 10^{-7} = 0.289$; reads give the same 0.289.
2. The table averages 30 % of peak. Provisioned at peak for 720 hours: $8,000 \times 0.00065 \times 720 = \$3,744$ plus $5,000 \times 0.00013 \times 720 = \$468$, total **\$4,212**.
3. On-demand over 2,592,000 s: $2,400 \times 2,592,000 = 6.22 \times 10^9$ write units → $\$3,888$; $1,500 \times 2,592,000 = 3.89 \times 10^9$ read units → \$486; total **\$4,374**.

Interpretation. At 30 % utilization the modes cost within 4 %, as the break-even predicts.

Engineering implication. Spiky traffic (average far below 29 % of peak) favors on-demand; steady traffic with auto scaling near 70 % utilization costs about 40 % of on-demand when provisioned. Storage and replication are billed separately.

Real-world industry applications

INDUSTRY EXAMPLE

Amazon DynamoDB at Prime Day. Amazon needed a store whose latency did not degrade with scale or noisy neighbors. DynamoDB combines hash partitioning, three-way Multi-Paxos replication, global admission control and splitting for heat; the ATC 2022 paper reports a peak of 89.2 million requests per second during Prime Day 2021 at single-digit-millisecond latency. The trade-off is a restrictive query model. *Evidence: Primary* — [Elhemali et al. 2022]

INDUSTRY EXAMPLE

Dynamo's shopping cart. The cart must accept "add to cart" even during partitions; divergent versions are tracked with vector clocks and merged by union, which can resurrect deleted items — availability bought with correctness. *Evidence: Primary* — [DeCandia et al. 2007]

Advantages and disadvantages

- **Advantages:** predictable latency at any size; near-linear scale-out; fully managed options; per-item TTL deletes without consuming write capacity.
- **Disadvantages:** only designed access patterns are cheap; new patterns need indexes or backfills; no joins or aggregations; hot keys cap throughput; single-table schemas are hard to read.

Failure scenarios

Table 12.5 — Key-value store failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Throttling with spare table capacity	One partition key exceeds the per-partition limit	Throttle metrics with low table utilization; key-level contributor insights	Write-shard the key with a suffix	Choose high-cardinality partition keys (§14.10)
Base-table writes throttled	GSI under-provisioned or hot	GSI throttle events	Raise GSI capacity	Size GSIs like tables; sparse projections
Stale read after write	Eventually consistent read or GSI read	Users see missing items briefly	Retry or read from base table strongly	Strong reads where read-your-writes matters (§25.6)

Common misconceptions

COMMON MISTAKE

“Scan is fine for small tables.” A Scan reads and bills every item, and tables grow. Design a key or index for each online pattern; keep Scan for offline jobs.

12.5 Document databases

12.5.1 The document model

DEFINITION

Definition — Document database. A database that stores self-describing, hierarchical records — **documents**, usually JSON or a binary encoding of it such as BSON — grouped into **collections**, and that can index and query fields inside the documents, including nested fields and array elements.

First-principles explanation

A doctor’s paper chart is a document: allergies, visits and each visit’s prescriptions sit in one folder, and a new kind of test result is just a new page. The cost appears with questions that cut across folders — “who was prescribed drug X last month?” — which need an index or opening every folder.

Why does this exist?

Application objects contain lists and nested objects; normalized tables (§11.5) split them apart and reassemble them with joins — the **object-relational impedance mismatch**. A document database stores the object as the application sees it, so one aggregate is one read and a new field needs no migration. MongoDB (2009) made the model mainstream; PostgreSQL’s `jsonb` brings much of it into a relational engine.

How it works internally

Using MongoDB as the reference [MongoDB Docs]:

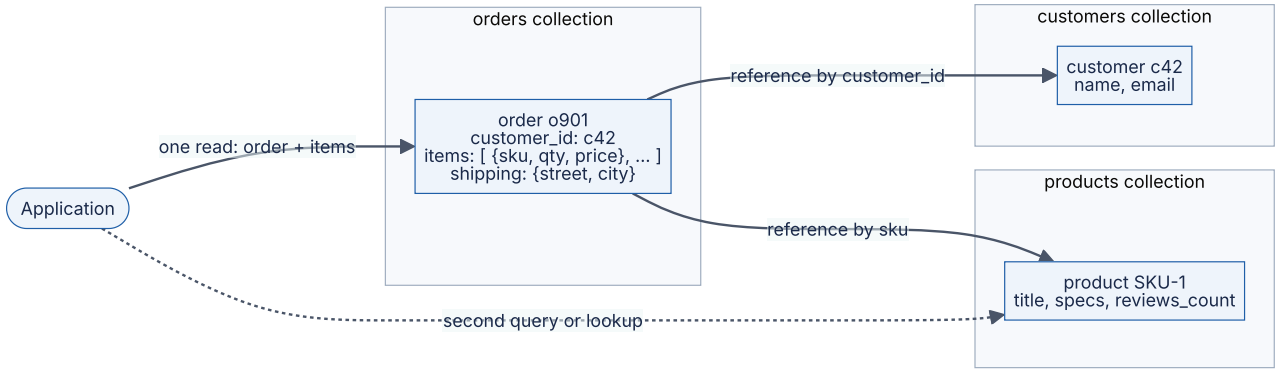
1. Documents are stored as **BSON**, a typed binary JSON (dates, decimals, binary), up to 16 MB each, in WiredTiger B-trees with document-level concurrency control and compression.
2. Every collection has a unique `_id` index; secondary indexes are separate B-trees, and an index on an array field is **multikey** — one entry per element.

3. A **replica set** (typically three members) elects a primary with a Raft-like protocol; secondaries replicate its operation log (**oplog**) asynchronously. With **write concern** `majority` — the default since MongoDB 5.0 — an acknowledged write survives failover.
4. **Sharding** splits a collection by a **shard key** (ranged or hashed) into chunks across replica sets; a `mongos` router targets one shard when the query includes the shard key and scatter-gathers otherwise (§14.11).

12.5.2 Embedding versus referencing

The central modeling decision is whether related data goes *inside* a document or *in another document* that you point to.

Figure 12.4 — Embedding versus referencing in a document model.



Reading the diagram. The application reads an order in one synchronous request because line items and the address are **embedded**: owned by the order, bounded and always read with it. Customers and products are **referenced** by ID because they are shared and change independently; fetching them needs a second query or a `$lookup` (dotted, optional). Each collection is a storage boundary that may sit on a different shard, so a reference can cost a network hop. Failure point: an embedded price is a deliberate snapshot, but an embedded copy expected to stay current will drift. Scaling: shard orders by customer or order ID; one order stays single-shard.

Table 12.6 — Embed or reference?

Embed when	Reference when
The child is read with the parent nearly every time	The child is often read on its own
The relationship is one-to-few and bounded	One-to-many is large or unbounded (comments, events)
The child has no identity outside the parent	Many parents share the child (many-to-many)
You need atomic updates of parent and child together	The child changes frequently and independently
Snapshot semantics are desired (price at purchase)	You need a single current value everywhere

> WARNING / TRADE-OFF
>
> **The unbounded array.** Embedding every comment or reading makes a document grow forever until the 16 MB limit rejects writes. Use the **bucket pattern** (one document per entity per hour or per 100 events) or a separate collection.

12.5.3 Indexes and queries

MongoDB offers compound, multikey, text, geospatial, hashed, wildcard, partial, unique and TTL indexes, up to 64 per collection; for compound indexes its documentation recommends the **ESR rule** — **E**quality fields first, then **S**ort, then **R**ange [MongoDB Docs].

```
        // Orders of one customer, newest first, above a value threshold
        db.orders.createIndex({ customer_id: 1, placed_at: -1, total: 1 });   // E, S, R

        db.orders.find({ customer_id: "c42", total: { $gte: 50 } })
                 .sort({ placed_at: -1 })
                 .limit(20);

        // A transaction across two documents (replica set or sharded cluster)
        const session = db.getMongo().startSession();
        session.withTransaction(() => {
          const s = session.getDatabase("shop");
          s.inventory.updateOne({ sku: "SKU-1", qty: { $gte: 2 } }, { $inc: { qty: -2 }
});
          s.orders.insertOne({ _id: "o902", customer_id: "c42", items: [{ sku: "SKU-1",
qty: 2 }] });
        }, { writeConcern: { w: "majority" } });
```

What to notice:

- The index jumps to one customer, finds entries already in `placed_at` order (no in-memory sort) and filters `total` while walking. With `total` before `placed_at`, the sort could not use the index.
- Multi-document ACID transactions exist since 4.0 (2018) on replica sets and 4.2 (2019) on sharded clusters; the default lifetime limit is 60 seconds, so keep them small.
- If stock is insufficient, `updateOne` matches nothing but does not throw; real code must check `modifiedCount` and abort.

Real-world industry applications

INDUSTRY EXAMPLE

Product catalog with heterogeneous attributes. Shoes have sizes, laptops CPUs, books ISBNs. Relationally this becomes an entity-attribute-value table or dozens of sparse columns; as documents each product carries its own attributes, a wildcard index covers searchable ones, and a catalog page is one read. *Evidence: Illustrative* — a common teaching pattern; not a claim about any company.

Advantages and disadvantages

- **Advantages:** natural object mapping; one-read aggregates; flexible schema; rich indexes and aggregation; built-in replication, sharding and transactions.
- **Disadvantages:** many-to-many needs application joins or `$lookup`; denormalized copies drift; poor shard keys create hot shards; schema drift without validation; queries lacking the shard key fan out.

Failure scenarios

Table 12.7 — Document database failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Acknowledged writes vanish after failover	Write concern below `majority`; primary failed before replication	Rollback files on old primary	Reconcile from rollback data	Use `w: "majority"` for important writes
Hot shard	Monotonic shard key (timestamps, ObjectIds) routes all inserts to one chunk	Per-shard insert rate skew	Reshard (supported since 5.0)	Hashed or compound shard key
Slow queries after growth	Missing or misordered compound index; collection scan	`explain()` shows `COLLSCAN`; slow-query log	Add ESR-ordered index	Review query shapes in code review

Common misconceptions

COMMON MISTAKE

“Documents mean you never need transactions.” Single-document writes are atomic, but an invariant spanning two documents — stock and order, debit and credit — needs a transaction or an idempotent workflow (§32.7). Keep invariants inside one document where you can; use transactions where you cannot.

12.6 Wide-column stores

12.6.1 The Bigtable model

> DEFINITION
>
> **Definition — Wide-column store.** A database whose rows are identified by a key, sorted (globally or within a partition) by that key, and contain a sparse, variable set of columns grouped into **column families**; each row may have millions of columns and each cell may hold several timestamped versions. Bigtable, HBase, Cassandra and ScyllaDB belong to this family.

First-principles explanation

Picture a spreadsheet with rows sorted by key, so wide that most cells are empty — and empty cells cost nothing. Reading one row, or sweeping every row starting with `com.cnn.`, is cheap because neighbors are stored together; finding rows by a column's value is not.

Why does this exist?

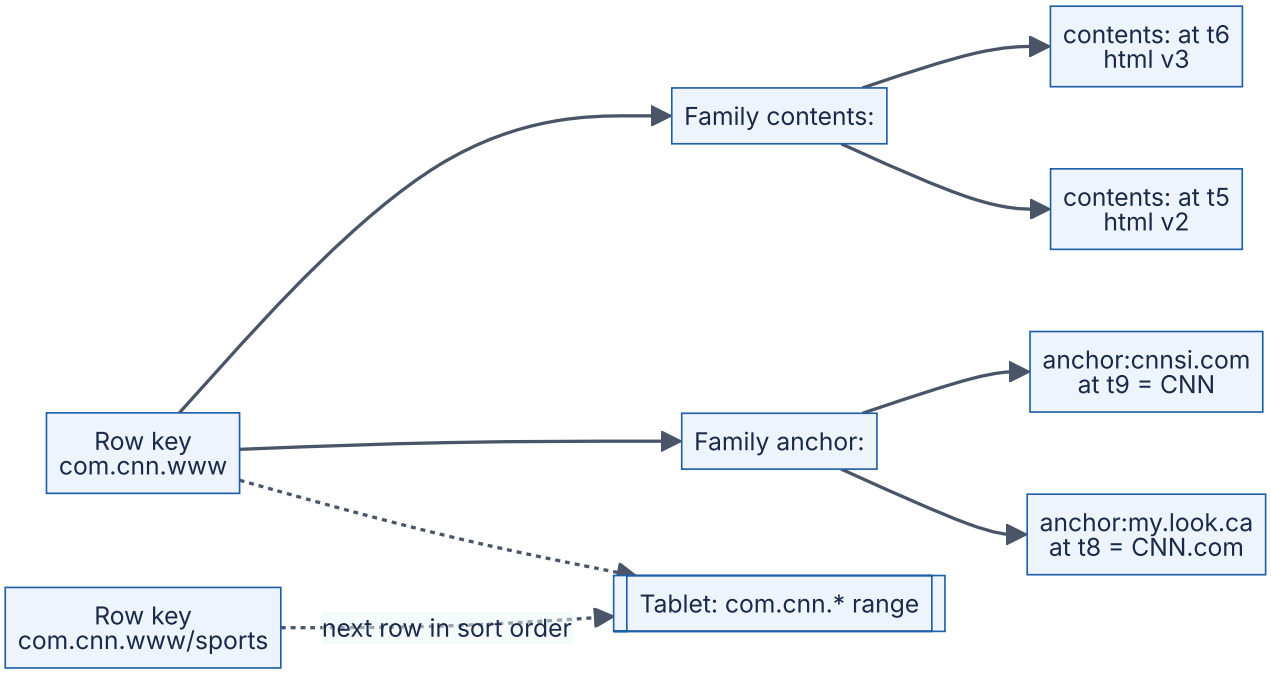
Google needed one store for the web crawl, Earth imagery and analytics across over sixty products, serving both batch scans and low-latency reads on thousands of commodity machines [Chang et al. 2006]. Relational schemas were too rigid for pages with arbitrary inbound links, and key-value stores could not scan ranges.

How it works internally

The Bigtable paper defines the model precisely: `(row: string, column: string, time: int64) → string` [Chang et al. 2006].

1. **Rows** are sorted by row key; single-row reads and writes are atomic.
2. **Column families** are declared in the schema and tuned together; **qualifiers** within a family are created freely at write time (`anchor:cnnsi.com`).
3. **Timestamps** version each cell; garbage collection keeps the last *n* versions or recent ones.
4. Contiguous row ranges called **tablets** (about 100–200 MB in the paper) are the unit of distribution; they split as they grow.
5. Writes go to a commit log and a memtable, flushed to immutable SSTables on GFS and merged by compaction — the log-structured merge design of §13.8.

Figure 12.5 — Bigtable data model: the Webtable example.



Reading the diagram. A Webtable row is keyed by the reversed URL `com.cnn.www`, so a domain's pages sort together into one tablet. Family `contents:` holds timestamped page versions; family `anchor:` has one qualifier per referring site, valued with the link text. Solid arrows show containment; dotted arrows show adjacent rows sharing a tablet, the storage and distribution unit. Failure point: a crashed tablet server's tablets are briefly unavailable until reassigned and the commit log replayed. Scaling: tablets split and move between servers.

HBase reproduces this design on Hadoop (regions, RegionServers, HDFS, ZooKeeper) with strongly consistent single-row operations; Facebook built its 2010 Messages product on it [Borthakur et al. 2011].

12.6.2 Cassandra: partition key and clustering columns

Cassandra keeps Bigtable's sorted layout within a partition but distributes data the Dynamo way: no master, and a Murmur3 hash of the partition key gives a **token** that decides the owning nodes on a ring (consistent hashing, §14.8) [Lakshman & Malik 2010; Apache Cassandra Docs].

DEFINITION

Definition — Primary key in CQL. In Cassandra Query Language, `PRIMARY KEY ((a, b), c, d)` declares `(a, b)` as the **partition key** — hashed to choose the replicas and defining what is stored together — and `c, d` as **clustering columns**, which order rows *within* the partition on disk.

1. Any node can **coordinate** a request, forwarding it to the RF replicas (replication factor, typically 3, across racks or zones), each of which writes its commit log and memtable (§13.8).
2. The client picks a **consistency level** per request — `ONE`, `QUORUM`, `LOCAL_QUORUM`, `ALL`; with RF = 3, `QUORUM` reads and writes overlap ($R + W > N$, §27.8).
3. Missed writes are repaired by hinted handoff, read repair and Merkle-tree anti-entropy (§27.9, §27.13); concurrent writes to a cell resolve by **last-write-wins** on timestamps (§27.14).

12.6.3 Query-first modeling with CQL

Because a query can efficiently read only one partition (or a contiguous slice of it), Cassandra modeling starts from the queries and creates **one table per query**, duplicating data [Chebotko et al. 2015; Apache Cassandra Docs]. Suppose an IoT platform must answer:

- Q1: readings of one sensor for one day, newest first.
- Q2: the latest reading of every sensor at one site.

```
-- Q1: one partition per sensor per day (the "bucket")
CREATE TABLE readings_by_sensor_day (
    sensor_id   uuid,
    day         date,
    ts          timestamp,
    temperature float,
    humidity    float,
    battery     float,
    PRIMARY KEY ((sensor_id, day), ts)
) WITH CLUSTERING ORDER BY (ts DESC)
  AND default_time_to_live = 7776000;      -- 90 days

-- Q2: one partition per site; one row per sensor, overwritten on each reading
CREATE TABLE latest_by_site (
    site_id     text,
    sensor_id   uuid,
    ts          timestamp,
    temperature float,
    PRIMARY KEY ((site_id), sensor_id)
);

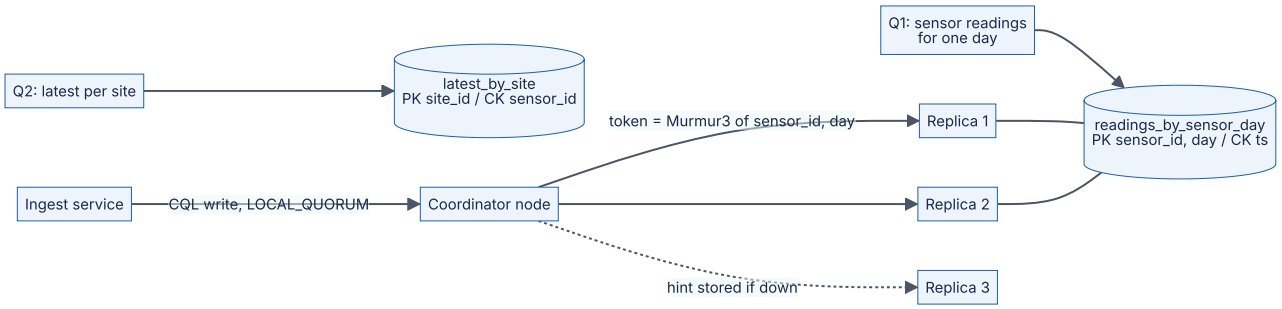
SELECT ts, temperature FROM readings_by_sensor_day
 WHERE sensor_id = 5b6e0f6a-1c1e-4a51-9a52-0c2f7f0b7d11 AND day = '2026-10-30'
 LIMIT 100;
```

What to notice:

- `(sensor_id, day)` bounds each partition to one sensor-day; without `day` it would grow forever.

- `CLUSTERING ORDER BY (ts DESC)` makes “latest 100” a sequential read of the partition’s head.
- Every reading is written to both tables — duplication is the price of single-partition reads.
- `WHERE temperature > 30` is rejected without `ALLOW FILTERING`, which scans: a sign the model lacks a table.
- TTL-expired cells become **tombstones** until compaction removes them.

Figure 12.6 — Query-first modeling and partition placement in Cassandra.



Reading the diagram. Left: each query gets a table whose partition key matches its equality conditions and whose clustering column gives its order. Right: the runtime write path — the ingest service sends a CQL write to any node, which hashes the partition key to a token and forwards to the three owning replicas. With `LOCAL_QUORUM` the write succeeds synchronously after two local acknowledgments; a down replica gets it later via a stored hint (dotted, asynchronous). Each table is a separate storage structure, so ingest writes twice. Failure points: one replica down is tolerated; two down fails `QUORUM` for those partitions. Scaling: add nodes and token ranges redistribute.

12.6.4 Sizing partitions

Oversized partitions slow compaction, repair and reads and concentrate load on *RF* nodes. The Cassandra documentation gives formulas for a partition’s cell count and size [Apache Cassandra Docs].

FORMULA

Cassandra partition cells and size

$$N_v = N_r \, (N_c - N_{pk} - N_s) + N_s$$

$$S_t = \sum_i \text{sizeOf}(c_{k_i}) + \sum_j \text{sizeOf}(c_{s_j}) + N_r \times \left(\sum_k \text{sizeOf}(c_{r_k}) + \sum_l \text{sizeOf}(c_{c_l}) \right) + N_v \times \text{sizeOf}(t_{\text{avg}})$$

Symbol	Meaning	Units
N_v	Number of cells (values) in the partition	cells
N_r	Number of rows in the partition	rows
N_c	Number of columns in the table	columns
N_{pk}	Number of partition-key columns	columns
N_s	Number of static columns	columns
S_t	Estimated partition size on disk, one replica, before compression	bytes
c_k, c_s, c_r, c_c	Partition-key, static, regular and clustering columns	bytes each
t_{avg}	Average per-cell metadata (the docs use the 8-byte timestamp)	bytes

WORKED EXAMPLE

Worked example — Sizing `readings_by_sensor_day`.

Each sensor reports every 10 s. Column sizes: `sensor_id` uuid 16 B, `day` date 4 B, `ts` timestamp 8 B, three floats 4 B each. $N_c = 6$, $N_{pk} = 2$, $N_s = 0$, $t_{\text{avg}} = 8$ B.

1. Rows per day: $86,400/10 = 8,640$.
2. Cells: $N_v = 8,640 \times (6 - 2 - 0) + 0 = 34,560$.
3. Size: partition key $16 + 4 = 20$ B; per row regular + clustering $= 12 + 8 = 20$ B; so $S_t = 20 + 8,640 \times 20 + 34,560 \times 8 = 20 + 172,800 + 276,480 = 449,300$ B $\approx$ **0.45 MB**.
4. Counterfactual — no `day` bucket, one year of data: $N_r = 3,153,600$, $N_v = 12,614,400$, $S_t \approx 63.1 + 100.9 = 164$ MB, and still growing.
5. Cluster: 10^6 sensors × 0.45 MB/day × RF 3 ≈ **1.35 TB/day** uncompressed; about 121 TB at the 90-day TTL.

Interpretation. Daily buckets keep partitions near 0.45 MB, far below the widely cited guidance of about 100 MB (and the hard limit of two billion cells); the unbucketed design passes 100 MB within a year and keeps growing. Per-cell metadata is 61 % of the bucketed size.

Engineering implication. Size buckets to what one query reads: “last 7 days” reads 7 partitions in parallel, which is fine. Use the uncompressed estimate as the safe bound.

Real-world industry applications

INDUSTRY EXAMPLE

Discord’s message store. Discord stored messages in Cassandra with primary key `((channel_id, bucket), message_id)` — a fixed time bucket and a time-ordered Snowflake ID — so recent messages are one partition slice. Its 2017 post covers bucketing, tombstones and hot partitions; a 2023 post covers migrating trillions of messages to ScyllaDB, a C++ Cassandra-compatible database, to cut tail latency. *Evidence: Primary* — [Discord 2017; Discord 2023]

Advantages and disadvantages

- **Advantages:** linear write scaling; masterless, no single point of failure (Cassandra); built-in multi-datacenter replication; per-request consistency; fast time-ordered slices.
- **Disadvantages:** one table per query multiplies writes; no joins; secondary indexes fan out (Cassandra 5.0’s Storage-Attached Indexes help); tombstones; last-write-wins drops concurrent updates; repair and compaction need skill.

Failure scenarios

Table 12.8 — Wide-column store failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Read timeouts on one partition	Large or hot partition; one key gets most traffic	Partition-size histograms; per-node latency skew	Re-model with buckets; migrate data	Size partitions with S_t; bounded buckets
Queries fail on tombstones	Delete-heavy or queue-like table; scans pass many tombstones	Tombstone warnings (default warn at 1,000, fail at 100,000 per query)	Compact; change model	Avoid queue patterns; use TTL with time-window compaction
Deleted data reappears	Node down longer than `gc_grace_seconds` (default 10 days) missed the tombstone	Zombie rows after node return	Rebuild the node rather than rejoining it	Run repair within the grace period
Lost concurrent update	Last-write-wins on cell timestamps; client clock skew	Application-level audits	Re-apply from source	Lightweight transactions (Paxos) for conditional writes; synchronized clocks

Common misconceptions

COMMON MISTAKE

"Cassandra is eventually consistent, so it cannot hold anything important." Consistency is per request: `QUORUM` reads and writes with RF = 3 return the latest acknowledged value in normal operation, and lightweight transactions (`IF NOT EXISTS`) give linearizable compare-and-set within a partition. What Cassandra lacks is multi-partition transactions (§25.10).

12.7 Graph databases

12.7.1 Property graphs and RDF

DEFINITION

Definition — Graph database. A database whose data model is a graph of **vertices** (nodes) and **edges** (relationships), optimized for traversing edges. In the **property graph** model, nodes carry labels, edges carry a type and a direction, and both carry key-value properties. In the **RDF** model, all data is a set of subject–predicate–object **triples**.

First-principles explanation

Asked “who knows someone who knows a cardiologist?”, you think of your friends and theirs — you never consult a city-wide list of friendships. A graph database stores each node with direct links to its neighbors, so a neighborhood question costs time proportional to the neighborhood, not the population.

Why does this exist?

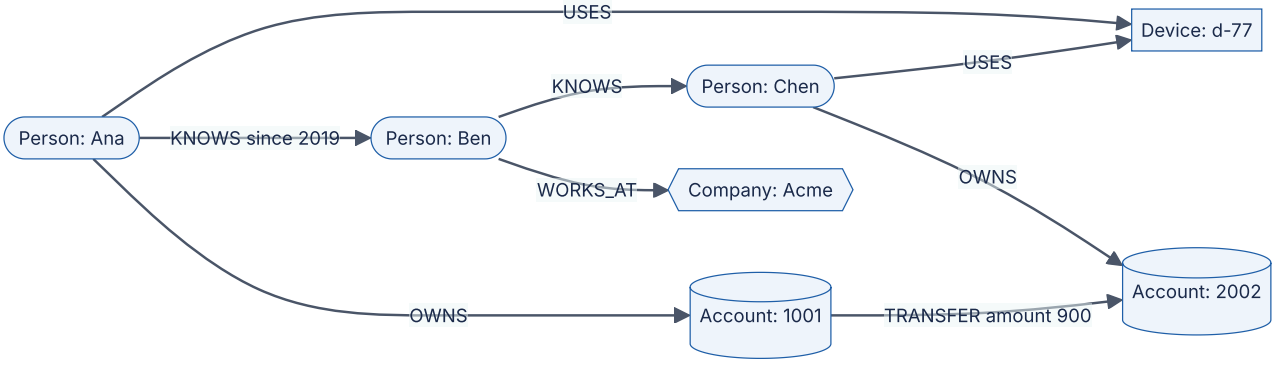
Some domains are mostly relationships: social networks, fraud rings, access-control hierarchies, knowledge graphs. In SQL each hop is a join, and a question of unknown depth needs a recursive common table expression with hard-to-predict cost. Graph databases make traversal the primitive.

Table 12.9 — Property graph versus RDF.

Aspect	Property graph	RDF
Unit of data	Nodes and edges with properties	Triples (subject, predicate, object)
Edge properties	Native	Need reification or RDF-star
Identifiers	Database-internal IDs	Global IRIs, mergeable across datasets
Query languages	Cypher / openCypher, Gremlin, GQL (ISO/IEC 39075:2024)	SPARQL (W3C)
Schema and reasoning	Optional constraints	Ontologies (RDFS, OWL) and inference
Typical systems	Neo4j, Memgraph, TigerGraph, Amazon Neptune	Amazon Neptune, GraphDB, Apache Jena, Virtuoso

[W3C 2014; ISO 2024; Robinson et al. 2015]

Figure 12.7 — A property graph for fraud and social queries.



Reading the diagram. Shapes here distinguish node labels (people, device, accounts, company), not the book’s infrastructure legend. Each arrow is a typed, directed relation-

ship that may carry properties (`since`, `amount`). The fraud signal is a short cycle: Ana and Chen share device `d-77` and money flows between their accounts — a pattern found by walking edges from Ana. This is a logical view with no network boundaries; deployments usually keep the whole graph on one primary with read replicas, because cutting a graph across machines turns hops into network calls.

12.7.2 Index-free adjacency and Cypher

How it works internally

Neo4j's native store illustrates **index-free adjacency** [Robinson et al. 2015; Neo4j Docs]:

1. Nodes, relationships and properties live in stores of fixed-size records, so node *n* is found by arithmetic on its ID, not an index search.
2. A node record points to its first relationship; each relationship points to its two nodes and to the next and previous relationships of both — a linked list per node.
3. A traversal follows these pointers; no global index is consulted per hop. Indexes are used once, to find the starting nodes.
4. Transactions are ACID on the primary; secondaries serve reads and failover.

Two Cypher queries — the fraud pattern and a friends-of-friends recommendation:

```
// Accounts of people within 2 KNOWS hops of Ana who use the same device as Ana
MATCH (a:Person {name: 'Ana'})-[:KNOWS*1..2]-(p:Person)-[:USES]->(d:Device)<-[:USES]-(a)
MATCH (p)-[:OWNS]->(acct:Account)
RETURN DISTINCT p.name, d.id, acct.id;

// People Ana's friends know, whom Ana does not know yet, ranked by mutual friends
MATCH (me:Person {name: 'Ana'})-[:KNOWS]-(f)-[:KNOWS]-(fof:Person)
WHERE fof <> me AND NOT (me)-[:KNOWS]-(fof)
RETURN fof.name, count(DISTINCT f) AS mutual
ORDER BY mutual DESC LIMIT 10;
```

What to notice:

- Patterns are ASCII art, `(node)-[:TYPE]->(node)`; `*1..2` is a variable-length path (a recursive CTE in SQL).
- Each query anchors on one indexed node and expands outward, so cost depends on Ana's neighborhood, not the population.
- `NOT (me)-[:KNOWS]-(fof)` is an anti-join written as a pattern.

12.7.3 When graphs beat joins

FORMULA

Cost of a k-hop traversal

$$E_k = \sum_{i=1}^{k} d^i \qquad T_{\text{graph}} \approx E_k \times t_{\text{ptr}} \qquad T_{\text{join}} \approx E_k \times t_{\text{idx}}$$

Symbol	Meaning	Units
E_k	Edges expanded by a k-hop traversal without pruning	edges
d	Average out-degree (neighbors per node)	edges/node
k	Number of hops	hops
t_{ptr}	Cost of following one adjacency pointer	µs
t_{idx}	Cost of one index lookup on the edge table, growing with $\log N$	µs

WORKED EXAMPLE

Worked example — Friends-of-friends-of-friends.

A social graph has $N = 100$ million people with average degree $d = 150$. Assume, for illustration only, $t_{\text{ptr}} \approx 0.2$ µs (one or two memory accesses) and $t_{\text{idx}} \approx 1$ µs (a cached B-tree descent of 4 levels, §11.8).

1. $k = 2$: $E_2 = 150 + 150^2 = 22,650$ expansions → graph ≈ 4.5 ms; join ≈ 23 ms.
2. $k = 3$: $E_3 = 22,650 + 3,375,000 = 3,397,650$ → graph ≈ 0.68 s; join ≈ 3.4 s.
3. Neither cost contains N except through the logarithm in t_{idx}: doubling the population barely changes either.

Interpretation. Index-free adjacency wins a constant factor per hop (here 5×, illustrative) and avoids large intermediate join results, but the d^k term defeats *both* systems by three hops.

Engineering implication. Graphs beat joins for variable-depth, pattern-shaped queries over bounded neighborhoods (fraud rings, permission inheritance). Prune or precompute deep traversals; for one or two fixed hops, a well-indexed relational database is usually as good.

Real-world industry applications

INDUSTRY EXAMPLE

Facebook TAO. Facebook serves its social graph of objects and typed associations through TAO, a geographically distributed, read-optimized graph cache over sharded MySQL. The API is graph-shaped, the storage relational: a graph *data model* does not require a graph *database* when queries are mostly one hop and scale is planetary. *Evidence: Primary* — [Bronson et al. 2013]

Advantages and disadvantages

- **Advantages:** expressive path queries; cost tied to the touched subgraph; easy to add relationship types; graph algorithm libraries.
- **Disadvantages:** hard to partition; writes and size usually bounded by one primary; scarcer expertise; whole-graph analytics belong in batch processing.

Failure scenarios

Table 12.10 — Graph database failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Query never returns	Unbounded variable-length path explodes as d^k	Slow-query log; memory alarms	Kill query; add bounds	Always bound `*1..k`; set query timeouts
Supernode slows everything	A node with millions of edges (celebrity, default device ID)	Degree distribution metrics	Split by relationship type or time	Model high-degree nodes specially
Primary saturates	Writes cannot scale beyond one node	CPU and commit latency on primary	Scale up; offload reads to replicas	Keep only the relationship-heavy subset in the graph

Common misconceptions

COMMON MISTAKE

"If my data has relationships, I need a graph database." Relational databases were built for relationships. Choose a graph database when questions are about *paths and patterns of unknown depth*.

12.8 Time-series databases

12.8.1 The time-series data model

DEFINITION

Definition — Time-series database (TSDB). A database optimized for sequences of timestamped measurements. Data is organized into **series**, each identified by a metric name plus a set of **labels** (tags) such as `{host="web-3", region="eu"}`, and each series is an append-only list of **samples** `(timestamp, value)`.

First-principles explanation

A ship's log records the position every hour, in order, and nobody edits last Tuesday's entry; old pages are summarized ("averaged 12 knots in March"). Because the next entry is usually "same as before, one hour later", the log can be written very compactly.

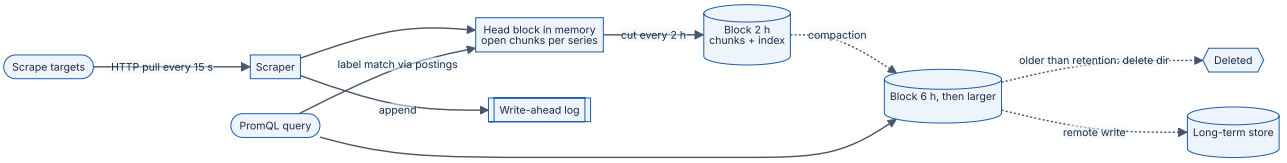
Why does this exist?

10,000 servers exporting 1,000 metrics every 15 s produce about 667,000 samples per second. A general-purpose database spends more on row headers and index entries than on each sample's 16 bytes (8-byte timestamp, 8-byte float). TSDBs exploit four properties: writes append near "now", reads scan recent ranges, adjacent samples are similar, and old data matters only in aggregate.

How it works internally

1. An **inverted index** maps each `label=value` pair to the series that have it (a postings list, §16.3), so `{region="eu", job="api"}` is a list intersection.
2. Each series' samples are buffered in memory and logged to a **write-ahead log**.
3. Buffers are cut into **chunks** (up to 120 samples in Prometheus) compressed Gorilla-style, grouped into time-partitioned **blocks** (2 hours in Prometheus) and compacted into larger blocks.
4. **Retention** deletes whole expired blocks — a directory removal, not row deletes — and **downsampling** replaces old samples with aggregates (min, max, sum, count per 5 minutes or hour).

Figure 12.8 — Prometheus TSDB write and storage path.



Reading the diagram. Prometheus pulls metrics over HTTP and appends each sample to the in-memory head block and the on-disk write-ahead log. Every two hours the head becomes an immutable block of compressed chunks plus an index; compaction (dotted, asynchronous) merges blocks, and retention (15 days by default) deletes old block directories. Queries use the postings index and read both head and blocks. The local disk is a single-node storage boundary; long retention and durability come from remote-write to systems such as Thanos, Cortex or Mimir. Failure points: a crash costs a WAL replay; a lost disk loses local history.

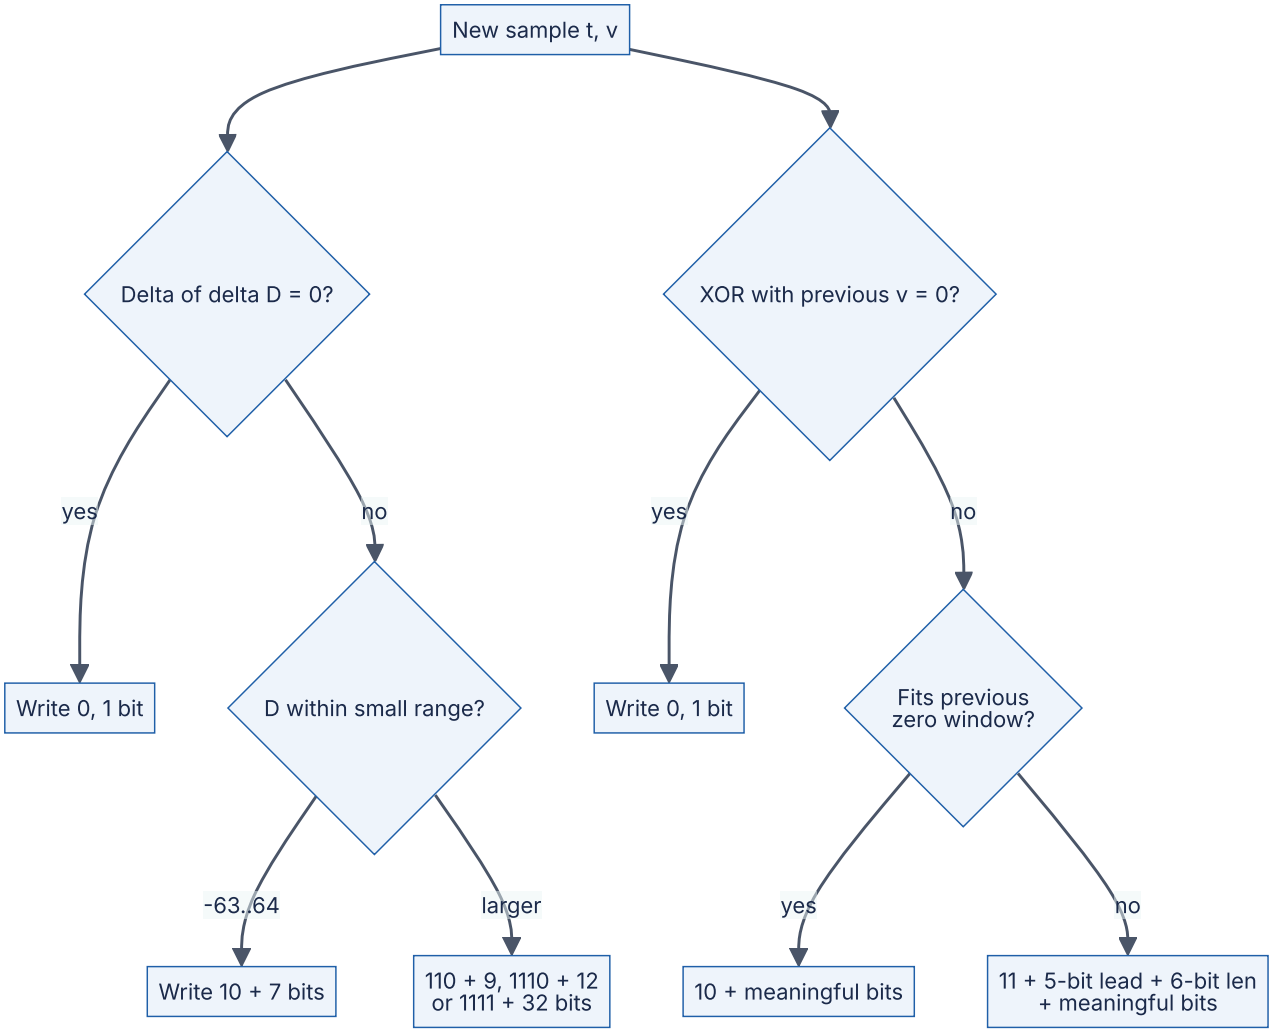
12.8.2 Gorilla compression: delta-of-delta and XOR

Facebook's Gorilla paper [Pelkonen et al. 2015] introduced the compression most modern TSDBs adapt, encoding timestamps and values separately against the previous sample.

Timestamps — delta-of-delta. With a fixed scrape interval, consecutive deltas are equal, so the encoder stores $D = (t_n - t_{n-1}) - (t_{n-1} - t_{n-2})$ with a prefix code: `0` if $D = 0$; `10` + 7 bits for $D \in [-63, 64]$; `110` + 9 bits for $[-255, 256]$; `1110` + 12 bits for $[-2047, 2048]$; else `1111` + 32 bits.

Values — XOR. Consecutive values share sign, exponent and leading mantissa bits, so XOR with the previous value is mostly zeros: store `0` if it is zero; otherwise `1`, then either `0` plus the meaningful bits within the previous leading/trailing-zero window, or `1`, a 5-bit leading-zero count, a 6-bit length and the meaningful bits.

Figure 12.9 — Gorilla's per-sample encoding decisions.



Reading the diagram. Each sample takes two independent paths, timestamp and value, both depending only on the previous sample — so chunks decode sequentially from the start. The common case on each path costs one bit. There are no network or storage boundaries; the failure point is data that defeats the assumptions (jittery timestamps, noisy values). Series encode independently, so compression parallelizes across cores.

This program counts the bits used for three kinds of series:

```
        """Gorilla-style compression (Pelkonen et al., VLDB 2015): delta-of-delta
        timestamps and XOR-encoded float values. Counts bits; returns bits per point."""
        import random
        import struct

        def float_bits(x: float) -> int:
            return struct.unpack(">Q", struct.pack(">d", x))[0]

        def encode(points):
            """points: list of (unix_seconds, float). Returns total bits used."""
            t0, v0 = points[0]
            bits = 64 + 64                          # first timestamp and value stored
raw
            prev_t, prev_delta, prev_v = t0, 0, float_bits(v0)
            prev_lead, prev_trail = None, None
            for t, v in points[1:]:
                delta = t - prev_t
                dod = delta - prev_delta            # delta of delta
                if dod == 0:
                    bits += 1                                   # '0'
                elif -63 <= dod <= 64:
                    bits += 2 + 7                               # '10' + 7 bits
                elif -255 <= dod <= 256:
                    bits += 3 + 9                               # '110' + 9 bits
                elif -2047 <= dod <= 2048:
                    bits += 4 + 12                              # '1110' + 12 bits
                else:
                    bits += 4 + 32                              # '1111' + 32 bits
                prev_t, prev_delta = t, delta

                x = float_bits(v) ^ prev_v
                if x == 0:
                    bits += 1                                   # '0': value repeated
                else:
                    lead = min(64 - x.bit_length(), 31)         # 5-bit field caps at 31
                    trail = (x & -x).bit_length() - 1
                    if prev_lead is not None and lead >= prev_lead and trail >=
prev_trail:
                        bits += 2 + (64 - prev_lead - prev_trail)   # '10' + reuse win-
dow
                    else:
                        bits += 2 + 5 + 6 + (64 - lead - trail)     # '11' + new window
                        prev_lead, prev_trail = lead, trail
                prev_v = float_bits(v)
            return bits

        random.seed(7)
        start = 1_793_318_400                       # 2026-10-30 00:00:00 UTC
        series = {
            "constant gauge":   [(start + 15 * i, 42.0) for i in range(120)],
            "counter (+1/scr)": [(start + 15 * i, float(1000 + i)) for i in range(120)],
            "noisy CPU %":      [(start + 15 * i + random.choice([0, 0, 0, 1]),
                                  round(random.uniform(20, 80), 1)) for i in
range(120)],
        }
        for name, pts in series.items():
```

```
            b = encode(pts)
            print(f"{name:18s} {b / len(pts) / 8:5.2f} bytes/point  ({128 / (b /
len(pts)):4.1f}x vs 16 B)")
```

Output:

```
constant gauge      0.39 bytes/point  (41.1x vs 16 B)
counter (+1/scr)    1.33 bytes/point  (12.0x vs 16 B)
noisy CPU %         7.90 bytes/point  ( 2.0x vs 16 B)
```

What to notice:

- A 120-sample chunk of a constant gauge costs 2 bits per sample once the interval is established (the second sample pays 9 bits to record the first delta); the 128-bit uncompressed header dominates, which is why chunks should not be too short.
- The steadily increasing counter lands at 1.33 bytes per point — close to the 1.37 bytes per point the Gorilla paper reports for Facebook's production data, a 12× reduction from 16 bytes [Pelkonen et al. 2015].
- Random one-decimal values compress only 2× because their mantissas differ in almost every bit; storing only the precision you need is a strong lever.
- The real format stores the first timestamp as a 14-bit offset from a block header.

12.8.3 Retention and downsampling

Prometheus documents a simple disk-sizing rule: needed disk ≈ retention time × ingested samples per second × bytes per sample, with 1–2 bytes per sample typical [Prometheus Docs]. Adding downsampled tiers generalizes it.

FORMULA

Tiered time-series storage

$$S = N_{\text{series}} \times \sum_{i} \frac{R_i}{\Delta_i} \times b_i$$

Symbol	Meaning	Units
S	Total storage	bytes
N_{series}	Number of active series	series
R_i	Retention period of tier i	seconds
Δ_i	Sample (or rollup) interval of tier i	seconds
b_i	Bytes per stored point in tier i after compression	bytes/point

WORKED EXAMPLE

Worked example — Metrics for a 1-million-series platform.

1 million active series scraped every 15 s ($66,667$ samples/s); raw points compress to 1.5 B. Rollups store five aggregates (min, max, sum, count, last) at about 2 B each, so 10 B per rollup point.

1. Raw for 15 days: $R/\Delta = 1,296,000/15 = 86,400$ points per series; $10^6 \times 86,400 \times 1.5 = 1.296 \times 10^{11}$ B $\approx$ **130 GB**.
2. Raw for one year instead: $31,536,000/15 = 2,102,400$ points; $10^6 \times 2,102,400 \times 1.5 \approx$ **3.15 TB**.
3. One-hour rollups for one year: $8,760$ points; $10^6 \times 8,760 \times 10 = 87.6$ GB.
4. Tiered total: $130 + 87.6 \approx$ **218 GB**, about 14× less than a year of raw data. Without compression (16 B/point) the 15-day raw tier alone would be 1.38 TB.

Interpretation. Compression buys about 10×; downsampling another order of magnitude, at the cost of detail older than 15 days.

Engineering implication. You cannot compute a correct p99 from averaged rollups, so keep histograms or sketches if old percentiles matter. Series count, not sample rate, is usually the first limit (Table 12.12).

12.8.4 Prometheus, InfluxDB and TimescaleDB

Table 12.11 — Three time-series databases compared (as of 2026).

Aspect	Prometheus TSDB	InfluxDB	TimescaleDB
What it is	Pull-based monitoring system with embedded TSDB	Purpose-built TSDB with push ingestion	PostgreSQL extension
Data model	Metric + labels → float samples	Measurement + tags + multiple typed fields	SQL tables turned into **hypertables**
Storage	2-hour blocks, Gorilla-style chunks, postings index	Version 3 rewritten on Apache Arrow, DataFusion and Parquet	Time-partitioned chunks (default 7 days); columnar compression of old chunks
Query	PromQL	SQL and InfluxQL (v3)	Full PostgreSQL SQL, joins with relational tables
Downsampling	Recording rules; long-term stores	Downsampling tasks or queries	Continuous aggregates; retention policies drop chunks
Choose when	Operational metrics and alerting	High-ingest metrics or IoT with tags and fields	You need SQL, joins and PostgreSQL tooling

[Prometheus Docs; InfluxData Docs; Timescale Docs]

Real-world industry applications

INDUSTRY EXAMPLE

Facebook Gorilla. Facebook's HBase-backed monitoring store was too slow for queries over recent data. Gorilla keeps the latest 26 hours in memory at 1.37 bytes per point, writes through to HBase, and reported 73× lower query latency and 14× higher throughput. *Evidence: Primary* — [Pelkonen et al. 2015]

Failure scenarios

Table 12.12 — Time-series database failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Memory exhaustion, ingestion stalls	**Cardinality explosion**: a label with unbounded values (user ID, request ID) creates millions of series	Active-series count jumps; head memory growth	Drop the label via relabeling; restart	Review labels; per-target series limits
Out-of-order samples rejected	Clock skew or delayed batches outside the accepted window	Ingestion error counters	Backfill as blocks	Synchronized clocks (§24.9); bounded delays
Wrong long-term percentiles	Averaged rollups cannot reproduce percentiles	Mismatch with raw data	Recompute from raw if still retained	Store histograms or sketches in rollups
Local history lost	Single-node TSDB disk failure	Gaps in dashboards	Restore from remote store	Remote-write or replicated pairs

Common misconceptions

COMMON MISTAKE

"A TSDB is just a table with a timestamp column." At small volume, yes. At scale the differences are physical: 1–2 bytes per sample, retention as file deletion, and an inverted label index. TimescaleDB keeps SQL but changes the storage layout underneath.

12.9 Search engines as databases

DEFINITION

Definition — Search engine (as a data store). A system such as Elasticsearch, OpenSearch or Apache Solr that stores JSON documents and builds an **inverted index** — a map from each term to the list of documents containing it — so it can answer full-text, relevance-ranked, faceted and fuzzy queries.

A relational `LIKE '%running shoes%'` scans every row and cannot rank; an inverted index intersects two postings lists and scores matches with BM25, and also serves faceted counts and log analytics (Chapter 16). As a *database* it has limits: indexing is **near-real-time** (Elasticsearch refreshes every 1 second by default), there are no multi-document transactions, and mapping changes often require reindexing [Elastic Docs]. The standard architecture keeps the system of record in a transactional database and feeds the index through change data capture (§32.6).

RECOMMENDATION

Do not make the search index your only copy. Treat it as a derived, rebuildable view. If you cannot regenerate it from a source of truth in hours, you have created a primary database without the durability features of one.

12.10 Vector databases

DEFINITION

Definition — Vector database. A data store that indexes high-dimensional numeric vectors (**embeddings** produced by machine-learning models) and answers **approximate nearest neighbor (ANN) search** queries: "the k stored vectors most similar to this query vector", by cosine similarity, dot product or Euclidean distance.

Embeddings place similar items — a beach photo and the text "sunny coast" — near each other in hundreds of dimensions. Exact search over 100 million 768-dimension vectors costs about 7.7×10^{10} multiply-adds per query; ANN indexes such as **HNSW** (a layered proximity graph [Malkov & Yashunin 2020]) and **IVF** (search only nearby clusters) trade a little recall for orders of magnitude less work. As of 2026 you meet vector search as dedicated databases (Milvus, Pinecone, Qdrant, Weaviate), as extensions (pgvector, MongoDB Atlas, Cassandra 5.0, Redis, Elasticsearch) and as libraries (FAISS). Treat it as a specialized secondary index, fed from a system of record and rebuilt when the embedding model changes; Chapter 74 covers the design in depth.

12.11 NewSQL

DEFINITION

Definition — NewSQL (distributed SQL). Relational databases that keep SQL and ACID transactions with serializable or strong isolation while scaling horizontally across nodes and regions, by partitioning data into ranges replicated with a consensus protocol. The term was coined by analyst Matthew Aslett in 2011 [Pavlo & Aslett 2016].

NewSQL scales out *without* giving up transactions and joins: split tables into key ranges, replicate each with Paxos or Raft (§26.6, §26.7), run cross-range transactions with a two-phase-commit variant (§28.4), and order transactions with timestamps.

Table 12.13 — Three distributed SQL systems (deep treatment in Chapter 28).

System	Origin	Replication	Clock and ordering	Notable feature
Spanner	Google, OSDI 2012	Paxos per split	TrueTime (GPS and atomic clocks) with commit wait	External consistency across the globe [Corbett et al. 2012]
CockroachDB	Cockroach Labs, SIGMOD 2020 paper	Raft per range	Hybrid logical clocks, bounded uncertainty	PostgreSQL wire compatibility; serializable by default [Taft et al. 2020]
TiDB	PingCAP, VLDB 2020 paper	Raft in TiKV	Timestamp oracle in the Placement Driver	MySQL compatibility; columnar TiFlash replicas for analytics [Huang et al. 2020]

The price is latency: a write must reach a majority of replicas (milliseconds within a region, tens of milliseconds across regions), cross-range transactions add coordination, and Spanner's commit wait pauses for clock uncertainty. Choose NewSQL when you have outgrown one PostgreSQL or MySQL primary *and* need multi-row transactions (§28.8, §28.10).

12.12 Selection framework and SQL versus NoSQL comparison

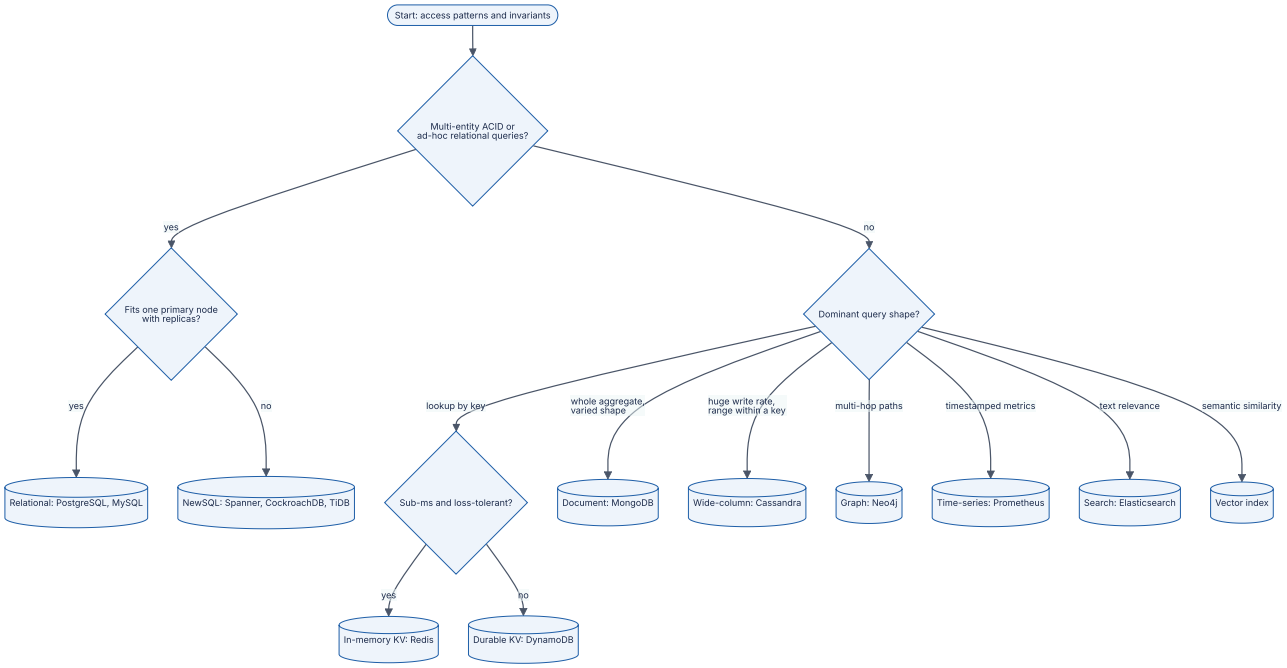
12.12.1 A decision procedure

Choosing a database is choosing which questions will be cheap and which impossible:

1. **List access patterns** with rates and latency targets ("get order by ID, 10,000/s, p99 < 20 ms").

2. **List invariants** and how many entities each spans (“stock never negative”: one; “debits equal credits”: two).
3. **Estimate size and growth** (§2.11).
4. **Pick the simplest store that serves the critical patterns**, adding specialized stores only for patterns it cannot serve.

Figure 12.10 — Database selection flowchart.



Reading the diagram. Diamonds ask about requirements, not technologies; cylinders are families with one example each. The first question routes toward relational storage: if invariants span entities or queries are not yet known, a relational database with replicas (§14.3) is the default, and NewSQL applies only when one primary cannot carry the load. Otherwise the dominant query shape picks the family. There are no protocols or failure paths; in practice one system serves several patterns and specialized stores are added as *derived* views (§12.13). Revisit the chart when access patterns change.

> RECOMMENDATION
>
> **Default to PostgreSQL until a requirement rules it out.** One PostgreSQL primary with replicas handles tens of thousands of transactions per second and terabytes of data, with `jsonb`, full-text search, TimescaleDB and pgvector covering many specialized needs. Move a workload when you can name and measure the requirement it fails.

12.12.2 Comparison table

Table 12.14 — Relational and NoSQL families compared.

Row	Relational (SQL)	Key-value	Document	Wide-column	Graph	Time-series
What it is	Tables, rows, joins, ACID	Opaque values by key	Nested JSON-like documents	Sorted sparse rows in partitions	Nodes and typed edges	Labeled series of samples
How it works	B-tree pages, WAL, cost-based planner	Hash partitioning, replicas	B-tree per collection, shard key	LSM storage, hash ring, clustering order	Linked records, pointer chasing	Compressed chunks, time blocks, label index
Advantages	Ad-hoc queries, integrity, transactions	Flat latency at any scale	Matches objects; flexible schema	Massive writes; multi-region	Multi-hop queries	1–2 B/sample; cheap retention
Disadvantages	Hard to scale writes past one node	Only designed queries	Cross-document joins weak	One table per query; tombstones	Hard to partition	Narrow query model; cardinality limits
Performance	~ms point reads; joins vary	~ms durable, sub-ms in memory	~ms by indexed field	~ms partition slices; fast writes	Cost tied to neighborhood	Millions of samples/s per node
Operational complexity	Low single-node; high when sharded	Low if managed	Medium	High (repair, compaction)	Medium	Low single-node; high clustered
Cost	Scale-up hardware, licenses	Pay per request or RAM	Moderate	Many commodity nodes	Large-memory nodes	Cheap disk per sample
Use cases	Orders, payments, inventory	Sessions, carts, counters	Catalogs, profiles, content	Messages, IoT, event logs	Fraud, social, permissions	Metrics, IoT telemetry
Choose when	Invariants span entities	Access is by key at scale	Aggregates read whole	Write volume dominates	Questions are paths	Data is timestamped samples

The boundaries are blurring — PostgreSQL stores documents, MongoDB runs transactions, DynamoDB speaks PartiQL (a SQL-compatible language) — so compare specific products against specific requirements.

INTERVIEW TIP

Interview tip — justify, don't recite. "We'll use Cassandra because it scales" earns little credit. "Messages are written 50,000/s and always read as the latest page of one channel, so I'll partition by `(channel_id, bucket)` with message ID as clustering column; there are no cross-channel transactions, so we don't need a relational store here" shows the access-pattern reasoning interviewers look for.

12.13 Polyglot persistence

12.13.1 One service, several stores

DEFINITION

Definition — Polyglot persistence. Using several different data-storage technologies within one system, each chosen for the access pattern it serves best, rather than forcing all data into one database [Fowler 2011; Sadalage & Fowler 2012].

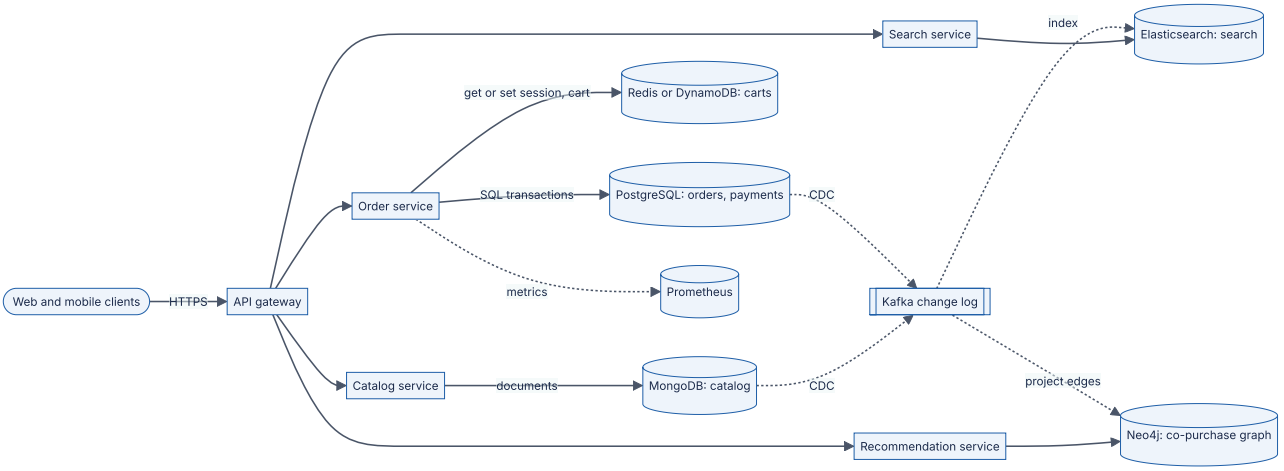
First-principles explanation

A household keeps money in a bank, documents in a cabinet and food in a fridge; nobody stores food in the cabinet for simplicity's sake. But every extra place needs upkeep, and each must be packed and checked when you move.

How it works internally

1. One store is the **system of record** for each piece of data — usually a relational or durable key-value database that enforces the invariants.
2. Other stores hold **derived views**: a search index, a cache, a graph projection, an analytics copy.
3. Changes flow from the system of record to derived stores **asynchronously** through change data capture or a transactional outbox (§32.5, §32.6) and an event log such as Kafka (Chapter 31) — never through application "dual writes" that can half-fail.
4. Each derived store can be rebuilt by replaying the log or re-exporting the source.

Figure 12.11 — Polyglot persistence in an e-commerce platform.



Reading the diagram. Clients reach services via an API gateway over HTTPS. Solid arrows are synchronous: the order service owns orders and payments in PostgreSQL and carts in a key-value store; the catalog service owns product documents in MongoDB.

Dotted arrows are asynchronous: CDC streams committed changes into Kafka, whose consumers build the Elasticsearch index and the Neo4j co-purchase graph; services emit metrics to Prometheus. Each database is a separate failure domain with its own backups. If the CDC pipeline stalls, search and recommendations go stale but orders keep working — the intended degradation. Each store scales independently, and derived stores can be rebuilt from Kafka.

12.13.2 The operational costs

Table 12.15 — What each additional database costs you.

Cost	What it involves
Expertise	On-call engineers who know its failure modes and tuning
Operations	Patching, upgrades, capacity planning, dashboards, alerts
Backup and recovery	Separate backups, restore drills and recovery objectives
Consistency	Lagging derived stores; reconciliation jobs
Security and compliance	Another access model and audit trail; deletions must reach every copy
Money	Baseline cluster cost even when idle; data stored several times

INDUSTRY EXAMPLE

Database-per-service. Microservices commonly give each service its own database (§34.11), so polyglot persistence follows naturally — and cross-service queries and consistency become pipeline problems. *Evidence: Illustrative* — a widely described architectural pattern; not a claim about any specific company.

WARNING / TRADE-OFF

Dual writes. Writing to PostgreSQL and then Elasticsearch in one handler diverges silently if the process crashes between them. Derive the second write from the committed first via an outbox or CDC.

RECOMMENDATION

Budget the number of stores. Add a technology only when its requirement justifies a permanent operational cost; many organizations keep an approved list and review exceptions.

Common misconceptions

COMMON MISTAKE

“Polyglot persistence means every service should use a different database.” The goal is fit, not variety; services with similar patterns should share technology, tooling and runbooks.

12.14 Summary and revision notes

SUMMARY

- NoSQL arose from scale-out, schema-flexibility and availability pressures plus “one size does not fit all”; Bigtable, Dynamo, PNUTS and Cassandra defined the designs.
- Key-value, document and wide-column stores are **aggregate-oriented**: data read together is stored together under one key.
- **DynamoDB:** partition key (hashed) + sort key (ordered item collection); GSIs are asynchronous, eventually consistent copies; LSIs share the partition key. Design keys from access patterns; use sparse and overloaded indexes. WCU = 1 KB writes/s, RCU = 4 KB strong reads/s (½ for eventual); per-partition limits 3,000 RCU / 1,000 WCU; on-demand versus provisioned break-even ≈ 29 % utilization (as of 2026 prices).
- **MongoDB:** embed what is owned, bounded and read together; reference what is shared or unbounded; order compound indexes Equality–Sort–Range; multi-document transactions since 4.0; use `w: "majority"`.
- **Bigtable/Cassandra:** sorted sparse rows; CQL `PRIMARY KEY ((partition), clustering)`; one table per query; bucket partitions and size them with $N_v = N_r(N_c - N_{pk} - N_s) + N_s$; beware tombstones and last-write-wins.
- **Graphs:** property graph versus RDF; index-free adjacency makes traversal cost depend on the neighborhood, but d^k growth still dominates deep queries.
- **Time-series:** labeled series, inverted label index, delta-of-delta and XOR compression (~1.37 B/sample in Gorilla), time blocks, retention by deletion, downsampling tiers; cardinality is the first limit.
- Search engines and vector databases are derived indexes fed by CDC; NewSQL adds scale-out SQL transactions at a latency cost (Chapter 28).
- Default to relational; add a specialized store for a named, measured requirement; feed derived stores asynchronously; budget each store’s operational cost.

12.15 Knowledge checkpoint

1. Name the three pressures that produced NoSQL and one paper associated with each design response.
2. Why must a DynamoDB Query name exactly one partition key?
3. Give two differences between an LSI and a GSI.
4. A Query returns three items of 1.2 KB each, eventually consistent. How many RCUs does it consume? How many would three GetItem calls consume?
5. What makes a GSI sparse, and what is it useful for?
6. State the ESR rule and explain why sort fields precede range fields.
7. In `PRIMARY KEY ((sensor_id, day), ts)`, which columns determine placement and which determine order?
8. How many cells does a Cassandra partition hold with 10,000 rows, 5 columns, 1 partition-key column and 1 static column?
9. Why can deleted data reappear in Cassandra?
10. What is index-free adjacency, and what does it not fix?
11. Which Gorilla encoding costs one bit for a timestamp and one bit for a value?
12. Why should a search index not be the only copy of data?

Answers

1. Scale-out (Bigtable, Dynamo: partition by key), schema flexibility (Bigtable's sparse columns; document stores), availability (Dynamo: sloppy quorums, always-writable).
2. Only the partition key is hashed to locate data; without it the request would have to visit every partition.
3. An LSI shares the table's partition key, must be created with the table, supports strong reads and limits item collections to 10 GB; a GSI has any key, can be added later, is eventually consistent and has its own throughput.
4. Query sums sizes: 3.6 KB → 1 unit × 0.5 = 0.5 RCU. GetItems round each item: 3 × 1 × 0.5 = 1.5 RCU.
5. Only items carrying the index key attribute appear in it; it is a cheap, self-maintaining list such as "orders awaiting shipment".
6. Equality, Sort, Range. Once a range condition is applied, matching entries are no longer in sort-field order, so the sort would need an in-memory step.
7. `(sensor_id, day)` is hashed for placement; `ts` orders rows within the partition.
8. $10,000 \times (5 - 1 - 1) + 1 = 30,001$ cells.
9. A replica that was down longer than `gc_grace_seconds` missed the tombstone; after the tombstone is purged elsewhere, the old value on that replica wins on repair.
10. Each node points directly to its relationships, so a hop is a pointer chase rather than an index lookup. It does not fix exponential growth of neighborhoods (d^k).
11. Delta-of-delta equal to 0 and XOR with the previous value equal to 0 (same interval, repeated value).

12. It is near-real-time, non-transactional and often needs reindexing after mapping changes; it must be rebuildable from a system of record.

12.16 Interview questions

Basic

Q1. When would you choose a NoSQL database over a relational one?

Answer. When a named requirement exceeds what a relational primary with replicas can deliver or fits another model better: write volume or data size beyond one node with simple per-key access (key-value, wide-column); aggregates of varying shape read whole (document); multi-hop path queries (graph); high-rate timestamped samples (time-series). If invariants span entities or queries are still unknown, start relational.

Q2. What is the difference between a partition key and a sort key?

Answer. The partition key is hashed to choose the partition, so it should have high cardinality and even load. The sort key orders items within a partition, enabling range, prefix and newest-first queries over one item collection.

Intermediate

Q3. Design a DynamoDB schema for a chat app: send a message, list a conversation's recent messages, list a user's conversations by latest activity.

Answer. Messages: `PK=CONV#id, SK=MSG#<time-ordered ID>`, read newest first with a descending Query. Membership: `PK=USER#u, SK=CONV#id` carrying `lastActivity`, plus a GSI keyed `USER#u` / `<lastActivity>#CONV#id` for recency order (update or batch on each message). A conversation above about 1,000 writes/s needs write sharding; use TTL for retention.

Q4. A Cassandra cluster shows read timeouts on a few nodes only. Diagnose.

Answer. Suspect a large or hot partition or tombstones: check partition-size histograms, tombstone warnings and key-level traffic. Typical causes are partition keys without a time bucket and queue-like deletes. Fix the model (bucket, avoid deletes, TTL with time-window compaction), migrate, and repair within `gc_grace_seconds`.

Advanced

Q5. Design storage for a social network: profiles, posts, follow graph, feed, search and metrics.

Answer. Profiles and posts in a sharded relational or document store keyed by user (system of record). The follow graph as adjacency lists in a key-value or wide-column store, since one-hop queries dominate (the TAO pattern), with a batch graph job for multi-hop recommendations. Feeds as precomputed lists in wide-column or Redis; search in Elasticsearch via CDC; metrics in Prometheus. Discuss read-your-writes for own posts, fan-out cost and the cost of operating many stores.

Q6. Your team proposes moving from PostgreSQL to MongoDB "for scale". How do you evaluate it?

Answer. Demand the measured bottleneck (write rate, size, latency) and check whether indexes, replicas, partitioning, `jsonb` or a cache fix it. MongoDB fits if the workload is aggregate-shaped and a shard key matches access patterns; otherwise you trade joins and constraints for application code. Price the migration (backfill, CDC cut-over), skills, and invariants needing transactions.

12.17 Practical exercises

Exercise 12.1 — Key design. Extend the toy store of §12.4.4 with AP6, "all orders containing a given SKU in the last 30 days". Propose a GSI, add it, and compute its WCU cost at 1,000 orders/s.

Exercise 12.2 — Capacity. Recompute the §12.4.5 example with strongly consistent reads and transactional header writes. At what average utilization does provisioned capacity become cheaper?

Exercise 12.3 — Cassandra modeling. In a Cassandra 5 container, create the §12.6.3 tables, load one day for 100 sensors, and compare `nodetool tablestats` partition sizes with S_t.

Exercise 12.4 — Compression. Modify the Gorilla program to round the CPU values to integers and to remove timestamp jitter. Report the bytes per point for each change.

12.18 Design challenges

1. **Ride-sharing trip store.** 2 million trips per day, GPS points every 4 s per active trip, queries by trip, by driver over 90 days, and live positions. Choose stores, keys and buckets; size storage for one year.
2. **Fraud detection platform.** Card transactions at 20,000/s must be scored in 50 ms using shared-device and shared-address rings up to 3 hops. Decide what lives in a graph, what is precomputed, and how the graph is fed.
3. **Migrating a monolith's database.** A 4 TB PostgreSQL database serves orders, catalog, search and analytics. Propose a polyglot target, the CDC pipeline, the cut-

over sequence and the operational budget.

12.20 Open verification items

- DynamoDB prices (on-demand $0.625/M write and $0.125/M read request units after the November 2024 reduction; provisioned $0.00065/WCU-h, $0.00013/RCU-h, us-east-1) confirmed only via third-party pages; aws.amazon.com was unreachable.
- DynamoDB limits (400 KB items, per-partition 3,000 RCU/1,000 WCU, 20 GSIs, 5 LSIs, 10 GB item collections) and the 89.2 M requests/s figure (ATC 2022).
- Cassandra "~100 MB per partition" is community guidance, not official docs; tombstone thresholds and `gc_grace_seconds` defaults per version.
- Redis 8 AGPLv3 option and InfluxDB 3 architecture (as of 2026).

- Pointer-chase and index-lookup costs in §12.7.3 are illustrative assumptions.

Chapter 13 — Storage Engine Internals

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 3.5 h

When you call `INSERT` on PostgreSQL, `Put` on RocksDB or `save()` on an ORM, a piece of software called the **storage engine** decides where those bytes live on disk, how they are found again, and what happens if the power fails halfway through. Two databases with the same SQL dialect can differ tenfold in write volume, disk space or tail latency purely because of their storage engines. This chapter opens the box: pages, buffer pools, write-ahead logs, B-trees and log-structured merge (LSM) trees, and the numbers that let you choose an engine for a workload instead of by reputation. For book-length treatments, see [Petrov 2019] and chapter 3 of [Kleppmann 2017].

13.1 Learning objectives

After this chapter you should be able to:

- Draw a slotted page and explain why records get stable identifiers.
- Explain a buffer pool's page table, pin counts and dirty flags; compare LRU, clock and LRU-K; and justify `O_DIRECT`.
- Describe WAL, LSNs, fuzzy checkpoints and the three ARIES passes, and estimate recovery time.
- Trace a B-tree page split, explain latch crabbing, and contrast in-place with copy-on-write B-trees.
- Build and run a toy LSM tree (memtable, SSTables, WAL replay, compaction), starting from Bitcask.
- Calculate write, read and space amplification for size-tiered, leveled and hybrid compaction, and apply the RUM conjecture.
- Explain torn writes, checksums, the doublewrite buffer and full-page writes.
- Explain why columnar layout, encoding and vectorized execution make analytical scans 10–100× cheaper.
- Choose between InnoDB-, PostgreSQL-heap- and RocksDB-style engines for a workload, with numbers.

13.2 Prerequisites

- Storage devices, IOPS and SSD write amplification — §5.6 (engine designs respond to device behavior).
- Page cache, `mmap`, copy-on-write — §6.6.5–§6.6.6 (buffer pools replace or sit beside them).
- `fsync`, journaling and group commit — §6.14 (the group-commit formula in §6.14.3 is not repeated).
- B+ trees, transactions and MVCC — §11.8, §11.11, §11.14 (here: how a B-tree is stored and made crash-safe).
- Logarithms — §4.4. Units: **KiB/MiB** for page and block sizes; **KB/MB/GB/TB** (powers of ten) for data volumes.

13.3 Pages and blocks

13.3.1 Why storage engines think in pages

> DEFINITION
>
> **Definition — Page.** The fixed-size unit (typically 4–16 KiB) in which a storage engine reads, writes, caches and logs data. A page on disk is sometimes called a **block**; the engine keeps a copy of a page in memory in a **frame** of its buffer pool.

First-principles explanation

Imagine a library that lends books only by the whole shelf: to read one sentence you carry a shelf. Storage devices behave like that library. An SSD reads flash in pages of 4–16 KiB; an HDD pays milliseconds of seek before transferring anything (§5.6.1), so reading 100 bytes costs almost the same as reading 8 KiB. A database therefore never asks the disk for “a row”; it asks for the page containing it, and organizes tables, indexes and logs in page-sized units.

Why does this exist?

Pages give **I/O efficiency** (one request moves many rows), **a unit of caching and recovery** (the buffer pool caches pages; the log describes changes to pages, §13.5) and **addressability** (a row is named by `(page, slot)`). Larger pages mean fewer I/Os for scans and shallower B-trees, but more bytes written when one small row changes and a larger unit that a crash can tear (§13.12).

Table 13.1 — Default page sizes (as of 2025).

Engine	Default page size	Configurable?
PostgreSQL heap and indexes	8 KiB	Only at compile time
MySQL InnoDB	16 KiB	4–64 KiB, at initialization (`innodb_page_size`)
SQLite	4 KiB	Yes, per database (`PRAGMA page_size`)
RocksDB data block (inside an SSTable)	4 KiB before compression	Yes (`block_size`)
LMDB	Operating-system page size (usually 4 KiB)	No

13.3.2 The slotted page

DEFINITION

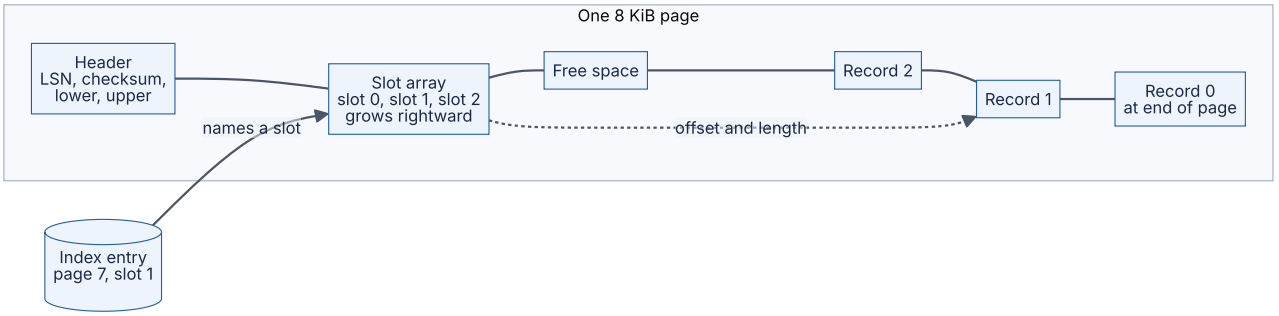
Definition — Slotted page. A page layout in which a **header** is followed by an array of **slots** (also called line pointers or item IDs) that grows from the front, while variable-length **records** (tuples) are packed from the back. Each slot stores the offset and length of one record; free space sits in the middle.

How it works internally

1. **Header:** page LSN (§13.5), checksum (§13.12), slot count and free-space pointers. PostgreSQL's header is 24 bytes, with `pd_lower` and `pd_upper` bounding the free-space hole [PostgreSQL Docs: Database Page Layout].
2. **Insert:** copy the record to the end of free space, then append a slot pointing to it. The record's identifier is `(page, slot)`.
3. **Read:** look up the slot and follow its offset.
4. **Delete:** mark the slot unused; the bytes become a hole.
5. **Grow or compact:** move records within the page and rewrite their slot offsets. Because indexes name *slots*, not byte offsets, these moves are invisible to them — the whole point of the indirection.

Architecture diagram

Figure 13.1 — A slotted page.



Reading the diagram. One contiguous 8 KiB buffer, left to right as on disk. The slot array grows rightward and records grow leftward from the end; the page is full when they meet in the free space. An index entry (a separate storage structure) names `(page 7, slot 1)`; the lookup is synchronous, and the dotted arrow marks the slot-to-record indirection, not an asynchronous path. Failure point: a crash that writes only part of the page leaves header, slots and records inconsistent, hence checksums and torn-write protection (§13.12). Tables scale by adding pages, never by growing one.

Mathematical foundations

FORMULA

Records per slotted page

$$n = \left\lfloor \frac{P - H}{r + s} \right\rfloor$$

Symbol	Meaning	Units
n	Records that fit in one page	records
P	Page size	bytes
H	Page header size	bytes
r	Stored record size including per-record header and alignment padding	bytes
s	Slot (line pointer) size	bytes

WORKED EXAMPLE

Worked example — How big is a 1-billion-row PostgreSQL table?

Each row holds 76 bytes of column data. PostgreSQL adds a 23-byte tuple header, padded to 24 bytes, and aligns the tuple to 8 bytes; each line pointer is 4 bytes; the page header is 24 bytes [PostgreSQL Docs: Database Page Layout].

1. Stored record: $24 + 76 = 100$ bytes, rounded up to a multiple of 8: $r = 104$ bytes.
2. Per record including its slot: $104 + 4 = 108$ bytes.
3. Records per page: $n = \lfloor (8192 - 24)/108 \rfloor = \lfloor 75.6 \rfloor = 75$.
4. Pages: $10^9/75 = 13\,333\,334$ pages; size $= 13\,333\,334 \times 8192 \approx 109.2$ GB.
5. Raw column data: $10^9 \times 76 = 76$ GB. Overhead factor: $109.2/76 \approx 1.44$.

Interpretation. Before any index or dead tuple, the table is 44% larger than its data, because of MVCC tuple headers (§11.14), slots and alignment. **Engineering implication.** Narrow rows pay proportionally more; ordering 8-byte columns first reduces padding, and a deliberate `fillfactor` below 100% trades space for cheaper updates (§13.14.3). This 1.44 is part of the **space amplification** of §13.11.

Code example

The following program implements a 4 KiB slotted page with insert, get, delete and compaction. It is standalone; run it with `python3`.

```
        """A minimal slotted page: header, slot array growing forward, records growing
        backward from the end of the page. Record IDs (slot numbers) never change."""
        import struct

        PAGE_SIZE = 4096
        HEADER = struct.Struct("<HH")      # slot_count, free_end (offset where record
space begins)
        SLOT = struct.Struct("<HH")        # record offset, record length (offset 0 =
deleted slot)

        class SlottedPage:
            def __init__(self):
                self.buf = bytearray(PAGE_SIZE)
                HEADER.pack_into(self.buf, 0, 0, PAGE_SIZE)

            def _header(self):
                return HEADER.unpack_from(self.buf, 0)

            def _slot_pos(self, slot):
                return HEADER.size + slot * SLOT.size

            def free_space(self):
                count, free_end = self._header()
                return free_end - (HEADER.size + count * SLOT.size)

            def insert(self, record: bytes) -> int:
                count, free_end = self._header()
                if len(record) + SLOT.size > self.free_space():
                    self.compact()                                    # reclaim holes,
then retry
                    count, free_end = self._header()
                    if len(record) + SLOT.size > self.free_space():
                        raise ValueError("page full")
                offset = free_end - len(record)
                self.buf[offset:free_end] = record                    # record grows
downward
                SLOT.pack_into(self.buf, self._slot_pos(count), offset, len(record))
                HEADER.pack_into(self.buf, 0, count + 1, offset)      # slot array grows
upward
                return count                                          # slot number =
stable record ID

            def get(self, slot: int) -> bytes:
                offset, length = SLOT.unpack_from(self.buf, self._slot_pos(slot))
                if offset == 0:
                    raise KeyError(f"slot {slot} deleted")
                return bytes(self.buf[offset:offset + length])

            def delete(self, slot: int) -> None:
                SLOT.pack_into(self.buf, self._slot_pos(slot), 0, 0) # leaves a hole un-
til compact()

            def compact(self) -> None:
                """Slide live records to the end of the page; slot numbers stay the
same."""
```

```
                count, _ = self._header()
                live = []
                for s in range(count):
                    off, length = SLOT.unpack_from(self.buf, self._slot_pos(s))
                    if off:
                        live.append((s, bytes(self.buf[off:off + length])))
                free_end = PAGE_SIZE
                for s, rec in live:
                    free_end -= len(rec)
                    self.buf[free_end:free_end + len(rec)] = rec
                    SLOT.pack_into(self.buf, self._slot_pos(s), free_end, len(rec))
                HEADER.pack_into(self.buf, 0, count, free_end)

        if __name__ == "__main__":
            page = SlottedPage()
            ids = [page.insert(b"row-%03d:" % i + b"x" * 90) for i in range(39)]
            print("inserted", len(ids), "records; free bytes:", page.free_space())
            for s in ids[::2]:
                page.delete(s)                                      # punch 20 holes
            print("after deleting 20, free bytes before compaction:", page.free_space())
            new = page.insert(b"a-larger-record:" + b"y" * 400)     # forces compaction
            print("new record got slot", new, "; slot 1 still reads", page.get(1)[:8])
            print("free bytes now:", page.free_space())
```

Output:

```
inserted 39 records; free bytes: 114
after deleting 20, free bytes before compaction: 114
new record got slot 39 ; slot 1 still reads b'row-001:'
free bytes now: 1654
```

What to notice:

- 39 records of 98 bytes plus 4-byte slots fill $4 + 39 \times 102 = 3982$ of 4096 bytes, leaving 114 — the formula with $H = 4$, $r = 98$, $s = 4$.
- Deleting does not raise `free_space()`: holes are unusable until `compact()` runs (PostgreSQL compacts during page pruning and `VACUUM`).
- After compaction slot 1 returns the same record from a different offset; that stability lets indexes store `(page, slot)`.

Alternatives and trade-offs

Fixed-length records need no slots (record i sits at offset $H + i \times r$). Clustered tables such as InnoDB's keep rows inside B-tree leaves, with slots in key order for binary search (§13.14.1). Values too large for a page move out of line (PostgreSQL TOAST above roughly 2 KB; InnoDB overflow pages).

COMMON MISTAKE

"A row is the unit of I/O." It never is. Updating one 50-byte field dirties a whole 8 or 16 KiB page, which is eventually written in full and, after a checkpoint, may also be copied into the log (§13.12). Reasoning in rows is the commonest cause of under-estimated write volume.

13.4 Buffer pools

13.4.1 What a buffer pool does

DEFINITION

Definition — Buffer pool. A region of memory, managed by the database itself, divided into page-sized **frames** that cache disk pages. A **page table** maps page IDs to frames; each frame carries a **pin count** (how many threads are using it right now), a **dirty flag** (whether it differs from the disk copy) and bookkeeping for the **replacement policy** that chooses which page to evict.

First-principles explanation

Think of a workbench with 1,000 trays beside a warehouse of a billion boxes. You fetch a box into a free tray and note its number on a whiteboard (the page table). While using it you clip the tray (a **pin**) so nobody swaps it out; if you change its contents you add a red dot (**dirty**), meaning it must be shelved before the tray is reused. When the trays are full, you pick an unclipped tray not needed for a while (the **replacement policy**).

Why does this exist?

RAM is about 1,000 times faster than NVMe for a random access (~100 ns versus ~80 µs, §5.6.5), and most databases' working sets are far smaller than the data. The database could leave caching to the kernel's page cache (§6.6.6), but it knows what the kernel does not: which pages are index roots and which belong to a one-off scan, and which dirty pages must not be written before their log records (§13.5).

How it works internally

A thread that needs page 42 calls `fetch(42)`:

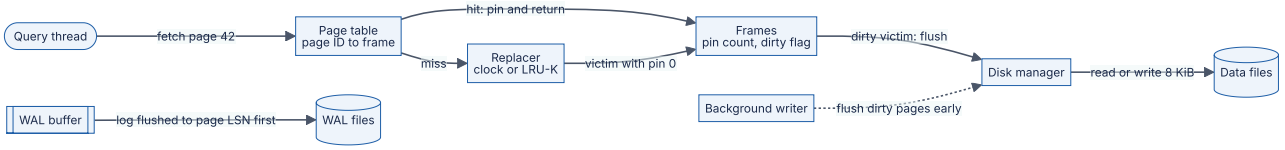
1. **Look up** 42 in the page table (a latched hash table). On a **hit**, increment the pin count, note the access for the replacer, return the frame.
2. On a **miss**, take a frame from the free list or ask the **replacer** for a victim with pin count 0.

3. If the victim is dirty, ensure the log is durable up to its page LSN (the **WAL rule**, §13.5.1), then write it.
4. Read page 42 into the frame, verify its checksum (§13.12), update the page table, pin and return it.
5. The caller later calls `unpin(42, dirty)`. Pinned pages are never evicted, so a leaked pin slowly shrinks the pool.

Background writers (PostgreSQL's bgwriter and checkpointer, InnoDB's page cleaners) flush dirty pages ahead of demand so step 3 rarely waits.

Architecture diagram

Figure 13.2 — Buffer pool components and the page request path.



Reading the diagram. Solid arrows are the synchronous request path: page table, then frame on a hit, or replacer and disk manager on a miss. A dirty victim is written only after the WAL is flushed past its page LSN, an ordering constraint between two storage boundaries (log files and data files). The background writer cleans frames asynchronously (dotted). Failure points: a crash loses dirty frames (recovered from the WAL); leaked pins exhaust evictable frames; a hot page-table latch limits concurrency, so InnoDB partitions large pools into instances. The pool scales vertically with RAM.

13.4.2 Eviction policies: LRU, clock and LRU-K

LRU evicts the page whose last access is oldest. Inside a database it has two problems: moving a list node on every hit makes the shared list a contention point, and **sequential flooding** — one scan of a 100 GB table pushes every hot index page out of a 32 GB pool although no scanned page is read again.

Clock approximates LRU cheaply: frames sit in a circle with a reference bit set on access; a sweeping hand clears set bits and evicts the first unpinned frame whose bit is already clear. PostgreSQL's **clock sweep** uses a usage count (capped at 5) instead of a bit, so frequently used pages survive several sweeps [PostgreSQL source: `src/backend/storage/buffer/README`].

LRU-K evicts the page whose K-th most recent access is oldest [O'Neil, O'Neil and Weikum 1993]. With $K = 2$, a page touched once by a scan is evicted first, so LRU-K resists scans and captures frequency, at the cost of access history. Related designs are **2Q** [Johnson and Shasha 1994] and ARC (§20.9).

InnoDB uses **midpoint insertion**: new pages enter the head of an "old" sublist (37% of the pool) and are promoted only if accessed again after `innodb_old_blocks_time` (1,000 ms by default), so a one-pass scan never reaches the "new" sublist [MySQL Docs: Making the Buffer Pool Scan Resistant]. PostgreSQL gives large scans and `VACUUM` a small private **ring buffer** of frames.

Table 13.2 — Buffer replacement policies.

Policy	How it works	Advantages	Disadvantages	Used in
LRU	Evict oldest last access; list move on every hit	Simple, good for recency	Hit path contention; scan flooding	Textbook baseline; with sublists in InnoDB
Clock / clock sweep	Reference bit or usage count; sweeping hand	Cheap hits; approximates LRU or LFU	Sweep cost when many pages are hot	PostgreSQL; OS page replacement
LRU-K (K = 2)	Evict oldest K-th last access	Scan resistant; frequency aware	History memory; tuning of correlation period	Research, commercial engines
Midpoint / 2Q	Probation queue before main queue	Scan resistant; cheap	Two parameters to tune	InnoDB (midpoint); 2Q variants
Ring buffer for scans	Bulk operations reuse a few private frames	Protects the main pool completely	Applies only to recognized bulk operations	PostgreSQL

13.4.3 Double buffering, `O_DIRECT` and the page cache

Reading files with ordinary `read()` caches every page twice, in the kernel page cache and in the buffer pool. This **double buffering** wastes RAM, and kernel read-ahead and write-back compete with the database's own. `O_DIRECT` transfers data directly between the device and aligned database buffers; the engine must then do its own read-ahead and asynchronous I/O, and still needs `fsync`, because `O_DIRECT` does not flush the drive cache (§6.14.3).

InnoDB owns memory: a buffer pool of most of RAM with `O_DIRECT`, the Linux default from MySQL 8.4 [MySQL Docs: InnoDB Startup Options]. **PostgreSQL** uses buffered I/O, with `shared_buffers` starting around 25% of RAM and the page cache as a second-level cache [PostgreSQL Docs: Resource Consumption]; direct I/O is only a developer option (`debug_io_direct`, version 16), and version 18 added asynchronous I/O (as of 2025). **RocksDB** defaults to buffered I/O plus its own block cache, with optional direct I/O [RocksDB Wiki: Direct IO]. **LMDB** maps the file with `mmap` and lets the kernel be its buffer pool, trading control for simplicity (§6.6.6, [Crotty et al. 2022]).

Mathematical foundations

How much RAM should the buffer pool have? Gray and Putzolu's **five-minute rule** answers by comparing the cost of keeping a page in memory with the cost of the device capacity needed to re-read it [Gray and Putzolu 1987; Gray and Graefe 1997].

FORMULA

Break-even reference interval (the "five-minute rule")

$$T_{BE} = \frac{C_{dev} / IOPS_{dev}}{C_{RAM} \times P}$$

Symbol	Meaning	Units
T_{BE}	Break-even interval: cache a page if it is re-referenced more often than once per T_{BE}	seconds
C_{dev}	Price of one storage device	dollars
$IOPS_{dev}$	Random reads per second the device sustains	reads/s
C_{RAM}	Price of memory	dollars/byte
P	Page size	bytes

WORKED EXAMPLE

Worked example — Break-even for HDD and NVMe (illustrative prices, as of 2025).

Assume DRAM at \$4/GB, so $C_{RAM} = 4 \times 10^{-9}$ \$/byte, and $P = 8192$ bytes. RAM cost of one cached page: $4 \times 10^{-9} \times 8192 = \$3.28 \times 10^{-5}$.

1. **HDD:** $C_{dev} = \$300$, $IOPS_{dev} = 200$. Cost per unit of read capacity: $300/200 = \$1.50$ per read/s. $T_{BE} = 1.50/(3.28 \times 10^{-5}) \approx 45\,700$ s ≈ 12.7 hours.
2. **NVMe SSD:** $C_{dev} = \$400$, $IOPS_{dev} = 400\,000$. Cost: $400/400\,000 = \$0.001$ per read/s. $T_{BE} = 0.001/(3.28 \times 10^{-5}) \approx 30.5$ s.

Interpretation. On HDDs, a page touched about twice a day earns its RAM; on NVMe, only pages re-referenced every half minute or so do. **Engineering implication.** With flash, size the pool for the hot working set and the latency target, not the whole database. CPU cost per I/O and latency SLOs, ignored here, push toward a somewhat larger pool.

Failure scenarios

Table 13.3 — Buffer pool failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Throughput collapses after a report	Scan floods the pool	Hit ratio drops	Re-warm	Scan-resistant policy; reports on a replica
Stalls waiting for free frames	All frames dirty	Wait events; dirty % near 100	Flush faster	Tune page cleaners or bgwriter
High p99 after restart	Cold pool	Low hit ratio	Warm before taking traffic	Dump/reload page list; `pg_prewarm`

COMMON MISTAKE

"A 99% buffer hit ratio means the disk does not matter." At 50,000 page requests per second, 1% misses is 500 random reads per second, each 80 µs on NVMe or 10 ms on an HDD — enough to saturate a hard disk (§5.6.1). Hit ratios must be read together with the absolute miss rate and the device's IOPS.

13.5 Write-ahead logging and recovery

13.5.1 The problem: fast commits without losing data

DEFINITION

Definition — Write-ahead log (WAL). An append-only file of **log records** describing every change to the database, written *before* the changed pages themselves reach disk. Each record is identified by a monotonically increasing **log sequence number (LSN)**, usually its byte offset in the log. Also called the redo log (InnoDB) or journal.

First-principles explanation

A shopkeeper writes every sale as one line at the bottom of a cash book the moment it happens, and tidies the stock ledger later. If a fire alarm interrupts the tidying, nothing is lost: she replays the cash book from the last time the ledger was known to be correct. Appending a line is fast; reorganizing shelves is slow. The cash book is the WAL, the ledger is the data pages, and "last known correct" is a **checkpoint**.

Why does this exist?

Writing a transaction's ten random pages at commit would cost ten random writes, and a crash midway would leave some pages new and some old. The WAL replaces them with one small *sequential* append and one `fsync` per commit group (§6.14.3). Two freedoms follow [Härder and Reuter 1983]: **no-force** — committed changes need not reach their pages at commit, because the log can **redo** them; and **steal** — pages with *uncommitted* changes may be written (say, on eviction), because the log can **undo** them. Steal/no-force gives the fastest commits and freest buffer pool, at the price of needing both redo and undo — the design point of ARIES.

How it works internally

An update record holds its LSN, transaction ID, `prevLSN` (the transaction's previous record, chaining backward), page ID, and **redo** and **undo** information. Records are usually **physiological**: physical to a page, logical within it ("insert at slot 3 of page 7"). Two rules make the WAL correct:

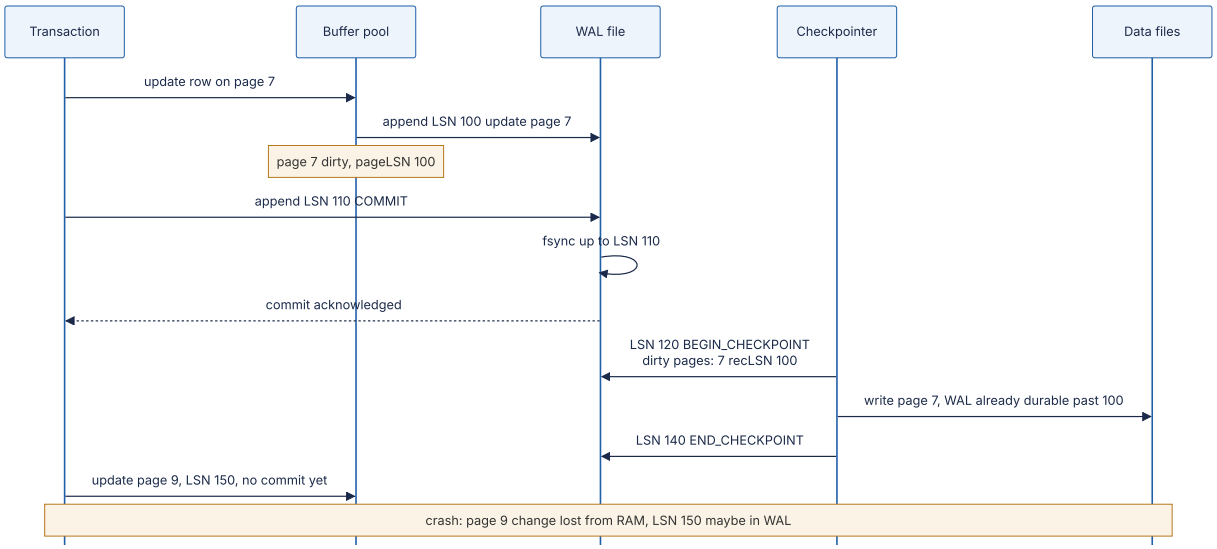
1. **WAL rule:** before a dirty page is written, the log must be durable up to that page's `pageLSN`: $\text{pageLSN} \le \text{flushedLSN}$. Otherwise a change could reach disk with no record able to undo it.
2. **Commit rule:** a transaction is acknowledged only after its commit record is durable.

Because each page stores the LSN of the last change applied to it, recovery can tell whether a record is already on the page, which makes redo **idempotent**.

13.5.2 Checkpoints

A **checkpoint** bounds how much log recovery must read and how much log must be kept. Rather than freezing the database to flush everything, engines take **fuzzy checkpoints**: log the **dirty page table** (each dirty page with its `recLSN`, the LSN that first dirtied it) and the **transaction table**, then flush pages gradually in the background. Redo starts from the smallest `recLSN`; older log can be recycled.

Figure 13.3 — WAL, commit and checkpoint timeline.



Reading the diagram. The WAL file and data files are separate durable storage boundaries; the buffer pool is RAM. Solid arrows are synchronous; the dashed arrow is the acknowledgment. The commit waits only for a sequential log `fsync` up to LSN 110, never for page 7, which the checkpointer writes later, respecting the WAL rule. At the crash, page 9's uncommitted change exists only in RAM and perhaps the log tail; recovery must ensure it does not appear. Scaling: the log is one sequential stream, so its device's flush latency bounds commit throughput; put it on fast, power-loss-protected storage.

13.5.3 ARIES recovery: analysis, redo, undo

ARIES, developed at IBM, is the reference design for steal/no-force recovery and underlies DB2 and SQL Server among others [Mohan et al. 1992]:

1. **Analysis** (forward from the last checkpoint): rebuild the dirty page and transaction tables; committed transactions are **winners**, active ones **losers**.
2. **Redo** (forward from the smallest `recLSN`): **repeat history** — reapply every change, losers' included, whose LSN exceeds the page's `pageLSN`, restoring the exact pre-crash state.
3. **Undo** (backward): roll back losers along their `prevLSN` chains, logging each step as a **compensation log record (CLR)** whose `undoNextLSN` says what to undo next. A crash during recovery redoes the CLRs and resumes, never undoing twice.

Repeating history first is what allows row-level locking and logical undo: after redo, pages are exactly as the undo records expect, even if committed transactions changed them since.

Figure 13.4 — The three ARIES passes over the log.

Reading the diagram. The boxes are positions in one WAL file, ordered by LSN. Analysis scans forward from the checkpoint; redo scans forward from the smallest `recLSN`, which precedes the checkpoint because fuzzy checkpoints do not flush pages; undo (dotted: it follows `prevLSN` chains, not a sequential scan) walks back to the oldest loser record, writing CLRs. The log is read; data pages are read and written through the buffer pool. Failure point: a long-running transaction pushes point A far back, lengthening undo and log retention. Scaling: redo parallelizes by page.

Mathematical foundations

FORMULA

Redo work after a crash

$$W_{redo} \approx r_{WAL} \times \Delta t_{ckpt}, \qquad T_{redo} \approx \frac{W_{redo}}{b_{replay}}$$

Symbol	Meaning	Units
W_{redo}	Log volume between the redo start point and the crash	bytes
r_{WAL}	Rate at which the workload generates log	bytes/s
Δt_{ckpt}	Time between checkpoints (worst case, crash just before the next one)	s
T_{redo}	Duration of the redo pass	s
b_{replay}	Replay throughput, usually limited by random page reads, not log reads	bytes/s

WORKED EXAMPLE

Worked example — Choosing a checkpoint interval.

A PostgreSQL server generates r_{WAL} = 30 MB/s of WAL at peak. Replay runs at b_{replay} = 150 MB/s (single-threaded redo, mostly cached pages).

1. Checkpoint every 5 minutes: $W_{redo} = 30 \times 300 = 9000$ MB $= 9$ GB. $T_{redo} = 9000/150 = 60$ s.
2. Checkpoint every 1 minute: $W_{redo} = 30 \times 60 = 1.8$ GB; $T_{redo} = 12$ s.
3. The cost: with full-page writes (§13.12.3), the first change to each page after a checkpoint logs the whole 8 KiB page. If 200,000 distinct pages are dirtied per minute, 1-minute checkpoints add up to $200\,000 \times 8192 \approx 1.64$ GB per minute, ≈ 27 MB/s — nearly doubling the WAL rate.

Interpretation. Checkpoint frequency trades recovery time against steady-state write volume. **Engineering implication.** Derive the interval from the recovery-time objective (RTO, §39.8) and the measured WAL rate; write-heavy PostgreSQL systems often raise `checkpoint_timeout` (default 5 min) and `max_wal_size` (default 1 GB), letting a standby failover (§27.11) hide the longer recovery.

13.5.4 Group commit and relaxed durability

Group commit lets one log `fsync` cover every commit that arrived during the previous flush (formula in §6.14.3). Engines also trade durability for speed explicitly: InnoDB's `innodb_flush_log_at_trx_commit = 1` (default) flushes at every commit, while `2` flushes about once per second, so an OS crash can lose about a second of commits. PostgreSQL's `synchronous_commit = off` risks the last fraction of a second of commits but never corruption, because the WAL rule still holds.

Real-world industry applications

INDUSTRY EXAMPLE

PostgreSQL versus InnoDB recovery. PostgreSQL recovers by redo only: MVCC never overwrites rows in place, so an aborted transaction's versions stay in the heap, invisible because `pg_xact` marks it aborted, until `VACUUM` removes them. The same WAL feeds replication and point-in-time recovery. InnoDB is ARIES-like: redo log plus separate **undo logs** that serve rollback and consistent reads; recovery applies redo, then rolls back incomplete transactions. *Evidence: Primary* — [PostgreSQL Docs: Reliability and the Write-Ahead Log; MySQL Docs: InnoDB Redo Log; InnoDB Undo Logs]

Failure scenarios

Table 13.4 — WAL and recovery failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Recovery takes 20 minutes	Long checkpoint interval, high WAL rate	Redo progress in logs	Fail over to a replica	Size interval from the RTO
Disk fills with WAL	Stalled checkpoints or unconsumed replication slot	WAL size alert	Fix consumer; drop slot	Monitor retention and slot lag
Acknowledged commits lost	Drive cache not flushed; relaxed settings	Gaps versus clients	Restore from replica	Power-loss protection; audit `fsync` settings
Undo grows without bound	Long-running transaction	Oldest transaction age	Kill or commit it	Transaction timeouts

COMMON MISTAKE

"The checkpoint is what makes a commit durable." Commits are durable when their log records are flushed. A checkpoint only bounds recovery work and lets old log be recycled.

13.6 B-tree storage engines

13.6.1 Storing a B+ tree in pages

DEFINITION

Definition — B-tree storage engine. A storage engine that keeps each table or index as a B+ tree of fixed-size pages and **updates pages in place**: a change to a key rewrites the page that holds it. Internal pages hold separator keys and child page numbers; leaf pages hold the keys with either the rows themselves (a clustered index) or pointers to them.

The logical structure of B+ trees is covered in §11.8. Here the questions are physical: how the tree grows in pages, what a lookup costs in I/O, and how threads share it.

First-principles explanation

Picture a filing cabinet with guide cards: one card per drawer, one per folder. To find a document you read three cards, not a million documents. When a folder overflows you split it and add a guide card above; rarely, the drawer overflows too. The cabinet stays balanced because it grows only by splitting, bottom up.

How it works internally

Lookup. From the root, binary-search separator keys and fetch the child through the buffer pool until reaching a leaf.

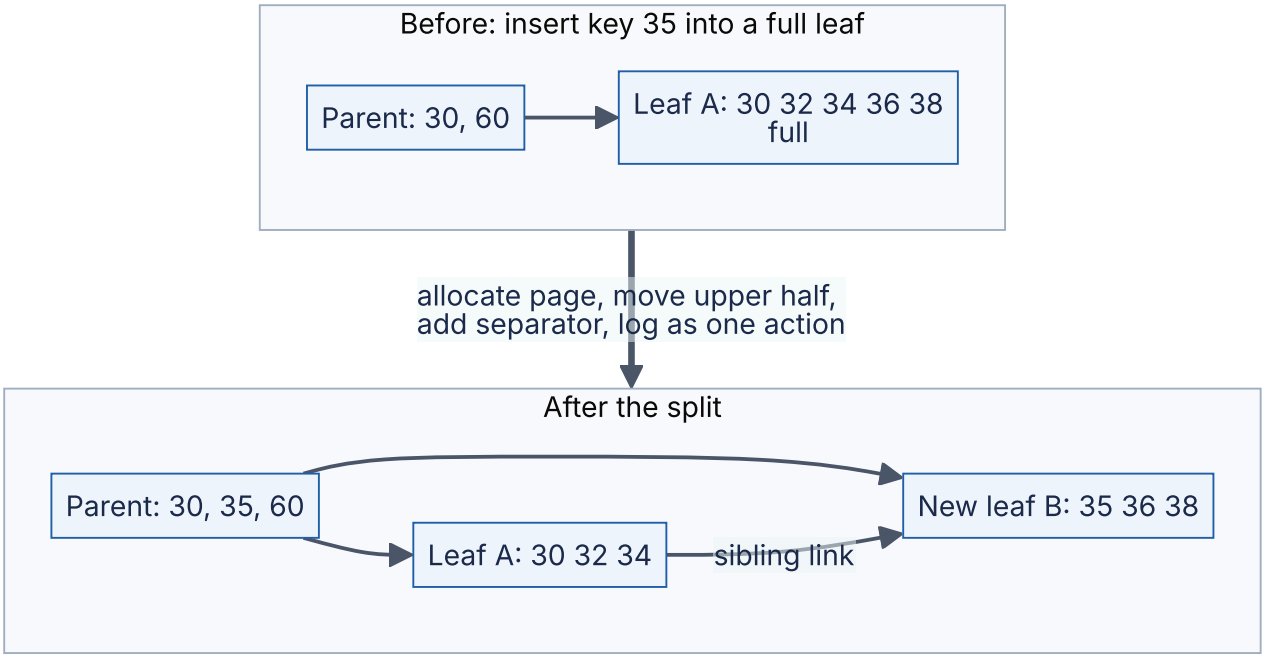
Insert and split. If the leaf has room, insert into its slotted page (§13.3) and log it. Otherwise:

1. Allocate a new page and move the upper half of the entries to it.
2. Link it into the leaf sibling chain.
3. Insert a separator into the parent, splitting the parent the same way if it is full; a root split adds a level.
4. Log the split as one unit. ARIES treats it as a **nested top action**: it is not undone if the triggering transaction aborts, because others may already use the new page [Mohan et al. 1992].

For rightmost inserts (auto-increment keys, timestamps), PostgreSQL and InnoDB split unevenly, leaving the old page nearly full instead of a trail of half-empty pages.

Delete and merge. Merging under-full pages reverses a split, but eager merging thrashes. InnoDB attempts a merge below `MERGE_THRESHOLD` (50% by default); PostgreSQL reclaims only pages `VACUUM` finds completely empty [MySQL Docs: Configuring the Merge Threshold for Index Pages; PostgreSQL source: `src/backend/access/nbtree/README`].

Figure 13.5 — A leaf page split propagating a separator to the parent.



Reading the diagram. Each box is a page in one data file; arrows are synchronous pointers. Inserting 35 into full leaf A allocates leaf B, moves the upper entries, links A to

B for range scans, and adds a separator to the parent. One logical insert dirties three pages — write amplification. Failure point: a crash between writing B and updating the parent would orphan B, hence logging the split atomically. Scaling: with 57 rows per leaf and fan-out 716 (below), a leaf splits about every 28 inserts into it and a parent about every 358 leaf splits.

Mathematical foundations

The height formula $h = 1 + \lceil \log_f \lceil n/L \rceil \rceil$ (fan-out f, L rows per leaf) is derived in §11.8.2, which works a billion-row InnoDB table at 80% usable space: fan-out 819, 65 rows per leaf, four levels, 294 MiB of internal pages. The physical question here is how sensitive those numbers are to page fill.

WORKED EXAMPLE

Worked example — A 1-billion-row InnoDB table.

Repeat the §11.8.2 example with 16 KiB pages filled to 70% (a typical steady state after random inserts; random B-tree fill averages about $\ln 2 \approx 69\%$ [Yao 1978]), rows of 200 bytes, and internal entries of 16 bytes (an 8-byte key, a page number and record overhead).

1. Usable bytes per page: $16\,384 \times 0.7 = 11\,469$.
2. Rows per leaf: $\lfloor 11\,469/200 \rfloor = 57$. Leaves: $10^9/57 = 17\,543\,860$.
3. Fan-out: $\lfloor 11\,469/16 \rfloor = 716$.
4. Height: $\log_{716} 17\,543\,860 = \ln(1.754 \times 10^7)/\ln 716 = 16.68/6.57 = 2.54$, so $\lceil 2.54 \rceil = 3$ internal levels and $h = 4$.
5. Internal pages: $17\,543\,860/716 \approx 24\,503$, then $\lceil 24\,503/716 \rceil = 35$, then 1 root: $24\,539$ pages $\times$ 16 KiB ≈ 402 MB.

Interpretation. Four levels index a billion rows, as at 80% fill, and the internal levels fit in about 400 MB (about 30% more than the 308 MB, or 294 MiB, of §11.8.2), so a point lookup costs at most **one** random read. **Engineering implication.** Read cost is nearly flat in table size while internal pages stay cached; the real danger is a working set of *leaves* larger than RAM. Wide keys cut fan-out and can add a level, one reason to prefer compact primary keys.

13.6.2 Concurrency: latches and latch crabbing

A **latch** is a short-term mutex on an in-memory structure such as a page frame, held for microseconds; a **lock** protects logical data for a transaction's lifetime and takes part in deadlock detection (§11.15). **Latch crabbing** descends like a crab: hold the parent's latch, acquire the child's, and release the parent when safe [Bayer and Schkolnick 1977].

1. **Readers** latch the child shared, then release the parent: at most two latches at a time.
2. **Writers** latch exclusively and release all ancestors on reaching a **safe** node, one that cannot split (has free space) or merge on this operation.
3. **Optimistically**, since splits are rare, writers descend with shared latches and latch only the leaf exclusively, restarting pessimistically if a split is needed. The root is then almost never exclusively latched.

B-link trees [Lehman and Yao 1981] add a high key and right-sibling pointer to every page, so a reader arriving just after a concurrent split follows the right-link instead of latching the parent. PostgreSQL's B-tree is based on this design.

13.6.3 Copy-on-write B-trees

A **copy-on-write (COW)** or shadowing B-tree never modifies a page reachable from the current root. Changing a leaf writes a new leaf, a new parent pointing to it, and so on to a new root; a commit atomically switches the root pointer. Readers that began earlier keep the old root — a consistent snapshot without locks — and no WAL is needed [Rodeh 2008].

> INDUSTRY EXAMPLE
>
> **LMDB.** Written for the read-dominated OpenLDAP directory server, LMDB memory-maps its file, allows one writer and any number of lock-free readers, and alternates between two **meta pages** recording the current root; after a crash the meta page with the higher valid transaction ID *is* the database, so there is no recovery procedure. Freed pages are reused once no reader needs them. Trade-offs: each commit copies the root-to-leaf path — with height 4 and 4 KiB pages, 16 KiB for a 100-byte update, about 160× write amplification unless a transaction batches many keys — long readers bloat the file, and one writer bounds write concurrency. Btrfs and ZFS use the same idea (§6.14.2). *Evidence: Primary* — [LMDB Docs]

Advantages and disadvantages

B-trees give predictable one-I/O point reads, efficient range scans along sibling links, and mature row-level locking. Their weaknesses come from in-place updates: random writes, page-sized write amplification (§13.11), partly empty pages ($SA \approx 1/0.69 \approx 1.45$ from fill factor alone) and torn-page risk (§13.12).

COMMON MISTAKE

“B-trees need one disk write per insert.” At commit only a small sequential log record is written; the page is written later, by which time many inserts may share it. Insert cost therefore depends on key locality (§13.11.2).

13.7 Log-structured storage

13.7.1 The idea: never overwrite, only append

DEFINITION

Definition — Log-structured storage. A storage design in which every write — insert, update or delete — is appended to the end of a file, and existing data is never modified in place. Old versions become garbage that a background **compaction** (or merge) process removes by copying live data into new files.

First-principles explanation

Suppose the shopkeeper’s cash book of §13.5 becomes *the* record: a balance is the most recent line about a customer. Writing is one append and recovery is trivial, but finding the latest line needs an index, and obsolete lines must be tidied away. Every log-structured engine answers those two problems; the idea goes back to the log-structured file system [Rosenblum and Ousterhout 1992].

Why does this exist?

Sequential writes are 100–600× faster than random ones on HDDs (§5.6.1) and still better on SSDs, where they also cut the drive’s internal write amplification (§5.6.3). Log structuring makes *all* writes sequential and moves the cost to reads and background compaction.

13.7.2 Bitcask: a hash index over a log

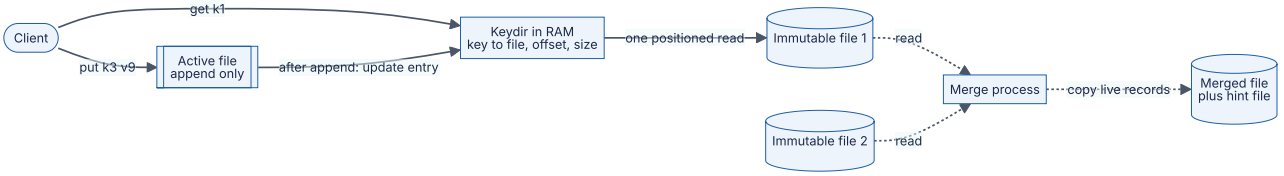
Bitcask, the default storage backend of the Riak key-value store, is the simplest complete log-structured engine and a good mental model [Sheehy and Smith 2010].

How it works internally

1. **Data files.** One **active** file takes appends of `CRC | timestamp | key size | value size | key | value`; full files become immutable. A delete appends a **tombstone**.
2. **Keydir.** An in-memory hash table maps every key to the file, position and size of its latest record.

3. **Read.** One keydir lookup and **one** positioned read.
4. **Merge.** In the background, copy records the keydir still references into new files, delete the old ones, and write **hint files** (keys and positions) for fast restarts.
5. **Recovery.** Rebuild the keydir from hint files and the active file's tail; a CRC mismatch marks a torn final record.

Figure 13.6 — Bitcask: an in-memory hash index over append-only files.



Reading the diagram. Writes append synchronously to the active file and then update the keydir; reads take one keydir lookup and one positioned read. Merging (dotted) is asynchronous. The storage boundary is stark: the whole index in RAM, all data on disk. Failure points: a crash loses the keydir, rebuilt from hint files; a torn final record fails its CRC. Scaling limit: every key must fit in RAM.

Mathematical foundations

With 200 million 32-byte keys and an assumed ~50 bytes of per-entry overhead (illustrative), the keydir needs $2 \times 10^8 \times 82 = 16.4$ GB of RAM whatever the value sizes: fine for 1 KB values (200 GB of data), absurd for 10-byte values.

Advantages and disadvantages

Bitcask gives one append per write, one seek per read and simple recovery, but no **range queries** (a hash has no order) and a RAM-bound key count. Sorting the files by key and allowing a sparse index removes both limits — which is the LSM tree.

13.8 LSM trees: memtables and SSTables

13.8.1 From a log to a log-structured merge tree

DEFINITION

Definition — Log-structured merge tree (LSM tree). A storage structure that buffers writes in a sorted in-memory table (the **memtable**), periodically writes it out as an immutable sorted file (a **sorted string table, SSTable**), and merges SSTables in the background (**compaction**) into progressively larger sorted runs organized in **levels**. Introduced by O'Neil, Cheng, Gawlick and O'Neil [O'Neil et al. 1996]; the memtable/SSTable design popularized by Google's Bigtable [Chang et al. 2006] and implemented in LevelDB, RocksDB, Cassandra, HBase, ScyllaDB and many others.

First-principles explanation

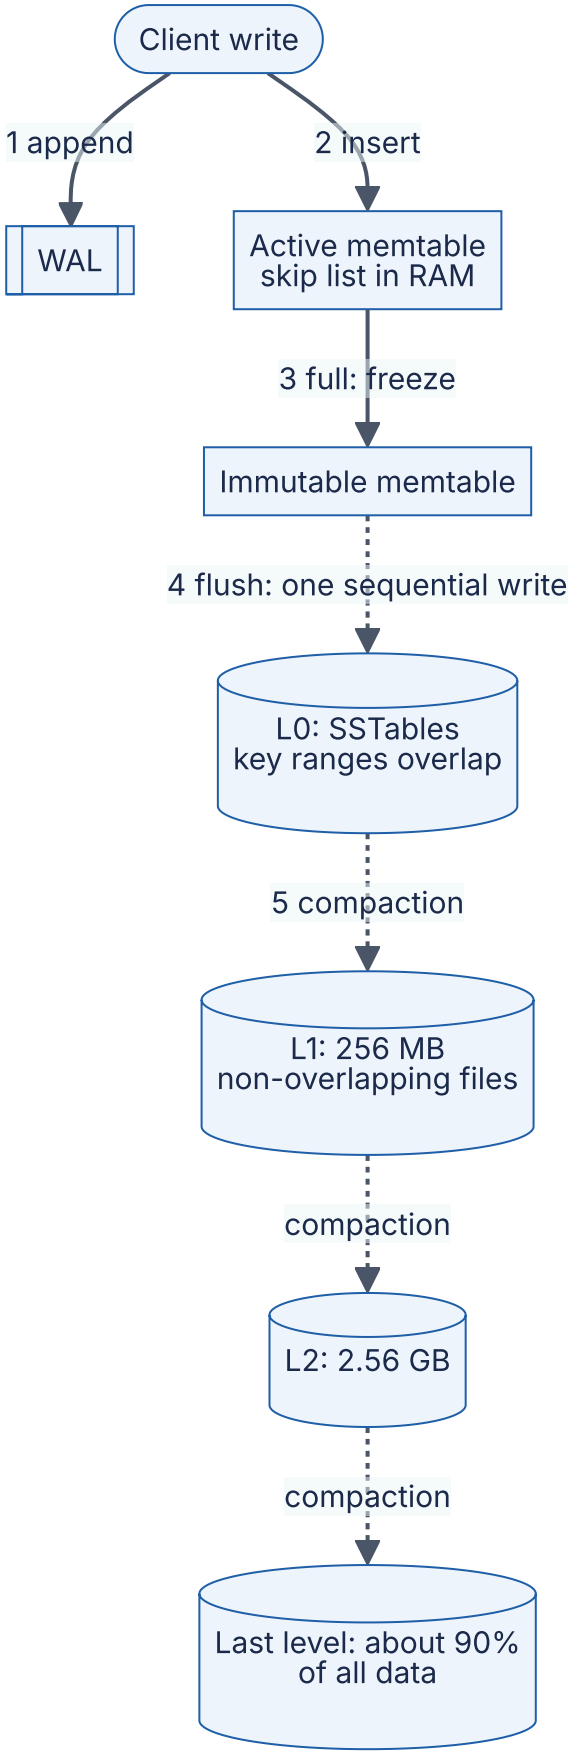
A librarian sorts returned books on a trolley instead of walking to a random shelf for each; when it is full she shelves the sorted batch on a side shelf in one pass. To find a book you check the trolley, then the newest batch, then older ones; nightly she merges batches into the main shelves. Trolley = memtable, batch = SSTable, nightly merge = compaction.

How it works internally: the write path

1. **Log:** append to the WAL (§13.5.4), which exists only to rebuild the memtable after a crash.
2. **Memtable:** insert into a sorted in-memory structure — a skip list in LevelDB and RocksDB (§17.7). A delete inserts a **tombstone**.
3. **Freeze:** at the size limit (RocksDB `write_buffer_size`, 64 MB by default) the memtable becomes immutable and a new one starts, so writes never wait.
4. **Flush:** write it as a new **level 0** SSTable in one sequential pass; drop the WAL segment it covered.
5. **Compact:** merge SSTables into larger non-overlapping runs in deeper levels (§13.9), discarding overwritten values and, at the bottom, tombstones.

An **SSTable** is immutable and sorted: **data blocks** (RocksDB default 4 KiB before compression), an **index block** with one entry per block, a **filter block** with a Bloom filter (§13.10), and a **footer** locating them. Sorting allows a sparse index and lets several SSTables be merged sequentially into a new one.

Figure 13.7 — LSM tree write path and levels.



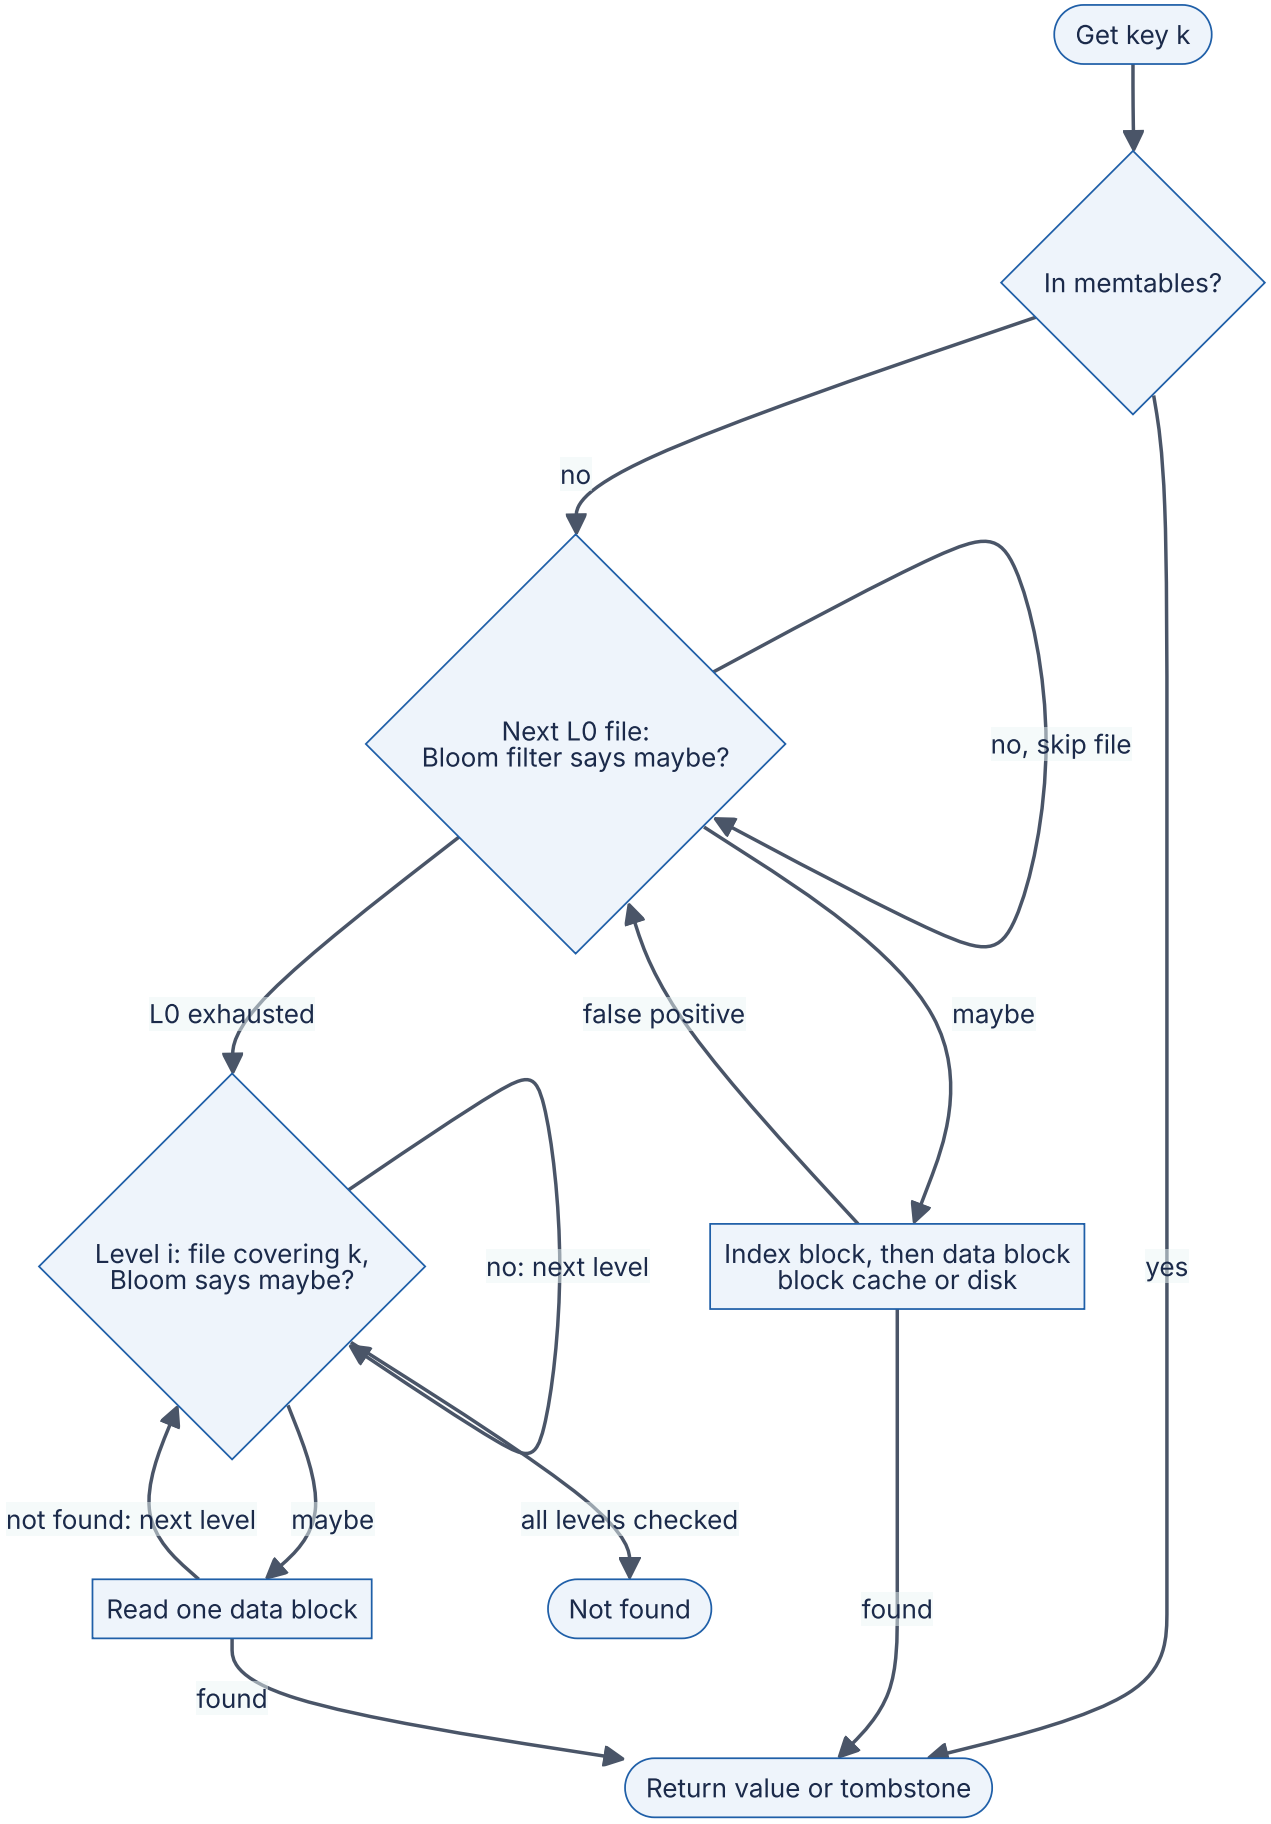
Client write
1 append
2 insert
WAL
Active memtable
skip list in RAM
3 full: freeze
Immutable memtable
4 flush: one sequential write
L0: SSTables
key ranges overlap
5 compaction
L1: 256 MB
non-overlapping files
compaction
L2: 2.56 GB
compaction
Last level: about 90%
of all data

Reading the diagram. Only steps 1 and 2 are synchronous: a sequential WAL append and an in-memory insert. Flushing and compaction are asynchronous (dotted). L0 holds whole flushes with overlapping key ranges; from L1 down, each level is one sorted run in non-overlapping files, about ten times larger than the level above (RocksDB defaults: `max_bytes_for_level_base` 256 MB, multiplier 10). Memtables live in RAM; WAL and SSTables on disk. Failure points: if compaction lags, L0 files pile up and the engine slows or stops writes (a **write stall**); a crash loses memtables, rebuilt from the WAL. Scaling is bounded by compaction bandwidth.

How it works internally: the read path

A point lookup searches newest to oldest and stops at the first version found (a tombstone means deleted): the memtables; every L0 file, newest first, since their ranges overlap; then the one file per deeper level whose range covers the key. In each file it checks the Bloom filter, then the index block, then reads one data block, from the **block cache** if present. A **range scan** cannot stop early: it merges iterators over every memtable and overlapping SSTable, and Bloom filters do not help it.

Figure 13.8 — LSM point-lookup read path.



Get key k
In memtables?
yes
no
Next L0 file:
Bloom filter says maybe?
no, skip file
maybe
false positive
L0 exhausted
Level i: file covering k,
Bloom says maybe?
no: next level
Index block, then data block
block cache or disk
found
all levels checked
not found: next level
maybe
Read one data block
Not found
found
Return value or tombstone

Reading the diagram. Every step is synchronous. Memtables are checked in RAM; each L0 file is tried in turn (the loop), and its in-memory Bloom filter usually rules it out without I/O; deeper levels need one file each. Only a “maybe” reaches the block cache or disk — the storage boundary where latency jumps from microseconds to tens of microseconds. A false positive wastes one block read. Failure points: L0 backlog lengthens every lookup; an undersized block cache turns index and data reads into I/O. Cost grows with the number of sorted runs, which compaction keeps small.

Mathematical foundations

FORMULA

Number of levels in a leveled LSM tree

$$L = \lceil \log_T \frac{N}{S_1} \rceil + 1 \quad (\text{levels } L_1 \ldots L_L, \text{ for } N > S_1)$$

Symbol	Meaning	Units
L	Number of levels below L0	levels
N	Total data size	bytes
S_1	Target size of level 1	bytes
T	Size ratio (fan-out) between adjacent levels	dimensionless

WORKED EXAMPLE

Worked example — Levels for 1 TB in RocksDB with default sizing.

$S_1 = 256$ MB, $T = 10$, $N = 1$ TB $= 10^{12}$ bytes.

1. $N/S_1 = 10^{12}/(2.56 \times 10^8) = 3906$.
2. $\log_{10} 3906 = 3.59$; $\lceil 3.59 \rceil = 4$; $L = 4 + 1 = 5$.
3. Check: capacities are L1 256 MB, L2 2.56 GB, L3 25.6 GB, L4 256 GB, L5 2.56 TB. Four levels hold at most 284 GB, so 1 TB needs L5.

Interpretation. Five levels plus L0 cover a terabyte; with upper levels sized backward from the last (`level_compaction_dynamic_level_bytes` , default since RocksDB 8.4), about 90% of data sits in the last level [RocksDB Wiki: Leveled Compaction]. **Engineering implication.** A lookup probes at most ~5 levels plus a few L0 files, and every level is another rewrite of each byte (§13.9); the size ratio T trades one against the other.

Code example

The program below is a complete, runnable toy LSM tree in about 250 lines of Python: WAL with replay, memtable, SSTables with a sparse index and Bloom filter, a manifest that records which SSTables are live, and full merge compaction. It counts the bytes written to measure write amplification. It is saved as `code/ch13/toy_lsm.py`.

```
        """A toy LSM tree: write-ahead log, memtable, SSTable flush, merge compaction,
        manifest and WAL replay. Teaching code: single-threaded, JSON-lines files."""
        import bisect
        import hashlib
        import heapq
        import json
        import os

                return disk / max(1, self.stats["user"])

        if __name__ == "__main__":
            import random
            import tempfile

            rng = random.Random(13)
            with tempfile.TemporaryDirectory() as d:
                db, model = LSMTree(d, sync=False), {}
                for i in range(20_000):
                    key = "user:%04d" % rng.randrange(2_000)
                    if rng.random() < 0.1:
                        db.delete(key)
                        model.pop(key, None)
                    else:
                        value = "v%d-%s" % (i, "x" * rng.randrange(20, 60))
                        db.put(key, value)
                        model[key] = value
                stats, wa = dict(db.stats), db.write_amplification()
                unflushed = len(db.memtable)

                db.wal.close()                            # simulate a crash: memtable
is lost
                db = LSMTree(d, sync=False)               # reopen: manifest + WAL re-
play
                assert len(db.memtable) == unflushed, "WAL replay lost records"
                for k in ("user:%04d" % n for n in range(2_000)):
                    assert db.get(k) == model.get(k), k
                print("all 2000 keys match after crash and WAL replay")
                print("live keys:", len(model), " SSTables:", len(db.tables),
                      " memtable entries replayed:", unflushed)
                print("bytes by user=%(user)d wal=%(wal)d flush=%(flush)d compaction=%
(compaction)d" % stats)
                print("write amplification = %.1f" % wa)
```

Output (Python 3.13):

```
all 2000 keys match after crash and WAL replay
live keys: 1799  SSTables: 1  memtable entries replayed: 12
bytes by user=1007515 wal=1191501 flush=1189724 compaction=2721866
write amplification = 5.1
```

What to notice:

- **Write-ahead order:** `put` logs before touching the memtable. After the simulated crash, 12 unflushed entries return from the WAL and all 2,000 keys (deleted ones included) match the reference dictionary.
- **Torn tail:** replay stops at the first unparsable record, as real engines stop at the first failed checksum (§13.12).
- **Manifest:** an SSTable joins the tree only when the atomically replaced `MANIFEST` names it (§6.14.3); orphans are deleted at startup, like RocksDB's MANIFEST. Switching the manifest before deleting compaction inputs stops an old input resurrecting a key whose tombstone was dropped.
- **Write amplification 5.1** = WAL 1.18 + flush 1.18 + compaction 2.70 (the 18% is JSON framing). Full merges rewrite everything, so real engines compact incrementally (§13.9).
- **Bloom filter:** 10 bits per key, 7 hashes; about 1% "maybe" on 10,000 absent keys, as §13.10 predicts.

13.9 Compaction strategies

13.9.1 Why compaction strategy is the central LSM decision

> DEFINITION
>
> **Definition — Compaction.** The background merge of sorted runs in an LSM tree that removes overwritten values and tombstones and bounds the number of runs a read must consult. A **compaction strategy** decides which runs to merge and when; it sets the engine's read, write and space amplification.

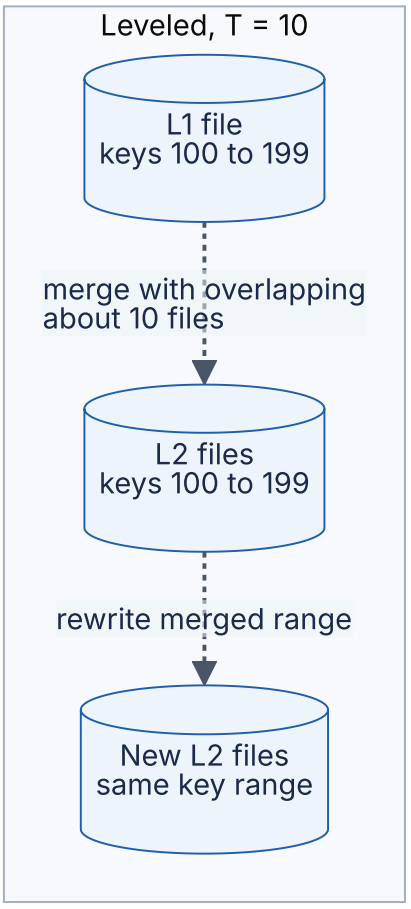
Every byte is rewritten by compaction several times on its way down. Merging eagerly makes reads cheap and writes expensive; merging lazily does the reverse.

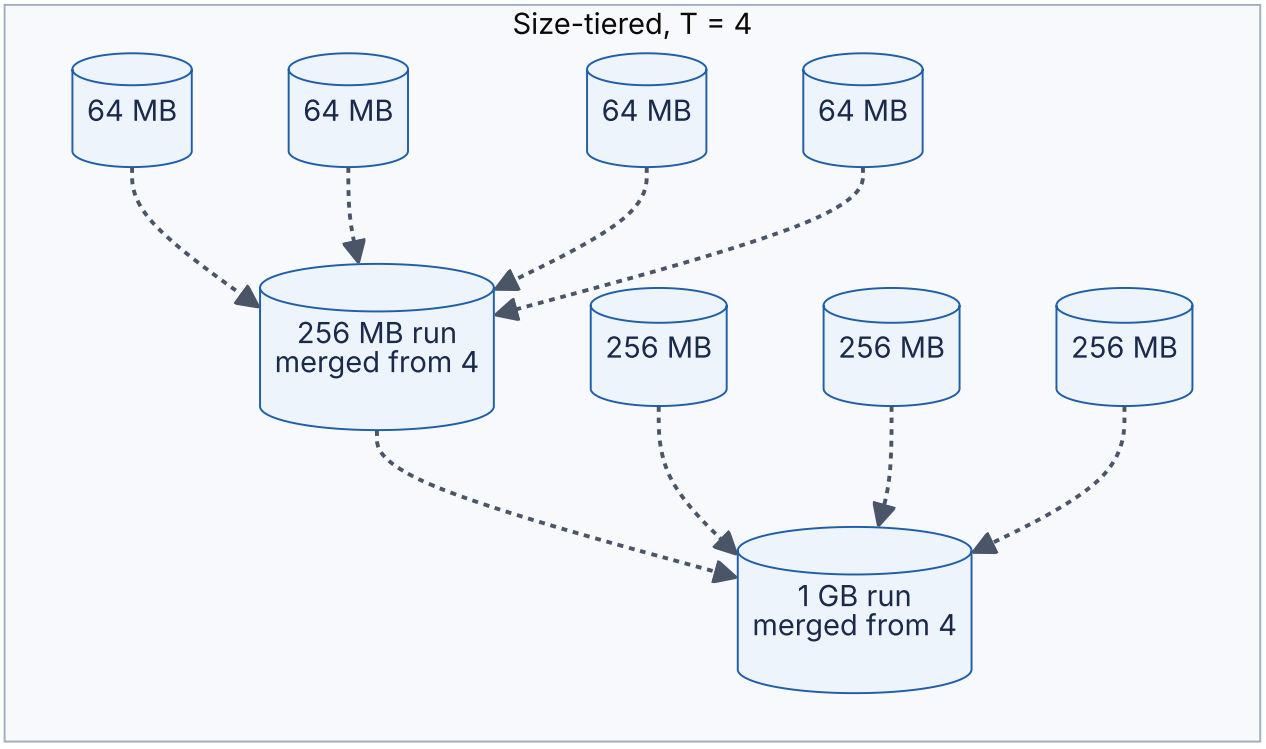
Size-tiered (tiering). When about T runs of similar size exist (Cassandra's default `min_threshold` is 4), merge them into one run of the next tier. Each byte is rewritten about once per tier, but up to $T - 1$ runs per tier may hold versions of a key, and merging the largest runs needs equal free space. Used by Cassandra STCS and RocksDB **universal** compaction.

Leveled (leveling). Each level is one sorted run of non-overlapping files, T times larger than the level above; an overflowing level pushes one file into the *overlapping* files of the next. Reads probe one file per level and obsolete data is bounded, but each byte entering a level is merged with up to T times its size. Used by LevelDB, RocksDB (default) and Cassandra LCS.

Hybrids. RocksDB’s default is already one: L0 tiered, deeper levels leveled. **Lazy leveling** tiers all levels but the last, which holds most data [Dayan and Idreos 2018]; Cassandra 5.0’s Unified Compaction Strategy slides between the two per level (as of 2025). **Time-window** compaction never merges across time windows, so expired windows are dropped whole.

Figure 13.9 — Size-tiered versus leveled compaction.





Reading the diagram. All arrows are asynchronous background compactions; clients wait only if a backlog triggers a write stall. Tiering copies each byte once per tier but

leaves up to three runs per tier. Leveling merges one L1 file (keys 100–199) with the ~10 overlapping L2 files and rewrites them: about ten bytes rewritten per byte promoted. All runs are SSTables on disk, read and written sequentially. Failure points: tiering's largest merge briefly needs double space; leveling can fall behind under heavy writes. Scaling: compaction parallelizes across key ranges and is rate-limited to protect foreground latency.

Mathematical foundations

FORMULA

Approximate amplification of compaction strategies

$$WA_{level} \approx 2 + L\,\frac{T+1}{2}, \qquad WA_{tier} \approx 2 + L, \qquad WA_{lazy} \approx 2 + (L-1) + \frac{T+1}{2}$$

$$R_{level} \approx L, \qquad R_{tier} \approx (T-1)L, \qquad R_{lazy} \approx (T-1)(L-1) + 1$$

Symbol	Meaning	Units
WA	Write amplification: bytes written to storage per byte written by the application (the 2 counts the WAL and the memtable flush)	dimensionless
R	Sorted runs a point lookup may probe in the worst case (excluding memtables)	runs
L	Number of levels (tiers), $\lceil \log_T (N/M) \rceil$	levels
T	Size ratio between levels; runs merged at once in tiering	dimensionless
N	Data size	bytes
M	Memtable flush size	bytes

The leveled term uses a simple average-case model: a byte entering a level is rewritten between about once (level nearly empty) and T times (level nearly full), so $(T+1)/2$ per level on average. The asymptotic analyses give leveling $O(T \cdot L)$ and tiering $O(L)$ write cost [Dayan et al. 2017]; real engines differ in constants (the RocksDB wiki notes leveled write amplification "often larger than 10").

WORKED EXAMPLE

Worked example — 1 TB of data, 100 MB flushes.

$N/M = 10^{12}/10^{8} = 10^{4}$.

1. **Leveled,** $T = 10$**:** $L = \log_{10} 10^{4} = 4$. $WA = 2 + 4 \times 5.5 = 24$. $R = 4$.
2. **Size-tiered,** $T = 4$**:** $L = \lceil \log_{4} 10^{4} \rceil = \lceil 6.64 \rceil = 7$. $WA = 2 + 7 = 9$. $R = 3 \times 7 = 21$.
3. **Lazy leveling,** $T = 10$**:** $L = 4$. $WA = 2 + 3 + 5.5 = 10.5$. $R = 9 \times 3 + 1 = 28$.
4. **Daily device writes** if the application writes 50 GB/day: leveled $24 \times 50 = 1200$ GB; tiered $9 \times 50 = 450$ GB; lazy $10.5 \times 50 = 525$ GB.
5. **Space amplification:** leveled $\approx 1 + 1/(T - 1) = 1.11$ (upper levels together are at most a ninth of the last); tiered, in the worst case of the whole dataset being overwritten, up to $T - 1 = 3$ copies at the largest tier plus temporary space for the merge in progress; lazy leveling ≈ 1.11, because its last level is leveled.

Interpretation. Tiering writes 2.7× less than leveling but may probe 5× more runs. Bloom filters (§13.10) make that cheap for point lookups — 21 runs at 1% false positives cost 0.21 wasted reads — but not for range scans. **Engineering implication.** Level for read-heavy, space-sensitive flash workloads; tier for write-heavy ingest. The SSD's own WAF multiplies on top: 1.2 TB/day at WAF 2 is 2.4 TB/day of flash wear (§5.6.3).

Table 13.5 — Compaction strategies compared.

	Size-tiered	Leveled	Tiered + leveled (lazy)
What it is	Merge runs of similar size	One sorted run per level	Tiers above, one run at the bottom
Write amplification	Low ($\approx L$)	High ($\approx T \cdot L/2$)	Low-medium
Point read (with Bloom filters)	Good	Best	Good
Range scan	Poor: many runs	Best	Medium
Space amplification	High; merge needs free space	~1.1	~1.1
Examples	Cassandra STCS, RocksDB universal	LevelDB, RocksDB default, Cassandra LCS	Dostoevsky; Cassandra UCS settings
Choose when	Ingest-heavy, few reads, ample disk	Read-heavy, updates, SSD cost matters	Mixed, write-heavy with point reads

Failure scenarios

Table 13.6 — LSM failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Writes stall or stop	Compaction cannot keep up; L0 file or pending-bytes limits hit	Stall counters; L0 file count	Add compaction threads; reduce ingest	Provision compaction I/O; tiered strategy for ingest
Disk full during compaction	Size-tiered merge needs free space for output	Free-space alerts during large merges	Add disk; switch strategy	Keep ~50% free with STCS; leveled compaction
Reads slow after mass delete	Tombstones not yet compacted away; scans skip millions	Tombstones scanned per query	Force compaction of the range	Range deletes; TTL-aware compaction
Deleted data reappears	Replica missed a tombstone that was purged before repair (Cassandra)	Repair or audit finds old values	Re-delete; repair	Repair within `gc_grace_seconds`

COMMON MISTAKE

"Compaction is housekeeping you can ignore." Compaction *is* the cost of an LSM tree: often 10–30 times the application's write volume, competing with reads for I/O, and its backlog decides whether writes stall. Budget compaction bandwidth, not just ingest.

13.10 Bloom filters in storage

A **Bloom filter** is a compact bit array answering "definitely not" or "probably yes" to set membership (full treatment in §17.4). LSM engines keep one per SSTable in memory, so most files lacking a key are skipped without I/O.

FORMULA

Bloom filter false-positive rate (summary of §17.4)

$$p \approx \left(1 - e^{-kn/m}\right)^{k}, \qquad k_{opt} = \frac{m}{n} \ln 2, \qquad p_{opt} \approx 0.6185^{m/n}$$

Symbol	Meaning	Units
p	Probability that an absent key gets "probably yes"	dimensionless
m	Bits in the filter	bits
n	Keys inserted	keys
k	Hash functions	count

WORKED EXAMPLE

Worked example — What filters save on a 1-billion-key LSM tree.

1. At $m/n = 10$ bits per key (the common RocksDB setting): $p = 0.6185^{10} = e^{10 \ln 0.6185} = e^{-4.805} \approx 0.0082$, with $k = 10 \ln 2 \approx 7$.
2. Memory: $10^9 \times 10/8 = 1.25$ GB.
3. A lookup for an absent key in a tree with 4 L0 files and 5 levels would otherwise read one data block per run: 9 reads. With filters: $9 \times 0.0082 \approx 0.07$ reads.
4. For a key that exists in the last level: 1 necessary read plus $8 \times 0.0082 \approx 0.07$ wasted reads.

Interpretation. Filters turn 9 I/Os into about one. **Engineering implication.** Keep filter memory (1.25 GB here) resident; evicted filter blocks make lookups regress sharply. Because ~90% of keys are in the last level, skipping its filters (RocksDB `optimize_filters_for_hits`) saves most of the memory when lookups usually succeed, and giving smaller levels more bits per key minimizes lookup cost for a fixed budget [Dayan et al. 2017].

13.11 Read, write and space amplification

13.11.1 The RUM conjecture

DEFINITION

Definition — RUM conjecture. For any access method, bounding two of **R**ead overhead, **U**pdate overhead and **M**emory (space) overhead forces the third to be worse: you can optimize for at most two [Athanassoulis et al. 2016].

A sorted array minimizes read and space overhead but makes inserts expensive; an append-only log minimizes update cost but reads slowly; a sparse hash table is fast both ways but wastes space. B-trees and LSM trees are two points in this triangle, and knobs such as fill factor, T and Bloom bits move an engine within it.

FORMULA

The three amplifications

$$RA = \frac{\text{bytes read from storage}}{\text{bytes returned}}, \qquad WA = \frac{\text{bytes written to storage}}{\text{bytes written by the application}}, \qquad SA = \frac{\text{bytes on storage}}{\text{bytes of live data}}$$

Symbol	Meaning	Units
RA	Read amplification (often counted instead as I/Os per lookup)	dimensionless
WA	Write amplification at the engine level, before the SSD's own WAF	dimensionless
SA	Space amplification	dimensionless

13.11.2 B-tree versus LSM, with numbers

WORKED EXAMPLE

Worked example — 100-byte random updates on a 2 TB table.

B-tree (InnoDB-style). Page $P = 16\,384$ bytes, doublewrite doubles each page write (§13.12), redo record about 150 bytes per update. Write amplification $WA \approx \frac{2P}{u \cdot r} + \frac{w}{r}$, where u is the number of updates a page absorbs before it is flushed, $r = 100$ and $w = 150$.

1. Uniformly random keys, data far larger than the buffer pool, so $u \approx 1$: $WA \approx 32\,768/100 + 1.5 = 329$.
2. Skewed keys so each flushed page carries $u = 20$ updates: $WA \approx 32\,768/2000 + 1.5 = 17.9$.

LSM (leveled, $T = 10$, from §13.9): $WA \approx 24$ regardless of key distribution, because compaction rewrites data in large sorted batches whatever the access pattern.

Reads. B-tree point lookup: 1 leaf read (internal pages cached). LSM: $1 + \approx 0.07$ block reads with Bloom filters; a range scan must merge every level, costing more CPU and up to one extra block per level.

Space. B-tree at 69% fill: $SA \approx 1.45$, and page compression is limited by fixed page boundaries. Leveled LSM: $SA \approx 1.11$, and SSTables compress well because blocks are packed densely.

Interpretation. For random small updates on large data the LSM tree writes about 14× less (329/24) and uses about 25% less space; with skewed updates the B-tree can write *less*. **Engineering implication.** Key locality, update size and read mix decide, not brand: measure bytes written to disk per byte written by the application on your workload.

INDUSTRY EXAMPLE

Uber’s move from PostgreSQL to MySQL (2016). Uber engineers reported that a PostgreSQL row update writes a new tuple version at a new physical location, so every index must be updated, multiplying writes and the WAL shipped to replicas; InnoDB’s secondary indexes point to the primary key, so updates to unindexed columns touch only the clustered index. Write amplification and replication bandwidth were among their reasons to migrate. Trade-off: InnoDB secondary lookups traverse two trees, and PostgreSQL HOT updates (§13.14.3) avoid index updates when no indexed column changes and the page has room. *Evidence: Primary* — [Klitzke 2016]

13.12 Durability: fsync, checksums and torn writes

`fsync`, its pitfalls and group commit are covered in §6.14.3. This section adds the database's defenses against storage that returns the wrong bytes.

13.12.1 Checksums

Storage can return the wrong bytes: **bit rot**, firmware bugs, **misdirected writes** and **lost writes** (acknowledged but never made). Engines checksum every layer: page headers, verified on each read (InnoDB CRC-32C by default; PostgreSQL's 16-bit page checksum, enabled by default by `initdb` from version 18); every WAL record, so recovery stops at the first torn record (as the toy LSM does); and every SSTable block. Checksums detect; repair comes from a replica, a backup or, for torn writes, the mechanisms below.

13.12.2 Torn writes

> DEFINITION
>
> **Definition — Torn write (torn page).** A page write that is interrupted by a crash so that part of the page on disk is new and part is old. It arises because the database page (8 or 16 KiB) is larger than the unit the device or file system writes atomically (commonly 4 KiB or 512 bytes).

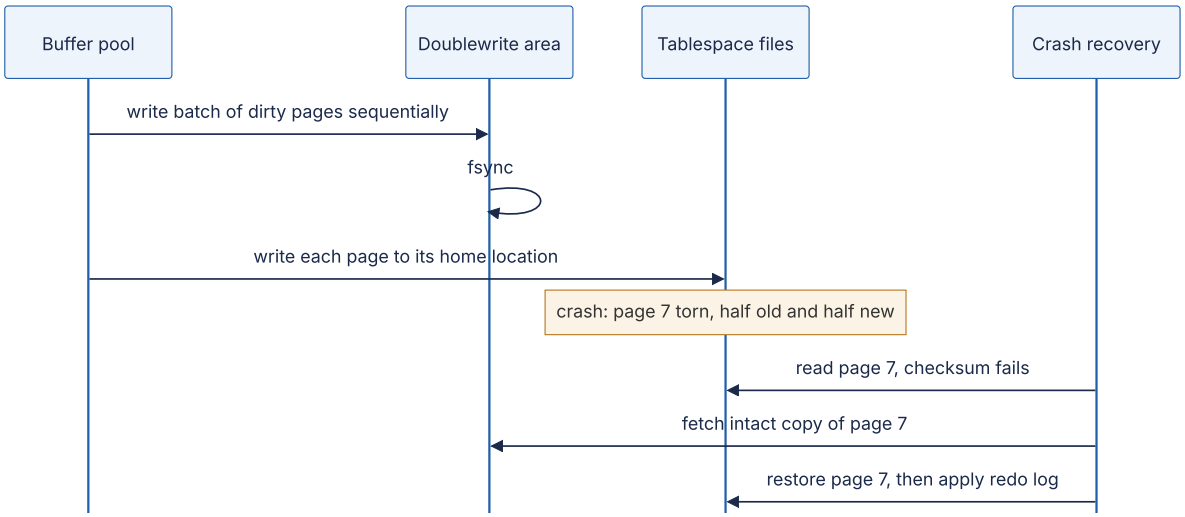
Physiological redo records assume an internally consistent page; applied to a half-old, half-new page they produce garbage, so the engine needs an intact copy from somewhere.

13.12.3 Full-page writes and the doublewrite buffer

PostgreSQL full-page writes. With `full_page_writes = on` (default), the first change to each page after a checkpoint logs the *whole* page; recovery restores the image and replays later records onto it [PostgreSQL Docs: WAL Configuration]. The cost is extra WAL after each checkpoint (§13.5.3).

InnoDB doublewrite buffer. Dirty pages are first written sequentially to a **doublewrite** area and flushed, then written in place; a page torn in place is restored from its intact copy. Because the extra writes are sequential batches with one flush, the cost is well under 2× [MySQL Docs: Doublewrite Buffer].

Figure 13.10 — InnoDB doublewrite protecting against a torn page.



Reading the diagram. Every arrow is synchronous. An intact copy of each page is durable in the doublewrite area (separate files since MySQL 8.0.20) before any home location is touched. At recovery, a checksum failure flags the torn page, its copy replaces it, and redo proceeds. A crash before the doublewrite flush leaves the home page intact, so redo alone suffices. The doublewrite area costs bandwidth, not IOPS. Failure point: disabling it on storage without atomic page writes silently reopens the torn-page window.

Both can be disabled when the layer below writes pages atomically (ZFS, some SSDs and cloud volumes). LSM trees and Bitcask never overwrite: a torn SSTable never entered the manifest, and a torn log tail fails its CRC.

Table 13.7 — Durability mechanisms in storage engines.

Threat	Mechanism	Cost	Examples
Lost committed transaction	WAL + `fsync` at commit (§6.14.3)	One flush per commit group	All engines
Torn data page	Full-page images in WAL	Extra WAL after checkpoints	PostgreSQL
Torn data page	Doublewrite buffer	Second sequential page write	InnoDB
Torn data page	Never overwrite in place	Path copying or compaction	LMDB, ZFS, LSM trees
Silent corruption	Page, record and block checksums	CPU per read; detection only	InnoDB, PostgreSQL, RocksDB
Corruption detected	Re-copy from replica or backup	Operational	All

13.13 Columnar storage

13.13.1 Rows versus columns

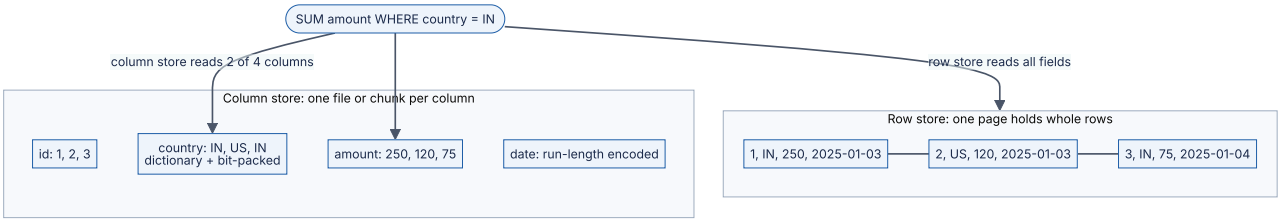
DEFINITION

Definition — Columnar storage (column store). A layout that stores each column of a table contiguously — all values of `price`, then all values of `country` — instead of storing each row's fields together. Column stores are optimized for analytical queries that read a few columns of many rows [Abadi et al. 2013].

First-principles explanation

A school keeps one card per student. To find one address, cards are perfect; to average 10,000 ages you handle 10,000 cards and ignore most of each, whereas one sheet of ages would do. Transaction processing (OLTP) touches whole rows by key: rows win. Analytics (OLAP) aggregates a few columns over millions of rows: columns win.

Figure 13.11 — Row-oriented versus column-oriented layout of the same table.



Reading the diagram. The same rows stored two ways; arrows are synchronous reads. The row store must read every field of every scanned row; the column store reads only `country` and `amount`, each encoded to suit its values. Failure point: a single-row insert or update touches every column file, so column stores buffer writes in a small row-oriented store and convert in batches. Scaling: columns are scanned in parallel or skipped entirely.

13.13.2 Encoding, vectorized execution and Parquet

Values in one column share a type and often repeat, so they compress far better than rows. Three encodings do most of the work:

- **Dictionary encoding** replaces each value with a small integer code into a dictionary of distinct values.
- **Bit-packing** stores codes in exactly $\lceil \log_2 d \rceil$ bits for d distinct values, with no byte padding.
- **Run-length encoding (RLE)** stores `(value, count)` pairs, ideal for sorted or clustered columns.

Queries can often run on encoded data directly: a filter `country = 'IN'` becomes “code = 3”, and on RLE data a count is a sum of run lengths.

```
        """Dictionary encoding, run-length encoding and bit-packing for one column."""
        import math
        import random

        def dictionary_encode(values):
            dictionary = sorted(set(values))
            code = {v: i for i, v in enumerate(dictionary)}
            return dictionary, [code[v] for v in values]

        def run_length_encode(codes):
            runs = []                                   # list of [value, run_length]
            for c in codes:
                if runs and runs[-1][0] == c:
                    runs[-1][1] += 1
                else:
                    runs.append([c, 1])
            return runs

        def bit_pack(codes, width):
            packed = 0
            for i, c in enumerate(codes):
                packed |= c << (i * width)              # width bits per value, no byte
padding
            return packed.to_bytes(math.ceil(len(codes) * width / 8), "little")

        def bit_unpack(data, width, n):
            packed, mask = int.from_bytes(data, "little"), (1 << width) - 1
            return [(packed >> (i * width)) & mask for i in range(n)]

        if __name__ == "__main__":
            rng = random.Random(7)
            countries = ["BR", "DE", "FR", "IN", "JP", "US"]
            # 100,000 rows sorted by country, as a column store would often keep them
            column = sorted(rng.choice(countries) for _ in range(100_000))
            raw = sum(len(v.encode()) for v in column)

            dictionary, codes = dictionary_encode(column)
            width = max(1, math.ceil(math.log2(len(dictionary))))
            packed = bit_pack(codes, width)
            runs = run_length_encode(codes)
            assert bit_unpack(packed, width, len(codes)) == codes

            print("raw bytes:", raw)
            print("dictionary:", dictionary, "-> width", width, "bits per value")
            print("bit-packed bytes:", len(packed), " ratio %.1fx" % (raw /
len(packed)))
            print("RLE runs:", len(runs), "-> about", len(runs) * 5, "bytes (1-byte code
+ 4-byte length)")
            # a filter can run on codes: count rows WHERE country = 'IN' without decod-
ing strings
```

```
target = dictionary.index("IN")
print("rows with IN:", sum(length for c, length in runs if c == target))
```

Output:

```
raw bytes: 200000
dictionary: ['BR', 'DE', 'FR', 'IN', 'JP', 'US'] -> width 3 bits per value
bit-packed bytes: 37500  ratio 5.3x
RLE runs: 6 -> about 30 bytes (1-byte code + 4-byte length)
rows with IN: 16536
```

What to notice:

- Six distinct values need $\lceil \log_2 6 \rceil = 3$ bits, so 100,000 values pack into $100\,000 \times 3/8 = 37\,500$ bytes.
- Sorted, the column collapses to six runs; the `WHERE country = 'IN'` count is computed from runs without decoding any string. Sort order is therefore a physical design decision in column stores.

FORMULA

Size of a dictionary-encoded, bit-packed column

$$S \approx \frac{N \lceil \log_2 d \rceil}{8} + d \cdot \bar{v}$$

Symbol	Meaning	Units
S	Encoded column size	bytes
N	Number of rows	rows
d	Number of distinct values	values
$\bar{v}$	Average size of one dictionary entry	bytes

WORKED EXAMPLE

Worked example — Scanning one column of a billion-row fact table.

A table has $N = 10^9$ rows and 20 columns averaging 8 bytes: 1.6×10^{11} bytes $= 160$ GB as rows. A query sums `amount` (8 bytes, uncompressed here) where `country` has $d = 200$ values of about 10 bytes.

1. Row store: reads all 160 GB.
2. Column store, `country`: $\lceil \log_2 200 \rceil = 8$ bits; $S = 10^9 \times 8/8 + 200 \times 10 = 1.0$ GB (the 2 KB dictionary is negligible).
3. Column store, `amount`: $10^9 \times 8 = 8$ GB. Total: 9 GB.
4. At 2 GB/s of scan bandwidth: row store $160/2 = 80$ s; column store $9/2 = 4.5$ s, about 18× faster before any further compression of `amount` or skipping of blocks.

Interpretation. Reading only needed columns, tightly encoded, cuts bytes scanned by an order of magnitude. **Engineering implication.** Use column formats for analytics, with per-block min/max statistics (**zone maps**) so filters skip blocks; the bottleneck then moves to CPU.

That CPU bottleneck is attacked with **vectorized execution**: operators process batches of about a thousand values from one column in tight loops, instead of one row at a time through a chain of virtual function calls. The loops stay in the CPU cache, avoid branch mispredictions and use SIMD instructions (§5.11) [Boncz et al. 2005]. **Late materialization** keeps data as column positions as long as possible and assembles full rows only for the final result.

Apache Parquet, the most widely used open columnar file format, applies all of this to files: a file is divided into **row groups**, each row group stores one **column chunk** per column, chunks are divided into pages with dictionary, RLE and bit-packed encodings, and a footer holds the schema and per-chunk statistics used to skip data [Apache Parquet Docs]. Parquet, ORC, and lakehouse table formats built on them are treated in Chapter 61; distributed scans over them in Chapter 29.

COMMON MISTAKE

“A column store is just a row store with column indexes.” A column store changes what is read, how it is compressed and how operators execute. Single-row writes and lookups are expensive in it, so OLTP stays in row stores, with changes streamed to a column store for analytics (§32.6).

13.14 Case studies: InnoDB, RocksDB and the PostgreSQL heap

13.14.1 InnoDB: a clustered B+ tree with redo, undo and doublewrite

InnoDB, MySQL's default engine, stores each table as a **clustered index**: a B+ tree keyed by the primary key whose leaf pages (16 KiB) hold the full rows. Secondary indexes store the primary-key value, not a physical address, so a secondary lookup traverses two trees, but rows can move between pages during splits without touching secondary indexes. The buffer pool uses midpoint-insertion LRU (§13.4.2) and, on Linux from MySQL 8.4, `O_DIRECT`. Durability combines the redo log, undo logs for rollback and MVCC reads (§13.5.4), and the doublewrite buffer (§13.12.3). Choose it for OLTP workloads accessed mostly by primary key, with compact, roughly increasing primary keys: random keys such as UUIDv4 cause splits all over the tree and poor page fill. *Evidence: Primary* — [MySQL Docs: InnoDB Architecture].

13.14.2 RocksDB: an embeddable LSM engine

RocksDB began at Facebook in 2012 as a fork of Google's LevelDB, optimized for flash and many cores. It is a library, not a server: applications embed it and get the full machinery of §13.8–§13.10 — WAL, skip-list memtables, block-based SSTables with Bloom (or the more compact Ribbon) filters, a block cache, leveled compaction by default with universal (tiered) and FIFO alternatives, and **column families** that share a WAL but have separate memtables and SSTables. It is the storage layer of many distributed databases and stream processors, including TiKV and Kafka Streams state stores.

> INDUSTRY EXAMPLE
>
> **MyRocks at Facebook.** Facebook built MyRocks, a MySQL storage engine on RocksDB, and migrated its main user database from compressed InnoDB to it. The motivation was space and write amplification on flash: B-tree pages were partly empty and compressed poorly at page granularity, and random page writes wore SSDs, whereas leveled LSM compaction stores data densely and writes sequentially. The authors report substantial reductions in storage and write volume, and describe the engineering needed to make LSM reads, range scans and tombstone handling competitive. *Evidence: Primary* — [Matsunobu et al. 2020; Dong et al. 2017]

13.14.3 PostgreSQL heap: append-friendly pages with MVCC versions

PostgreSQL stores a table as an unordered **heap** of 8 KiB slotted pages (§13.3). A row version (tuple) carries `xmin` / `xmax`, the IDs of the transactions that created and deleted it (visibility rules: §11.14.2). An `UPDATE` never overwrites: it writes a new tuple version — on the same page if there is room, else elsewhere — and marks the old one deleted. All in-

dexes are secondary and point to a tuple's physical location `(block, slot)`, the `ctid`. Two optimizations limit the cost. A **heap-only tuple (HOT)** update, possible when no indexed column changes and the new version fits on the same page, links the versions within the page and adds no index entries; a lower `fillfactor` leaves room for it. **`VACUUM`** later removes dead versions, records reusable space in the **free space map**, and marks all-visible pages in the **visibility map**, which enables index-only scans. Large values are moved out of line by TOAST. Recovery is redo-only from the WAL with full-page writes (§13.5, §13.12.3). *Evidence: Primary* — [PostgreSQL Docs: Database Physical Storage; Routine Vacuuming].

Table 13.8 — B-tree versus LSM storage engines.

	B-tree (in place)	LSM tree
What it is	Pages updated in place in a balanced tree	Memtable flushed to immutable sorted runs, merged by compaction
How it works	WAL + buffer pool; splits on overflow	WAL + memtable; flush; tiered or leveled compaction
Advantages	One I/O point reads; fast range scans; mature locking	Sequential writes; low WA for random updates; dense, compressible storage
Disadvantages	Random writes; page-sized WA; fragmentation; torn-page protection	Many runs per read; compaction debt and write stalls; tombstones
Performance	Read-optimized; writes depend on key locality	Write-optimized; point reads near B-tree with Bloom filters; scans slower
Operational complexity	Fill factor, checkpoints, `VACUUM` (PostgreSQL)	Compaction strategy, L0 limits, filters, rate limits: many knobs
Cost	More space (SA ≈ 1.45); more flash wear for random updates	Less space (SA ≈ 1.1); compaction CPU and I/O
Use cases	OLTP, relational databases, secondary-index-heavy workloads	Ingest-heavy, key-value, time series, wide-column stores
Choose when	Read-heavy or locality-rich updates; latency predictability	Write-heavy or random updates on large data; space-sensitive SSD fleets

13.15 Summary and revision notes

SUMMARY

- Engines read, write, cache and log in **pages** (4–16 KiB). **Slotted pages** give records stable `(page, slot)` IDs while allowing variable lengths and in-page compaction; per-row and per-page overhead alone can make a table ~1.4× its raw data.
- A **buffer pool** maps page IDs to frames with pin counts and dirty flags. Clock and LRU-K approximate LRU cheaply and resist scans; `O_DIRECT` avoids double buffering. The five-minute rule says that on NVMe only pages re-referenced every ~30 s are worth caching on cost.
- **WAL** turns random page writes into sequential log appends. The WAL rule ($\text{pageLSN} \le \text{flushedLSN}$) and commit rule enable steal/no-force. **ARIES** recovers with analysis, redo (repeat history) and undo (with CLRs). Checkpoint interval trades recovery time (W_{redo}/b_{replay}) against full-page-image volume.
- **B-trees** of height 3–4 index billions of rows; lookups cost about one I/O when internal pages are cached. Splits are logged atomically; latch crabbing and B-link trees provide concurrency; **COW B-trees** (LMDB) need no WAL but copy the root-to-leaf path on each commit.
- **Log-structured** storage appends everything. **Bitcask** keeps every key in RAM for one-seek reads; **LSM trees** add sorted memtables, SSTables with sparse indexes and Bloom filters, and compaction.
- **Compaction**: leveled $WA \approx 2 + L(T + 1)/2$, few runs, $SA \approx 1.1$; tiered $WA \approx 2 + L$, many runs, more space; hybrids sit between. Compaction bandwidth must be capacity-planned.
- **Bloom filters** at 10 bits/key give ~0.8% false positives and reduce absent-key lookups from one read per run to a few hundredths of a read.
- **RUM**: you can bound only two of read, update and space overhead. For random small updates, LSM WA (~24) can be >10× lower than a B-tree's (~329); for skewed updates the B-tree can win.
- **Durability** needs `fsync` plus checksums (detection) plus torn-page protection (full-page writes, doublewrite, or never overwriting).
- **Column stores** read only needed columns, encode them (dictionary, bit-packing, RLE) and execute vectorized; Parquet brings this to files.

13.16 Knowledge checkpoint

1. Why does a slotted page store slot numbers in index entries rather than byte offsets?

2. Compute the rows per 8 KiB page for 50-byte rows in PostgreSQL (24-byte tuple header, 8-byte alignment, 4-byte slots, 24-byte page header).
3. What are a pin count and a dirty flag for, and what happens if a thread forgets to unpin?
4. Explain sequential flooding and two mechanisms that prevent it.
5. State the WAL rule and the commit rule.
6. What do steal and no-force mean, and which one requires undo?
7. Why does ARIES redo the changes of loser transactions before undoing them?
8. What is a CLR and why does it make recovery safe against crashes during recovery?
9. Calculate the height of a B+ tree with 500 million rows, 100 rows per leaf and fan-out 500.
10. What limits Bitcask's scalability?
11. List the steps of an LSM point lookup.
12. For $N/M = 10^4$, compute the write amplification of leveled ($T = 10$) and tiered ($T = 4$) compaction with the chapter's model.
13. What is a torn write and how do PostgreSQL and InnoDB each defend against it?
14. How many bits per value does bit-packing need for a column with 1,000 distinct values?

Answers

1. So records can move within the page (updates, compaction) without changing their identifier or any index entry.
2. Tuple $24 + 50 = 74$, aligned to 80; with slot 84 bytes. $\lfloor 8168/84 \rfloor = 97$ rows.
3. Pin count prevents eviction of a page in use; dirty flag means it must be written back before reuse. A leaked pin keeps the frame unevictable forever, shrinking the pool.
4. A large scan touches each page once and evicts the hot set under LRU. Prevent with LRU-K/2Q/midpoint insertion (one-touch pages never reach the protected list) or ring buffers for bulk scans.
5. WAL rule: log records up to a page's LSN must be durable before the page is written. Commit rule: a commit is acknowledged only after its commit record is durable.
6. Steal: uncommitted changes may be written to disk (requires undo). No-force: committed changes need not be written at commit (requires redo).
7. Repeating history restores the exact pre-crash page state, so logical undo records apply correctly and fine-grained locking is supported.
8. A compensation log record logs each undo action with `undoNextLSN`; after a crash during recovery, CLRs are redone and undo resumes where it stopped, never undoing twice.
9. Leaves $= 5 \times 10^6$; $\log_{500} 5 \times 10^6 = 15.42/6.21 = 2.48 \rightarrow 3$ internal levels; $h = 4$.
10. Every key must fit in the in-memory keydir; no range queries.
11. Active and immutable memtables; each L0 file newest first; one file per deeper level; within each, Bloom filter, index block, one data block; first version found wins;

tombstone means deleted.

12. Leveled: $L = 4$, $WA = 2 + 4 \times 5.5 = 24$. Tiered: $L = 7$, $WA = 9$.
13. A crash leaves a page part old, part new. PostgreSQL logs a full page image on first modification after a checkpoint; InnoDB writes pages to a doublewrite area and flushes before writing in place.
14. $\lceil \log_2 1000 \rceil = 10$ bits.

13.17 Interview questions

Basic

Q1. What is a write-ahead log and why does it make databases fast as well as safe? Answer. An append-only log of changes, made durable before the changed pages. Commits need one sequential append and `fsync` (shared across concurrent commits by group commit) instead of random page writes; pages are flushed later in batches. After a crash, redo restores committed changes and undo removes uncommitted ones.

Q2. When would you choose an LSM-based store over a B-tree-based one? Answer. For write-heavy workloads with random keys on large data — event ingestion, time series, key-value at scale — and when space on SSD matters: LSM writes sequentially with lower write and space amplification. Prefer a B-tree for read-heavy OLTP, range scans and predictable latency. Then check compaction bandwidth and read amplification.

Intermediate

Q3. Your RocksDB-backed service shows periodic write latency spikes of several seconds. What is happening and what do you do? Answer. Most likely write stalls: compaction falls behind, L0 file count or pending compaction bytes exceed thresholds, and RocksDB slows or stops writes. Confirm with stall statistics and L0 counts. Fixes: more compaction threads and I/O budget, larger memtables, a rate limiter to smooth compaction, faster disks, or a tiered strategy if writes dominate; reduce ingest bursts with backpressure (§22.10).

Q4. Why do many databases bypass the operating system page cache, and why does PostgreSQL traditionally not? Answer. Bypassing with `O_DIRECT` avoids double caching, gives the engine control over eviction, read-ahead and write ordering, and makes memory use predictable — InnoDB's design. PostgreSQL uses buffered I/O with a moderate `shared_buffers`, letting the page cache act as a second-level cache; this is simpler and portable but double-caches some pages and cedes writeback control to the kernel. Either way durability still requires `fsync`.

Advanced

Q5. Estimate and compare write amplification for a B-tree and a leveled LSM tree on 100-byte random updates, and say when the answer flips. Answer. B-tree: each flushed 16 KiB page, doubled by doublewrite, carries about one update when keys are random and data exceeds RAM: $32\,768/100 + 1.5 \approx 329$. Leveled LSM with $T = 10$, $L = 4$: ≈ 24. The answer flips with locality: if each page absorbs 20+ updates before flushing, the B-tree drops below 20. Add the SSD's own WAF on top and compare `bytes written / bytes ingested` in production.

Q6. Walk through crash recovery in an ARIES-style engine after a crash during a long transaction. Answer. Analysis from the last checkpoint rebuilds the dirty page table and finds the long transaction as a loser. Redo from the minimum `recLSN` reapplies every change whose LSN exceeds the page's `pageLSN`, including the loser's. Undo follows the loser's `prevLSN` chain backward, writing CLRs; a crash during undo is handled by redoing CLRs and continuing from `undoNextLSN`. Undo time grows with the transaction's size, which is why long transactions lengthen recovery and should be bounded.

13.18 Practical exercises

1. **Extend the toy LSM.** Replace full-merge compaction in `toy_lsm.py` with leveled compaction (L0 plus levels of non-overlapping files with $T = 4$). Measure write amplification as data grows and compare with $2 + L(T + 1)/2$.
2. **Measure Bloom filters.** Count SSTable reads per `get` with and without Bloom filters for absent keys in the toy LSM; vary bits per key from 2 to 16 and compare with $0.6185^{m/n}$.
3. **Observe PostgreSQL pages.** With the `pageinspect` extension, insert rows into a table, run `UPDATE`s, and inspect `page_header` and `heap_page_items` before and after `VACUUM`; identify HOT chains and dead line pointers.
4. **Checkpoint trade-off.** On a test PostgreSQL instance under `pgbench`, measure WAL volume per minute with `checkpoint_timeout` at 1 and 15 minutes, then crash it (`kill -9`) and time recovery. Compare with §13.5.3.

13.19 Design challenges

1. **Metrics ingestion store.** Design the storage engine configuration for 2 million data points per second (16 bytes each), 30-day retention and queries over the last hour. Choose B-tree, leveled, tiered or time-window compaction; estimate write amplification, daily device writes, disk size and SSD lifetime (§5.6.3); explain how expired data is deleted cheaply.

2. **User-profile database.** 500 million profiles of 2 KB, 50,000 reads/s by user ID, 5,000 updates/s of single fields, p99 read latency under 5 ms. Compare InnoDB, PostgreSQL and RocksDB; size the buffer pool or block cache with the five-minute rule; estimate write and space amplification; describe torn-page and checksum protection.

13.21 Open verification items

- MySQL 8.4 Linux default `innodb_flush_method = O_DIRECT` (confirmed via secondary sources and the 8.4 manual summary; primary page not fetched).

- PostgreSQL `debug_io_direct` introduced in version 16 and the version-18 asynchronous I/O subsystem: wording and defaults.
- PostgreSQL clock-sweep usage-count cap of 5 and ring-buffer behavior (from the buffer README; not re-read for this edition).
- Exact storage and write reductions reported in [Matsunobu et al. 2020]; deliberately not quoted.
- Cassandra guidance to keep ~50% free disk for STCS; Cassandra 5.0 UCS description.
- Uber blog URL (original path may have changed).
- The compaction formulas are a simplified average-case model, not taken verbatim from one source.

Chapter 14 — Database Scaling: Replication, Partitioning and Sharding

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

A single database server is the most comfortable place your data will ever live: every row in one place, every transaction consistent, every join just a join. Three limits end that comfort. Reads outgrow one machine, writes outgrow one machine, or the data outgrows its disks. Chapter 2 sketched this for QuickBite: one PostgreSQL primary handles 60 orders per second easily, 600 needs read replicas, and 6,000 probably needs partitioning (§2.10).

Replication keeps copies of the same data on several nodes. It adds read capacity and survives failures but adds no write capacity or storage. **Partitioning** (also called **sharding**) splits the data into subsets on different nodes. It adds write capacity and storage but makes queries that span subsets harder. Real systems do both: every partition is replicated. Consistency guarantees are treated in depth in Chapter 25, leaderless replication and conflict resolution in Chapter 27, and distributed transactions in Chapter 28.

14.1 Learning objectives

After this chapter you should be able to:

- Draw a primary–replica architecture and compare synchronous, asynchronous and semi-synchronous replication by latency, durability and availability.
- Explain how replication lag causes read-your-writes and monotonic-read anomalies, and design routing that prevents them.
- Distinguish statement-based, row-based, physical and logical replication, and say when multi-primary replication is worth its conflicts.
- Compare range, hash, list and directory partitioning, choose a shard key, and compute the number of shards from data size, write rate and per-node limits.
- Build a consistent-hash ring with virtual nodes, derive how load imbalance shrinks with the number of virtual nodes V, and compare it with jump and rendezvous hashing.
- Plan an online resharding, mitigate hot partitions and choose local or global secondary indexes.
- Explain the cost of cross-shard queries and transactions, and place PgBouncer, ProxySQL and Vitess in an architecture.

14.2 Prerequisites

- Transactions, ACID and isolation levels — §11.11–§11.13 (replication and sharding change what a transaction can guarantee).
- Indexes and B+ trees — §11.7–§11.8 (secondary indexes become a distributed problem).
- Write-ahead logging — §13.5 (physical replication ships the WAL).
- Little's Law and connection pools — §4.11 and the pool-sizing examples in Chapter 4 (used again in §14.13).
- Hash functions — §17.3 at an intuitive level: a hash maps any key to a well-mixed number.

14.3 Read replicas and primary–replica architecture

14.3.1 The primary–replica model

> DEFINITION
>
> **Definition — Replication.** Keeping a copy of the same data on more than one node. Each copy is a **replica**. In **primary-replica replication**, exactly one node, the **primary** (called the "master" in older documentation), accepts writes and streams its changes to the **replicas**, which apply them in the same order and serve reads.

First-principles explanation

Think of a newspaper. One newsroom writes the stories, and printing plants in many cities print identical copies. Readers get the paper quickly from a local plant, but every correction must go through the newsroom, every plant must print every story, and a distant reader may hold yesterday's edition for a while. The newsroom is the primary, the plants are replicas and the delay is **replication lag**. Reads scale with the number of plants. Writes do not scale at all.

Why does this exist?

Most applications read far more than they write, often 10 to 100 reads per write. Copying the data to more nodes and spreading the reads is the cheapest way to multiply read capacity, with no schema change. Replicas are also a **hot standby**: a replica that already holds nearly all the data can be promoted in seconds if the primary dies.

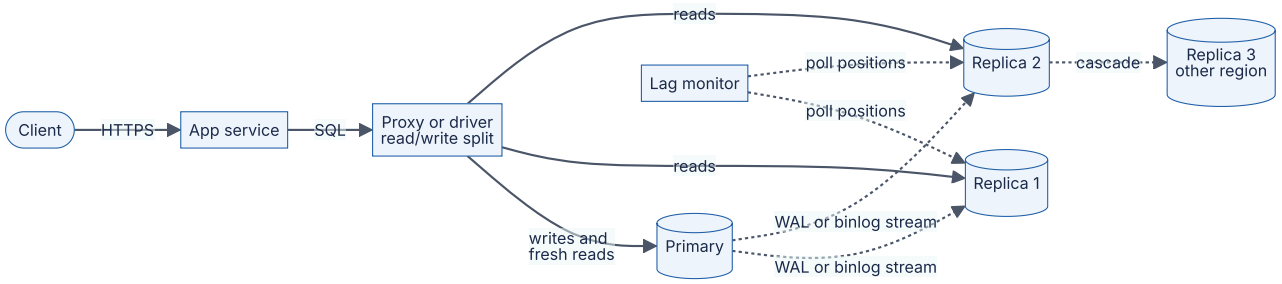
How it works internally

1. A client sends a write (`INSERT`, `UPDATE`, `DELETE`) to the primary.

2. The primary records the change in its **replication log**: the write-ahead log (WAL, §13.5) in PostgreSQL, the **binary log** (binlog) in MySQL.
3. It commits, waiting first for replica acknowledgments if the replication mode requires it (§14.4).
4. A sender process streams new log records to each replica over a long-lived TCP connection. Each replica logs them and **applies** them in order.
5. Read-only queries go to replicas, routed by the application, a driver or a proxy (§14.13).
6. Each replica tracks its applied position: a log sequence number (LSN) in PostgreSQL or a global transaction identifier (GTID) set in MySQL. The gap to the primary's position is the replication lag.

Architecture diagram

Figure 14.1 — Primary–replica architecture with read/write splitting.



Reading the diagram. A proxy or driver sends writes and must-be-fresh reads to the primary and other reads to replicas, synchronously. Replication (dotted) is asynchronous by default, so replicas lag. Replica 3 is fed by Replica 2 (**cascading replication**), sparing the primary's fan-out to distant regions. Each node stores a full copy. The lag monitor removes lagging replicas from rotation. Failure points: the primary, until a replica is promoted (§27.11), and the intermediate replica for everything below it.

Mathematical foundations

Every write is applied on every node, so the write stream consumes part of each replica's capacity.

FORMULA

Read capacity of a replicated group

$$R_{\max} = n \cdot (u \cdot c - w) \qquad \text{valid only while } w < u \cdot c$$

Symbol	Meaning	Units
$R_{\max}$	Maximum sustainable read rate across the group	reads/s
n	Number of nodes serving reads (replicas, plus the primary if it serves reads)	nodes
c	Capacity of one node, expressed in read-equivalent operations	ops/s
u	Target utilization, leaving headroom for spikes and failover	dimensionless (0–1)
w	Cost of applying the full write stream on one node, in read-equivalent operations	ops/s

WORKED EXAMPLE

Worked example — When do more replicas stop helping? Assume one node handles $c = 20,000$ read-equivalent operations per second, and you run it at $u = 0.6$, so 12,000 ops/s of budget. Applying one write costs about as much as 3 reads.

1. At 1,000 writes/s, $w = 3,000$. Each replica has $12,000 - 3,000 = 9,000$ ops/s for reads. Four replicas give $R_{\max} = 4 \times 9,000 = 36,000$ reads/s.
2. At 3,000 writes/s, $w = 9,000$. Each replica has 3,000 ops/s left. Four replicas give only 12,000 reads/s. Even 12 replicas give 36,000.
3. At 4,000 writes/s, $w = 12,000 = u \cdot c$. Replicas have no read budget left at all, and they can barely keep up with the write stream.

Interpretation. Replicas multiply *spare* capacity, and the write stream eats into every node's spare capacity equally. **Engineering implication.** Read replicas are the right first move when writes are a small fraction of load. Once applying writes uses about half a node's budget, partition (§14.6).

Real-world industry applications

INDUSTRY EXAMPLE

PostgreSQL and MySQL. PostgreSQL streams WAL to **hot standby** servers, which serve read-only queries while applying changes. MySQL replicas pull binlog events and apply them with one or more parallel applier threads. Managed services such as Amazon RDS expose the same mechanism as "read replicas". *Evidence: Primary* — [PostgreSQL Docs: High Availability], [MySQL Docs: Replication]

Advantages and disadvantages

Replicas are simple to add, give a warm standby and can isolate heavy analytical queries. But they add no write or storage capacity, each one is a full copy, reads may be stale, and asynchronous failover can lose the last few transactions (§14.4).

Failure scenarios

Table 14.1 — Failure scenarios for read replicas.

What goes wrong	Why	Detection	Recovery	Prevention
Users see stale data	Replica applies changes seconds behind	Lag metric; user reports "my edit vanished"	Route that user's reads to primary	Read-your-writes routing (§14.4.4)
Replica falls ever further behind	Single-threaded apply, or a long query blocks apply	Lag grows steadily	Kill blocking queries; enable parallel apply	Parallel apply; cap query time on replicas
Data lost on failover	Async replica promoted before receiving last commits	Gap in GTIDs or LSNs after promotion	Reconcile from old primary if it is reachable	Semi-sync or sync replica as failover target

Common misconceptions

COMMON MISTAKE

Mistake — "Add replicas until the database is fast enough." Replicas help only reads that tolerate staleness. If the primary is busy with writes or must-be-fresh reads, more replicas change nothing.

14.4 Synchronous, asynchronous and semi-synchronous replication

14.4.1 Three modes of acknowledgment

DEFINITION

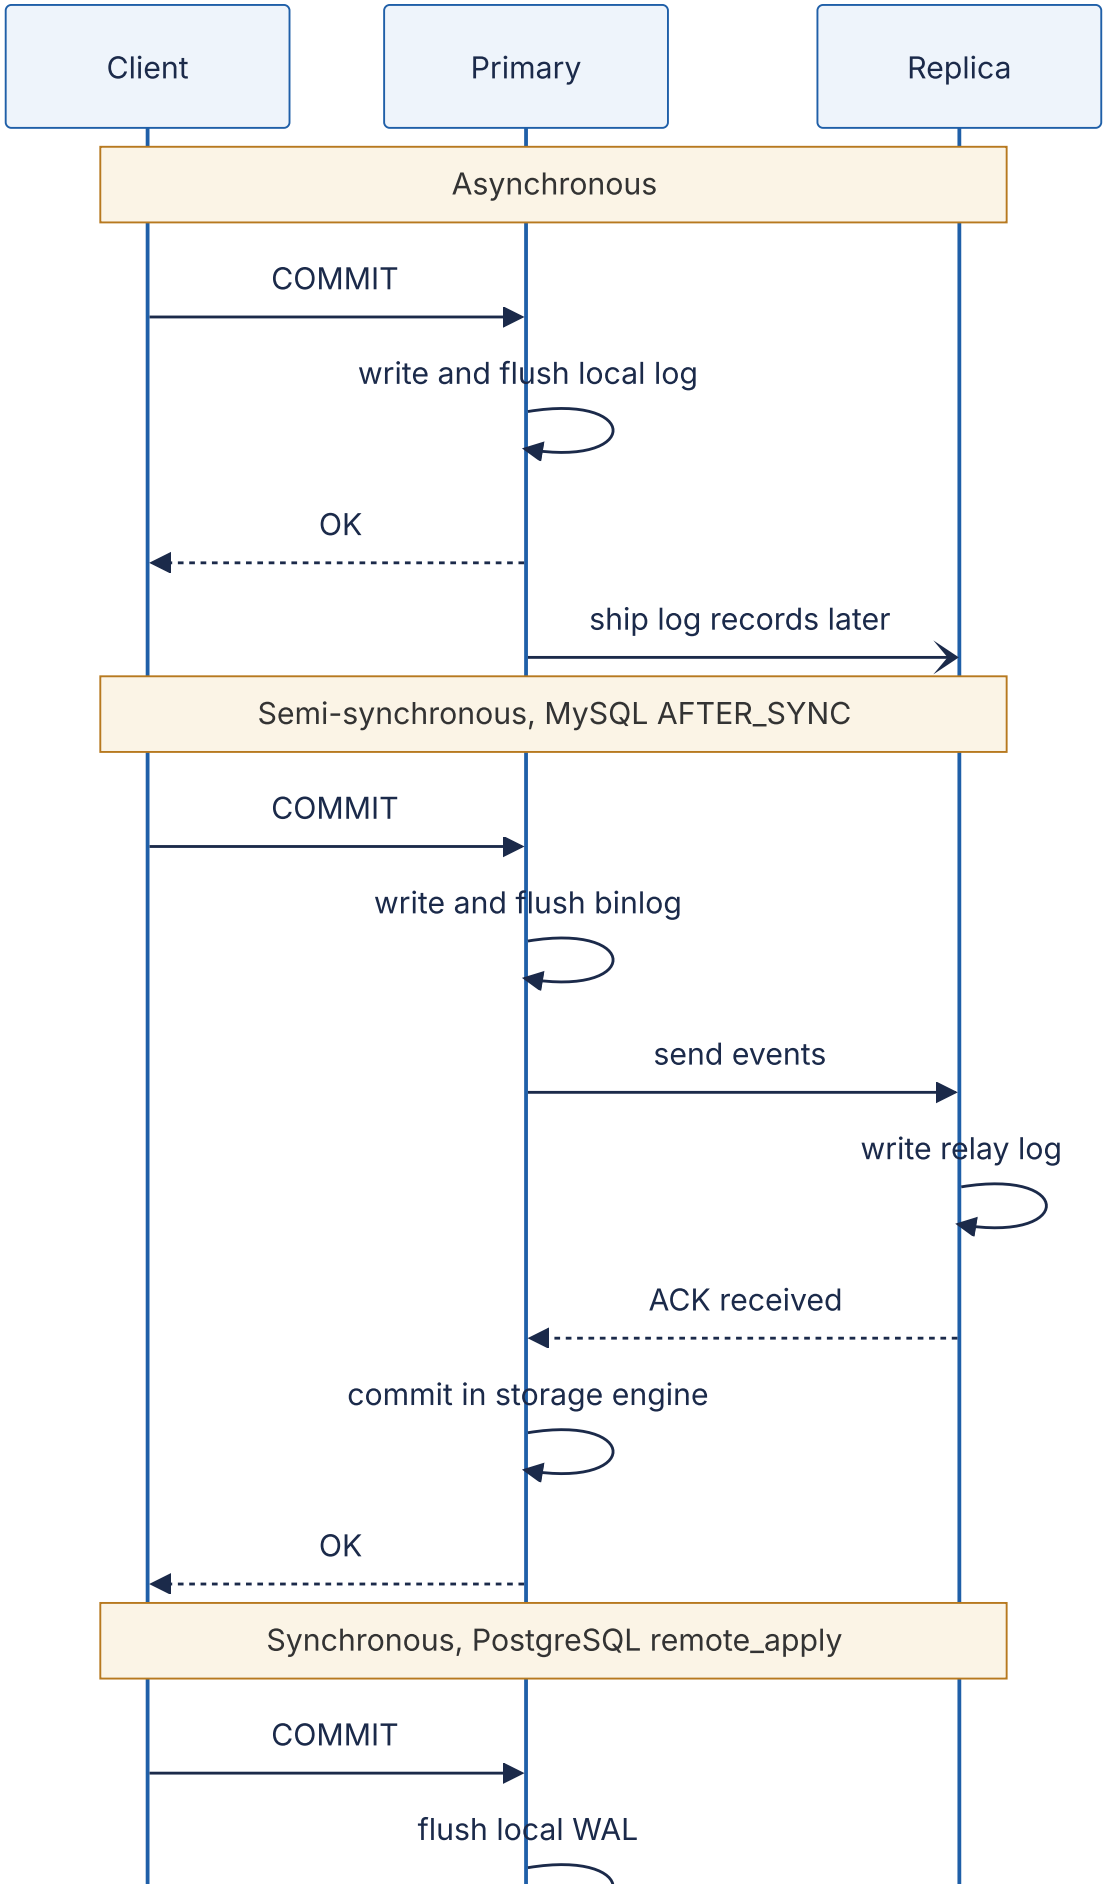
Definition — Replication modes. In **synchronous replication**, the primary reports a commit only after at least one designated replica has durably received (or applied) it. In **asynchronous replication**, it reports success after its local commit and ships the change afterwards. **Semi-synchronous replication**, MySQL's middle ground, waits until a replica has *received and logged* the change and falls back to asynchronous mode after a timeout.

First-principles explanation

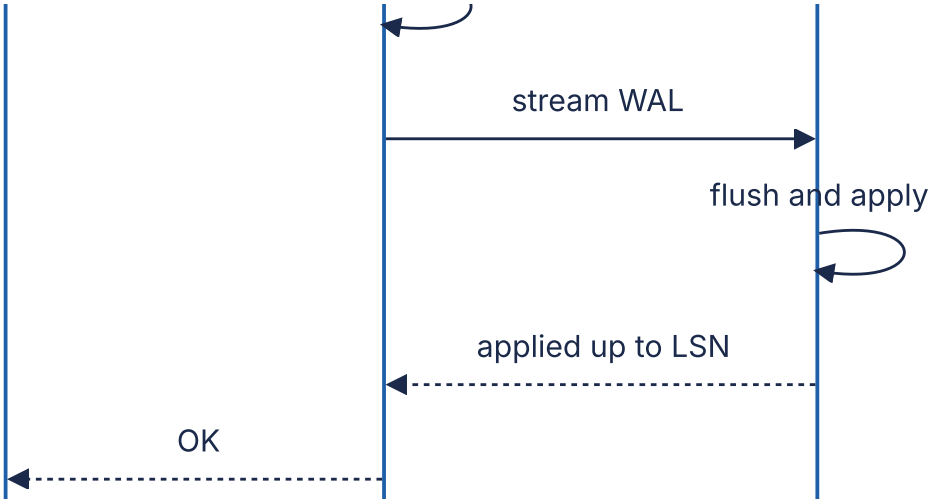
Imagine posting an important letter. Asynchronous is dropping it in a mailbox and walking away: fast, but if the post office burns down tonight the letter is lost. Synchronous is waiting for a signed receipt from the recipient: slow, and you are stuck if the courier is. Semi-synchronous is waiting only until the courier confirms the letter is in the van, and giving up after ten seconds. The trade-off is **durability on failover versus commit latency and availability**.

How it works internally

Figure 14.2 — Commit paths under asynchronous, semi-synchronous and synchronous replication.



Client
Primary
Replica
Asynchronous
COMMIT
write and flush local log
OK
ship log records later
Semi-synchronous, MySQL AFTER_SYNC
COMMIT
write and flush binlog
send events
write relay log
ACK received
commit in storage engine
OK
Synchronous, PostgreSQL remote_apply
COMMIT
flush local WAL



Reading the diagram. Solid arrows are steps the client waits for. In the asynchronous path, shipping (open arrowhead) happens after the reply, so a primary crash then loses the transaction. MySQL's lossless semi-sync (`AFTER_SYNC`) waits for a replica to write its **relay log** before the engine commit, so no client sees a transaction no replica has. PostgreSQL's `remote_apply` waits until the standby has *applied* the change. Storage boundaries are the two logs. The failure point is the replica: a slow synchronous replica stalls every commit, which quorum commit over several replicas mitigates.

The two products expose different knobs:

- **PostgreSQL.** `synchronous_standby_names` chooses which standbys count: `FIRST 1 (a, b)` by priority or `ANY 2 (a, b, c)` as a quorum. `synchronous_commit` sets how far to wait: `off`, `local`, `remote_write`, `on` (standby flushed) or `remote_apply` (standby applied) [PostgreSQL Docs: synchronous_commit].
- **MySQL.** Semi-synchronous replication has a wait point (`AFTER_SYNC`, lossless and the default since 5.7, or `AFTER_COMMIT`), a number of replicas that must acknowledge, and a timeout after which the primary silently reverts to asynchronous mode [MySQL Docs: Semisynchronous Replication]. Semi-sync protects you only while replicas are healthy.

Mathematical foundations

FORMULA

Commit latency with k acknowledgments

$$T_{\text{commit}} \approx T_{\text{local}} + \text{RTT}_{(k)} + T_{\text{remote}}$$

Symbol	Meaning	Units
T_{commit}	Time from the client's `COMMIT` to the primary's reply	ms
T_{local}	Time to flush the log on the primary	ms
$\text{RTT}_{(k)}$	The k-th smallest round-trip time among the eligible replicas	ms
T_{remote}	Work the replica does before acknowledging (write, flush or apply)	ms
k	Number of replica acknowledgments required ($k = 0$ for asynchronous)	count

WORKED EXAMPLE

Worked example — Where to put the synchronous replica. A primary flushes its WAL in 0.2 ms on NVMe with power-loss protection (a drive without it can take about 2 ms per `fsync`, §6.14.3). Replica A is in the same availability zone (RTT 0.3 ms), replica B is in another zone of the same region (RTT 1.2 ms), and replica C is in another region (RTT 70 ms). Each replica flushes in 0.2 ms.

1. Asynchronous ($k = 0$): $T \approx 0.2$ ms.
2. Synchronous, `ANY 1 (A, B)`: the fastest acknowledgment is A's. $T \approx 0.2 + 0.3 + 0.2 = 0.7$ ms.
3. Synchronous, `ANY 2 (A, B, C)`: the second-fastest is B. $T \approx 0.2 + 1.2 + 0.2 = 1.6$ ms.
4. Synchronous to C only: $T \approx 0.2 + 70 + 0.2 \approx 70.4$ ms.
5. A single session committing sequentially manages $1/0.7\,\text{ms} \approx 1,430$ commits/s in case 2 but only $1/70.4\,\text{ms} \approx 14$ in case 4. Group commit helps concurrent sessions, but each transaction still pays the latency.

Interpretation. A cross-zone acknowledgment costs about a millisecond. A cross-region one costs the inter-region RTT on every commit. **Engineering implication.** A common pattern is synchronous replication to a replica in another zone of the same region plus asynchronous replicas in remote regions. A zone loss then loses no data, and a region loss risks a few seconds of writes (a nonzero recovery point objective, §39.8).

Table 14.2 — Replication modes compared.

	Asynchronous	Semi-synchronous (MySQL)	Synchronous / quorum (PostgreSQL)
Client waits for	Local flush only	≥ 1 replica has *received*	*k* replicas have flushed or applied
Commit latency	Lowest	+ 1 RTT	+ RTT of *k*-th fastest replica
Data loss on primary crash	Possible (seconds of writes)	None while healthy; possible after timeout fallback	None, if failover picks an acknowledged replica
Availability if replicas fail	Unaffected	Unaffected after timeout	Commits block until *k* replicas return
Stale reads on replicas	Yes	Yes (received, not yet applied)	Only `remote_apply` avoids them on the waited-for replicas
Choose when	Throughput first; remote regions	MySQL fleets wanting near-zero loss	Financial data; zone-level failure tolerance

Common misconceptions

COMMON MISTAKE

Mistake — "Synchronous replication means replicas never serve stale data." PostgreSQL's default synchronous setting (`on`) waits for the standby to *flush*, not *apply*, so a read there a millisecond later can miss the change. Only `remote_apply` closes the gap, and only on the standbys waited for.

14.4.2 Replication lag

DEFINITION

Definition — Replication lag. The delay between a change committing on the primary and becoming visible on a replica, measured in seconds, bytes of log or transactions.

Within one region, asynchronous lag is typically well under a second, but it is unbounded. It grows whenever the replica applies changes more slowly than the primary produces them: a single-threaded applier, a bulk `UPDATE` of millions of rows, a replica returning from maintenance, a network partition, or replica queries that block replay. Catching up is draining a queue.

FORMULA

Replica catch-up time

$$T_{\text{catch-up}} = \frac{B}{r_{\text{apply}} - r_{\text{in}}} \qquad (r_{\text{apply}} > r_{\text{in}})$$

Symbol	Meaning	Units
$T_{\text{catch-up}}$	Time until the replica's lag returns to near zero	s
B	Backlog of unapplied changes when catch-up starts	transactions
r_{apply}	Rate at which the replica can apply changes	transactions/s
r_{in}	Rate at which the primary generates new changes during catch-up	transactions/s

WORKED EXAMPLE

Worked example — A replica returns from 10 minutes of maintenance. The primary commits $r_{\text{in}} = 5,000$ transactions/s. The replica can apply $r_{\text{apply}} = 8,000$ transactions/s with parallel apply.

1. Backlog: $B = 5,000 \times 600\,\text{s} = 3,000,000$ transactions.
2. Net drain rate: $8,000 - 5,000 = 3,000$ transactions/s.
3. Catch-up time: $3,000,000/3,000 = 1,000$ s, about 17 minutes.
4. At 5,500 transactions/s the net drain is 500/s and catch-up takes 6,000 s (100 minutes); at 5,000/s it never ends.

Interpretation. Catch-up time depends on the *margin* between apply and arrival rates. A replica with 10 % spare apply capacity takes ten times as long to recover as the outage lasted. **Engineering implication.** Keep replicas out of the read pool until lag is within your staleness budget, and track apply headroom $r_{\text{apply}}/r_{\text{in}}$ as a capacity metric.

14.4.3 Anomalies caused by lag

Lag is invisible until it violates a user's expectations. Two violations are common. Chapter 25 (§25.6) treats these **session guarantees** formally.

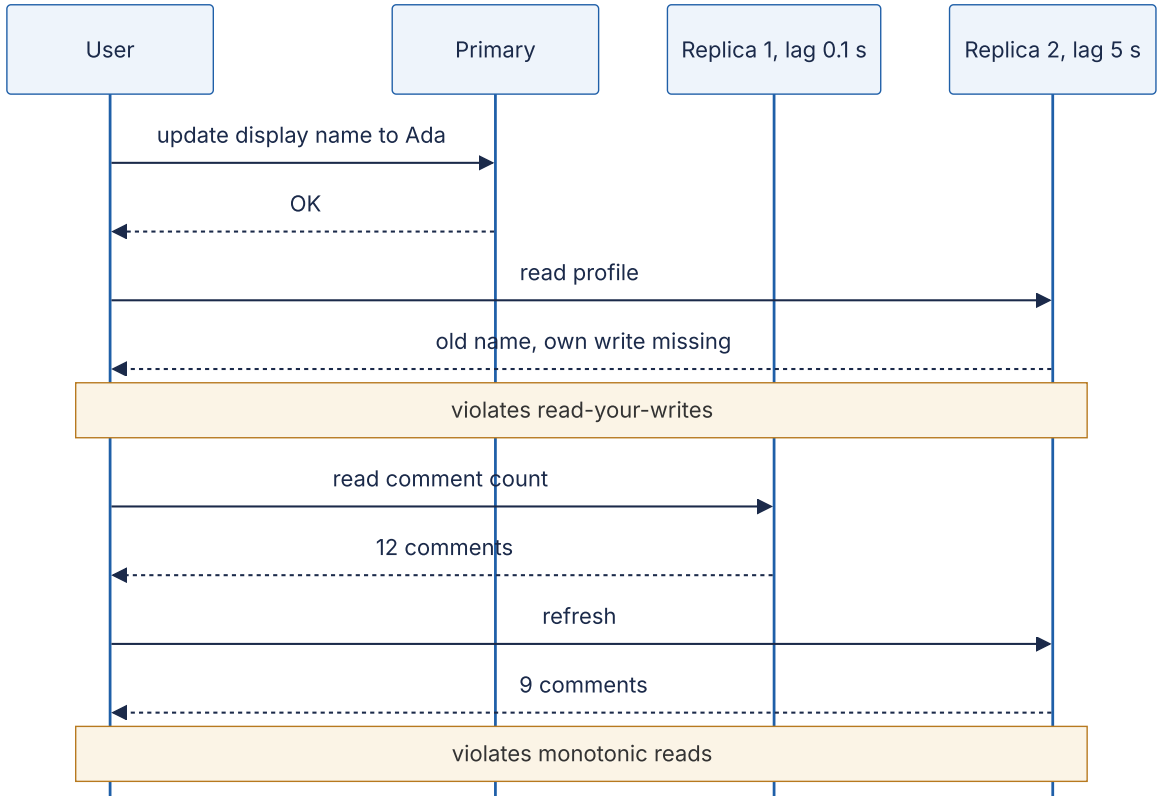
DEFINITION

Definition — Read-your-writes consistency. After a client writes a value, its own later reads return that value or a newer one. Other clients get no such promise.

DEFINITION

Definition — Monotonic reads. A client never sees data move backwards: after reading some version, its later reads return that version or newer.

Figure 14.3 — Two lag anomalies: lost own write and time going backwards.



Reading the diagram. Calls are synchronous; replication (not drawn) is asynchronous. The read after the write lands on Replica 2, five seconds behind, so the edit seems lost. Then successive reads hit different replicas, and the comment count falls from 12 to 9. The failure point is the router's freedom to pick any replica, and it bites more often as replicas are added.

14.4.4 Designing around lag

Each fix narrows the router's freedom and so costs some read scalability.

1. **Read recent writers from the primary.** For a window after a user writes, such as 10 seconds, route that user's reads to the primary. PhotoShare used this rule (Figure 1.6, §1.9). It is simple but fails silently if lag exceeds the window.
2. **Track the write's log position.** Return the primary's LSN or GTID after a write and read only from replicas that have applied it, or wait briefly until one has. MySQL offers `WAIT_FOR_EXECUTED_GTID_SET()`, and PostgreSQL exposes `pg_last_wal_replay_lsn()`. This is precise but needs a token plumbed through the application.
3. **Sticky replica per session.** Always read a session from the same replica. This gives monotonic reads but not read-your-writes.
4. **Synchronous apply where it matters.** Use `remote_apply` for the replica that serves a specific critical read path.

The program below implements option 2 with a per-session watermark.

```
        """Read-your-writes and monotonic reads with log-position tokens (simula-
tion)."""
        import random

        class Replica:
            def __init__(self, name):
                self.name, self.applied = name, 0       # applied log position (LSN)

        class Router:
            """Routes reads to any replica that has applied the session's watermark."""

            def __init__(self, replicas):
                self.primary_lsn = 0
                self.replicas = replicas
                self.watermark = {}                     # session -> minimum LSN to
read

            def write(self, session):
                self.primary_lsn += 1                   # commit on the primary
                self.watermark[session] = self.primary_lsn
                return self.primary_lsn

            def read(self, session):
                need = self.watermark.get(session, 0)
                fresh = [r for r in self.replicas if r.applied >= need]
                if not fresh:
                    return "primary"                    # nobody is fresh enough yet
                chosen = random.choice(fresh)
                # monotonic reads: later reads must be at least as fresh as this one
                self.watermark[session] = max(need, chosen.applied)
                return chosen.name

        if __name__ == "__main__":
            random.seed(7)
            r1, r2 = Replica("replica-1"), Replica("replica-2")
            router = Router([r1, r2])
            lsn = router.write("alice")                 # alice writes; LSN 1
            print("right after write  ->", router.read("alice"))   # nobody has LSN 1
            r1.applied = lsn                            # replica-1 catches up
            print("replica-1 caught up ->", router.read("alice"))
            print("bob (no writes)     ->", router.read("bob"))    # any replica is fine
```

What to notice:

- Only the user who wrote pays for freshness. Other sessions read from any replica.
- With no fresh replica, the router falls back to the primary. A production router might wait a few milliseconds first to avoid a stampede.
- Raising the watermark to the replica just read also gives monotonic reads.

14.4.5 What travels on the wire: statement, row, physical and logical replication

DEFINITION

Definition — Replication log formats. What the log describes: the SQL statements executed (**statement-based**), the changed rows (**row-based**), the storage engine's page-level byte changes (**physical**, or WAL shipping), or decoded, engine-independent row changes per table (**logical**).

How each works

- **Statement-based.** Replicas re-execute the primary's SQL text. The log is compact, but non-determinism (`NOW()`, `RAND()`, `UPDATE ... LIMIT` without `ORDER BY`) makes copies diverge silently. MySQL's `MIXED` mode falls back to rows for statements it knows are unsafe.
- **Row-based.** The log carries each changed row's key and new values, so replay is deterministic, at the cost of volume: a million-row `UPDATE` yields a million events. `ROW` has been MySQL's default since 5.7.7 [MySQL Docs: Replication Formats].
- **Physical (WAL shipping).** PostgreSQL streams the WAL itself, page-level byte changes, so the replica is a byte-for-byte copy including indexes and replay is cheap. The coupling is tight: same major version, the whole cluster, no extra tables or indexes.
- **Logical.** The primary decodes its WAL into per-table row changes and publishes them; in PostgreSQL (since version 10) a **publication** on the source feeds a **subscription** on the target [PostgreSQL Docs: Logical Replication]. This enables cross-version upgrades, partial copies and **change data capture (CDC)** into brokers and search indexes (§32.6). Built-in logical replication does not carry DDL, and a writable subscriber can conflict.

Table 14.3 — Replication log formats compared.

	Statement-based	Row-based	Physical (WAL)	Logical
What is shipped	SQL text	Changed rows	Page-level byte changes	Decoded row changes per table
Log volume for bulk update	Tiny	Large	Large (includes indexes)	Large
Determinism	Fragile	Exact	Exact	Exact
Version coupling	Loose	Loose	Same major version	Cross-version
Replica can differ (extra indexes, subset)	Partly	Partly	No	Yes
Feeds CDC and other systems	No	Yes (binlog readers)	No	Yes

RECOMMENDATION

Recommendation — Default choices. Use row-based binlogs in MySQL and physical streaming for PostgreSQL high-availability replicas. Add logical replication for upgrades, partial copies or CDC.

Failure scenarios

Table 14.4 — Failure scenarios in replication modes and formats.

What goes wrong	Why	Detection	Recovery	Prevention
All commits hang	Sole synchronous standby is down	Commit latency spikes to timeout	Remove it from `synchronous_standby_names`	Quorum `ANY k` over ≥ $k+1$ standbys
Silent loss of the durability guarantee	Semi-sync timed out and fell back to async	Semi-sync status counters	Restore replica health	Alert on fallback, not just on lag
Split brain after failover	Old primary still accepts writes	Two nodes report primary role	Fence old primary; reconcile	Fencing tokens and leases (§26.11–§26.13)

14.5 Multi-primary replication

14.5.1 Writes in more than one place

DEFINITION

Definition — Multi-primary replication. More than one node accepts writes for the same data and replicates to the others (also **multi-leader** or **active-active**). Concurrent uncoordinated changes to the same row create **write conflicts** that must be detected and resolved.

First-principles explanation

Two offices each keep a copy of the customer address book and exchange changes every evening. Each can edit at full speed even when the phone lines are down, but if both change Mrs. Rivera's address on the same day, somebody needs a rule for which one wins.

Why does this exist?

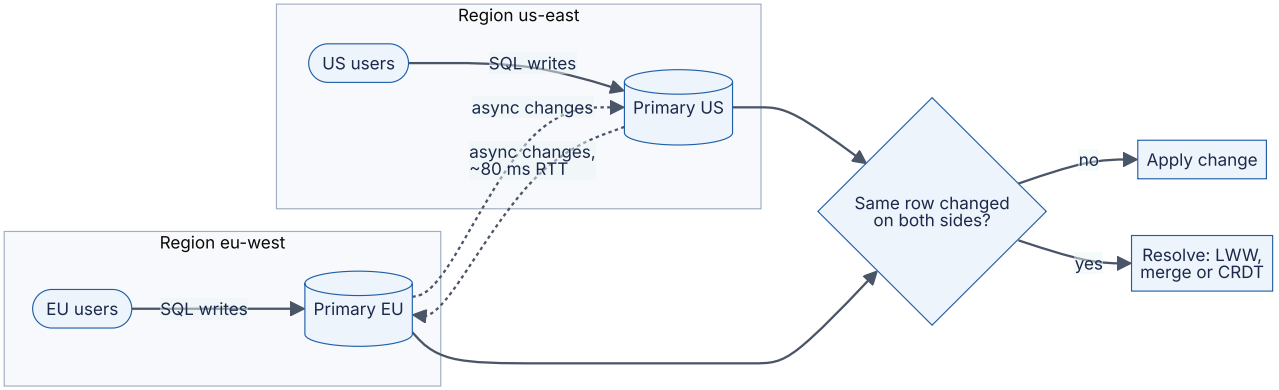
Single-primary replication makes distant users pay 70–150 ms per write and stops all writes if the primary's region is cut off. Multi-primary puts a writable primary in each re-

gion. Offline-capable clients, such as a calendar app, are the same pattern with each device as a primary.

How it works internally

1. Each region's primary accepts local writes and commits them locally.
2. Changes are replicated asynchronously to the other primaries, tagged with their origin so they are not echoed back.
3. When a change arrives that touches a row also changed locally since the last sync, the receiving primary detects a conflict.
4. A **conflict-resolution** policy picks the outcome. Common policies are **last-writer-wins** (LWW, the change with the later timestamp wins, which silently discards the other), a custom merge function, keeping both versions for the application to resolve, or **conflict-free replicated data types** (CRDTs) whose merges are mathematically guaranteed to converge. Chapter 27 (§27.14) covers these in depth.

Figure 14.4 — Two-region multi-primary replication and a write conflict.



Reading the diagram. Each region writes synchronously to its local primary (about 1 ms), and the primaries exchange changes asynchronously, so the two storage boundaries differ until replication catches up. Every incoming change passes the conflict detector. The resolver is the failure point: LWW depends on clocks (§24.9) and silently drops a write, and uniqueness cannot be enforced across regions. Each added region adds pairs of primaries that can conflict.

Advantages, disadvantages and when to choose it

Multi-primary buys local write latency and partition tolerance at the cost of global constraints, linearizable reads, colliding auto-increment keys and much harder debugging. A common compromise is **partitioned ownership**: each row has one home region that is its only primary, which gives most of the latency benefit with no conflicts. Choose true multi-primary only when the same data must be written concurrently in several regions *and* you can define a merge.

INDUSTRY EXAMPLE

MySQL Group Replication. In multi-primary mode, all members accept writes. Transactions are certified through a group-communication protocol, and one that conflicts with an earlier-certified transaction is rolled back rather than merged. It needs a low-latency network, so it is typically used within one region. *Evidence: Primary* — [MySQL Docs: Group Replication]

COMMON MISTAKE

Mistake — "Active-active doubles write capacity." Every primary still applies every other primary's writes. Multi-primary improves write *latency* and *availability*, not total write throughput.

14.6 Partitioning: range, hash, list and directory-based

14.6.1 What partitioning is

DEFINITION

Definition — Partition (shard). A subset of a dataset's rows, stored and served together, such that every row belongs to exactly one partition. **Partitioning** spreads partitions over nodes; **sharding** is a synonym used mostly for separate database servers. This book uses *partition* and *shard* interchangeably and reserves **network partition** for network splits (§24.7). The columns that choose a row's partition form the **partition key** (or **shard key**).

First-principles explanation

A library that outgrows one room does not photocopy every book into a second room; that would be replication. It moves A–M to one room and N–Z to another. Each room holds and serves half the books, and a visitor seeking one title goes straight to the right room. A visitor asking "which books were published in 1987?" must search both. Capacity scales with rooms, lookups by the partitioning attribute stay cheap, and everything else gets more expensive.

Why does this exist?

Replication cannot fix three limits: one primary's write rate, one node's storage and one node's memory for the working set. Partitioning divides all three by the number of partitions. It is the only general way to scale writes horizontally. (PostgreSQL's declarative ta-

ble partitioning splits a table on the *same* node, which helps maintenance but adds no machines.)

How it works internally

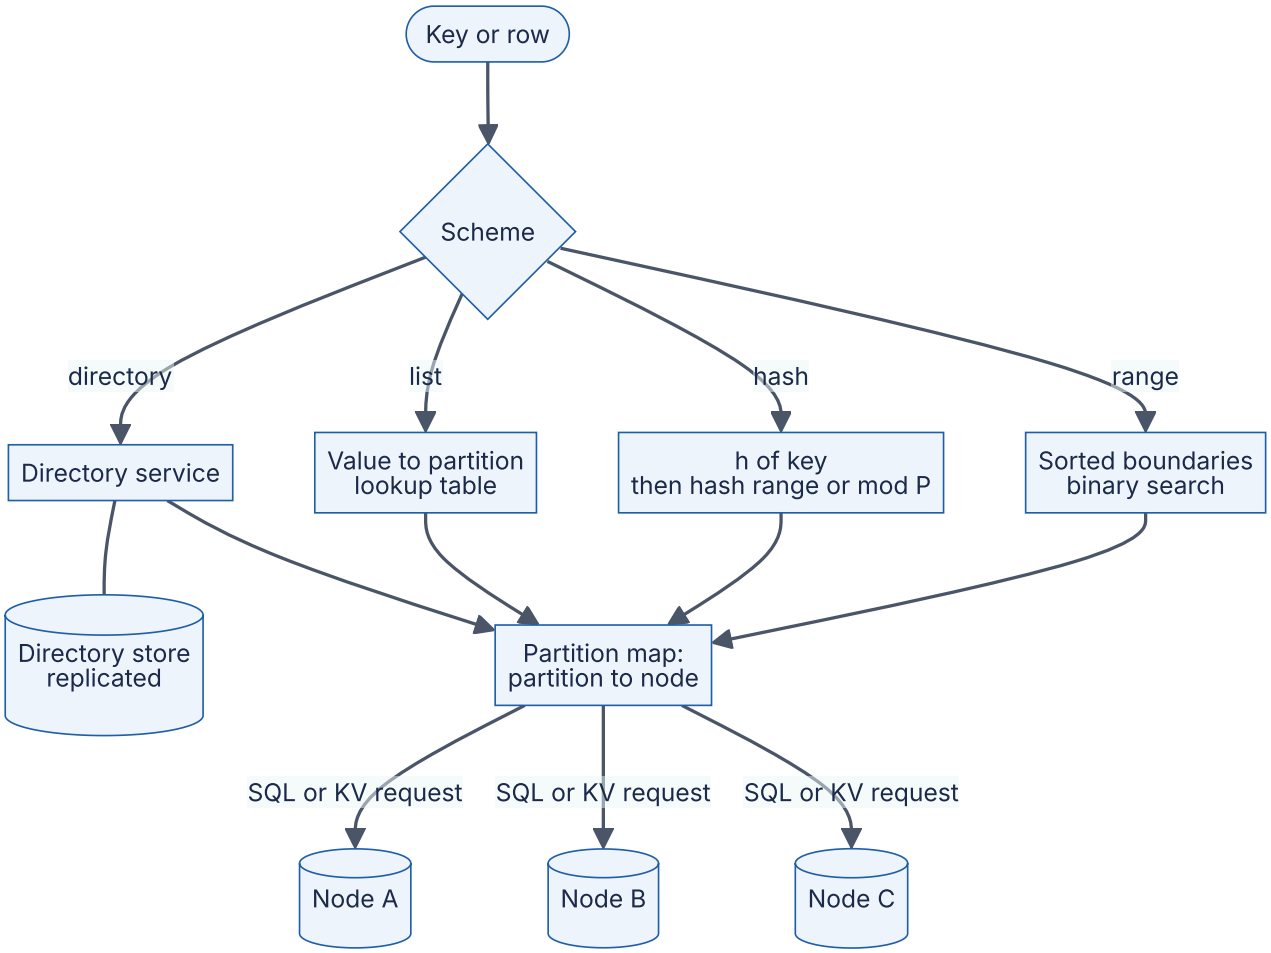
Every partitioned system answers two questions per request: **which partition holds this key?** and **which node holds that partition?** The schemes differ in the first answer.

1. **Range partitioning.** Each partition owns a contiguous key range, found by binary search over a small boundary table. Range scans touch only overlapping partitions. But sequential keys, such as timestamps or auto-increment IDs, send *all* new writes to the last partition. Bigtable, HBase and the distributed SQL systems of Chapter 28 range-partition and split ranges as they grow [Chang et al. 2006].
2. **Hash partitioning.** Partitions own ranges of $h(\text{key})$, or $h(\text{key}) \bmod P$ for a fixed P. Even sequential keys spread evenly, but range queries on the key must ask every partition. Mapping hashes to a changing set of nodes is §14.8.
3. **List partitioning.** Each partition owns an explicit list of values, such as `country IN ('DE', 'FR', 'IT')`. It suits low-cardinality attributes with business meaning, especially **data residency** (Chapter 44).
4. **Directory-based partitioning.** A lookup service maps each key, or group of keys such as a tenant, to its partition. Any placement is possible, and moving a tenant means copying its data and editing one entry. The directory is on every request's path, so it is cached and stored in a strongly consistent replicated store.

Compound keys combine schemes: Cassandra's primary key `((user_id), created_at)` hashes `user_id` to place the partition and keeps each user's rows sorted by time inside it, so "user 42's latest 20 posts" is one sequential read [Lakshman and Malik 2010].

Architecture diagram

Figure 14.5 — Four ways to answer "which partition holds this key?"



Reading the diagram. The scheme is a design-time choice, not a runtime branch. Range, hash and list are pure functions plus a small cached table; a directory adds a synchronous lookup unless cached. All yield a partition ID that a separate map turns into a node, so rebalancing edits only that map (§14.9). Failure points: a stale map (nodes must reject misrouted requests) and a directory outage. Scaling: add nodes and move partitions; the key-to-partition function never changes.

Table 14.5 — Partitioning schemes compared.

	Range	Hash	List	Directory
What it is	Contiguous key ranges	Ranges of hashed key	Explicit value lists	Explicit key-to-partition map
Load balance	Poor for sequential keys	Good	Depends on value sizes	Whatever you place
Range scans on key	Efficient	Scatter to all partitions	Efficient within a value	Depends
Routing cost	Binary search, cacheable	Arithmetic	Table lookup	Remote lookup, cached
Rebalancing	Split or merge ranges	Move hash ranges (§14.8–§14.9)	Edit lists	Move one entry at a time
Operational complexity	Medium	Low	Low	High (directory is critical)
Choose when	Time series, ordered scans	Point lookups, uniform load	Residency, regions	Tenants of very different sizes

Common misconceptions

COMMON MISTAKE

Mistake — "Hashing removes hot spots." Hashing spreads *distinct* keys. It cannot split one key's traffic. A celebrity key drawing 30 % of reads puts at least 30 % on its partition under any hash (§14.10).

14.7 Sharding strategies and choosing shard keys

14.7.1 Properties of a good shard key

The shard key is the least reversible decision in a partitioned database, because changing it means moving every row (§14.9). Evaluate candidates against five properties:

1. **High cardinality.** Many more distinct values than shards: `country` has about 200, `user_id` billions.
2. **Even load.** Data and request rate per value roughly uniform, or dominated by many small values.
3. **Query locality.** Frequent queries include the key and touch one shard. Others **scatter** to every shard and **gather** results.
4. **Transaction locality.** Rows changed atomically together share a key value, avoiding distributed commit (§14.12).
5. **Stability.** The key never changes. Otherwise a row must move between shards.

No key is perfect. List the top five queries by frequency and pick the candidate that keeps the most traffic on one shard.

14.7.2 Worked example: a multi-tenant SaaS product

Consider **TaskForge**, a hypothetical project-management SaaS with 40,000 customer organizations (tenants). Nearly every query is tenant-scoped: “this project’s open tasks”, “search this workspace”. Tenant sizes are heavy-tailed: the median has 15 users and the largest has 60,000 and about 2 % of all data.

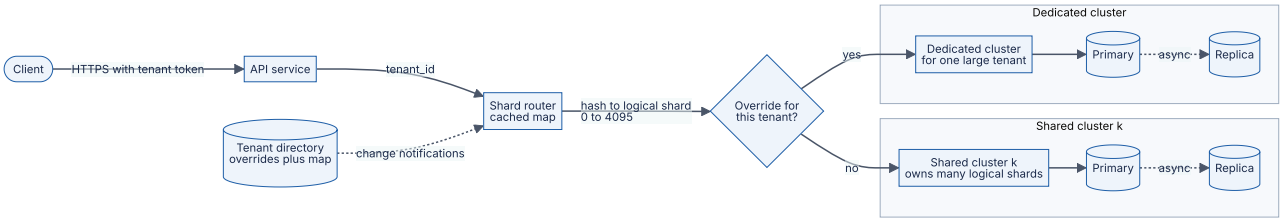
Table 14.6 — Shard-key candidates for TaskForge.

Candidate	Cardinality	Even load	Query locality	Transaction locality	Verdict
`task_id`	Very high	Excellent	Poor: “open tasks in project” scatters	Poor	Reject
`user_id`	High	Good	Poor: shared projects span users	Poor	Reject
`tenant_id`	40,000	Skewed by large tenants	Excellent: almost all queries	Excellent	**Choose**, with mitigation
`project_id`	High	Good	Good within a project; cross-project reports scatter	Good	Second choice

`tenant_id` keeps almost every query and transaction on one shard and simplifies tenant isolation, backup, residency and deletion. Its weakness is skew from giant tenants, fixed with directory placement on top of hashing:

1. Hash `tenant_id` into one of $L = 4,096$ **logical shards** (fixed partitions, §14.9).
2. Map logical shards to physical database clusters through a small directory.
3. Give the few giant tenants a **dedicated** cluster through a directory override. If one outgrows even that, partition it by `(tenant_id, project_id)`.

Figure 14.6 — Multi-tenant sharding with logical shards and a tenant directory.



Reading the diagram. The API takes the tenant ID from the authenticated token, never from user input. The router caches the shard-to-cluster map and override list, updated asynchronously from the directory, so databases must reject writes for logical shards they do not own. SQL to the chosen primary is synchronous, and each cluster is a replicated storage boundary (§14.3–§14.4). A cluster failure affects only its tenants, a smaller **blast radius** than one big database. Scaling: add clusters and move logical shards, or give a growing tenant its own cluster.

INDUSTRY EXAMPLE

Notion. Notion sharded its PostgreSQL block data by workspace ID, because each block belongs to one workspace. It created 480 logical shards (PostgreSQL schemas) spread over 32 physical databases, 15 each, with routing in application code. It chose 480 because its many divisors let the fleet grow to 40 or 48 hosts with equal shard counts, whereas 512 would force doubling. *Evidence: Primary* — [Fidalgo 2021]

14.7.3 Worked example: a social application

Now take **PhotoShare**, the hypothetical photo-sharing app of Chapter 1. Its top queries are “show user X’s profile and photos”, “post a photo”, “like a photo” and “build my home feed”.

- **`photos` by `owner_user_id`.** Profiles and posting become single-shard, and a compound key `((owner_user_id), created_at DESC)` keeps photos time-ordered. Celebrity profiles concentrate reads on one shard (§14.10).
- **`likes` by `photo_id`.** Like counts and “did I like it?” are single-shard. “Photos I liked” becomes a scatter query, served by an index or denormalized copy (§14.11).
- **`follows`, stored twice.** “Who does X follow?” wants partitioning by follower and “who follows X?” by followee, so write both copies, usually asynchronously (§32.6), and accept brief inconsistency.
- **Home feed.** Querying every followed user’s shard per page view is a large fan-out. Large social systems typically precompute feeds on write, except for celebrities whose posts are merged at read time [Kleppmann 2017].

KEY CONCEPT

Key insight — Partition by the entity your hottest queries name, and denormalize for the rest. No single key localizes every social-graph query. Pick the key for the dominant path and keep an eventually consistent, differently partitioned copy for the next.

INDUSTRY EXAMPLE

Instagram (2012). Instagram sharded PostgreSQL into several thousand **logical shards** (schemas) mapped onto far fewer servers. Each 64-bit ID embeds 41 bits of milliseconds since a custom epoch, 13 bits of logical shard ID and 10 bits of per-shard sequence, so any service can route from an ID alone. *Evidence: Primary* — [Instagram Engineering 2012]

14.7.4 How many shards? A capacity calculation

Shard count is set by whichever resource runs out first, computed at the end of the planning horizon because resharding is expensive.

FORMULA

Number of shards required

$$S = \left\lceil \max\left(\frac{D}{C_{\text{disk}} \cdot f},\ \frac{W}{w_{\text{node}} \cdot u},\ \frac{R}{n_{\text{read}} \cdot r_{\text{node}} \cdot u}\right)\right\rceil$$

Symbol	Meaning	Units
S	Number of shards (each one a replicated group)	shards
D	Data size at the planning horizon, one copy, including indexes	TB
C_{disk}	Usable storage per node	TB
f	Target fill fraction, leaving room for compaction, backups and growth between reshards	dimensionless (0–1)
W	Peak write rate at the horizon	writes/s
w_{node}	Sustainable write rate of one primary (from benchmarks)	writes/s
R	Peak read rate that reaches the database, after caches	reads/s
n_{read}	Nodes per shard that serve reads	nodes
r_{node}	Sustainable read rate of one node	reads/s
u	Target utilization at peak	dimensionless (0–1)

WORKED EXAMPLE

Worked example — Sharding PhotoShare's metadata store. SI units (1 TB = 10^{12} bytes). Assumptions are stated, not measured.

1. **Storage.** Metadata is 30 TB today, including indexes, and grows by 1.5 TB per month. The planning horizon is 24 months, so $D = 30 + 24 \times 1.5 = 66$ TB. Each node has 8 TB of usable NVMe, and you fill it to at most $f = 0.6$. Storage term: $66/(8 \times 0.6) = 66/4.8 = 13.75$.
2. **Writes.** Peak writes are 90,000/s today and expected to grow 1.5×, so $W = 135,000$/s. A benchmarked primary sustains $w_{\text{node}} = 10,000$ writes/s, and you run at $u = 0.6$. Write term: $135,000/(10,000 \times 0.6) = 135,000/6,000 = 22.5$.
3. **Reads.** Peak reads are 1,200,000/s, and the cache hit ratio is 90 %, so $R = 120,000$/s reach the database. Each shard has one primary and two replicas, and only the replicas serve reads, so $n_{\text{read}} = 2$. A replica sustains $r_{\text{node}} = 20,000$ reads/s, and $u = 0.6$. Read term: $120,000/(2 \times 20,000 \times 0.6) = 120,000/24,000 = 5$.
4. **Take the maximum.** $S = \lceil \max(13.75, 22.5, 5) \rceil = 23$. The store is **write-bound**.
5. **Round for operations.** Choose 24 shards so the fleet splits evenly over 3 availability zones (8 primaries per zone). Total nodes: $24 \times 3 = 72$.
6. **Logical shards.** Create $L = 960$ logical shards, 40 per physical shard. 960 is divisible by 24, 30, 32, 40, 48, 60, 64, 80 and 96, so the fleet can grow in modest steps and stay perfectly even.
7. **Sanity check after sharding.** Each shard stores $66/24 = 2.75$ TB (34 % of a node's disk) and takes $135,000/24 \approx 5,600$ writes/s (56 % of w_{node}) at the horizon.

Interpretation. Storage alone suggests 14 shards, which would under-provision by 40 %. **Engineering implication.** Compute all three terms and benchmark the binding one carefully: a 20 % error in w_{node} moves the answer by about five shards. Choose the logical count once, for years, and the physical count for the next 18–24 months.

The program below implements the formula and reproduces the example.

```
        """Shard-count calculator: the binding constraint among storage, writes and
reads."""
        import math

        def shards_needed(data_tb, disk_tb, fill, writes, write_cap, reads,
                          read_nodes, read_cap, util):
            terms = {
                "storage": data_tb / (disk_tb * fill),
                "writes": writes / (write_cap * util),
                "reads": reads / (read_nodes * read_cap * util),
            }
            binding = max(terms, key=terms.get)
            return math.ceil(terms[binding]), binding, terms

        def even_logical_counts(physical, candidates=(512, 720, 960, 1024, 4096)):
            """Logical-shard counts that divide evenly over `physical` shards."""
            return [c for c in candidates if c % physical == 0]

        if __name__ == "__main__":
            s, binding, terms = shards_needed(
                data_tb=30 + 24 * 1.5, disk_tb=8, fill=0.6,
                writes=90_000 * 1.5, write_cap=10_000,
                reads=1_200_000 * (1 - 0.90), read_nodes=2, read_cap=20_000, util=0.6)
            print({k: round(v, 2) for k, v in terms.items()})
            print(f"minimum shards = {s} ({binding}-bound)")
            physical = 3 * math.ceil(s / 3)          # round up to a multiple of 3 zones
            print(f"physical shards = {physical}, nodes = {physical * 3}, "
                  f"even logical counts = {even_logical_counts(physical)}")
```

Running it prints:

```
{'storage': 13.75, 'writes': 22.5, 'reads': 5.0}
minimum shards = 23 (writes-bound)
physical shards = 24, nodes = 72, even logical counts = [720, 960]
```

What to notice:

- It reports *which* term binds, which is where a real benchmark is needed.
- 1,024 and 4,096 do not divide evenly over 24 shards. Power-of-two counts suit fleets that double; highly composite counts suit fleets that grow in small steps.
- A cache outage multiplies R by 10, turning the read term from 5 into 50 (§20.13).

Failure scenarios

Table 14.7 — Failure scenarios from shard-key choice.

What goes wrong	Why	Detection	Recovery	Prevention
One shard runs out of disk	Key with large, uneven entities (a giant tenant)	Per-shard disk and growth dashboards	Move logical shards; split the tenant	Directory overrides; size by largest entity
All new writes hit one shard	Monotonic key under range partitioning	Per-shard write rate, one hot	Switch to hash or prefix the key	Avoid timestamps or sequences as the leading key
Cross-shard transactions everywhere	Related rows have different keys	2PC or saga volume	Re-key so related rows co-locate	Transaction locality as a key criterion

14.8 Consistent hashing and virtual nodes

This is the book's full treatment of consistent hashing. Section 3.3.2 used it as a study example, and Chapters 17, 19, 20 and 27 point back here.

14.8.1 The problem: `hash mod N` moves almost everything

The obvious rule, `node = h(key) mod N`, balances perfectly and needs no state, but a key keeps its node only if $h \bmod N = h \bmod (N+1)$, which holds for about $1/(N+1)$ of keys. Growing from 4 to 5 nodes moves about 80 % of keys, and from 100 to 101 about 99 %: a miss storm for a cache (§3.3.2) and a near-total copy for a database. We want a rule under which adding a node moves only the keys it should own.

DEFINITION

Definition — Consistent hashing. Keys and nodes are hashed onto the same circular space (the **ring**), and each key belongs to the first node position clockwise from its hash. Adding or removing a node changes the owner of an expected K/N of K keys for N nodes [Karger et al. 1997].

DEFINITION

Definition — Virtual node (vnode). One of V ring positions belonging to the same physical node, typically obtained by hashing labels such as `db-3#vn17`; also called a **token**.

14.8.2 Ring construction and lookup

First-principles explanation

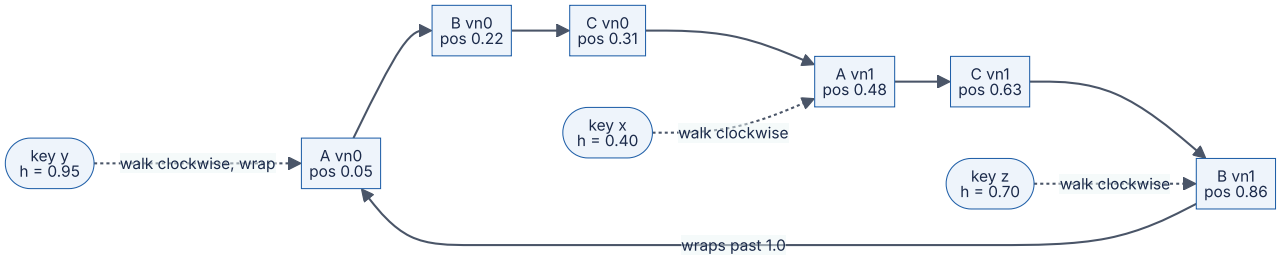
Picture a circular running track marked from 0 to just under 2^{64}. Each server stands at a few spots. Each key is dropped at the spot given by its hash and walks clockwise until it

meets a server, which owns it. A new server intercepts only the keys walking toward its spots; every other walk ends where it did before.

How it works internally

1. **Choose a hash** giving well-mixed 64-bit integers, identical in every router process (MD5 truncated to 64 bits, MurmurHash3, xxHash). Python's per-process randomized `hash()` is unsuitable.
2. **Place vnodes.** For each physical node and each i from 0 to $V - 1$, hash a label such as `db-3#vn17` to get a position. Store all positions in a sorted array, with a parallel array of owners.
3. **Look up a key.** Binary-search for the first position strictly greater than $h(\text{key})$, wrapping to index 0 past the end. Cost: $O(\log M)$ for M positions, about 15 comparisons for 100 nodes × 256 vnodes.
4. **Add a node.** Insert its positions. Each takes over the arc from its predecessor, so only keys in those arcs move, all *to* the new node.
5. **Remove a node.** Delete its positions. Its arcs merge into their clockwise successors, which, with scattered vnodes, belong to many different survivors.
6. **Weight nodes** by giving a bigger node proportionally more vnodes.
7. **Distribute membership** through a coordination service (§26.8–§26.9) or gossip (§27.10), versioned so a router can detect a stale copy.

Figure 14.7 — A ring with three nodes and two vnodes each.



Reading the diagram. Rectangles are vnode positions normalized to $[0, 1)$, linked clockwise and wrapping from 0.86 to 0.05. Each vnode owns the arc *ending* at it, for example A vn1 owns $(0.31, 0.48]$. Dotted lookups: x at 0.40 goes to A vn1, y at 0.95 wraps to A vn0, z at 0.70 goes to B vn1. Lookup happens in router memory; data lives on A, B and C, whose shares (0.36, 0.40, 0.24) are uneven with two vnodes each. Failure point: routers with different membership disagree about owners.

14.8.3 How many keys move?

FORMULA

Expected keys moved on a membership change

$$E[\text{moved on add}] = \frac{K}{N+1} \qquad E[\text{moved on remove}] = \frac{K}{N}$$

Symbol	Meaning	Units
K	Total number of keys	keys
N	Number of nodes before the change	nodes

By symmetry, a new node's expected share is $1/(N+1)$, and only keys in its new arcs move. A removed node's keys are its share, $1/N$ in expectation. These are the minimum any balanced scheme can achieve. Karger et al. call the property **monotonicity**: keys move only to the new node, never between old nodes [Karger et al. 1997].

WORKED EXAMPLE

Worked example — Adding a ninth database node. A store holds $K = 2 \times 10^9$ rows of 1 KB each (2 TB, SI units) on $N = 8$ nodes, ring-partitioned with 128 vnodes per node.

1. Rows moved: $2 \times 10^9 / 9 \approx 2.22 \times 10^8$ rows, about 222 GB.
2. Under `mod N`: about $8/9$ of rows, 1.78×10^9 rows or 1.78 TB, would move.
3. Time to move 222 GB if rebalancing is throttled to 100 MB/s to protect foreground traffic: $222 \times 10^9 / 10^8 = 2,220$ s, about 37 minutes. Moving 1.78 TB at the same rate takes 17,800 s, about 5 hours.
4. Sources: with 128 vnodes, the new node's 128 arcs are cut from all 8 existing nodes, each contributing roughly $222/8 \approx 28$ GB, so all 8 can stream in parallel.

Interpretation. The ring cuts data movement by a factor of N and spreads it over every node. **Engineering implication.** Adding capacity becomes a routine sub-hour operation, and the vnode count decides how many nodes share the copying.

The runnable ring below checks these claims. It supports weights and returns a replica **preference list**.

```
        """Consistent-hash ring with virtual nodes, weights and replica placement."""
        import bisect
        import hashlib
        from collections import Counter

        def h(key: str) -> int:
            """Map a string to a 64-bit ring position (MD5 used only for mixing)."""
            return int.from_bytes(hashlib.md5(key.encode("utf-8")).digest()[:8], "big")

        class HashRing:
            def __init__(self, vnodes_per_weight: int = 100):
                self.vpw = vnodes_per_weight
                self.weights = {}          # physical node -> weight
                self._positions = []       # sorted vnode positions
                self._owners = []          # owner of _positions[i]

            def _rebuild(self) -> None:
                points = sorted(
                    (h(f"{node}#vn{i}"), node)
                    for node, w in self.weights.items()
                    for i in range(self.vpw * w)
                )
                self._positions = [p for p, _ in points]
                self._owners = [n for _, n in points]

            def add_node(self, node: str, weight: int = 1) -> None:
                self.weights[node] = weight
                self._rebuild()            # one sort per membership change

            def remove_node(self, node: str) -> None:
                del self.weights[node]
                self._rebuild()

            def _index(self, key: str) -> int:
                i = bisect.bisect_right(self._positions, h(key))
                return 0 if i == len(self._positions) else i   # wrap around

            def owner(self, key: str) -> str:
                return self._owners[self._index(key)]

            def preference_list(self, key: str, r: int) -> list:
                """First r *distinct physical* nodes clockwise from the key."""
                r = min(r, len(self.weights))
                result, i = [], self._index(key)
                while len(result) < r:
                    node = self._owners[i]
                    if node not in result:
                        result.append(node)
                    i = (i + 1) % len(self._owners)
                return result

        if __name__ == "__main__":
            keys = [f"user:{i}" for i in range(200_000)]
            ring = HashRing(vnodes_per_weight=128)
            for n in range(8):
                ring.add_node(f"db-{n}")
```

```
before = {k: ring.owner(k) for k in keys}
ring.add_node("db-8")
after = {k: ring.owner(k) for k in keys}
moved = [k for k in keys if before[k] != after[k]]
print(f"add 9th node : {len(moved) / len(keys):.2%} of keys moved "
      f"(theory 1/9 = {1 / 9:.2%}); all moved keys went to "
      f"{set(after[k] for k in moved)}")

share = sum(1 for k in keys if after[k] == "db-3") / len(keys)
ring.remove_node("db-3")
gone = {k: ring.owner(k) for k in keys}
moved = [k for k in keys if after[k] != gone[k]]
receivers = Counter(gone[k] for k in moved)
print(f"remove db-3  : {len(moved) / len(keys):.2%} moved, exactly db-3's "
      f"share ({share:.2%}); spread over {len(receivers)} survivors, "
      f"largest receiver took {max(receivers.values()) / len(moved):.0%}")

ring.add_node("db-big", weight=2)        # twice the vnodes
load = Counter(ring.owner(k) for k in keys)
mean = len(keys) / (len(ring.weights) + 1)   # db-big counts as two
print(f"weighted node: db-big holds {load['db-big'] / mean:.2f}x a "
      f"weight-1 share")
print("replicas of user:42 ->", ring.preference_list("user:42", 3))
```

Running it with Python 3.8 or later prints:

```
add 9th node : 10.85% of keys moved (theory 1/9 = 11.11%); all moved keys went to {'db-
8'}
remove db-3  : 9.84% moved, exactly db-3's share (9.84%); spread over 8 survivors,
largest receiver took 20%
weighted node: db-big holds 1.88x a weight-1 share
replicas of user:42 -> ['db-0', 'db-5', 'db-big']
```

What to notice:

- Every moved key went to `db-8`: monotonicity, observed.
- Removal moved exactly the removed node's *actual* share, 9.84 % rather than the ideal 11.1 %; §14.8.4 quantifies that randomness.
- Those keys landed on all 8 survivors, the largest taking 20 %. With $V = 1$, one neighbor would take 100 %.
- `preference_list` skips nodes already chosen, so two replicas never share a machine.
- The weight-2 node got $1.88\times$, not $2\times$: weights set the *expected* share.

14.8.4 Virtual nodes and load balance: a derivation

With one position per node, §3.3.2 measured the busiest node at $2.6\times$ its fair share. Section 3.3.2 also claimed that the relative spread shrinks "roughly in proportion to $1/\sqrt{V}$". Here is the exact result for the standard model, checked by simulation.

The model. Assume an ideal hash, so each of the $M = NV$ vnode positions is independent and uniform on a ring of circumference 1. Each physical node owns V of them. A node's **load** L is the total length of the arcs ending at its vnodes, which is the fraction of a uniformly hashed key space it receives.

Step 1 — The arcs are Dirichlet-distributed. Cutting a circle at M independent uniform points gives M arc lengths that sum to 1 and are jointly $\text{Dirichlet}(1, \ldots, 1)$: fix one point as the origin by rotational symmetry, and the other $M - 1$ points cut the unit interval into pieces uniformly distributed on the simplex. This is the classical **uniform spacings** result [David and Nagaraja 2003]. The arcs are *exchangeable*, each with mean $1/M$.

Step 2 — A node's load is a Beta random variable. Which positions belong to which node depends only on labels, independent of where positions fall, so a node's arcs are in distribution any fixed V of the M exchangeable arcs. By the **aggregation property** of the Dirichlet distribution, their sum is $\text{Beta}(V, M - V)$:

$$L \sim \text{Beta}(V,\ (N-1)V).$$

Step 3 — Mean and variance. For $\text{Beta}(a, b)$, the mean is $a/(a+b)$ and the variance is $ab/((a+b)^2\,(a+b+1))$. With $a = V$ and $b = (N-1)V$:

$$E[L] = \frac{1}{N}, \qquad \text{Var}[L] = \frac{N-1}{N^2\,(NV+1)}.$$

Step 4 — Relative spread. Divide the standard deviation by the mean to get the coefficient of variation.

FORMULA

Load imbalance on a ring with virtual nodes

$$\mathrm{CV}(N,V) = \frac{\sqrt{\mathrm{Var}[L]}}{E[L]} = \sqrt{\frac{N-1}{NV+1}} \approx \frac{1}{\sqrt{V}} \quad (N \gg 1)$$

$$\frac{E[\max_i L_i]}{1/N} \approx 1 + z_N \cdot \mathrm{CV}(N,V) \quad (V \gtrsim 16), \qquad \frac{E[\max_i L_i]}{1/N} = H_N \quad (V = 1)$$

Symbol	Meaning	Units
L, L_i	Fraction of the key space owned by a node (by node i)	dimensionless (0–1)
N	Number of physical nodes	nodes
V	Virtual nodes per physical node	vnodes/node
CV	Coefficient of variation: standard deviation of a node's load divided by its mean	dimensionless
z_N	Expected maximum of N independent standard normal variables: 1.16 for $N = 5$, 1.54 for $N = 10$, 2.51 for $N = 100$, 3.24 for $N = 1,000$	dimensionless
H_N	N-th harmonic number $1 + \frac{1}{2} + \ldots + \frac{1}{N} \approx \ln N + 0.577$	dimensionless

Three remarks:

- **Why $1/\sqrt{V}$.** Each arc behaves almost like an independent exponential variable, whose standard deviation equals its mean. A sum of V of them has mean $\propto V$ and standard deviation $\propto \sqrt{V}$. The factor $(N-1)/N$ appears because the loads sum to 1.
- **The busiest node.** For large V each load is nearly normal, so the busiest of N sits about z_N standard deviations above the mean; z_N grows slowly, roughly as $\sqrt{2 \ln N}$. For $V = 1$, the longest of N uniform spacings has expected length H_N/N. The normal approximation slightly underestimates the maximum because the Beta distribution is right-skewed.
- **Agreement with published results.** Lamping and Veach report a 3.2 % standard error for a ring with 1,000 points per bucket, with about 1 % of buckets still at least 8 % off average [Lamping and Veach 2014]. The formula gives $\sqrt{1/1000} \approx 3.16$ %, and a two-sided 1 % normal tail sits at $2.58 \times 3.16\% \approx 8.1$ %. Karger et al. proved the asymptotic version: a logarithmic number of points per cache keeps every share within a constant factor of fair with high probability [Karger et al. 1997].

WORKED EXAMPLE

Worked example — Choosing V for a 100-node cluster. You want the busiest of $N = 100$ nodes to carry at most 10 % more than the mean, so $E[\max]/\text{mean} \le 1.10$.

1. Requirement: $z_{100} \cdot \text{CV} \le 0.10$, so $\text{CV} \le 0.10/2.51 = 0.0398$.
2. Solve $\sqrt{(N-1)/(NV+1)} \le 0.0398$: $(NV+1) \ge 99/0.0398^2 = 99/0.001584 \approx 62,500$, so $V \ge 625$.
3. Check a common default, $V = 256$: $\text{CV} = \sqrt{99/25,601} = 0.0622$, and $E[\max]/\text{mean} \approx 1 + 2.51 \times 0.0622 = 1.156$. A 30-ring simulation gives 1.17.
4. Check $V = 1$: $E[\max]/\text{mean} = H_{100} \approx 5.19$. The busiest node would carry over five times its fair share.
5. Memory for $V = 625$: 62,500 positions × about 16 bytes ≈ 1 MB per router, which is negligible.

Interpretation. Halving the imbalance costs four times the vnodes. **Engineering implication.** Either provision 15–20 % headroom per node with a few hundred vnodes, or place partitions deliberately: fixed equal-sized partitions (§14.9), token allocation, or bounded-load hashing (§14.8.6). More vnodes also mean more ranges to stream, repair and gossip.

The experiment below builds 200 random rings of 10 nodes for each V, computes each node’s exact share from the arc lengths and compares with the formula.

```
        """How load imbalance on a hash ring shrinks as virtual nodes V grow.

        For each V, build many independent rings of N nodes, compute every node's
        exact share of the key space (the total length of the arcs it owns) and
        compare the spread with the closed form sqrt((N-1)/(N*V+1)).
        """
        import hashlib
        import math
        import statistics

        RING = 2 ** 64

                cvs, maxes = [], []
                for t in range(trials):
                    s = node_shares(N, v, t)
                    cvs.append(statistics.pstdev(s) * N)      # std / mean, mean = 1/N
                    maxes.append(max(s) * N)
                # shares sum to exactly 1, so pstdev about the mean 1/N is unbiased
                cv_sim = math.sqrt(statistics.fmean(c * c for c in cvs))
                cv_th = math.sqrt((N - 1) / (N * v + 1))
                rows.append((v, cv_sim))
```

```
                print(f"{v:>5} {cv_sim:>8.4f} {cv_th:>10.4f} "
                      f"{statistics.fmean(maxes):>13.3f} {1 + z * cv_th:>16.3f}")
            harmonic = sum(1 / k for k in range(1, N + 1))
            print(f"V=1 exact: E[max/mean] = H_N = {harmonic:.3f}")
            (v1, c1), (v2, c2) = rows[1], rows[-1]
            slope = math.log(c2 / c1) / math.log(v2 / v1)
            print(f"log-log slope of CV vs V between V={v1} and V={v2}: {slope:.3f}")
```

Running it takes about two seconds and prints:

```
N = 10 nodes, 200 rings per row, E[max of 10 normals] = 1.539
    V   CV sim  CV theory  max/mean sim  max/mean approx
    1   0.8977     0.9045         2.912           2.392
    4   0.4655     0.4685         1.885           1.721
   16   0.2358     0.2364         1.416           1.364
   64   0.1187     0.1185         1.199           1.182
  256   0.0585     0.0593         1.095           1.091
 1024   0.0302     0.0296         1.050           1.046
V=1 exact: E[max/mean] = H_N = 2.929
log-log slope of CV vs V between V=4 and V=1024: -0.493
```

What to notice:

- The simulated CV matches $\sqrt{(N-1)/(NV+1)}$ within sampling error, and the log–log slope of -0.49 is the signature of $1/\sqrt{V}$ (slope -0.5). Each $4\times$ increase in V halves the spread.
- For $V = 1$, the simulated maximum (2.91) matches $H_{10} = 2.93$ and the normal approximation (2.39) is poor; use it only from about $V = 16$.
- With K actual keys, counts add sampling noise of CV about $\sqrt{N/K}$ (1 % for $K = 10^5$, $N = 10$), which is why the weight-2 node above showed $1.88\times$.
- The model assumes uniform key popularity. Hot keys are a separate problem (§14.10).

> NOTE
>
> **Note — Resolution of the $1/\sqrt{V}$ question.** Under the ideal-hash model a node's share is exactly $\mathrm{Beta}(V, (N-1)V)$, with coefficient of variation $\sqrt{(N-1)/(NV+1)} \to 1/\sqrt{V}$. The simulation and [Lamping and Veach 2014] confirm it, so §3.3.2's statement holds for the relative standard deviation. The busiest node's excess also shrinks as $1/\sqrt{V}$, multiplied by a slowly growing z_N.

14.8.5 Replication on the ring

On a ring, each key is stored on the first R **distinct physical** nodes clockwise, its preference list (R here is the replication factor, which §27.8 calls N because there R is the read quorum). Dynamo does this, typically with three replicas, and also skips nodes in the

same failure domain [DeCandia et al. 2007]. With vnodes, a failed node's replicas are spread over many nodes, so re-replication copies from all of them in parallel. Quorum reads and writes over preference lists are in §27.7–§27.9.

INDUSTRY EXAMPLE

Amazon Dynamo. Dynamo began with T random tokens per node. The paper reports that bootstrapping a node required scanning others' data and that shifting partition boundaries complicated archiving and Merkle-tree maintenance. Dynamo moved to Q equal-sized partitions with Q/S assigned to each of S nodes, which the paper reports gave the best load-balancing efficiency and the smallest membership metadata of the strategies compared: the fixed-partitions approach of §14.9. *Evidence: Primary* — [DeCandia et al. 2007]

INDUSTRY EXAMPLE

Apache Cassandra. Early Cassandra used one token per node and moved tokens to rebalance [Lakshman and Malik 2010]. Later releases defaulted to 256 random vnodes per node. Cassandra 4.0 lowered the default `num_tokens` to 16 with an allocation algorithm that places tokens to balance load for a replication factor, cutting repair and streaming cost (as of Cassandra 4.0). *Evidence: Primary* — [Apache Cassandra Docs]

14.8.6 Alternatives: jump consistent hash and rendezvous hashing

Two other algorithms give the same minimal movement with different trade-offs.

Jump consistent hash

Jump consistent hash maps a 64-bit key and a bucket count n to a bucket in $[0, n)$ using a few registers and no table [Lamping and Veach 2014]. Growing from b to $b+1$ buckets should move a key to the new bucket with probability exactly $1/(b+1)$. Seeding a pseudo-random generator with the key makes those jump decisions deterministic, and the algorithm draws the position of the key's *next* jump directly, so the loop runs only $O(\ln n)$ times on average. The Python port below follows the paper's C++ code and compares it with rendezvous hashing.

```
        """Jump consistent hash and rendezvous (HRW) hashing, compared on movement and
balance."""
        import hashlib
        import statistics

        MASK64 = (1 << 64) - 1

        def h64(s: str) -> int:
            return int.from_bytes(hashlib.md5(s.encode("utf-8")).digest()[:8], "big")

        def jump_hash(key: int, num_buckets: int) -> int:
            """Lamping & Veach (2014): 64-bit key -> bucket in [0, num_buckets)."""
            b, j = -1, 0
            while j < num_buckets:
                b = j
                key = (key * 2862933555777941757 + 1) & MASK64   # 64-bit LCG step
                j = int((b + 1) * (float(1 << 31) / float((key >> 33) + 1)))
            return b

        def rendezvous(key: str, nodes: list) -> str:
            """Highest random weight: every node scores the key; the top score wins."""
            return max(nodes, key=lambda node: h64(f"{node}|{key}"))

        def report(name, assign_before, assign_after, keys, n_after):
            moved = sum(assign_before(k) != assign_after(k) for k in keys) / len(keys)
            counts = {}
            for k in keys:
                b = assign_after(k)
                counts[b] = counts.get(b, 0) + 1
            mean = len(keys) / n_after
            cv = statistics.pstdev(counts.values()) / mean
            print(f"{name:<11} moved {moved:6.2%} (ideal {1 / n_after:.2%})  "
                  f"key-count CV {cv:.4f}  max/mean {max(counts.values()) / mean:.3f}")

        if __name__ == "__main__":
            keys = [f"order:{i}" for i in range(100_000)]
            hashed = {k: h64(k) for k in keys}
            n = 10
            names = [f"db-{i}" for i in range(n + 1)]
            report("jump", lambda k: jump_hash(hashed[k], n),
                   lambda k: jump_hash(hashed[k], n + 1), keys, n + 1)
            report("rendezvous", lambda k: rendezvous(k, names[:n]),
                   lambda k: rendezvous(k, names), keys, n + 1)
            # Binomial noise alone (perfectly fair assignment of 100,000 random keys)
            p = 1 / (n + 1)
            print(f"{'noise floor':<11} key-count CV of a perfect hash = "
                  f"{((1 - p) / (len(keys) * p)) ** 0.5:.4f}")
```

Running it prints:

```
jump        moved  9.10% (ideal 9.09%)  key-count CV 0.0081  max/mean 1.019
rendezvous  moved  9.14% (ideal 9.09%)  key-count CV 0.0133  max/mean 1.017
noise floor key-count CV of a perfect hash = 0.0100
```

What to notice:

- Both move almost exactly the ideal $1/(N+1)$ of keys.
- Both balance at the **noise floor**, the variation of assigning keys by fair coin; differences from 0.010 are sampling noise over just 11 buckets. A ring with $V = 100$ has a structural CV near 0.10 for $N = 10$.
- `& MASK64` reproduces C's unsigned 64-bit overflow, which Python integers lack.
- `rendezvous` computes N hashes per lookup, trivial for 10 nodes, significant for thousands.

Jump hash's limitation is structural: buckets are numbered 0 to $n-1$ and only the *last* can be added or removed. It suits logical shard numbers that never disappear, because each shard is a replicated group whose machines are replaced underneath it, not cache tiers where arbitrary nodes come and go.

Rendezvous (highest random weight) hashing

Rendezvous hashing, or **highest random weight (HRW) hashing**, scores every node with $h(\text{node} \parallel \text{key})$ and picks the highest [Thaler and Ravishankar 1998]. Adding a node moves an expected $1/(N+1)$ of keys. Removing one sends each of its keys to that key's second-highest scorer, spreading load evenly with no vnodes, and the top R scores form a replica list. Lookups cost $O(N)$; weighted and hierarchical variants exist.

Table 14.8 — Key-to-node assignment schemes compared.

	`hash mod N`	Ring + vnodes	Jump hash	Rendezvous (HRW)
Keys moved on add	$\sim N/(N+1)$	$\sim 1/(N+1)$	$\sim 1/(N+1)$	$\sim 1/(N+1)$
Load balance (CV)	Noise floor	$\sqrt{(N-1)/(NV+1)}$	Noise floor	Noise floor
Lookup cost	$O(1)$	$O(\log NV)$	$O(\log N)$ expected	$O(N)$
Memory	None	$O(NV)$ positions	None	$O(N)$ names
Remove arbitrary node	Remaps nearly all	Yes	No, only the last bucket	Yes
Weights	Awkward	More vnodes	No	Weighted scores
Replica list	Ad hoc	Walk to R distinct nodes	Ad hoc	Top-R scores
Choose when	N fixed forever	Caches, Dynamo-style stores	Numbered shards that only grow	Small N; simple, even spread

Table 3.2 gives a brief version. **Maglev hashing** fills a fixed lookup table for $O(1)$ lookups in load balancers (§19.4) at the cost of slightly more disruption [Eisenbud et al. 2016]. **Consistent hashing with bounded loads** caps each node at $(1+\varepsilon)$ times the average and forwards overflow clockwise, a hard bound random vnodes cannot give [Mirrokni et al. 2018].

Failure scenarios

Table 3.3 (§3.3.2) lists generic ring failures. Three more matter for databases.

Table 14.9 — Additional ring failure scenarios in partitioned databases.

What goes wrong	Why	Detection	Recovery	Prevention
Two replicas on one machine or rack	Preference list counted vnodes, not physical nodes or zones	Placement audit	Re-replicate	Skip duplicate nodes and zones when walking
Data unreachable after hash change	Library upgrade changed the hash function or seed	Sudden 100 % miss or not-found rate	Roll back the library	Pin hash algorithm and seed in the ring's metadata
Rebalance overloads cluster	Many vnodes stream at once after a join	Foreground p99 latency rises during join	Throttle streaming	Rate-limit streaming; join one node at a time

COMMON MISTAKE

Mistake — "More vnodes are always better." Balance improves only as $1/\sqrt{V}$, while ranges to repair and stream grow linearly with V. With $V = 256$ and three replicas, a node's ranges overlap most other nodes, so losing almost any two nodes leaves some range without a quorum.

14.9 Rebalancing

14.9.1 What rebalancing must achieve

DEFINITION

Definition — Rebalancing. Moving partitions, or parts of them, between nodes so that data and load stay even as nodes join, leave or fail and as data grows, while staying available and moving no more data than necessary.

First-principles explanation

When a third library room opens, you could renumber every shelf and carry two-thirds of the books around. Or, if the books were already packed in 300 numbered crates, you could carry 100 crates to the new room and update the crate list at the front desk. Rebalancing is cheap when the unit you move is decided *before* you need to move it. It must also be *online*: a store serving 100,000 requests per second cannot pause for a five-hour copy. Kleppmann describes three strategies [Kleppmann 2017].

Why does this exist?

14.9.2 Fixed number of partitions

Create many more partitions than nodes up front, say 1,024 for 16 nodes, and never change the number. A key's partition is fixed forever; only the **partition-to-node map** changes, and a joining node takes whole partitions from the others. Elasticsearch fixes primary shards at index creation, Riak and Couchbase (vBuckets) use fixed partition sets, and the logical shards of Notion and Instagram (§14.7) and Dynamo's final strategy are the same idea.

The difficulty is choosing P. Each partition has fixed overhead, so P cannot be huge, yet P caps the node count and sets the granularity of balance. Choose P at least 10× the largest plausible node count and divisible by likely fleet sizes (§14.7.4). If data grows 100×, each partition does too and may become slow to move.

14.9.3 Dynamic splitting

Start with one partition, or a few, and **split** any partition that passes a size threshold, merging ones that shrink. This adapts to data volume and suits range partitioning, where the key distribution is unknown. Bigtable splits tablets at roughly 100–200 MB [Chang et al. 2006]; HBase regions, MongoDB chunks and distributed SQL ranges split the same way. An empty database starts on one node, so bulk loads should **pre-split** on known boundaries.

14.9.4 Partitions proportional to nodes

Give each node a fixed number of partitions, such as Cassandra's `num_tokens`. A joining node picks that many split points and takes over half of each range it cuts, so the partition count grows with the cluster. This is consistent hashing with vnodes viewed as a rebalancing strategy.

Table 14.10 — Rebalancing strategies compared.

	Fixed partitions	Dynamic splitting	Proportional to nodes
What moves on node join	Whole partitions, map edit	Split halves	Arcs cut by new tokens
Partition count	Constant *P*	Grows with data	Grows with nodes
Partition size	Grows with data	Bounded by threshold	Grows with data per node
Range scans	With hash, no	Yes (range keys)	With hash, no
Main risk	*P* chosen too small or too large	Cold start; split storms	Random imbalance (§14.8.4)
Examples	Elasticsearch, Riak, Couchbase, logical shards, Dynamo	Bigtable, HBase, MongoDB, distributed SQL	Cassandra
Choose when	Predictable growth; simple ops	Range access; unknown key distribution	Peer-to-peer ring stores

WARNING / TRADE-OFF

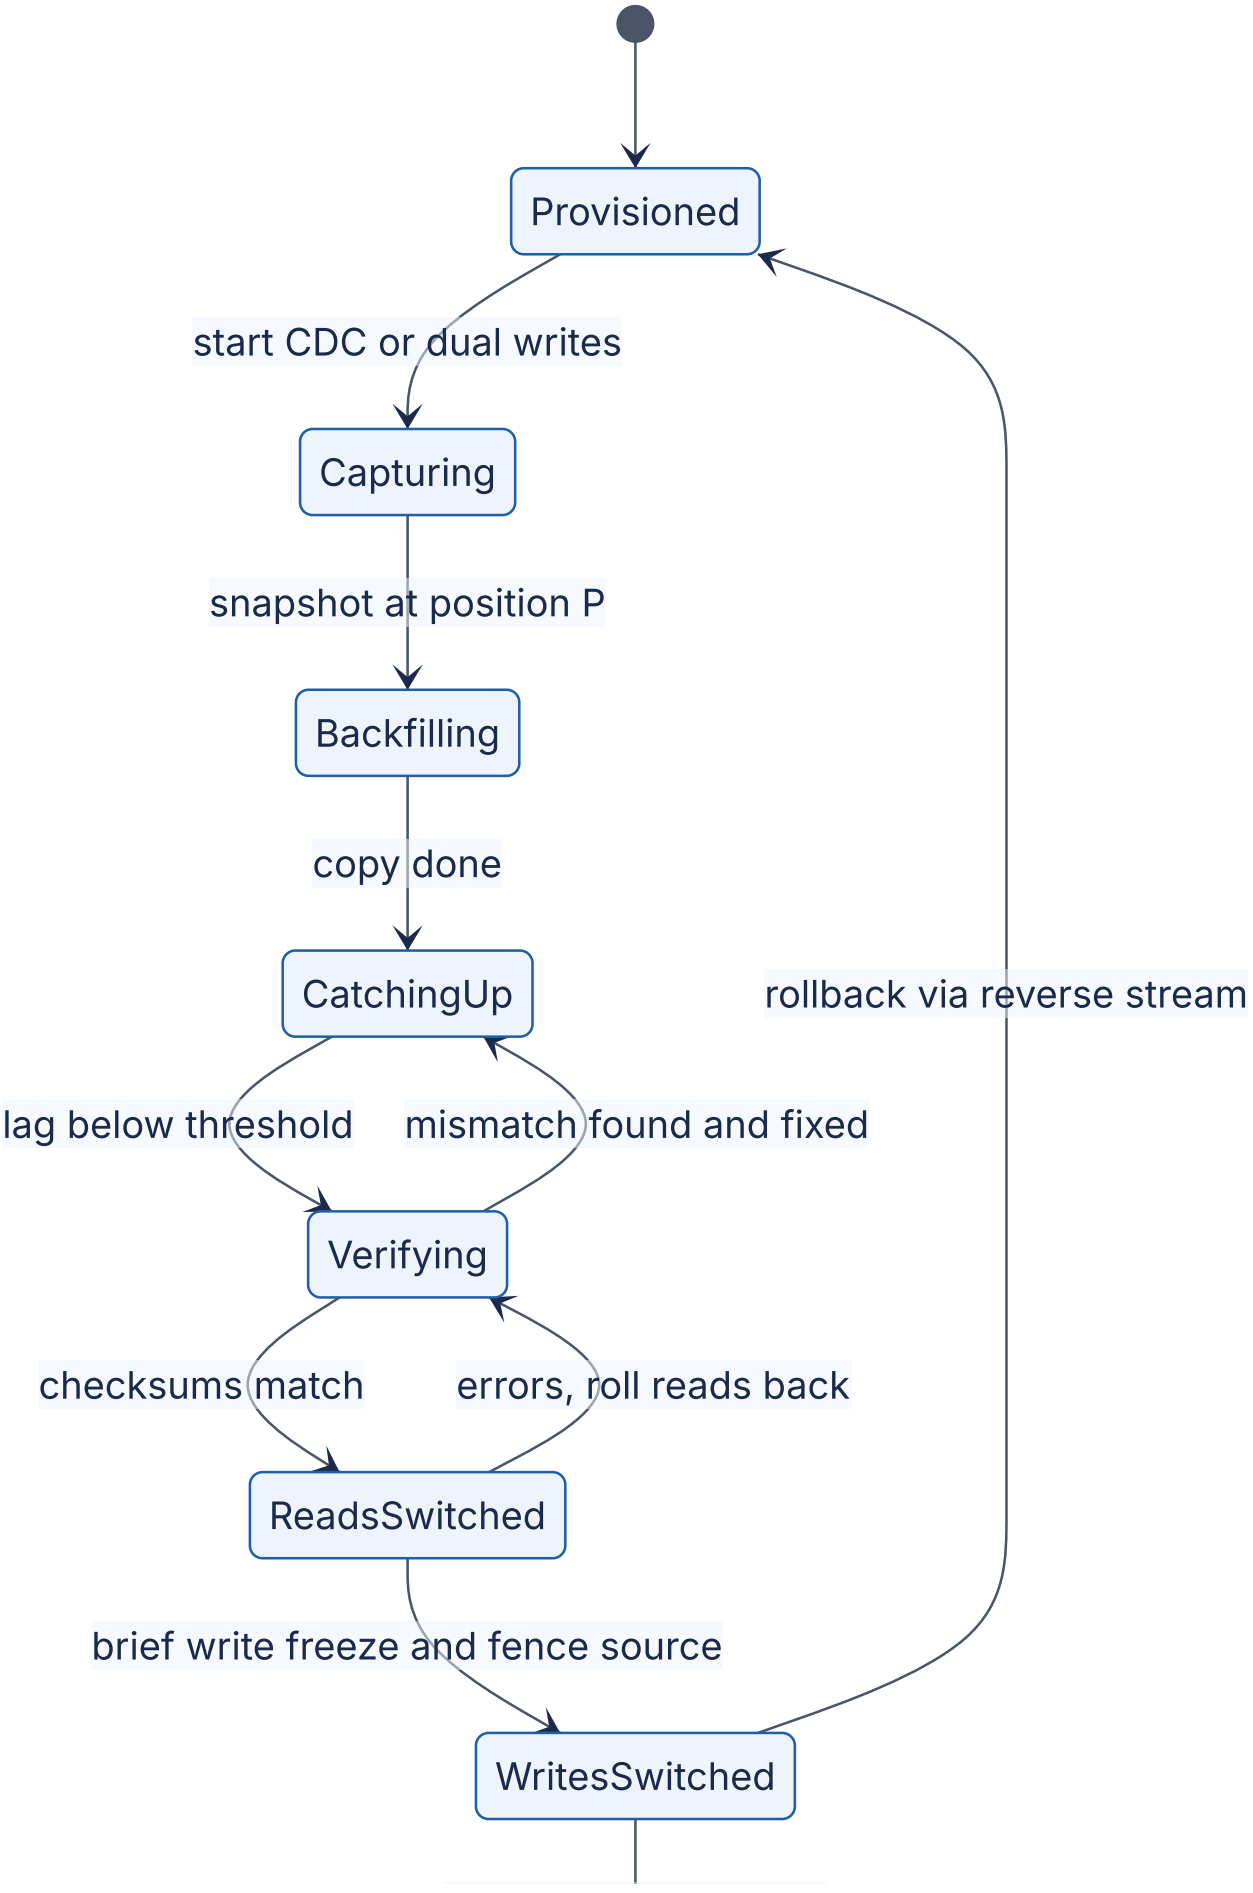
Warning — Fully automatic rebalancing can turn a slow node into an outage. If the failure detector mistakes an overloaded node for a dead one, streaming its partitions away adds load to it and its peers, more nodes look dead, and the cascade grows. Many operators let the system *propose* plans but require a human or rate-limited controller to execute them [Kleppmann 2017].

14.9.5 Online migration: dual writes, backfill and cutover

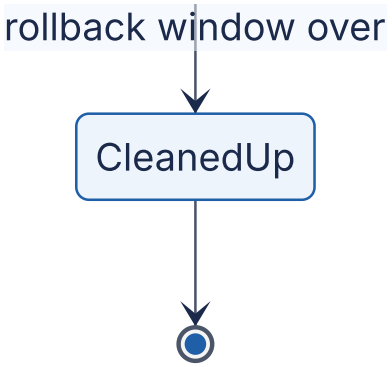
Changing the shard key, splitting a shard or moving a tenant means copying data while the application keeps writing. The safe procedure is the same whether done by Vitess VReplication, a CDC pipeline or by hand:

1. **Provision** the target shards with the new schema and partitioning.
2. **Start capturing changes** at a known source position *before* copying, from the change stream (CDC, §14.4.5) or application **dual writes**.
3. **Backfill** existing rows from a snapshot at that position, throttled.
4. **Catch up** by applying captured changes until the target is seconds behind.
5. **Verify** with per-range checksums and **shadow reads** that query both sides and log differences.
6. **Switch reads**, gradually if possible; the source still takes writes.
7. **Switch writes**: freeze writes for seconds, wait for the target to apply the last position, redirect writes and fence the source.
8. **Keep a reverse stream** to the source for a rollback window.
9. **Clean up** after the window closes.

Figure 14.8 — Online resharding as a state machine.



Provisioned
start CDC or dual writes
Capturing
snapshot at position P
Backfilling
copy done
CatchingUp
rollback via reverse stream
lag below threshold
mismatch found and fixed
Verifying
checksums match
errors, roll reads back
ReadsSwitched
brief write freeze and fence source
WritesSwitched



Reading the diagram. Capture starts *before* the snapshot so no write is missed. Until reads switch, the source alone serves users while the change stream updates the target asynchronously. Backward arrows are the safety net, including the reverse stream after the write switch. The write switch is the riskiest step, since two writable copies would be split brain, hence fencing. Shards migrate in parallel, each throttled.

WORKED EXAMPLE

Worked example — How long does a shard split take? A 3 TB shard is split in two, so 1.5 TB moves to a new shard (SI units). The backfill is throttled to 150 MB/s. During the copy, the moving half of the shard receives 2,000 writes/s, and the target can apply 6,000 writes/s.

1. Backfill: $1.5 \times 10^{12} / 1.5 \times 10^{8} = 10,000$ s, about 2.8 hours.
2. Backlog when the backfill ends: $B = 2,000 \times 10,000 = 2 \times 10^{7}$ writes.
3. Catch-up (§14.4.2): $T = 2 \times 10^{7} / (6,000 - 2,000) = 5,000$ s, about 1.4 hours. Production tools apply changes *during* the backfill, which shortens this.
4. Verification by range checksums: about 1 hour. The cutover freeze lasts a few seconds.

Interpretation. About 5 hours, with seconds of write unavailability. **Engineering implication.** Resharding takes hours per shard and competes for I/O, so start at 60–70 % of a shard's limit, not 95 %, and rehearse the runbook.

INDUSTRY EXAMPLE

Vitess resharding. Vitess's `Reshard` and `MoveTables` VReplication workflows copy rows while streaming binlog changes, compare source and target with `VDiff`, switch reads and writes as separate steps (`SwitchTraffic`) and keep reverse replication so the switch can be undone (`ReverseTraffic`) until the workflow completes. *Evidence: Primary* — [Vitess Docs]

Failure scenarios

Table 14.11 — Failure scenarios during rebalancing and migration.

What goes wrong	Why	Detection	Recovery	Prevention
Rows missing on target	Capture started after the snapshot	Count or checksum mismatch	Re-copy affected ranges	Start capture first; snapshot at a known position
Lost or duplicated writes on cutover	Writes accepted on both sides	Divergent checksums after switch	Reconcile from logs	Freeze and fence the source; idempotent apply
Production latency rises	Backfill saturates disk or network	p99 latency during copy	Lower the throttle	Throttle by measured headroom

COMMON MISTAKE

Mistake — "Dual writes are simple: just write to both." Two independent writes are not atomic. A crash between them, or concurrent writers applying in different orders, makes the stores diverge silently. Prefer deriving the copy from the source's ordered change log (CDC), or reconcile continuously.

14.10 Hot partitions and skew

14.10.1 Causes, detection and mitigation

DEFINITION

Definition — Hot partition and hot key. A **hot partition** receives enough excess requests or data to saturate its node while peers idle. A **hot key** is a single key causing that excess. **Skew** is uneven distribution of data or load in general.

First-principles explanation

A supermarket assigns customers to ten lanes by surname initial. Then a celebrity named K signs autographs at lane 6, and its queue reaches the car park while nine cashiers wait. An eleventh lane does not help; the celebrity's crowd still follows the letter K. The fix is a *different rule for the celebrity*.

Why does this exist?

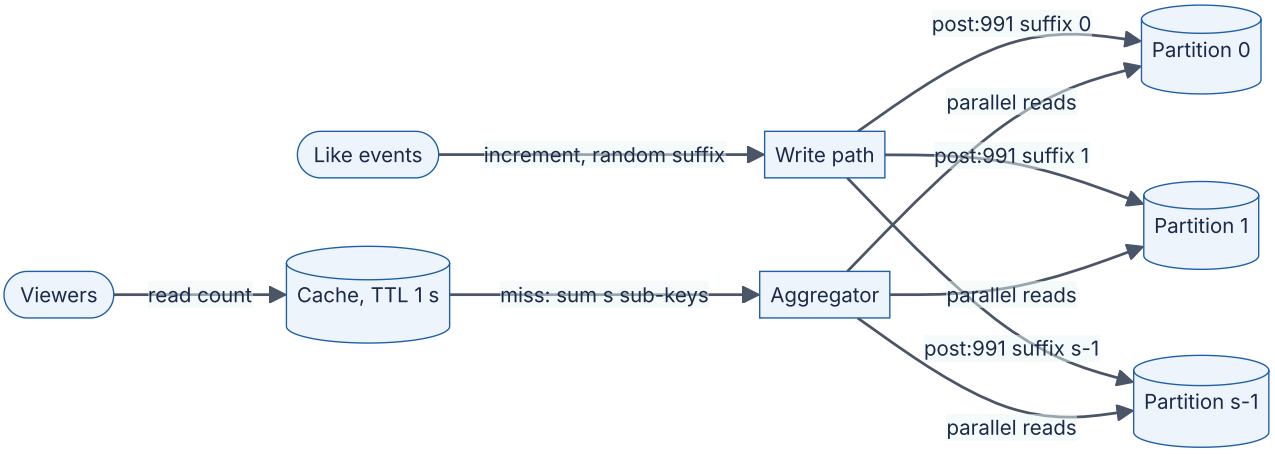
Popularity is typically heavy-tailed (§4.7.2): celebrity accounts, flash sales, the newest partition of a timestamp-ranged table, a giant tenant. Partitioning divides capacity evenly, so any concentration of load becomes a bottleneck. Detect it with per-partition request,

CPU, size and throttling metrics, alerting on the busiest-to-median ratio, and find hot keys with sampling or a heavy-hitters sketch (§17.6). Distinguish **data skew** from **load skew**; they need different fixes.

Mitigation techniques

1. **Key salting.** Append a suffix $0..s-1$ to a hot key, such as `post:991#7`, spreading its writes over s partitions; readers query and combine all s sub-keys. Good for counters and append-only data, bad for objects read as one consistent unit.
2. **Caching and replicas** for hot reads (Chapter 20), with request coalescing so one miss per key reaches the database (§20.11).
3. **Special-case the giants**: dedicated shards (§14.7.2) or fan-out on read for celebrities (§14.7.3).
4. **Avoid monotonic leading keys**: prefix timestamps with a hashed or bucketed component, such as `(sensor_id, day)`.
5. **Bound partition size** with a time bucket, such as `(channel_id, bucket)`.
6. **Adaptive capacity**: the store lends hot partitions unused capacity or splits them by traffic, not just size.
7. **Rate-limit** keys heated by buggy or malicious clients (Chapter 22).

Figure 14.9 — Salting a hot counter across partitions.



Reading the diagram. Each increment gets a random suffix, so each of the s partitions receives $1/s$ of the hot key's writes. Viewers read a cached total (TTL 1 s); only a miss makes the aggregator read all s sub-keys in parallel. Failure points: one slow sub-key partition delays the aggregate, and a cache failure turns every view into s reads. Raise s only for keys detected as hot.

FORMULA

Salt factor for a hot key

$$s = \left\lceil \frac{\lambda_{\text{key}}}{u \cdot c_{\text{part}}} \right\rceil \qquad \text{read amplification} = s$$

Symbol	Meaning	Units
s	Number of sub-keys (salt factor)	sub-keys
λ_{key}	Write rate to the hot key	writes/s
c_{part}	Write capacity of one partition	writes/s
u	Target utilization of a partition	dimensionless (0–1)

WORKED EXAMPLE

Worked example — A viral post's like counter. A post receives $\lambda_{\text{key}} = 50,000$ likes per second at its peak. The store's partitions each sustain $c_{\text{part}} = 1,000$ writes/s, a figure of the same order as DynamoDB's documented per-partition limit of 1,000 write capacity units per second (as of 2026; §12.4.5), and you target $u = 0.7$.

1. Salt factor: $s = \lceil 50,000/(0.7 \times 1,000) \rceil = \lceil 71.4 \rceil = 72$ sub-keys.
2. Writes per sub-key: $50,000/72 \approx 694$ writes/s, which is 69 % of a partition's capacity.
3. Reads without a cache: 20,000 viewers per second each read the count, so $20,000 \times 72 = 1,440,000$ partition reads/s. That is far worse than the problem you solved.
4. Reads with a 1-second cached total: at most 1 aggregation per second per cache node, so with 10 cache nodes, about $10 \times 72 = 720$ partition reads/s.

Interpretation. Salting turns one impossible hot spot into 72 manageable ones but multiplies read cost by s. **Engineering implication.** Pair it with cached or pre-aggregated reads, apply it only to detected hot keys, and accept a count that lags by the TTL.

INDUSTRY EXAMPLE

Amazon DynamoDB. DynamoDB documents per-partition throughput limits plus **burst capacity** (briefly using recently unused capacity) and **adaptive capacity** (letting a hot partition use more than an even share of the table's throughput and isolating frequently accessed items). The 2022 paper describes the evolution from static per-partition allocation, which throttled unevenly accessed tables, to these mechanisms and to splitting partitions by observed traffic. *Evidence: Primary* — [AWS Docs: DynamoDB], [Elhemali et al. 2022]

INDUSTRY EXAMPLE

Discord. Discord stored messages in Cassandra keyed by channel ID plus a time bucket, so a busy channel's history spans many bounded partitions rather than one ever-growing partition, which the post identifies as a performance problem. *Evidence: Primary* — [Discord Engineering 2017]

Failure scenarios

Table 14.12 — Failure scenarios for hot partitions.

What goes wrong	Why	Detection	Recovery	Prevention
One shard throttles while others idle	Celebrity or viral key	Busiest-to-median partition ratio	Cache or salt the key	Hot-key detection; per-key special handling
Newest partition saturated	Timestamp as leading range key	All writes on last range	Re-key with hash prefix	Hash or bucket the leading key
Salted reads become slow	Read fan-out over s partitions	Read p99 grows with s	Cache aggregate	Pre-aggregate; salt only hot keys

14.11 Secondary indexes in partitioned databases

14.11.1 Local and global indexes

Queries by anything other than the partition key, such as orders by `status` in a table partitioned by `customer_id`, need a **secondary index**, and its key differs from the data's key. There are two designs.

DEFINITION

Definition — Local and global secondary indexes. A **local** (document-partitioned) index lives in each partition and covers only its rows. A **global** (term-partitioned) index covers all rows and is partitioned by the *indexed value*, so all entries for one value live together [Kleppmann 2017].

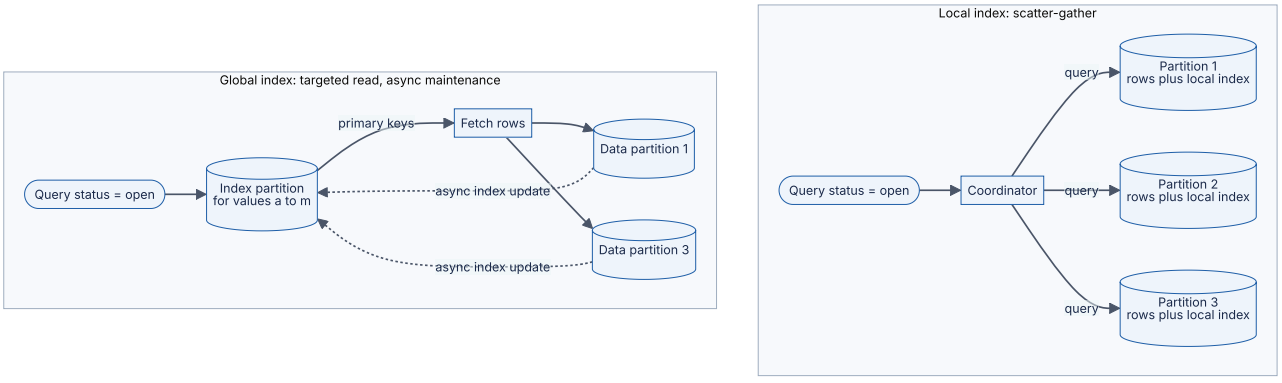
First-principles explanation

Each library room can keep a card catalog of its own books, so finding every Le Guin means checking every room: a local index. Or one central author catalog, itself split by author name across rooms, says where each book is: one visit finds Le Guin, but every new book updates its own room *and* perhaps a catalog section elsewhere: a global index.

How it works internally

- **Local index.** Queries scatter to every partition and a coordinator gathers results. Writes stay in one partition and one local transaction.
- **Global index.** A query visits the one index partition owning the value, gets primary keys, then fetches rows. A write must also update index partitions on other nodes; doing so synchronously needs a distributed transaction (§14.12), so most systems update global indexes **asynchronously** and they briefly lag.

Figure 14.10 — Local versus global secondary index for a query on `status`.



Reading the diagram. Top: the coordinator queries every partition synchronously and waits for the slowest. Bottom: the query reads the one index partition owning `open`, then fetches only the needed rows; dotted arrows show asynchronous index maintenance, so new rows may briefly be missing. Local indexes suffer from slow partitions; global ones from lag and from hot values concentrating on one index partition.

Mathematical foundations

Scatter-gather pays the fan-out tail cost of §4.8.4: if each partition is slow with probability q, a query over n partitions waits for at least one slow response with probability $P_{\text{slow}} = 1 - (1 - q)^n$.

WORKED EXAMPLE

Worked example — A local-index query across 32 shards. Each shard answers within 10 ms at p99, so $q = 0.01$.

1. With $n = 1$, $P_{\text{slow}} = 0.01$.
2. With $n = 32$, $P_{\text{slow}} = 1 - 0.99^{32} = 1 - 0.725 = 0.275$.
3. With $n = 128$, $P_{\text{slow}} = 1 - 0.99^{128} = 1 - 0.276 = 0.724$.

Interpretation. At 128 shards the *median* scatter-gather query is as slow as one shard's p99. **Engineering implication.** Keep scatter-gather off hot paths: use a global index or denormalized copy for frequent non-key lookups, and hedged requests (§23.7) or partial results where fan-out is unavoidable.

Table 14.13 — Local and global secondary indexes compared.

	Local (document-partitioned)	Global (term-partitioned)
Write cost	One partition, local transaction	Row partition + index partition(s) on other nodes
Read by indexed value	All partitions (scatter-gather)	One index partition, then targeted fetches
Index freshness	Synchronous with the row	Usually asynchronous: briefly stale
Tail latency	Grows with partition count	Independent of partition count
Hot indexed values	Spread over partitions	Concentrated on one index partition
Examples	Elasticsearch shards, MongoDB, Cassandra secondary indexes, DynamoDB LSIs	DynamoDB GSIs, distributed SQL global indexes, Vitess lookup vindexes
Choose when	Writes dominate; queries usually include the partition key	Frequent lookups by non-key attribute

INDUSTRY EXAMPLE

Amazon DynamoDB indexes. A **local secondary index** shares the table's partition key, lives with the base data and supports strongly consistent reads. A **global secondary index** has its own partition key, is maintained asynchronously with eventually consistent reads, and has its own throughput, which can throttle base-table writes if it falls behind. *Evidence: Primary* — [AWS Docs: DynamoDB]

COMMON MISTAKE

Mistake — "A global index is as consistent as the table." Usually it is an asynchronously updated copy, so querying it right after a write can miss the row: read-your-writes again (§14.4.3).

14.12 Cross-shard queries and distributed transactions

Partitioning makes single-key operations cheap and everything else harder. This is a preview; Chapter 28 covers distributed transactions and Chapter 32 sagas.

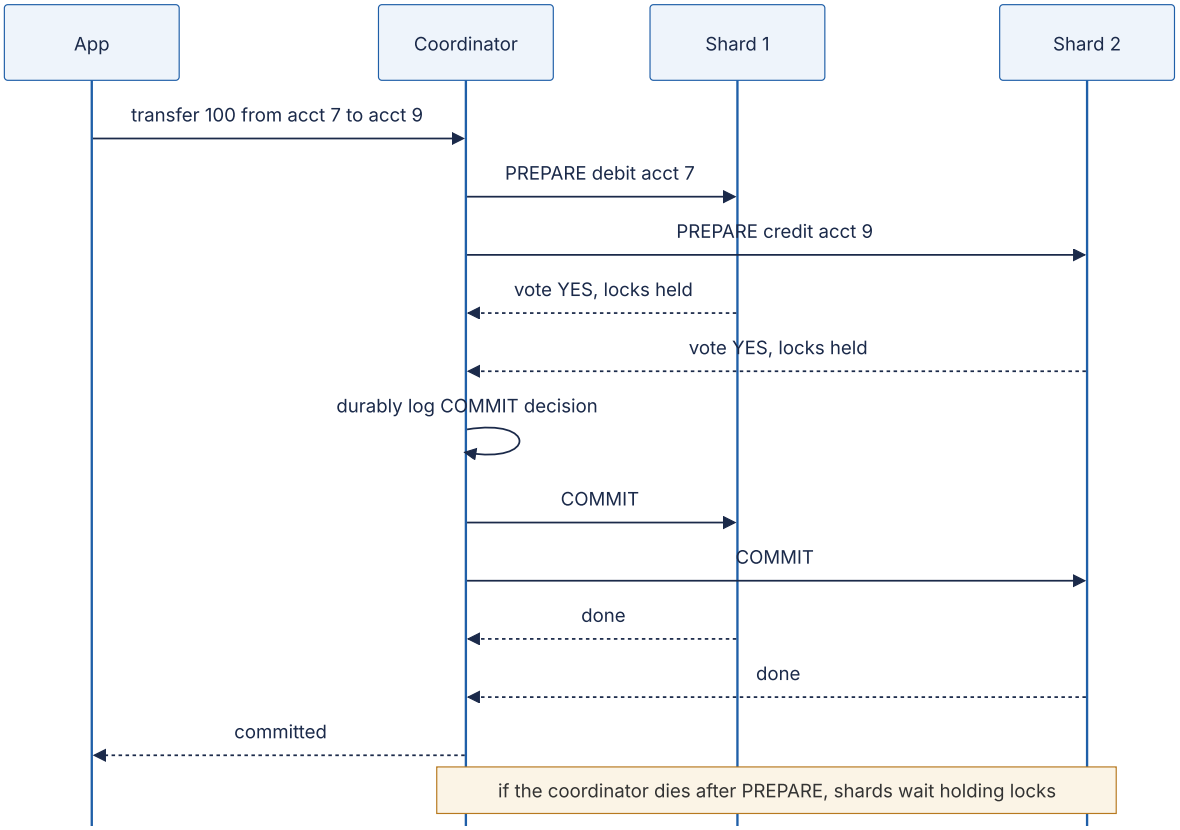
14.12.1 Cross-shard queries

1. **Scatter-gather aggregates** must be decomposed: sum per-shard `COUNT`s, compute `AVG` from per-shard sums and counts (never average averages), and merge per-shard top 10s for `ORDER BY ... LIMIT 10`. Routers such as VTGate do this automatically for supported queries.
2. **Joins** between tables sharded on the same key, such as `orders` and `order_items` by `customer_id`, run locally (**co-location**). Small reference tables can be copied to every shard. Other joins belong in analytical systems (Chapter 29).
3. **Global uniqueness** on a non-key column such as `email` needs a lookup table partitioned by that column.
4. **Global IDs** cannot come from per-shard auto-increment; embed the shard (§14.7.3) or use §17.10's schemes.

14.12.2 Cross-shard transactions: a preview

A transaction writing two shards must commit on both or neither. **Two-phase commit (2PC)** has a coordinator ask every participant to *prepare* (make the change durable but invisible and promise to commit); only if all vote yes does it log the decision and tell them to *commit*.

Figure 14.11 — Two-phase commit across two shards (preview of Chapter 28).



Reading the diagram. Every call is synchronous: two round trips per participant plus a durable decision log at the coordinator. After voting YES, a shard holds locks and *cannot* decide alone, so a coordinator crash blocks those rows (the note). Latency is at least two RTTs plus several fsyncs, and throughput falls as participants increase.

Teams avoid distributed transactions in roughly this order: (1) choose the shard key so transactions stay on one shard (§14.7.2); (2) use a saga of local transactions with compensations (Chapter 32); (3) use a database that implements distributed transactions internally (Chapter 28); (4) use explicit 2PC with careful recovery of in-doubt transactions.

WARNING / TRADE-OFF

Warning — Multi-shard writes through a proxy may not be atomic. A proxy may commit shards one after another, so a failed second commit leaves the first committed. Vitess documents this best-effort default and an optional two-phase commit mode with its own constraints.

14.13 Connection pooling and proxies

14.13.1 Why connections become a scaling problem

DEFINITION

Definition — Connection pooler. A component that keeps a few open database connections and lends them to many clients per session, transaction or statement, either inside the application or as a shared proxy.

First-principles explanation

A restaurant employs waiters for the tables being served, not one per customer who might walk in. Database connections are waiters: each costs server memory even when idle, and most application connections are idle most of the time.

Why does this exist?

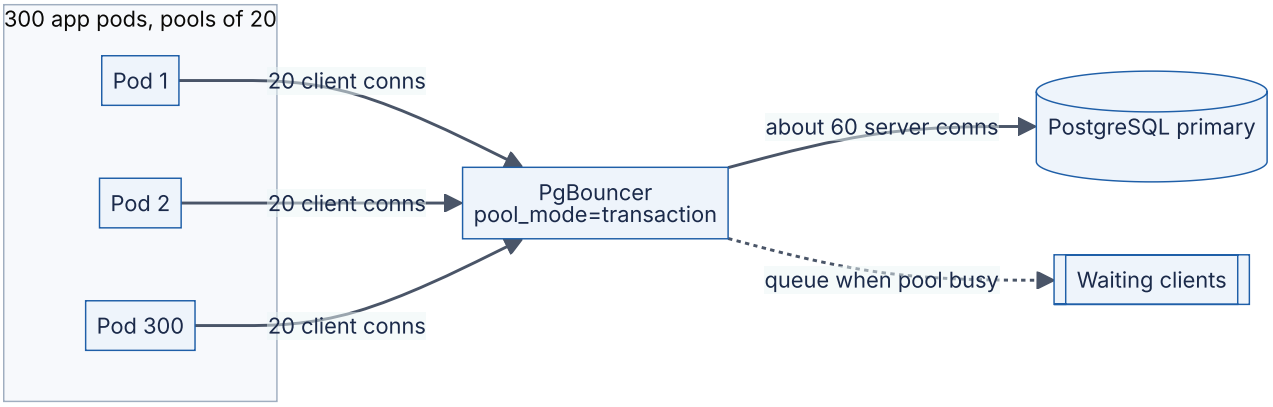
PostgreSQL runs a process per connection and MySQL a thread, so practical limits are hundreds to low thousands per server. Yet 300 application pods with pools of 20 open 6,000 connections while Little's Law says far fewer are busy (§4.11). A pooler accepts thousands of cheap client connections and multiplexes them onto tens of server connections.

How it works internally: PgBouncer

PgBouncer is a lightweight, single-process, event-driven pooler that speaks the PostgreSQL protocol, keeps a pool per database and user pair, and offers three **pool modes** [PgBouncer Docs]:

- **Session pooling** lends a server connection for the client's whole session: fully compatible, small savings.
- **Transaction pooling** lends it for one transaction, the source of the big savings. Session state breaks: session `SET`, `LISTEN`, session advisory locks, temporary tables and `WITH HOLD` cursors. Protocol-level prepared statements were supported in this mode from PgBouncer 1.21 (as of 2026).
- **Statement pooling** returns it after each statement, forbidding multi-statement transactions.

Figure 14.12 — PgBouncer in transaction-pooling mode.



Reading the diagram. PgBouncer holds 6,000 cheap client connections in one event loop and forwards each transaction synchronously over one of about 60 server connections, queuing the rest (dotted). It stores no data. Failure points: PgBouncer itself (run several), long transactions starving the pool, and session features breaking silently. It is single-threaded, so very high connection counts need several instances.

FORMULA

Server connections needed behind a transaction pooler (Little’s Law)

$$C_{\text{server}} = \lambda_{\text{tx}} \cdot W_{\text{tx}} \cdot (1 + h)$$

Symbol	Meaning	Units
C_{server}	Server connections the pool needs	connections
λ_{tx}	Transaction rate through the pooler	transactions/s
W_{tx}	Time a transaction holds a server connection, from `BEGIN` to `COMMIT`	s
h	Headroom fraction for bursts	dimensionless

WORKED EXAMPLE

Worked example — Sizing PgBouncer for 300 pods. The application runs 15,000 transactions/s at peak. Each holds a server connection for 3 ms on average. You add $h = 0.3$ headroom.

1. Average busy connections: $L = 15,000 \times 0.003 = 45$.
2. With headroom: $C_{\text{server}} = 45 \times 1.3 = 58.5$, so configure a pool of about 60.
3. Direct connections would be $300 \times 20 = 6,000$ server processes, 100× more.
4. If a slow query raises W_{tx} to 30 ms, demand becomes 450 connections; clients queue in PgBouncer, *but* the database still sees only 60 concurrent transactions.

Interpretation. The pooler turns unbounded concurrency at the database into a bounded queue in front of it. **Engineering implication.** Size the server pool by Little's Law, `max_client_conn` by client count, and add transaction timeouts so incidents fail fast.

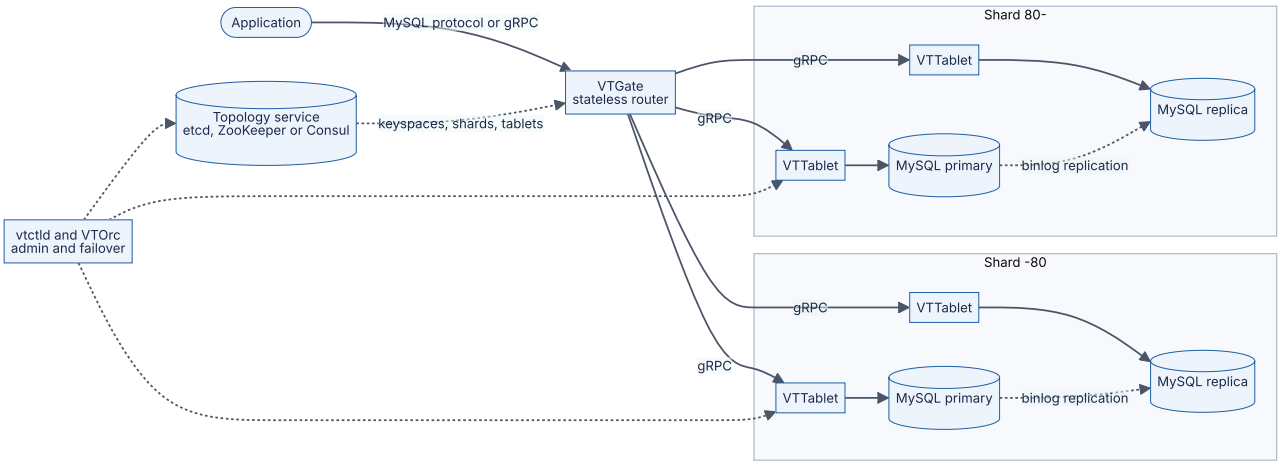
14.13.2 ProxySQL: protocol-aware routing for MySQL

ProxySQL is a MySQL-protocol proxy that groups backends into **hostgroups** (writer, readers) and uses **query rules** to route statements, giving read/write splitting without code changes. It multiplexes connections when safe and can stop sending reads to replicas whose lag exceeds a configured maximum, lag-aware routing at the proxy layer [ProxySQL Docs].

14.13.3 Vitess: a sharding layer for MySQL

Vitess makes a fleet of sharded MySQL databases look like one database. It began at YouTube and is a Cloud Native Computing Foundation project [Vitess Docs].

Figure 14.13 — Vitess architecture.



Reading the diagram. Applications speak MySQL protocol to **VTGate**, a stateless router that uses the **VSchema** and its **vindexes** (sharding functions) to compute each row's **keyspace ID** and route the query, scattering queries that lack the key. Shard `-80` holds keyspace IDs whose first byte is below hex 80 and `80-` the rest (§14.6). A **VTTablet** beside each MySQL instance pools connections and reports health. The strongly consistent topology service holds the shard map, which VTGate watches asynchronously; tablets reject queries for shards they do not serve, catching stale views. Inside a shard, binlog replication is asynchronous or semi-synchronous, and **VTOrc** promotes a replica when a primary fails. Scaling: more VTGates, and `Reshard` to split shards (§14.9).

INDUSTRY EXAMPLE

Slack. Slack described migrating its MySQL datastores to Vitess to shard by keys other than workspace, including channel for its largest customers, while keeping MySQL tooling; it moved table by table, comparing results with shadow traffic first. *Evidence: Primary* — [Slack Engineering 2020]

Table 14.14 — Connection poolers and sharding proxies compared.

	PgBouncer	ProxySQL	Vitess
What it is	PostgreSQL connection pooler	MySQL-protocol routing proxy	Sharding and management layer for MySQL
Pools connections	Yes	Yes	Yes (in VTTablet)
Read/write split	No (separate pools by name)	Yes (query rules)	Yes (tablet types)
Understands shards	No	Only via manual rules	Yes (VSchema, vindexes)
Resharding	No	No	Yes (VReplication workflows)
Failover	No	Detects and reroutes	Yes (VTOrc)
Operational complexity	Low	Medium	High
Choose when	Any PostgreSQL with many clients	MySQL replica fleets	MySQL beyond one primary's write capacity

RECOMMENDATION

Recommendation — Layer the tools in order of need. Start with a client-side pool sized by Little's Law, add PgBouncer or ProxySQL when instance counts make direct connections expensive, and adopt Vitess or distributed SQL (Chapter 28) only when write capacity or data size forces partitioning. Each layer adds a fraction of a millisecond per hop and real operational work.

Failure scenarios

Table 14.15 — Failure scenarios for poolers and proxies.

What goes wrong	Why	Detection	Recovery	Prevention
Wrong data from session settings	`SET search_path` leaks between clients in transaction mode	Intermittent wrong-schema errors	Move setting into each transaction	Use `SET LOCAL`; ban session state
All requests stall	Long transactions hold every server connection	Pool wait time; `cl_waiting` grows	Kill long transactions	Transaction time-outs; separate pools
Proxy becomes a single point of failure	One pooler instance	Health checks fail; total outage	Restart or fail over	Multiple instances; one per host

14.14 Summary and revision notes

SUMMARY

- **Replication** copies data for read capacity and availability; **partitioning** splits data for write capacity and storage. Production systems replicate every partition.
- Replicas cannot scale writes: each applies the whole write stream, so read capacity is $n(uc - w)$.
- Asynchronous replication is fast but can lose recent commits on failover; synchronous or quorum commit adds the k-th fastest replica's RTT; MySQL semi-sync silently degrades to async after a timeout.
- Lag is unbounded and drains at $r_{\text{apply}} - r_{\text{in}}$. It breaks read-your-writes and monotonic reads; fix with primary reads after writes, LSN/GTID watermarks or sticky replicas (§25.6 for theory).
- Prefer row-based or physical replication; use logical replication for upgrades, subsets and CDC. Multi-primary buys local writes at the cost of conflicts; partitioned ownership avoids most of them.
- Range partitioning serves scans but suffers monotonic keys; hash balances but scatters scans; list serves residency; directories place giant tenants. Separate key→partition from partition→node.
- Good shard keys have high cardinality, even load, query and transaction locality, and stability. Shard count is the maximum of storage, write and read terms at the planning horizon.
- Consistent hashing moves an expected $K/(N+1)$ keys on add. With V random vnodes a node's share is $\text{Beta}(V, (N-1)V)$, so its CV is $\sqrt{(N-1)/(NV+1)} \approx 1/\sqrt{V}$ and the busiest node sits near $1 + z_N/\sqrt{V}$.
- Jump hash balances perfectly with no memory but only for numbered buckets; rendezvous hashing balances perfectly at $O(N)$ per lookup.
- Rebalance with fixed partitions, dynamic splitting or per-node tokens; migrate online by capture → backfill → catch-up → verify → switch reads → switch writes → reverse stream.
- Hot keys defeat hashing: salt writes (read cost $\times s$), cache reads, special-case giants, bucket unbounded partitions.
- Local indexes make reads scatter; global indexes make writes cross partitions and lag. Avoid cross-shard transactions by co-location; 2PC blocks on coordinator failure (Chapter 28).
- Poolers turn unbounded database concurrency into a bounded queue sized by Little's Law; Vitess adds routing, resharding and failover for MySQL.

14.15 Knowledge checkpoint

1. Why does adding read replicas eventually stop increasing read capacity?
2. What exactly does MySQL's `AFTER_SYNC` semi-synchronous mode wait for, and when does it stop protecting you?
3. A replica was offline for 20 minutes with $r_{\text{in}} = 2,000$/s and $r_{\text{apply}} = 2,500$/s. How long does catch-up take?
4. Give a sequence of events that violates monotonic reads.
5. Why is statement-based replication unsafe for `UPDATE ... LIMIT 10` without `ORDER BY`?
6. Why does range partitioning on an auto-increment ID create a hot partition?
7. Name the five properties of a good shard key.
8. Under `hash mod N`, what fraction of keys moves going from 9 to 10 nodes? Under consistent hashing?
9. Compute the load CV for $N = 20$ nodes and $V = 50$ vnodes.
10. Why can jump consistent hash not remove an arbitrary failed bucket?
11. Why must change capture start before the backfill snapshot?
12. A counter key receives 12,000 writes/s and partitions sustain 1,000 writes/s at $u = 0.75$. What salt factor do you need?
13. Why are global secondary indexes usually eventually consistent?
14. Which PostgreSQL features break under PgBouncer transaction pooling?

Answers

1. Each replica applies every write, so per-node read budget is $uc - w$; as writes grow it approaches zero no matter how many replicas exist.
2. A replica writing the events to its relay log before the primary commits in the storage engine. After the timeout with no acknowledgment, the primary falls back to asynchronous replication.
3. $B = 2,000 \times 1,200 = 2.4 \times 10^6$; $T = 2.4 \times 10^6 / 500 = 4,800$ s, 80 minutes.
4. A user reads a fresh replica (12 comments), then a more lagged replica (9 comments).
5. Which 10 rows are updated depends on scan order, which can differ on the replica, so copies diverge silently.
6. Every new row has the largest key, so all inserts land in the last range.
7. High cardinality, even load, query locality, transaction locality, stability.
8. $9/10 = 90$ %; about $1/10 = 10$ %.
9. $\sqrt{19/1001} \approx 0.138$, about 14 %.
10. Buckets must be numbered $0..n-1$; only the last can be removed without remapping, so failures are handled inside a replicated bucket.
11. Writes between snapshot and capture start would be in neither copy.
12. $\lceil 12,000/750 \rceil = 16$.

13. Updating index partitions on other nodes synchronously needs a distributed transaction, so most systems update them asynchronously.
14. Session-level `SET`, `LISTEN`, session advisory locks, temporary tables and `WITH HOLD` cursors (and protocol prepared statements before PgBouncer 1.21).

14.16 Interview questions

Basic

Q1. When would you add read replicas, and when would you shard? Answer. Add replicas when reads dominate, can tolerate some staleness and the primary has write headroom; they also provide failover. Shard when writes, data size or working set exceed one primary, or when applying writes consumes most of each replica's budget. State the read/write ratio, freshness needs and growth, then show which limit binds using the shard-count formula.

Q2. Explain consistent hashing and why virtual nodes are used. Answer. Keys and nodes hash onto a ring; each key belongs to the next node clockwise, so adding a node moves only about $K/(N+1)$ keys, all to the new node, versus nearly all under mod-N. With one position per node, shares vary widely (busiest about H_N times fair). With V random vnodes each share is a sum of V arcs, CV $\approx 1/\sqrt{V}$, and a failed node's load spreads over many survivors. Mention weights, preference lists and the alternatives (jump, rendezvous, bounded loads).

Intermediate

Q3. Choose a shard key for a B2B SaaS product where one customer is 500× the median. Answer. `tenant_id`, because nearly all queries and transactions are tenant-scoped, giving locality, isolation and per-tenant deletion. Hash tenants into many logical shards mapped to physical clusters by a directory, put the giant on a dedicated cluster via an override, and if it outgrows that, sub-partition it by a second key such as project. Discuss cross-tenant analytics (move to a warehouse), routing cache staleness and fencing, and the resharding procedure.

Q4. Users report that a post disappears right after they publish it, then reappears. Diagnose and fix. Answer. Reads after the write are served by lagging asynchronous replicas: a read-your-writes violation. Confirm with lag metrics and request traces. Fixes: return the commit LSN/GTID and read only from replicas that have applied it (or wait briefly), or route the author's reads to the primary for a window; add sticky sessions for monotonic reads. Keep lagging replicas out of rotation and investigate why lag spikes (single-threaded apply, bulk jobs).

Advanced

Q5. Reshard a live 40 TB MySQL fleet from 8 to 32 shards with no more than seconds of write downtime. Answer. Introduce a routing layer (Vitess, or a proxy plus directory) if one does not exist. Choose logical shards so future growth needs only moves. For each source shard: start binlog-based capture, snapshot and backfill the target ranges with throttling, catch up, verify with checksums and shadow reads, switch reads, then freeze writes for seconds, wait for the final position, switch writes and fence the source, keeping reverse replication for rollback. Estimate time: splitting each shard into four moves three quarters of the data, 30 TB; at 150 MB/s per stream with 8 streams in parallel that is about 7 hours of copy plus catch-up. Address hot shards, cross-shard queries during transition, and monitoring of lag and p99.

Q6. Your ring-partitioned store has 200 nodes with 32 random vnodes each, and the busiest node runs at 1.6× the mean. Is that expected, and what would you do? Answer. CV $= \sqrt{199/6401} \approx 0.176$, and $z_{200} \approx 2.7$, so the expected busiest node is about $1 + 2.7 \times 0.176 \approx 1.48\times$; $1.6\times$ is plausible from randomness alone, though request skew may contribute, so check per-key heat first. To reduce imbalance: raise V (to reach $1.1\times$ needs about $(2.7/0.1)^2 \approx 730$ vnodes, with repair and streaming costs), allocate tokens deliberately, move to fixed equal-sized partitions, or use bounded-load assignment. For hot keys, salt or cache instead.

14.17 Practical exercises

1. Extend the ring in §14.8.3 with zone awareness so that a preference list never places two replicas in one zone. Measure the balance cost.
2. Modify the experiment in §14.8.4 to measure the busiest node for $N = 1,000$ and compare with $1 + z_N \cdot \mathrm{CV}$.
3. Implement weighted rendezvous hashing and verify that a weight-2 node receives twice the keys of a weight-1 node.
4. Set up PostgreSQL with one streaming standby, run `pgbench`, and measure commit latency under `synchronous_commit` set to `local`, `on` and `remote_apply`.
5. Put PgBouncer in front of PostgreSQL in transaction mode and demonstrate one session-state feature that breaks; then fix the application code.

14.18 Design challenges

1. **Global chat history.** 500 million messages per day, channels from two members to 2 million. Choose partition keys, bounded partitions and indexes for “latest 50 messages in channel” and “search my messages”.

2. **Multi-region SaaS with residency.** EU tenants' data must stay in the EU, writes must be local, and tenants occasionally move region. Combine list partitioning, directories and the migration procedure of §14.9.5.
3. **Flash-sale inventory.** One product receives 200,000 purchase attempts per second for 5 minutes. Design inventory decrements that neither oversell nor saturate one partition.

Chapter 15 — Object, Block and File Storage

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 2.5 h

Chapters 11–14 were about databases: systems that store small, structured records and answer questions about them. Most of the bytes a company stores are not records at all. They are photos, videos, log files, backups, machine-learning datasets and database snapshots: large, mostly immutable blobs that are written once and read many times or never. In Chapter 1, PhotoShare's ADR-0003 moved every photo into "managed object storage", and at 10 million daily users that meant about 5 TB of new data per day (§1.9). This chapter opens that box. You will learn the three storage interfaces (blocks, files, objects), how S3-style object stores and GFS-style file systems are built, how erasure coding buys high durability for 1.4× raw capacity instead of 3×, why metadata is the real scaling limit, and how chunking, multipart upload and lifecycle tiers keep petabytes affordable.

15.1 Learning objectives

After this chapter you should be able to:

- Choose between block, file and object storage by interface, semantics, latency and throughput.
- Draw an S3-style object store (front end, metadata/index, placement, storage nodes) and trace a PUT and a GET through it.
- Explain GFS (single master, 64 MB chunks, leases, record append) and HDFS NameNode high availability.
- Calculate the storage overhead, fault tolerance, approximate durability and repair traffic of 3× replication, Reed–Solomon RS(10,4) and an Azure-style local reconstruction code.
- Estimate metadata memory and explain how namespaces are partitioned.
- Size a multipart upload, use presigned URLs safely, and explain why content-defined chunking survives insertions.
- Design and cost a lifecycle policy across hot, warm, cold and archive tiers.

15.2 Prerequisites

- Disks, SSDs, IOPS and throughput — §5.6 (block devices are the bottom layer of every design here).

- File systems, `fsync` and the page cache — §6.6 and §6.14 (file semantics and durability).
- MTBF, AFR and durability as a race between failure and repair — §4.15–§4.16 (the loss formula is generalized in §15.6).
- Hash functions and HMAC — §10.4.1 and §10.4.6 (content addressing and pre-signed URLs).
- Partitioning and consistent hashing — §14.6 and §14.8 (metadata and data placement).
- Units: in this chapter **MB/GB/TB/PB** are powers of ten for capacity and cost; **KiB/MiB/GiB** appear where a system defines a limit in powers of two (for example S3's 5 MiB minimum part size).

15.3 Block, file and object storage compared

15.3.1 Three interfaces to the same disks

> DEFINITION
>
> **Definition — Block, file and object storage. Block storage** exposes a numbered array of fixed-size blocks (typically 512 B or 4 KiB) that a client reads and writes by offset; the client's own file system or database gives the blocks meaning. **File storage** exposes a hierarchical namespace of directories and byte-addressable files with POSIX-like operations (open, read at offset, write at offset, rename, lock), shared by many clients over a protocol such as NFS or SMB. **Object storage** exposes a flat namespace of immutable **objects**, each a byte string plus metadata addressed by a key within a **bucket**, accessed over HTTP with whole-object PUT, GET (optionally a byte range), DELETE and LIST.

First-principles explanation

Picture a warehouse. **Block storage** rents you a bare floor marked in numbered squares: you decide what goes where and keep your own map; the warehouse knows nothing about your boxes. **File storage** is a filing cabinet shared by an office: folders inside folders, anyone can open a document, change page 7 and put it back, and the cabinet makes sure two people do not scribble on the same page at once. **Object storage** is a coat check: you hand over a sealed parcel, get a ticket (the key), and later hand the ticket back to get the identical parcel. You cannot change one page of a parcel; you hand in a new parcel under the same ticket.

The more an interface promises (in-place updates, shared locks, atomic rename of a directory tree), the more coordination every operation needs and the harder it is to scale

out. Object storage promises the least, which is why it routinely scales to trillions of items.

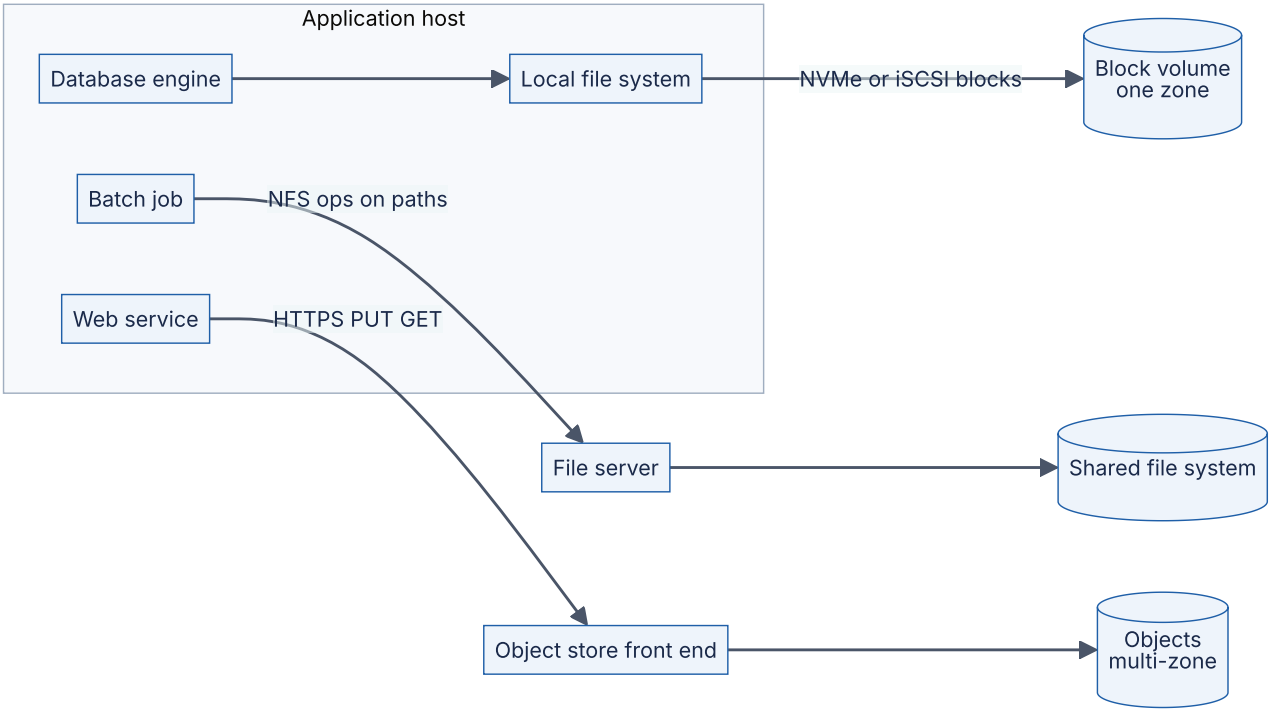
Why does this exist?

All three exist because applications need different contracts. A database engine (Chapter 13) wants raw blocks so that it controls page layout, write-ahead logging and `fsync` ordering itself. Many machines sharing a directory of model checkpoints want a POSIX file system. A web application storing uploads wants unlimited capacity, HTTP access and someone else to worry about durability; it never rewrites byte 4,000 of a photo.

How it works internally

1. **Block.** A volume is a virtual disk. Cloud services such as Amazon EBS and Google Persistent Disk attach a network volume to one VM over NVMe or iSCSI-style protocols, replicate its blocks within one zone, and let the guest run ext4, XFS or a database on it.
2. **File.** An NFS or SMB server (or a distributed service such as Amazon EFS, which speaks NFSv4.1) owns the namespace. Clients send `LOOKUP`, `READ(offset, count)`, `WRITE`, `RENAME`; the server keeps inodes, directories, permissions and locks and serializes conflicting updates.
3. **Object.** A client sends `PUT /bucket/key` with the full body; the service stores the bytes redundantly, records key → location in an index, and acknowledges. GET looks up the key and streams the bytes. There is no rename, append or partial overwrite: a “change” is a new PUT of the whole object.

Figure 15.1 — Three storage interfaces over shared disks.



Reading the diagram. Three clients on one host use three interfaces. The *database engine* runs its own file system on a *block volume*: the protocol carries block reads and writes by offset, and all meaning (files, pages) lives on the host. The *batch job* sends path-based NFS operations to a *file server*, which owns the namespace and locking for every client that mounts it. The *web service* sends whole-object HTTPS requests to an *object store front end*. All arrows are synchronous request/response. Storage boundaries: the block volume lives in one zone and attaches to one VM; the file system is shared; objects are spread across zones. Failure points: a zone outage takes the block volume with it (restore from snapshots); the file server's metadata path is a shared bottleneck. Scaling: block volumes scale up (bigger, faster volume); file systems scale up or partition the namespace (§15.7); object stores scale out horizontally.

Mathematical foundations

The single most useful model for comparing the three is the time to fetch S bytes: a fixed first-byte latency plus a transfer term.

FORMULA

Access time for one read

$$t \approx t_{\text{first}} + \frac{S}{B} \qquad t_{\text{parallel}} \approx t_{\text{first}} + \frac{S}{\min(c \cdot B,\ B_{\text{NIC}})}$$

Symbol	Meaning	Units
t	Time to read the whole request	s
t_{first}	Time to first byte (network round trip, lookup, seek or flash read)	s
S	Bytes requested	bytes
B	Throughput of one stream (connection or volume)	bytes/s
c	Number of parallel streams (for example byte-range GETs)	count
B_{NIC}	Client network interface limit	bytes/s

WORKED EXAMPLE

Worked example — Small random reads versus bulk reads. Use illustrative values: a network SSD block volume with $t_{\text{first}} = 0.5$ ms and $B = 125$ MB/s; an object store with $t_{\text{first}} = 30$ ms and $B = 80$ MB/s per connection; a 10 Gb/s client NIC ($B_{\text{NIC}} = 1.25$ GB/s).

1. 4 KiB (4,096 B) read, block: $0.5 + 4096/125,000,000 \times 1000 = 0.5 + 0.033 = 0.53$ ms.
2. 4 KiB read, object: $30 + 4096/80,000,000 \times 1000 = 30 + 0.05 = 30.05$ ms, about 57× slower.
3. 1 GB read, block (one volume): $0.0005 + 10^9/1.25 \times 10^8 = 8.0$ s.
4. 1 GB read, object, one connection: $0.03 + 10^9/8 \times 10^7 = 12.5$ s.
5. 1 GB read, object, 16 parallel range GETs: $\min(16 \times 80, 1250) = 1250$ MB/s, so $0.03 + 0.8 = 0.83$ s.

Interpretation. For tiny random reads the fixed latency dominates and the block volume wins by more than an order of magnitude. For bulk reads the transfer term dominates, and the object store wins because it lets you open many independent streams to many storage nodes, while one volume has a fixed throughput cap.
Engineering implication. Put latency-sensitive random I/O (database pages) on block storage; put large, sequentially read data (media, logs, training data, backups) on object storage and read it with parallel range requests. Never use an object store as if it were a disk for a database.

Table 15.1 — Block, file and object storage compared. Latency figures are typical orders of magnitude (as of 2026), not guarantees.

Aspect	Block	File	Object
What it is	Virtual disk of numbered blocks	Shared directory tree of files	Flat bucket of immutable key → blob
Interface	NVMe/iSCSI/SCSI commands	NFS, SMB, POSIX	HTTP REST: PUT, GET, DELETE, LIST
Update model	Overwrite any block in place	Overwrite/append at any offset; rename; locks	Replace whole object (new version)
Sharing	One host (multi-attach rare)	Many hosts concurrently	Unlimited clients over the internet
Typical first-byte latency	~0.1–2 ms (network SSD)	~1–10 ms	~10–100+ ms (single-digit ms for premium one-zone classes)
Throughput scaling	Per-volume cap	Per file system; often bursts	Near-linear with parallel requests
Consistency	Strong (single writer)	Close-to-open (NFS) to strong	Strong read-after-write (S3 since Dec 2020; GCS; Azure Blob)
Cost (relative)	Highest per GB, pay for provisioned size	High	Lowest, pay for bytes stored and requests
Examples	Amazon EBS, Google Persistent Disk, Azure Managed Disks	NFS, Amazon EFS, Google Filestore, Azure Files, Lustre	Amazon S3, Google Cloud Storage, Azure Blob Storage, Ceph RGW, MinIO
Choose when	Databases, boot disks, low-latency random I/O	Shared POSIX access, legacy apps, HPC scratch	Media, backups, logs, data lakes, ML datasets

Real-world industry applications

INDUSTRY EXAMPLE

Cloud block, file and object services. AWS documents EBS gp3 volumes with a baseline of 3,000 IOPS and 125 MiB/s that can be provisioned higher, and EBS volumes are created in a single Availability Zone; Amazon EFS is accessed with NFSv4.1 and stores data across multiple zones in its regional classes; Amazon S3 is designed for 99.999999999% durability and, since December 2020, provides strong read-after-write consistency for PUT and DELETE of objects and for LIST, automatically and at no extra cost [AWS S3 consistency docs; AWS EBS docs]. Google Cloud Storage documents strong global consistency for read-after-write, read-after-delete and object listing [Google Cloud Storage consistency docs]. *Evidence: Primary* — [AWS S3 consistency docs; AWS EBS docs; Google Cloud Storage consistency docs]

Common misconceptions

COMMON MISTAKE

“S3 is a file system.” Tools that mount a bucket as a directory make it look like one, but `rename` becomes copy-plus-delete of every object, appending means rewriting the whole object, and there are no locks. Programs that assume POSIX semantics (for example, writing a file in place and renaming it atomically) can be slow or incorrect on such mounts.

15.4 Object storage architecture (the S3 model)

15.4.1 Buckets, keys and a flat namespace

DEFINITION

Definition — Bucket, key, object and flat namespace. A **bucket** is a named container with its own access policy, region and configuration. An **object** is an immutable byte string (from zero bytes to tens of terabytes) plus system metadata (size, content type, checksum, version ID) and user metadata. A **key** is the object’s full name within the bucket, for example `photos/2026/10/u42/abc.jpg`. The namespace is **flat**: the slashes are ordinary characters, and “folders” are an illusion produced by listing keys that share a **prefix** and grouping them at a **delimiter** (usually `/`).

First-principles explanation

A hierarchical file system is a tree, and trees need coordination: renaming a directory atomically moves everything beneath it, and creating a file must check and update its parent directory. If millions of clients create files in the same directory, that one directory becomes a lock everyone fights over. A flat namespace removes the tree. Each key is independent, so the system can sort all keys and split the sorted list into ranges, giving each range to a different metadata server, exactly like range partitioning a database table (§14.6). Listing “the folder” `photos/2026/10/` becomes a range scan from that prefix to the next one.

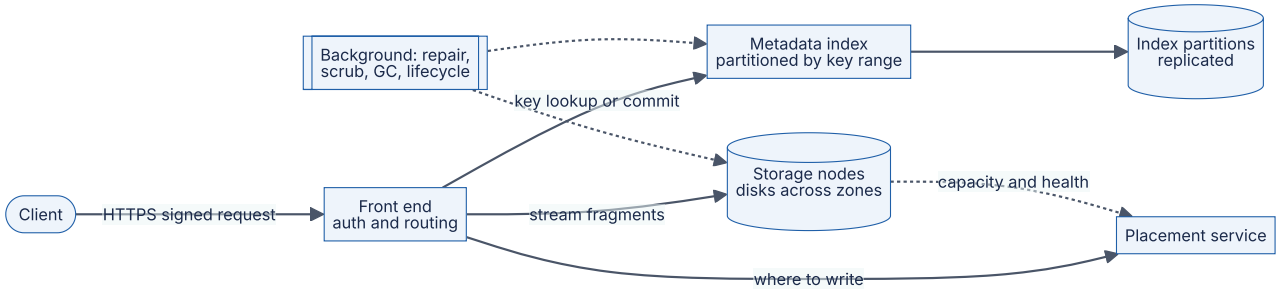
Why does this exist?

The web needed storage reachable over HTTP that never filled up. Immutable whole objects make that tractable: no partial overwrites to replicate, no locks to hold across a network partition, and bytes that never change, so caches and CDNs (Chapter 21) can store them safely.

15.4.2 Components of an S3-style object store

AWS has published only fragments of S3's internals (cited below). The design that follows is a generic, teaching architecture that matches the public behavior of S3, Google Cloud Storage, Azure Blob Storage and open-source systems such as Ceph's RADOS Gateway; it is not a description of any one product.

Figure 15.2 — Generic S3-style object store (illustrative).



Reading the diagram. The *client* sends an HTTPS request signed with its credentials. The stateless *front end* authenticates, authorizes and routes it. The *metadata index* maps (bucket, key, version) to the locations of the object's data; it is partitioned by key range so that LIST by prefix is a range scan, and each partition is replicated (a consensus-replicated store is the usual choice, Chapter 26). The *placement service* chooses which storage nodes, in which failure domains, receive a new object's fragments, using asynchronous health and capacity reports (dotted). *Storage nodes* own disks and store fragments with checksums. All client-facing arrows are synchronous. *Background workers* (dotted, asynchronous) re-create lost fragments, scrub checksums, garbage-collect unreferenced data and apply lifecycle rules (§15.9). Storage boundaries: small, hot, strongly consistent metadata is separated from huge, append-only data. Failure points: an unavailable index partition makes intact data unreachable; storage-node failures are routine and repaired in the background. Scaling: add front ends for request rate, split index partitions for key-space hot spots, add storage nodes for capacity.

How it works internally

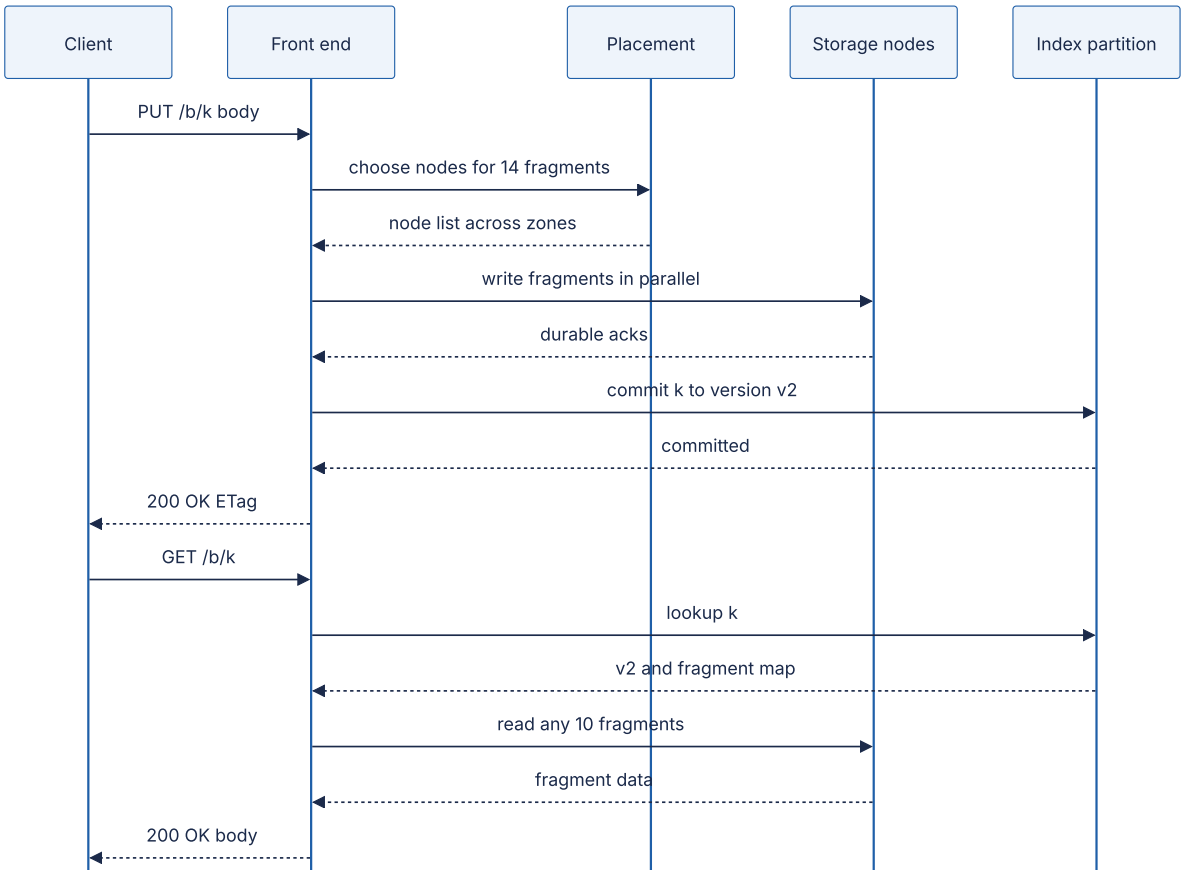
PUT (write path):

1. The front end authenticates the request (for example AWS Signature Version 4, an HMAC over the request, §10.4.6) and checks the bucket policy.
2. It asks the placement service for a set of storage nodes spread across failure domains (disks, racks, zones).
3. It streams the body, splits it into chunks if it is large, and writes each chunk redundantly: replicas or erasure-coded fragments (§15.6). It computes a checksum and verifies any checksum the client sent.

4. Only after enough fragments are durable does it **commit** a new metadata record (key, version ID, size, checksum, fragment locations) to the index partition that owns the key. This commit is the linearization point: before it, readers see the old version (or nothing); after it, every reader sees the new one.
5. It returns `200 OK` with an ETag. Data written by a PUT that failed before step 4 is unreferenced and later removed by garbage collection.

GET (read path): authenticate → look up the key's latest committed version in the index → read fragments from storage nodes (only k of $k + m$ are needed for an erasure-coded object, so the front end can ignore the slowest) → verify checksums → stream to the client.

Figure 15.3 — PUT then GET in an S3-style store (illustrative).



Reading the diagram. Five participants exchange synchronous HTTP or RPC messages, top to bottom in time. On the write, data flows to the *storage nodes* before any metadata changes; the *index partition* commit is the single step that makes version v2 visible. On the read, the *front end* first resolves the key to a version and a fragment map, then fetches fragments; in this RS(10,4) illustration any 10 of 14 suffice. Failure points: if the front end crashes after writing fragments but before the commit, the client sees an error and retries, and the orphaned fragments are garbage; if it crashes after the commit but before replying, the object exists and a retry simply writes it again (PUT of the same bytes is idempotent). Scaling: the fragment writes and reads fan out in parallel, so large objects are limited by aggregate node bandwidth, not by one disk.

Consistency: what “strong read-after-write” means

Because the index commit is a single atomic step per key, a store that keeps each index partition linearizable (§25.3) can promise that once a PUT returns, any subsequent GET or LIST anywhere sees it. Historically S3 cached metadata in a way that let reads miss recent writes; AWS described adding a cache-coherence protocol in which a “witness” component is notified of every object change, so that front ends can tell when their cached metadata is stale [Vogels 2021]. Two caveats remain. Concurrent PUTs to one key are not merged: the last commit wins, so read-modify-write needs conditional writes (`If-None-Match`, `If-Match`, supported by S3 since 2024). Bucket configuration and cross-region replication remain asynchronous.

Mathematical foundations

Index partitions have finite throughput, so request rate per key range is a design input. AWS documents that an application can achieve at least 3,500 PUT/COPY/POST/DELETE or 5,500 GET/HEAD requests per second per partitioned prefix, and that S3 scales by partitioning further as load grows [AWS S3 performance docs].

FORMULA

Prefixes needed for a target request rate

$$N_{\text{prefix}} = \lceil \frac{R_{\text{peak}}}{r_{\text{prefix}}} \rceil$$

Symbol	Meaning	Units
N_{prefix}	Distinct key prefixes over which requests must be spread	count
R_{peak}	Peak request rate of one type (writes or reads)	requests/s
r_{prefix}	Sustained rate one partitioned prefix supports	requests/s

WORKED EXAMPLE

Worked example — Log ingestion into an object store. A logging pipeline writes 20,000 small objects per second at peak with keys like `logs/2026-10-30T12/<host>/<seq>`.

1. $N_{\text{prefix}} = \lceil 20,000/3,500 \rceil = \lceil 5.71 \rceil = 6$ prefixes at minimum.
2. Problem: every key in the current hour shares one leading prefix, so all writes land in one key range until the store splits it.
3. Fix: put a short hash of the host first, for example `logs/a7/2026-10-30T12/<host>/<seq>` with 16 hex buckets, giving at least 16 prefixes and headroom of $16 \times 3,500 = 56,000$ writes/s.

Interpretation. Time-ordered keys concentrate load on the newest range (the hot-partition problem of §14.10). **Engineering implication.** Design keys for the index, not for humans: spread writes with a hashed component and keep the time component later in the key. Better still, batch 20,000 tiny records per second into a few larger objects (§15.8), which also cuts request fees.

Real-world industry applications

INDUSTRY EXAMPLE

Amazon S3 — what AWS has published. AWS's report on the February 2017 US-EAST-1 disruption names two S3 subsystems: an *index subsystem* that manages the metadata and location information of all objects in the region, and a *placement subsystem* that allocates storage for new objects and depends on the index subsystem; both had to be fully restarted [AWS 2017]. AWS engineers have described ShardStore, the key-value storage engine on S3 storage nodes that holds shards of customer objects, and its validation with lightweight formal methods [Bornholt et al. 2021]. Vogels described the metadata cache-coherence protocol behind strong consistency [Vogels 2021]. Anything beyond these statements in Figure 15.2 is illustrative. *Evidence: Primary* — [AWS 2017; Bornholt et al. 2021; Vogels 2021]

INDUSTRY EXAMPLE

Facebook Haystack — packing small objects. Storing each photo as a file cost Facebook several disk reads per photo just for directory and inode metadata. Haystack appends many photos ("needles") into large volume files and keeps an in-memory index from photo ID to (volume, offset, size), so a read needs about one disk operation [Beaver et al. 2010]. The lesson generalizes: an object store's per-object metadata cost, not its byte capacity, is what small objects stress. *Evidence: Primary* — [Beaver et al. 2010]

Advantages and disadvantages

Object storage gives unlimited capacity, high durability, parallel throughput and the lowest price per GB, in exchange for tens of milliseconds of first-byte latency, per-request charges, no in-place updates or multi-key rename, and coordination left to the application.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Orphaned storage	PUTs that failed after writing data, abandoned multipart uploads	Storage used exceeds sum of indexed sizes	Garbage collection; abort-incomplete-upload lifecycle rule	Make GC and lifecycle rules part of the design
Lost update	Two clients read-modify-write the same key	Missing data reported by users	Restore from versioning	Conditional writes (`If-Match`) or a database as the source of truth

Common misconceptions

COMMON MISTAKE

“Renaming a folder is cheap.” There is no folder. Renaming `photos/2026/` means copying and deleting every object under that prefix, one request each. Design keys so that you never need to rename them, and keep human-facing names in a database.

15.5 Distributed file systems: GFS, HDFS, Colossus and Tectonic

15.5.1 The Google File System (GFS)

DEFINITION

Definition — Distributed file system. A file system whose namespace and data are spread across many machines, so that files can be larger than any one disk and throughput can grow with the number of machines, while clients still use file-like operations (create, open, read, write or append, delete).

First-principles explanation

Think of a library with one head librarian and a thousand shelves in separate rooms. The librarian keeps only the catalog: which book is split into which volumes and which rooms hold each volume. Readers ask the librarian once, then walk directly to the rooms. The li-

brarian never carries books, so one person can manage a huge library. That is the GFS design.

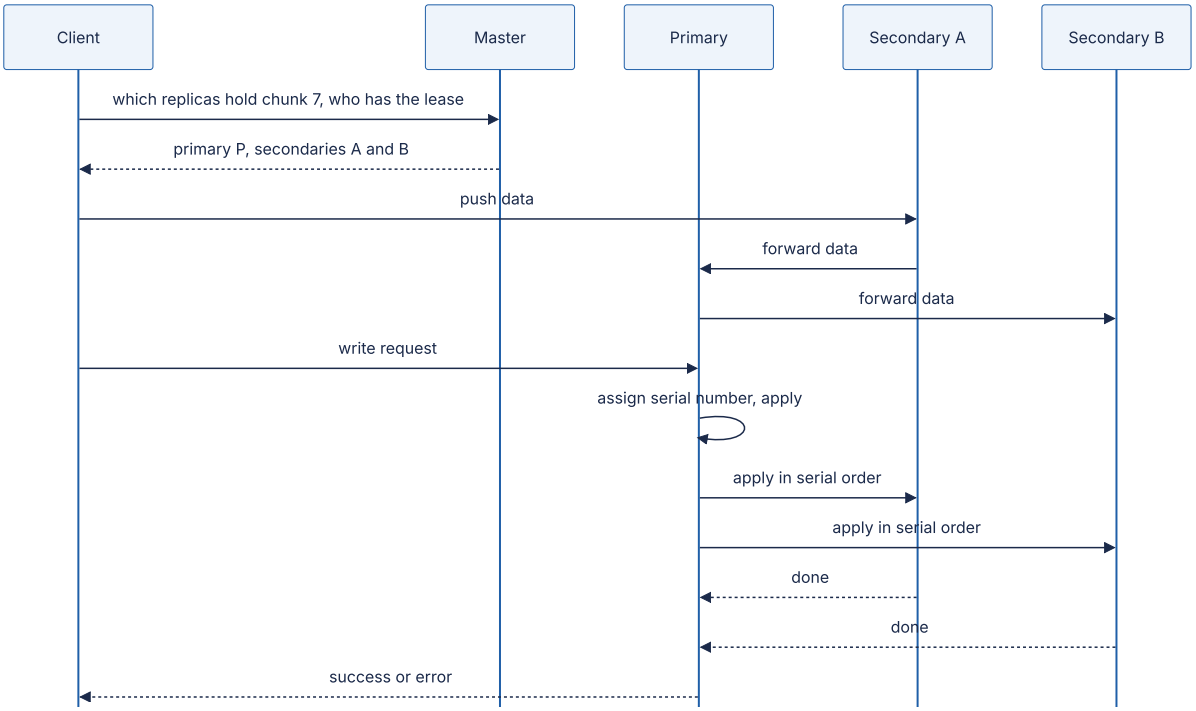
Why does this exist?

Google needed to store web crawls and indexes on thousands of commodity machines, some always failing, for workloads dominated by large sequential reads and concurrent *appends*. GFS was designed for exactly that: component failure as the norm, multi-gigabyte files, appends, and high sustained bandwidth over low latency [Ghemawat et al. 2003].

How it works internally

1. **One master, many chunkservers.** Files are split into fixed **64 MB chunks**, each identified by a globally unique 64-bit handle and stored as a Linux file on **chunkservers**, by default as three replicas. A single **master** holds all metadata in memory: the namespace, the file → chunk mapping, and chunk locations. The master persists namespace and mapping changes in an **operation log** replicated to other machines, with periodic checkpoints; it does *not* persist chunk locations but learns them from chunkservers at start-up and through heartbeats.
2. **Why 64 MB.** Large chunks mean few chunks, so the master needs less than 64 bytes of metadata per chunk and clients rarely need to ask it anything; a client caches chunk locations and talks to chunkservers directly. The cost: a popular small file is one chunk on three servers, a hot spot.
3. **Reads.** The client converts (file, byte offset) into a chunk index, asks the master for the handle and replica locations, caches them, and reads from the nearest replica.
4. **Leases and mutation order.** For each chunk being modified the master grants a **lease** (initially 60 seconds, renewable through heartbeats) to one replica, the **primary**. The primary picks a serial order for all mutations to that chunk, so all replicas apply them in the same order without the master on the data path. (Leases in general: §26.11.)
5. **Decoupled data and control flow.** The client pushes data to all replicas along a chain of chunkservers, each forwarding to the next nearest while still receiving (pipelining), so each machine's full outbound bandwidth is used. Only after all replicas hold the data does the client send the small write request to the primary.
6. **Record append.** The client supplies only data; the primary chooses the offset and appends the record atomically *at least once*. A failed append is retried, so replicas may contain duplicates or padding, which applications skip using checksums and unique record IDs.
7. **Housekeeping.** Each chunk has a version number to detect stale replicas that missed mutations while down; deleted files are renamed to hidden names and garbage-collected lazily; chunkservers checksum every 64 KB block on read.

Figure 15.4 — GFS write with a lease-holding primary.



Reading the diagram. The *client* asks the *master* (control flow) which replica holds the lease, and caches the answer. Data flows along a chain ordered by network topology, not roles, so the client uploads each byte once. The small write request goes to the *primary*, which assigns a serial number and tells both *secondaries* to apply mutations in that order. All messages are synchronous RPCs. Storage boundaries: metadata on the master, chunk bytes only on chunkservers. Failure points: a failed secondary makes the client retry (the region is inconsistent until it succeeds); a dead primary's lease expires and the master grants a new one. Scaling: the master handles only small metadata RPCs, so data bandwidth grows with the number of chunkservers.

Mathematical foundations

FORMULA

Metadata memory for an in-memory namespace

$$M = N_{\text{files}} \cdot b_{\text{file}} + N_{\text{chunks}} \cdot b_{\text{chunk}} \qquad N_{\text{chunks}} \approx \sum_{\text{files}} \left\lceil \frac{\text{file size}}{C} \right\rceil$$

Symbol	Meaning	Units
M	Memory needed by the metadata server	bytes
N_{files}	Number of files (and directories)	count
N_{chunks}	Number of chunks or blocks	count
$b_{\text{file}}, b_{\text{chunk}}$	Bytes of metadata per file and per chunk	bytes
C	Chunk (block) size	bytes

WORKED EXAMPLE

Worked example — Why chunk size and file count limit the master. Use GFS's figure of under 64 bytes per chunk and a commonly quoted HDFS rule of thumb of about 150 bytes per file or block object in the NameNode heap.

1. GFS, 1 PB of large files in 64 MB chunks: $10^{15} / 6.4 \times 10^{7} = 1.56 \times 10^{7}$ chunks; $\times$ 64 B $= 1.0 \times 10^{9}$ B ≈ 1 GB. One machine copes easily.
2. Same 1 PB in 4 MB chunks: 16× as many chunks, about 16 GB. Still feasible, but every client request now also hits the master 16× as often.
3. HDFS cluster with 300 million files averaging 1.5 blocks: $N = 3 \times 10^{8} + 4.5 \times 10^{8} = 7.5 \times 10^{8}$ objects; $\times$ 150 B $= 1.1 \times 10^{11}$ B ≈ 113 GB of heap.
4. The same bytes stored as 3 billion small files: at least 6×10^{9} objects, about 900 GB, beyond any practical single heap.

Interpretation. A single metadata server scales with the *number* of files and chunks, not with bytes. **Engineering implication.** Single-master designs work for large files; small-file workloads must either pack files together (Haystack, §15.4; HAR or sequence files in Hadoop) or move to a partitioned metadata service (§15.7).

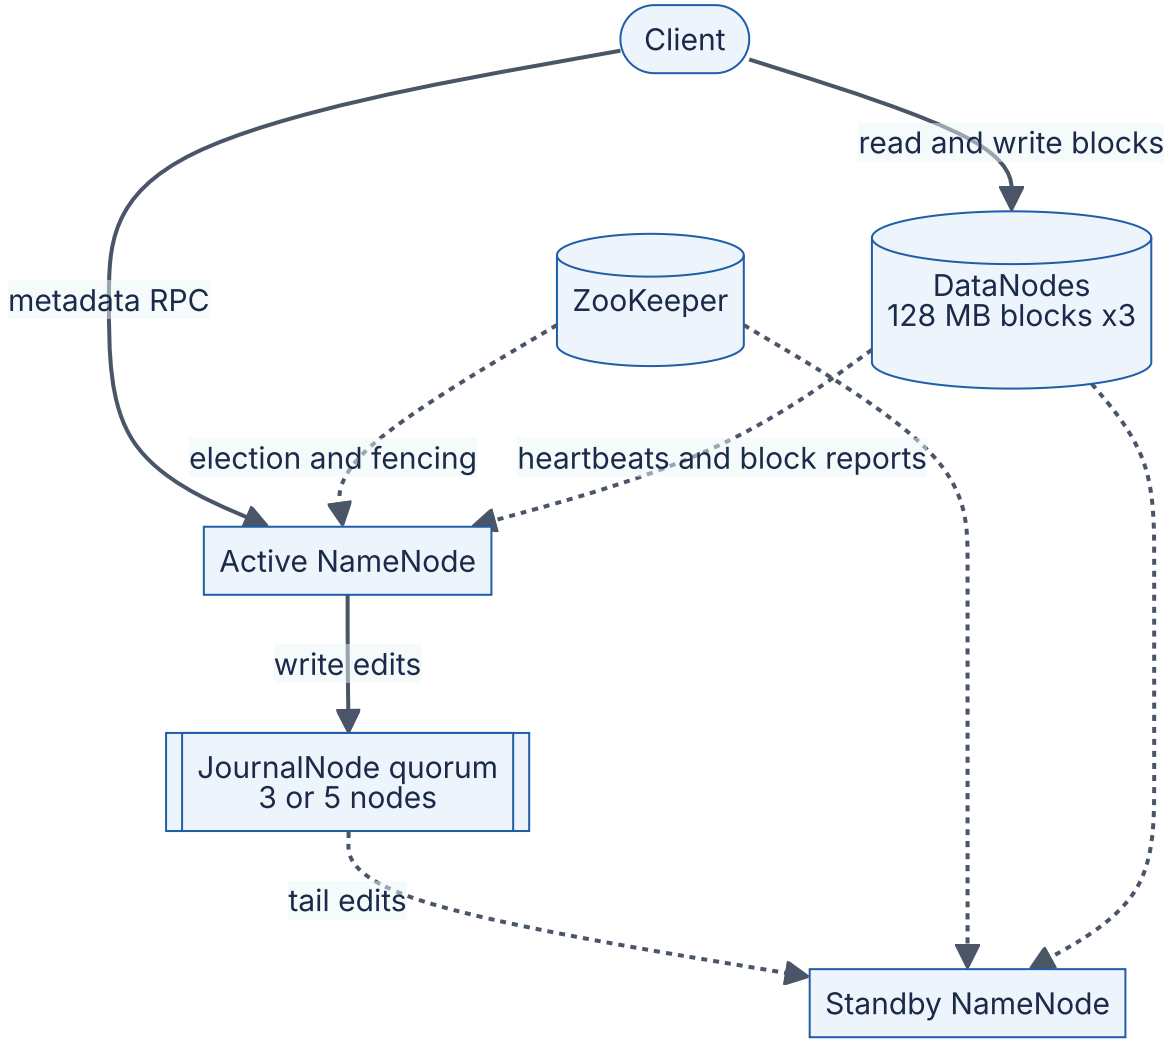
15.5.2 HDFS and NameNode high availability

HDFS, the Hadoop Distributed File System, follows the GFS design with different names: a **NameNode** (the master) keeps the namespace and block map in RAM, and **DataNodes** (chunkservers) store **blocks**, typically 128 MB, with a default replication factor of three

[Shvachko et al. 2010]. DataNodes send heartbeats every few seconds and periodic block reports; a DataNode silent for about ten minutes is considered dead and its blocks are re-replicated. Writes go through a pipeline of DataNodes, as in GFS. HDFS supports single-writer append rather than concurrent record append, and places replicas rack-aware.

The original NameNode was a single point of failure. Hadoop 2 added **high availability**: an *active* and a *standby* NameNode share the edit log through a quorum of **JournalNodes**, DataNodes report blocks to both, and a ZooKeeper-based failover controller elects the active one and fences the old one [Apache Hadoop HA docs]. **Federation** runs several independent NameNodes, each owning part of the namespace, to go past one heap's limit.

Figure 15.5 — HDFS with NameNode high availability.



Reading the diagram. The *client* sends metadata RPCs to the *active NameNode* and streams block data directly to and from *DataNodes*. The active NameNode writes every namespace change to a majority of *JournalNodes* (synchronously) before acknowledging; the *standby* tails those edits asynchronously and stays nearly current. *DataNodes* report

to both, so the standby knows block locations at failover. *ZooKeeper* (dotted) holds the election lock; failover controllers on each NameNode use it to promote the standby and fence the old active, preventing split brain (§26.12–§26.13). Storage boundaries: the namespace is in NameNode RAM backed by the journal; block bytes are on DataNodes. Failure points: active NameNode loss costs seconds of metadata unavailability; losing a JournalNode majority blocks writes. Scaling: data scales with DataNodes; metadata scales only by federation.

15.5.3 Colossus and Tectonic: distributing the master

Both GFS and HDFS hit the same wall: one metadata server's memory and request rate. Their successors keep the client library and chunk servers but move metadata into a scalable database.

INDUSTRY EXAMPLE

Google Colossus. Google has published only an overview. A 2021 Google Cloud blog describes GFS's successor as a client library, scalable metadata services ("curators") storing metadata in Bigtable, "D" file servers holding data, and background "custodians" for durability and rebalancing; data is replicated or Reed–Solomon encoded per workload [Hildebrand and Serenyi 2021]. *Evidence: Primary* — [Hildebrand and Serenyi 2021]

INDUSTRY EXAMPLE

Facebook Tectonic. Tectonic, an exabyte-scale multitenant file system, consolidated Facebook's blob storage (Haystack and f4) and its data-warehouse HDFS clusters. Its metadata is split into Name, File and Block layers (Figure 15.8) stored in ZippyDB, a sharded key-value store, behind stateless metadata services; data flows directly between client library and chunk-store nodes. ZippyDB lacks cross-shard transactions, so some recursive operations are restricted. Blocks are replicated or Reed–Solomon encoded; blob storage appends small writes to replicas and Reed–Solomon encodes them later [Pan et al. 2021]. *Evidence: Primary* — [Pan et al. 2021]

Alternatives and trade-offs

Table 15.2 — GFS, HDFS and Tectonic compared.

Aspect	GFS (2003)	HDFS (2010)	Tectonic (2021)
Metadata	Single in-memory master + replicated log	NameNode in RAM; HA standby; federation	Sharded key-value store, stateless services
Unit	64 MB chunk	128 MB block (configurable)	Block of chunks
Redundancy	3× replication	3× replication; erasure coding from Hadoop 3	Replication or Reed–Solomon per tenant
Write semantics	Concurrent record append, at least once	Single writer, append	Single writer per file; tenant-specific
Scaling limit	Master memory and RPC rate	NameNode heap	Key-value store shards (horizontally scalable)

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate records after append	Client retried a partially failed record append	Duplicate record IDs downstream	Deduplicate on read	Unique record IDs and checksums in the payload
Re-replication storm	Rack failure loses thousands of blocks at once	Under-replicated block count spikes	Throttled, prioritized re-replication (blocks with one copy first)	Rack-aware placement; repair bandwidth budgets

15.6 Replication versus erasure coding

15.6.1 Reed–Solomon codes

DEFINITION

Definition — Erasure code and RS(k, m). An **erasure code** transforms k data fragments into $k + m$ fragments such that the original data can be rebuilt from some subset of them after the others are lost (“erased”). A **Reed-Solomon** code RS(k, m) is a **maximum distance separable (MDS)** code: *any* k of the $k + m$ fragments suffice, so it tolerates the loss of any m fragments. A code is **systematic** when the first k fragments are the unmodified data, so healthy reads need no decoding.

First-principles explanation

Store 5, 7 and 2 together with their sum, 14. Lose any one of the four and you can recompute it: $14 - 5 - 2 = 7$. RAID-5 does this with XOR: one parity block protects against any one loss. Reed–Solomon generalizes it. Treat the k data symbols as the values of a polynomial of degree less than k at k known points. Two points fix a line and three fix a parabola; in general k points fix a degree-$(k - 1)$ polynomial. Evaluate that polynomial at m extra points

and store those values as parity. Any k surviving values pin down the polynomial again, and therefore all the data. The arithmetic is done in a finite field (in practice GF(2^8), so each symbol is one byte) so that values never grow and division always works [Reed and Solomon 1960; Plank 1997].

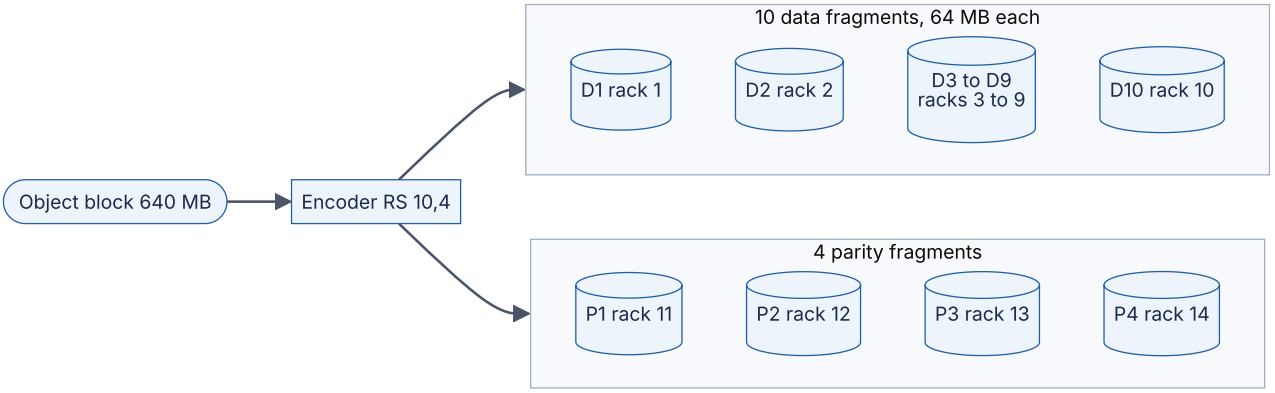
Why does this exist?

Three-way replication tolerates two failures but stores 3 bytes per byte. At exabyte scale the extra copies cost real money: hundreds of thousands of disks, the racks and the power for them. Erasure coding reaches the same or better durability for 1.2–1.5× overhead. Facebook's f4 warm-blob store reports moving from an effective replication factor of 3.6 in Haystack to 2.1 by using RS(10,4) within a datacenter and XOR across datacenters [Muralidhar et al. 2014].

How it works internally

1. Split an object (or a large block) into k equal data fragments, padding the last.
2. Compute m parity fragments, byte position by byte position, by multiplying the data symbols by a fixed encoding matrix (or, equivalently, evaluating the polynomial at the parity points).
3. Place all $k + m$ fragments of a **stripe** on different disks, ideally different racks or zones, so one failure domain holds at most a few fragments.
4. Reads normally fetch the k data fragments (systematic code). If one is slow or missing, fetch any parity fragment instead and decode: a degraded read.
5. Repair: when a disk dies, for each stripe that lost a fragment, read k surviving fragments, decode, and write the lost one to a new disk.

Figure 15.6 — An RS(10,4) stripe across 14 failure domains.



Reading the diagram. A 640 MB block enters the *encoder*, which writes ten 64 MB data fragments and four 64 MB parity fragments, each to a different rack. Arrows are synchronous writes. Failure points: any four of the fourteen racks can fail with no data loss; a fifth concurrent loss before repair loses the stripe. Raw capacity used is $14 \times 64 = 896$ MB for 640 MB of data (1.4×), versus 1,920 MB for three replicas. Scaling: stripes are inde-

pendent, so encoding and repair parallelize across the cluster, but rebuilding one fragment reads ten, from ten racks.

Mathematical foundations

FORMULA

Overhead, fault tolerance and repair reads of a (k, m) code

$$\text{overhead} = \frac{k+m}{k} \qquad \text{tolerated losses} = m \qquad \text{repair read per lost fragment} = r \times F$$

Symbol	Meaning	Units
k	Data fragments per stripe	count
m	Parity fragments per stripe	count
overhead	Raw bytes stored per logical byte	dimensionless (×)
r	Fragments read to rebuild one: 1 for replication, k for RS, local group size for LRC	count
F	Fragment size	bytes

Replication is the special case $k = 1$: three-way replication is a (1, 2) code with overhead 3× and $r = 1$.

FORMULA

Approximate annual probability of losing a stripe (generalizing §4.16)

$$P_{\text{loss/yr}} \approx \frac{n!}{(n-m-1)!}\,\lambda^{m+1}\,T^{m} \times H, \qquad n = k+m, \;\; \lambda T \ll 1$$

Symbol	Meaning	Units
n	Fragments per stripe (replicas for replication)	count
m	Losses tolerated	count
λ	Per-fragment (per-disk) failure rate, AFR/8,760	failures/hour
T	Mean time to detect and rebuild one lost fragment	hours
H	Hours per year (8,760)	hours/year

Derivation. Exactly as in §4.16: the first loss happens at rate $n\lambda$; the stripe is lost if m more of the survivors fail, one after another, each before the previous repair completes, with probabilities $(n-1)\lambda T, (n-2)\lambda T, \ldots, (n-m)\lambda T$. Multiplying gives $n(n-1)\cdots(n-m)\,\lambda^{m+1}T^m$ per hour. For three replicas ($n=3$, $m=2$) this is $6\lambda^3T^2$, the §4.16 result.

WORKED EXAMPLE

Worked example — 3× replication versus RS(10,4): durability and cost. Use the §4.16 assumptions: AFR 2%, so $\lambda = 2.28\times10^{-6}$ per hour; $T = 24$ h, so $\lambda T = 5.48\times10^{-5}$. Note that $\lambda^{m+1}T^mH = \mathrm{AFR}\times(\lambda T)^m$.

1. 3× replication: $\frac{3!}{0!} = 6$; $P = 6\times0.02\times(5.48\times10^{-5})^2 = 6\times0.02\times3.00\times10^{-9} = 3.6\times10^{-10}$ per group per year.
2. RS(10,4): $n=14$, $m=4$; $\frac{14!}{9!} = 14\times13\times12\times11\times10 = 240,240$; $(\lambda T)^4 = 9.01\times10^{-18}$; $P = 240,240\times0.02\times9.01\times10^{-18} = 4.3\times10^{-14}$ per stripe per year.
3. Per petabyte with 64 MB fragments: replication has $10^{15}/6.4\times10^7 = 1.56\times10^7$ groups, so 5.6×10^{-3} expected loss events per year; RS(10,4) stripes hold 640 MB of data, so 1.56×10^6 stripes and 6.8×10^{-8} loss events per year.
4. Cost for 10 PB of logical data at an illustrative $10 per raw TB-month: replication needs 30 PB raw, $300,000 per month; RS(10,4) needs 14 PB raw, $140,000 per month, saving $1.92 million per year.

Interpretation. Under independent failures RS(10,4) is both cheaper (1.4× against 3×) and far more durable, because it tolerates four losses instead of two: about 8,000 times less likely to lose a given stripe, and, since each stripe holds ten times as much data as a replica group, about 80,000 times fewer expected loss events per petabyte.
Engineering implication. Erasure-code large, cold or warm data. The independence assumption is optimistic for both schemes (§4.16): correlated failures dominate real loss [Ford et al. 2010], so spread a stripe's fragments across racks and zones, and remember the hidden costs below — CPU for encoding, latency for small objects, and repair traffic.

FORMULA

Daily repair read traffic in a fleet

$$R_{\text{day}} = \frac{N_{\text{disk}} \times \text{AFR}}{365} \times D_{\text{used}} \times r$$

Symbol	Meaning	Units
R_{day}	Bytes read per day to rebuild failed disks	bytes/day
N_{disk}	Disks in the fleet	count
AFR	Annualized failure rate	fraction/year
D_{used}	Data stored per disk	bytes
r	Fragments read per fragment rebuilt	count

WORKED EXAMPLE

Worked example — Repair bandwidth for a 10,000-disk cluster. Disks of 20 TB at 60% full ($D_{\text{used}} = 12$ TB), AFR 2%.

1. Failures per day: $10,000 \times 0.02/365 = 0.548$.
2. Data lost per day: $0.548 \times 12 = 6.58$ TB.
3. 3× replication ($r = 1$): 6.58 TB/day of reads.
4. RS(10,4) ($r = 10$): 65.8 TB/day, a sustained $65.8 \times 10^{12}/86,400 = 761$ MB/s, about 6.1 Gb/s, most of it crossing racks.
5. LRC(12,2,2) (below, $r = 6$ for one lost data fragment): 39.5 TB/day, about 457 MB/s.

Interpretation. Erasure coding saves capacity but multiplies repair traffic by k. Briefly unavailable machines (reboots, upgrades) add more reconstruction: a study of a Facebook warehouse cluster using RS(10,4) reported recovery traffic on the order of a hundred terabytes per day crossing racks [Rashmi et al. 2013]. **Engineering implication.** Budget network capacity for repair, delay repair of transient failures for a few minutes, and consider codes that reduce r.

Code example

The program below implements XOR parity and a toy systematic Reed–Solomon-style code. For readability it works over the prime field GF(257) with Lagrange interpolation, so a parity symbol can be 256; production libraries (for example Intel ISA-L or Jerasure) use GF(2^8), but the "any k of $k + m$" property is identical.

```
        # A toy erasure code: XOR parity (m = 1) and a Reed-Solomon-style (k, m) code.
        # The RS code works over the prime field GF(257) so the arithmetic is plain
        # modular integer maths; production systems use GF(2^8) so every symbol is a
byte.
        import itertools
        import random

        P = 257  # prime modulus; symbols are integers 0..256

        def xor_parity(blocks):
            """RAID-5 style parity: byte-wise XOR of all data blocks."""
            parity = bytearray(len(blocks[0]))
            for b in blocks:
                for i, byte in enumerate(b):
                    parity[i] ^= byte
            return bytes(parity)

        def lagrange_at(points, x):
            """Evaluate, at x, the unique polynomial of degree < len(points)
            passing through points [(xi, yi)], all arithmetic mod P."""
            total = 0
            for i, (xi, yi) in enumerate(points):
                num, den = 1, 1
                for j, (xj, _) in enumerate(points):
                    if j != i:
                        num = num * (x - xj) % P
                        den = den * (xi - xj) % P
                total = (total + yi * num * pow(den, P - 2, P)) % P  # pow(.., P-2) =
inverse
            return total

        def rs_encode(data, k, m):
            """Systematic encoding of one stripe column: fragment i (i = 1..k) holds
            data[i-1]; parity fragments k+1..k+m hold the polynomial's values there."""
            pts = list(zip(range(1, k + 1), data))
            return data + [lagrange_at(pts, x) for x in range(k + 1, k + m + 1)]

        def rs_decode(survivors, k):
            """Rebuild the k data symbols from ANY k surviving (index, value) pairs."""
            pts = survivors[:k]
            return [lagrange_at(pts, x) for x in range(1, k + 1)]

        if __name__ == "__main__":
            # 1. XOR parity: lose any one block, rebuild it from the others.
            d = [b"GFS!", b"HDFS", b"S3ok"]
            p = xor_parity(d)
            rebuilt = xor_parity([d[0], d[2], p])  # pretend d[1] was lost
            print("XOR rebuilt block 1:", rebuilt, rebuilt == d[1])

            # 2. RS(4, 2): 4 data symbols, 2 parity symbols, survives ANY 2 losses.
            k, m = 4, 2
```

```
            data = [ord(c) for c in "EC4u"]
            stripe = rs_encode(data, k, m)
            print("stripe (data + parity):", stripe)
            ok = 0
            for lost in itertools.combinations(range(k + m), m):
                survivors = [(i + 1, v) for i, v in enumerate(stripe) if i not in lost]
                ok += rs_decode(survivors, k) == data
            print(f"RS({k},{m}) recovered data in {ok} of "
                  f"{len(list(itertools.combinations(range(k + m), m)))} two-loss pat-
terns")

            # 3. RS(10, 4) on random bytes: lose 4 random fragments, decode, compare.
            rng = random.Random(7)
            k, m = 10, 4
            data = [rng.randrange(256) for _ in range(k)]
            stripe = rs_encode(data, k, m)
            lost = set(rng.sample(range(k + m), m))
            survivors = [(i + 1, v) for i, v in enumerate(stripe) if i not in lost]
            print("RS(10,4) lost fragments", sorted(lost), "-> recovered:",
                  rs_decode(survivors, k) == data, "| symbols read for repair:", k)
```

Output (Python 3):

```
XOR rebuilt block 1: b'HDFS' True
stripe (data + parity): [69, 67, 52, 117, 98, 88]
RS(4,2) recovered data in 15 of 15 two-loss patterns
RS(10,4) lost fragments [1, 6, 12, 13] -> recovered: True | symbols read for repair: 10
```

What to notice:

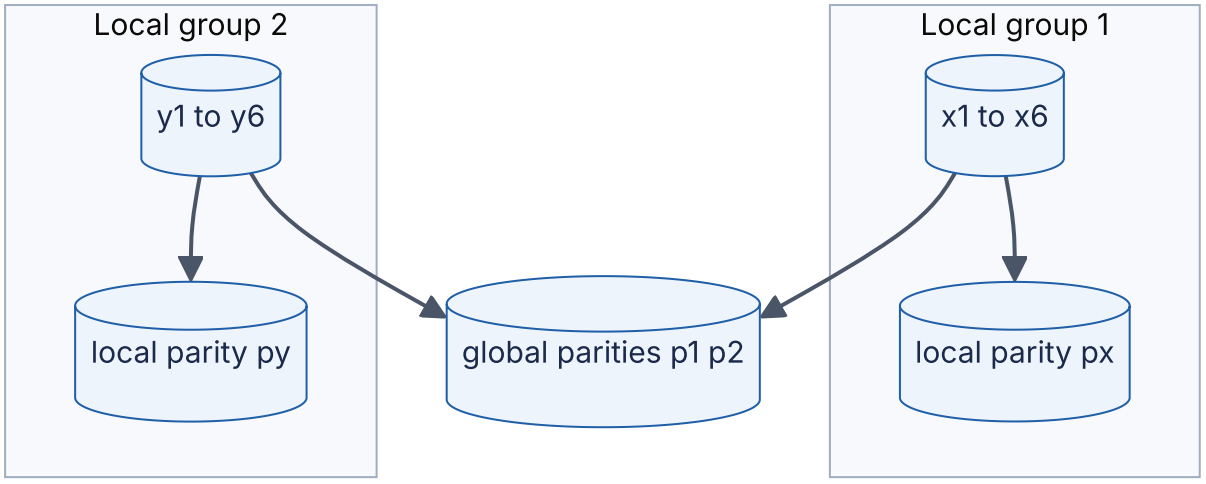
- XOR parity is its own inverse: XOR-ing the survivors with the parity yields the missing block. It tolerates exactly one loss.
- `rs_encode` keeps the data unchanged (systematic) and appends parity, so healthy reads never decode.
- The RS(4,2) loop tries all $\binom{6}{2} = 15$ ways to lose two fragments and recovers every time: the MDS property.
- Rebuilding any fragment reads k others; that is the repair-traffic multiplier of the formula above. Real codes apply this per byte position across fragments of many megabytes.

15.6.2 Local reconstruction codes

Repair cost led Microsoft to design **local reconstruction codes (LRC)** for Windows Azure Storage. LRC(k, l, g) splits the k data fragments into l local groups, adds one XOR-like **local parity** per group, and adds g **global parities** computed over all data. A single lost data fragment, by far the most common case, is rebuilt from its local group only. Azure's LRC(12,2,2) uses two groups of six: overhead $16/12 = 1.33\times$, a single-fragment repair reads 6 fragments instead of 12, it tolerates any three failures, and it also survives a

large fraction of four-failure patterns [Huang et al. 2012]. Compared with RS(6,3), which also reads 6 fragments per repair, LRC(12,2,2) stores less (1.33× against 1.5×) with similar durability.

Figure 15.7 — Azure-style LRC(12,2,2) stripe.



Reading the diagram. Twelve data fragments form two *local groups* of six. Each group has its own *local parity*, computed only from that group; the two *global parities* are computed from all twelve. Arrows are write-time dependencies; all sixteen fragments sit in different failure domains. Failure points and recovery: if `x3` fails, the system reads `x1`, `x2`, `x4`, `x5`, `x6` and `px` (six fragments) and never touches group 2; only rarer multi-failure patterns need the global parities and wider reads. Scaling: smaller repair reads mean less cross-rack traffic and faster repair, which also shrinks T in the durability formula.

Table 15.3 — Redundancy schemes compared (independent failures, AFR 2%, T = 24 h).

Scheme	Overhead	Losses tolerated	Reads per single repair	Approx. $P_{\text{loss/yr}}$ per group	Typical use
3× replication	3.0×	2	1	3.6×10^{-10}	Hot data, small objects, metadata
RS(6,3)	1.5×	3	6	1.0×10^{-11}	HDFS default EC policy (RS-6-3)
LRC(12,2,2)	1.33×	any 3 (some 4)	6	$\leq 1.4 \times 10^{-10}$ (counting only 3-loss tolerance)	Azure storage
RS(10,4)	1.4×	4	10	4.3×10^{-14}	f4; HDFS-RAID [Sathiamoorthy et al. 2013]

Alternatives and trade-offs

Replication wins for small objects (a 4 KB object should not become ten 400-byte fragments), hot data and low write latency. Erasure coding wins for large, warm and cold data. Many systems use both: write new data replicated (fast, simple), then **re-encode** it asynchronously once it is sealed or cold, as Azure does for sealed extents and as Tectonic does for blob storage [Huang et al. 2012; Pan et al. 2021].

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Repair saturates the network	*k*-fold repair reads after a rack failure	Cross-rack link utilization, repair queue depth	Throttle and prioritize stripes with the fewest survivors	LRC or smaller *k*; repair bandwidth budget
Too many fragments in one domain	Placement ignores racks or zones	Placement audit	Migrate fragments	Placement constraint: at most *m* per failure domain, ideally fewer

COMMON MISTAKE

"RS(10,4) means 4 out of 10 can fail." It means 4 out of 14 fragments can fail, any 4, data or parity. And it does not mean "40% overhead buys 4 failures" for free: every single repair reads 10 fragments.

15.7 Metadata services

15.7.1 Scaling the namespace

DEFINITION

Definition — Metadata service. The component that maps names to data: directory entries, file or object attributes (size, owner, permissions, version, checksum) and the locations of each chunk or fragment. It is on the path of every open, create, list and delete, while the data path bypasses it.

First-principles explanation

Return to the library. Adding shelves is easy; the catalog is the hard part, because every reader consults it and every new book changes it. Data scales by adding disks; metadata scales only if the catalog itself can be split without breaking operations that span several entries, such as moving a directory.

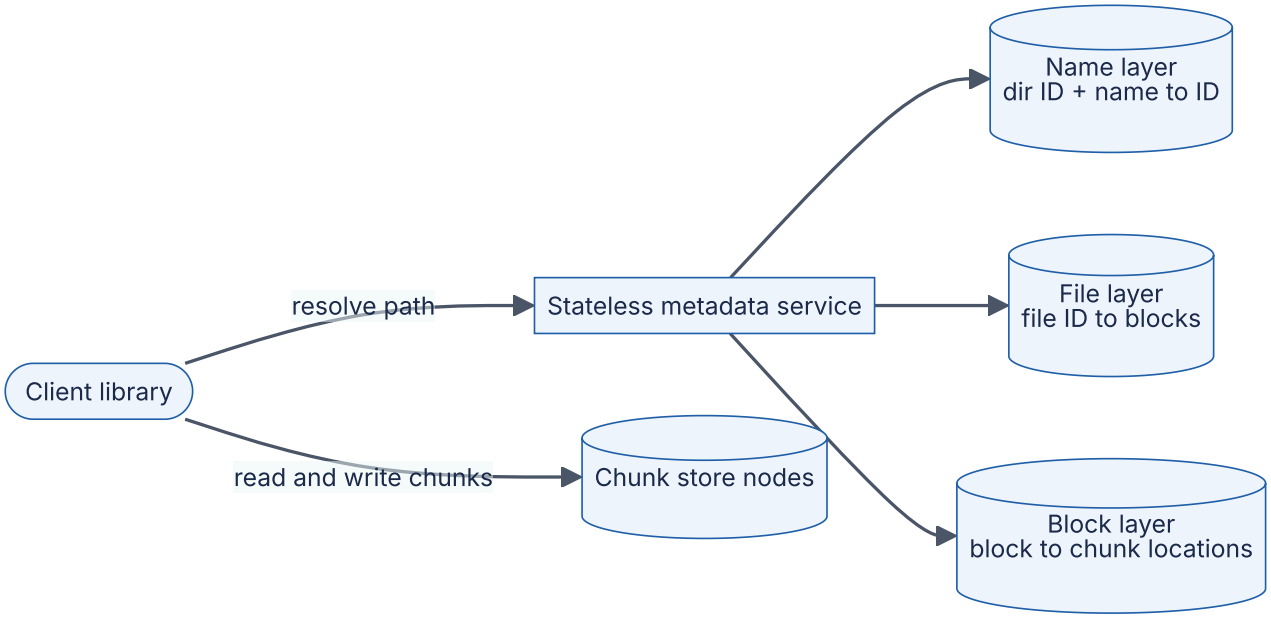
How it works internally

Five techniques recur, usually in combination:

1. **One in-memory server plus a replicated log** (GFS, HDFS): simple and fast, limited by RAM and request rate (§15.5 example).
2. **Static namespace partitioning**: several independent NameNodes or file systems under one tree (HDFS federation); cross-volume rename becomes a copy and load is balanced by hand.
3. **Dynamic subtree partitioning**: Ceph's metadata servers migrate hot directory subtrees between servers as load shifts [Weil et al. 2006].
4. **Hash partitioning in a scalable database**: entries keyed by (parent-directory ID, name) and (file ID, block index) in a sharded store, as in Tectonic (ZippyDB) and Colossus (Bigtable). Listing a directory stays on one shard; cross-shard operations such as directory rename need distributed transactions (Chapter 28) or are restricted.
5. **Compute placement instead of storing it**: Ceph's CRUSH function derives an object's storage nodes from its name and the cluster map, the same idea as consistent hashing (§14.8), so the metadata service need not store per-object locations at all [Weil et al. 2006].

Object stores avoid the hardest part, directory semantics, by having a flat namespace partitioned by key range (§15.4).

Figure 15.8 — Layered, partitioned file-system metadata (after Tectonic).



Reading the diagram. The *client library* resolves a path through a *stateless metadata service*, which reads three layers stored in a sharded key-value store: the *Name layer* (directory entries, sharded by directory ID), the *File layer* (file → block list, sharded by file

ID) and the *Block layer* (block → chunk locations, sharded by block ID). All metadata calls are synchronous. Data then flows directly between client and *chunk store nodes*. Storage boundary: metadata in the key-value store, bytes on chunk nodes. Failure points: a hot directory concentrates load on one Name-layer shard; a multi-shard operation can fail halfway without transactions. Scaling: each layer scales independently by adding shards, and the metadata service scales by adding stateless instances [Pan et al. 2021].

Advantages, disadvantages and failure scenarios

Partitioned metadata removes the single-server ceiling but brings back every problem of a partitioned database: hot partitions (one directory receiving millions of creates), cross-partition operations and consistency between layers.

RECOMMENDATION

Design for metadata first. Estimate the number of files or objects and the metadata operations per second before estimating bytes. Prefer fewer, larger objects; avoid huge single directories; and avoid workflows that rename or list large trees.

15.8 Multipart upload, chunking and deduplication

15.8.1 Multipart upload

DEFINITION

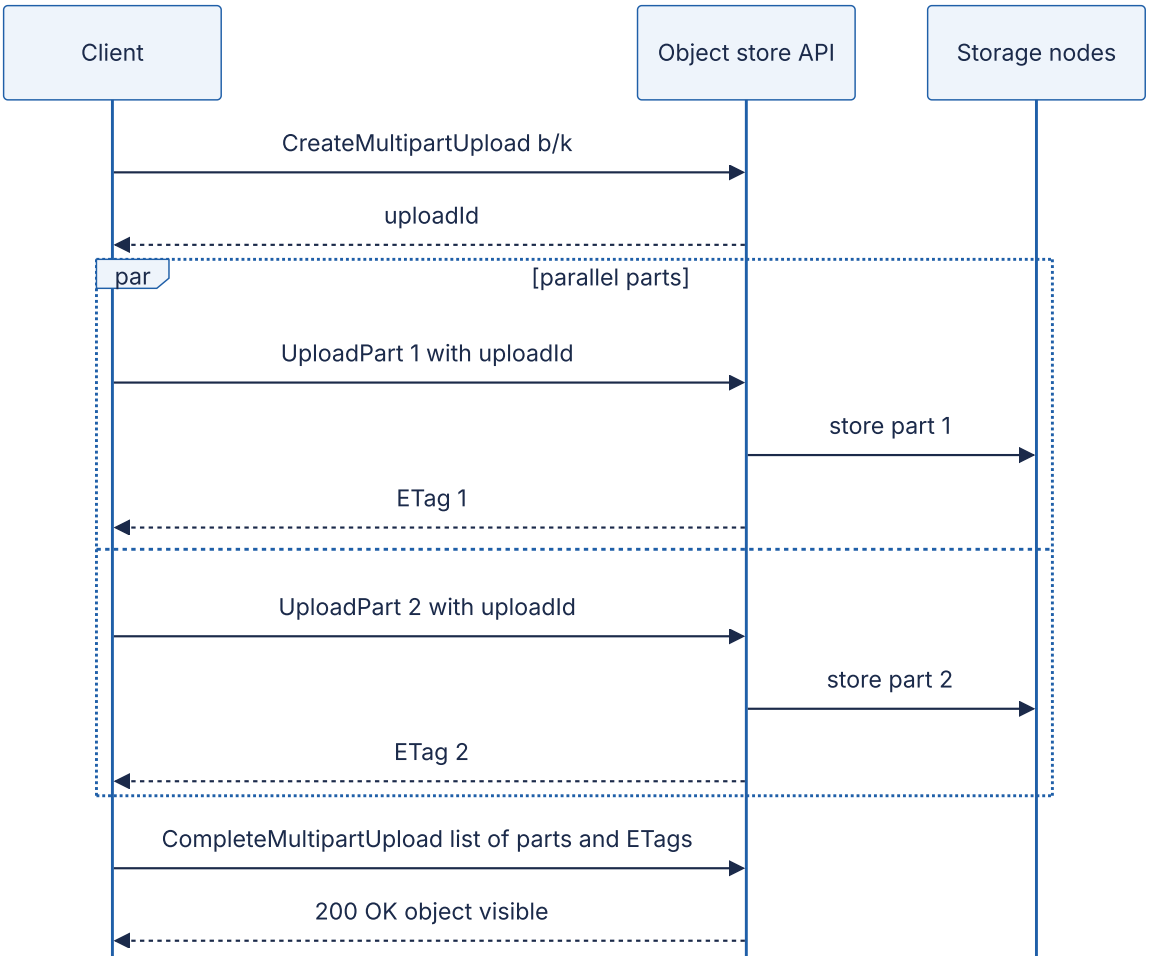
Definition — Multipart upload. A protocol for uploading one large object as independently uploaded **parts**: the client *initiates* an upload and receives an upload ID, uploads numbered parts (in any order, in parallel, retrying any part), then *completes* the upload with the list of part numbers and their ETags, at which point the store assembles the object atomically. Until completion, or after an *abort*, the object is not visible.

Why does this exist?

A single 200 GB PUT over one connection at 50 MB/s takes over an hour, and a network blip at 95% forces a restart from zero. Splitting the object makes the upload parallel (faster) and restartable (only the failed part is retried). As of 2026, Amazon S3 documents parts of 5 MiB to 5 GiB (the last part may be smaller), up to 10,000 parts per upload, a maximum single PUT of 5 GB, and a maximum object size of about 50 TB (48.8 TiB, raised from the long-standing 5 TB) [AWS S3 multipart docs].

How it works internally

Figure 15.9 — Multipart upload sequence.



Reading the diagram. The *client* initiates an upload and receives an `uploadId`. It then uploads parts concurrently (the `par` block), each a synchronous HTTP request stored durably on *storage nodes* and acknowledged with an ETag (a checksum the client keeps). The final *Complete* request is the commit point: the index records the object as the ordered concatenation of the listed parts, and only then does it become visible. Failure points: a failed part is retried; an upload never completed or aborted leaves billed, invisible parts for a lifecycle rule to delete (§15.9). Scaling: parts upload over many connections and land on many storage nodes, so throughput grows until the client's NIC saturates.

FORMULA

Part sizing and upload time

$$p_{\min} = \max\left(5\ \text{MiB}, \frac{S}{N_{\max}}\right) \qquad N = \left\lceil \frac{S}{p} \right\rceil \qquad t \approx \frac{S}{\min\left(c \cdot b,\ B_{\text{NIC}}\right)}$$

Symbol	Meaning	Units
S	Object size	bytes
p, $p_{\min}$	Chosen and minimum part size	bytes
$N_{\max}$	Maximum parts per upload (10,000 in S3)	count
N	Number of parts	count
c	Concurrent part uploads	count
b	Throughput per connection	bytes/s
B_{NIC}	Client network limit	bytes/s

WORKED EXAMPLE

Worked example — Uploading a 200 GB database backup. One connection achieves 50 MB/s; the NIC is 10 Gb/s (1.25 GB/s).

1. Minimum part size: $200 \times 10^9 / 10,000 = 20$ MB, which is above 5 MiB (5.24 MB), so $p_{\min} = 20$ MB.
2. Choose $p = 64$ MiB $= 67.1$ MB: $N = \lceil 2 \times 10^{11} / 6.71 \times 10^7 \rceil = 2,981$ parts.
3. Single PUT: not allowed (above 5 GB), and would take $2 \times 10^{11} / 5 \times 10^7 = 4,000$ s.
4. Sixteen concurrent parts: $\min(16 \times 50, 1250) = 800$ MB/s, so $t = 2 \times 10^{11} / 8 \times 10^8 = 250$ s.
5. Cost of a network error: retry one 67 MB part, about 1.3 s at 50 MB/s, instead of restarting.

Interpretation. Parallelism gives a 16× speed-up until the NIC is the limit (at 25 connections). **Engineering implication.** Choose a part size that keeps N well under 10,000 with headroom for growth, use 8–32 concurrent parts, verify each part's checksum, and always configure an abort rule for incomplete uploads.

15.8.2 Presigned URLs

A **presigned URL** is an object URL that carries the bucket, key, HTTP method, an expiry time and a signature computed with the issuer's credentials (an HMAC under AWS Signature Version 4, §10.4.6). Anyone holding it can perform exactly that operation until expiry (at most seven days with SigV4) [AWS S3 presigned URL docs]. PhotoShare uses them so that a phone uploads a photo *directly* to object storage: the API server authenti-

cates the user, chooses the key and returns a presigned PUT URL valid for a few minutes, so upload bandwidth never touches the application tier.

WARNING / TRADE-OFF

A presigned URL is a bearer token. Keep expiries short, scope each URL to one key and one method, enforce size and content type (for example with signed POST policies or post-upload validation), never log URLs in full, and note that the URL's power ends when the signing credential is revoked or expires.

15.8.3 Content-defined chunking and deduplication

DEFINITION

Definition — Content-defined chunking (CDC). Splitting a byte stream into variable-size chunks whose boundaries are chosen by the content itself: a rolling hash is computed over a small sliding window, and a boundary is declared wherever the hash matches a pattern (for example, its low 13 bits equal a fixed value). Each chunk is then identified by a cryptographic hash of its bytes, so identical chunks are stored once (**deduplication**).

First-principles explanation

Cut a book into pieces of exactly 1,000 characters, insert one word on page 1, and every later piece shifts: a backup system sees a new book. Cut instead after every sentence ending in a particular word, and the insertion changes only the first piece; later cuts stay put relative to the text. That is content-defined chunking. LBFS introduced it for network file systems, using Rabin fingerprints over a 48-byte window and declaring a boundary when the low 13 bits matched, for an expected 8 KB chunk, with minimum and maximum chunk sizes of 2 KB and 64 KB [Muthitacharoen et al. 2001; Rabin 1981].

Mathematical foundations

FORMULA

Expected chunk size and deduplication index size

$$E[\text{chunk}] \approx s_{\min} + 2^{b} \qquad M_{\text{index}} = \frac{U}{E[\text{chunk}]} \times e$$

Symbol	Meaning	Units
b	Number of hash bits that must match (boundary probability 2^{-b} per byte)	bits
$s_{\min}$	Minimum chunk size (no boundary is accepted earlier)	bytes
$E[\text{chunk}]$	Expected chunk size (ignoring the maximum cap)	bytes
U	Unique data stored	bytes
e	Index entry size (hash plus location)	bytes

WORKED EXAMPLE

Worked example — LBFS parameters and a backup index. With $b = 13$ and $s_{\min} = 2$ KiB: $E \approx 2,048 + 8,192 = 10,240$ B. A backup service with $U = 100$ TB of unique data and 40-byte entries (a 32-byte SHA-256 plus an 8-byte location):

1. Chunks: $10^{14}/10,240 = 9.77 \times 10^{9}$.
2. Index: $9.77 \times 10^{9} \times 40 = 3.9 \times 10^{11}$ B ≈ 391 GB.
3. With $b = 20$ (about 1 MiB chunks): $10^{14}/(2,048 + 1,048,576) \times 40 \approx 3.8$ GB.

Interpretation. Smaller chunks find more duplicates but the index grows inversely with chunk size and soon exceeds RAM. **Engineering implication.** Choose the chunk size from the index budget and the expected edit granularity; large-scale systems use larger chunks, sampled or tiered indexes, and keep only hot index entries in memory.

Code example

```
        # Content-defined chunking (CDC) versus fixed-size chunking, LBFS-style parame-
ters.
        # A Rabin-Karp polynomial rolling hash stands in for a true Rabin fingerprint
        # (which uses polynomial arithmetic over GF(2)); the boundary logic is the same.
        import hashlib
        import random

        WINDOW = 48                      # bytes in the rolling window (as in LBFS)
        MASK = (1 << 13) - 1             # 13 low bits -> expected chunk ~ 2^13 = 8 KiB
        MAGIC = 0x78                     # boundary when (hash & MASK) == MAGIC
        MIN_CHUNK, MAX_CHUNK = 2 * 1024, 64 * 1024
        BASE, MOD = 257, (1 << 61) - 1
        BASE_OUT = pow(BASE, WINDOW, MOD)  # weight of the byte leaving the window

        def cdc_chunks(data):
            chunks, start, h = [], 0, 0
            for i, byte in enumerate(data):
                h = (h * BASE + byte) % MOD
                if i >= WINDOW:
                    h = (h - data[i - WINDOW] * BASE_OUT) % MOD   # roll the oldest byte
out
                size = i - start + 1
                if (size >= MIN_CHUNK and (h & MASK) == MAGIC) or size >= MAX_CHUNK:
                    chunks.append(data[start:i + 1])
                    start = i + 1
            if start < len(data):
                chunks.append(data[start:])
            return chunks

        def fixed_chunks(data, size=8 * 1024):
            return [data[i:i + size] for i in range(0, len(data), size)]

        def shared_fraction(old, new):
            """Fraction of the new version's bytes found in chunks already stored."""
            stored = {hashlib.sha256(c).digest() for c in old}
            reused = sum(len(c) for c in new if hashlib.sha256(c).digest() in stored)
            return reused / sum(len(c) for c in new)

        if __name__ == "__main__":
            rng = random.Random(42)
            v1 = bytes(rng.randrange(256) for _ in range(2_000_000))   # 2 MB "file"
            v2 = b"inserted header!" + v1[:900_000] + b"edit" + v1[900_000:]

            for name, chunker in (("fixed 8 KiB", fixed_chunks), ("content-defined",
cdc_chunks)):
                a, b = chunker(v1), chunker(v2)
                avg = sum(map(len, a)) / len(a)
                print(f"{name:16s} chunks={len(a):4d} avg={avg:8.0f} B "
                      f"reused after edit={shared_fraction(a, b):6.1%}")
```

Output (Python 3, about 2 s):

```
fixed 8 KiB      chunks= 245 avg=    8163 B reused after edit=  0.0%
content-defined  chunks= 185 avg=   10811 B reused after edit= 98.5%
```

What to notice:

- The hash depends only on the last 48 bytes, so after an insertion the boundaries re-synchronize within one chunk, and every later chunk is byte-identical to before.
- Fixed-size chunking reuses nothing: a 16-byte insertion at the front shifts every block boundary.
- The measured average (about 10.8 KB) matches $s_{\min} + 2^{13} \approx 10.2$ KB within sampling noise.

COMMON MISTAKE

“Deduplicate everything, including encrypted data.” Encryption with random IVs makes identical plaintext produce different ciphertext, so deduplication must happen before encryption or use deliberate (and privacy-weakening) convergent encryption. Cross-user deduplication can also leak whether a file exists elsewhere; many services deduplicate only within one account.

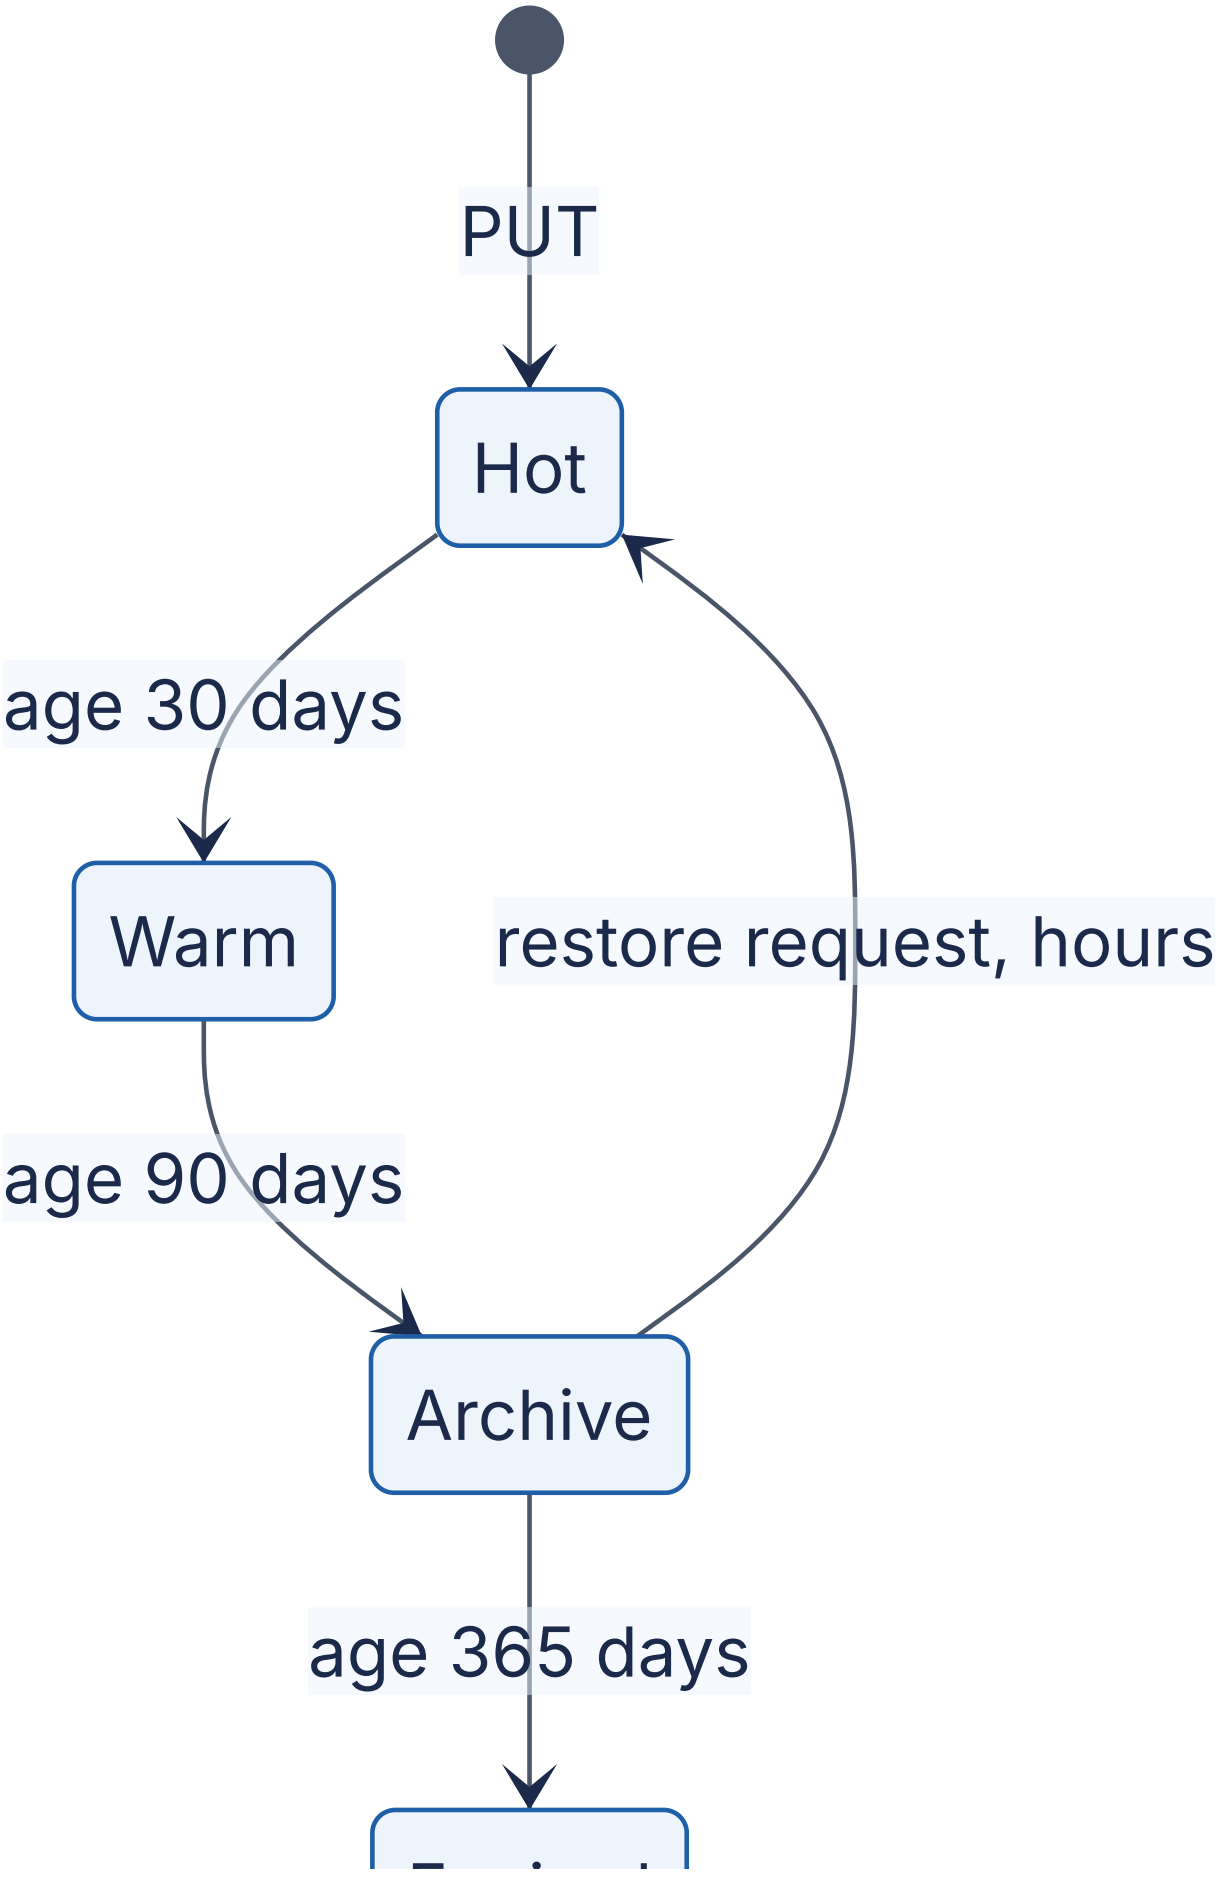
15.9 Storage tiers and lifecycle policies

DEFINITION

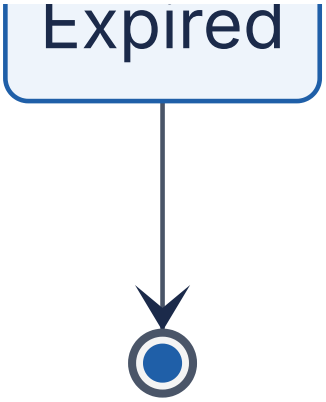
Definition — Storage tier and lifecycle policy. A **storage tier** (storage class) is a price/performance point for the same data: **hot** (frequent access, highest storage price, no retrieval fee), **warm** or infrequent access (cheaper storage, per-GB retrieval fee, minimum storage duration), **cold** (cheaper again, slower or costlier retrieval) and **archive** (cheapest storage, retrieval in hours). A **lifecycle policy** is a set of rules, usually by prefix, tag or age, that automatically transitions objects between tiers and expires (deletes) them.

Access frequency falls with age: photos are viewed for days, logs queried for a week and kept for years. Facebook built f4 specifically for such “warm” blobs, moving them from triple-replicated Haystack to erasure-coded storage [Muralidhar et al. 2014].

Figure 15.10 — A lifecycle policy for log objects.



PUT
Hot
age 30 days
Warm
restore request, hours
age 90 days
Archive
age 365 days



Reading the diagram. Each state is a storage class; transitions are applied asynchronously by the store's lifecycle engine, typically once a day, so ages are approximate. *Hot* serves reads in milliseconds; *Warm* serves them in milliseconds but charges per GB retrieved; *Archive* requires a restore that takes hours before the object can be read and creates a temporary hot copy. Failure points: a rule on the wrong prefix makes data unreadable for hours or deletes it; test rules and enable versioning. Every transition is a billed request.

Table 15.4 — Illustrative object-storage classes (Amazon S3, us-east-1 list prices, as of 2026).

Tier	Example class	Storage $/GB-month	Retrieval	Minimum duration
Hot	S3 Standard	0.023	none	none
Warm	S3 Standard-IA	0.0125	$0.01/GB	30 days; 128 KB minimum billable size
Cold	S3 Glacier Instant Retrieval	0.004	$0.03/GB, milliseconds	90 days
Archive	S3 Glacier Deep Archive	0.00099	hours (about 12 h standard)	180 days

FORMULA

Cost of one cohort of data over its lifetime

$$C = \sum_{\text{tiers } i} V \cdot p_i \cdot t_i + \sum_{\text{transitions } j} N_{\text{obj}} \cdot q_j + V_{\text{read}} \cdot g$$

Symbol	Meaning	Units
V	Volume of the cohort	GB
p_i, t_i	Storage price and months spent in tier i	$/GB-month, months
N_{obj}	Number of objects	count
q_j	Price per lifecycle transition request into tier j	$/request
V_{read}, g	Data retrieved and its per-GB retrieval fee	GB, $/GB

WORKED EXAMPLE

Worked example — One month of logs kept for a year (as of 2026, illustrative list prices). A cohort of $V = 100$ TB $= 100,000$ GB of logs in 1 million objects of 100 MB. Assume transition requests cost $\$0.01$ per 1,000 into Standard-IA and $\$0.05$ per 1,000 into Deep Archive (verify current prices).

1. All Standard for 12 months: $100,000 \times 0.023 \times 12 = \$27,600$.
2. Lifecycle: 1 month Standard $= \$2,300$; 2 months Standard-IA $= 100,000 \times 0.0125 \times 2 = \$2,500$; 9 months Deep Archive $= 100,000 \times 0.00099 \times 9 = \$891$. Storage subtotal $\$5,691$.
3. Transitions: $10^6 \times 0.01/1000 + 10^6 \times 0.05/1000 = \$10 + \$50 = \$60$.
4. Total $\approx \$5,751$: a 79% saving.
5. Small-object trap: the same 100 TB as 1 billion 100 KB objects makes the Deep Archive transitions alone cost $10^9 \times 0.05/1000 = \$50,000$, more than the whole Standard-only bill, and every 100 KB object in Standard-IA is billed as 128 KB.

Interpretation. Tiering is worth roughly 4–5× for large objects that cool predictably. **Engineering implication.** Aggregate small objects before tiering them, respect minimum durations (deleting a Deep Archive object after 30 days still bills 180), and use automatic access-based tiering when access patterns are unknown.

RECOMMENDATION

Lifecycle hygiene. Always add rules to abort incomplete multipart uploads after a few days and to expire noncurrent versions in versioned buckets. Without them, invisible parts and old versions quietly become a large share of the bill.

15.10 Summary and revision notes

SUMMARY

- **Block** storage exposes numbered blocks to one host (databases, boot disks; sub-millisecond to millisecond latency). **File** storage exposes a shared POSIX tree (NFS/SMB; shared access, metadata-bound). **Object** storage exposes immutable key → blob over HTTP (unlimited scale, tens of ms first byte, parallel throughput, cheapest per GB).
- An S3-style store separates a stateless **front end**, a key-range-partitioned **metadata index**, a **placement** service and **storage nodes**. A PUT writes data first and commits metadata last; the commit is the linearization point that gives strong read-after-write consistency (S3 since December 2020).
- **GFS**: one in-memory master off the data path, 64 MB chunks, three replicas, leases that let a primary order mutations, pipelined data flow, at-least-once record append. **HDFS** copies the design; HA adds a standby NameNode, a JournalNode quorum and ZooKeeper fencing. **Colossus** and **Tectonic** move metadata into scalable databases (Bigtable, ZippyDB).
- **Erasure coding** RS(k,m): overhead $(k+m)/k$, survives any m losses, repair reads k fragments. RS(10,4) costs 1.4× versus 3× for replication and, under independence, is far more durable; loss $\approx \frac{n!}{(n-m-1)!}\lambda^{m+1}T^{m}H$. **LRC** cuts single-fragment repair reads (Azure LRC(12,2,2): 1.33×, 6 reads).
- Metadata, not bytes, limits scale: memory ≈ objects × bytes per entry. Partition it by subtree, by hash in a sharded store, or compute placement (CRUSH).
- **Multipart upload** makes large uploads parallel and restartable (S3: 5 MiB–5 GiB parts, ≤ 10,000 parts). **Presigned URLs** delegate one operation for a limited time. **Content-defined chunking** keeps chunk boundaries stable under insertion, enabling deduplication; index size ∝ 1/chunk size.
- **Lifecycle policies** move cooling data to cheaper tiers (4–5× savings for large objects); minimum durations, transition fees and minimum billable sizes punish small objects.

15.11 Knowledge checkpoint

1. Name one workload that fits each of block, file and object storage, and say why.
2. In an object-store PUT, why is data written before metadata is committed?
3. What did S3's December 2020 change guarantee, and what remains asynchronous?
4. Why did GFS choose 64 MB chunks? Give one benefit and one cost.
5. What is a lease in GFS and what problem does it solve?
6. Compute the overhead and tolerated losses of RS(6,3) and RS(10,4).
7. Why does RS(10,4) generate about ten times the repair traffic of replication?
8. How does LRC(12,2,2) repair a single lost data fragment?
9. Estimate NameNode heap for 200 million files of one block each at 150 bytes per object.
10. What is the minimum part size for a 300 GB object in S3, and why?
11. Why does inserting one byte at the start of a file defeat fixed-size deduplication but not CDC?

Answers

1. Block: a PostgreSQL data directory (random page I/O, one host). File: shared model checkpoints read by many training nodes (POSIX, shared). Object: user photos (immutable, large, HTTP, unlimited).
2. So that the key never points at incomplete data: the metadata commit is the atomic visibility point, and orphaned data from failed PUTs can be garbage-collected.
3. Strong read-after-write for PUT and DELETE of objects and for LIST. Bucket configuration changes and cross-region replication remain eventually consistent.
4. Benefit: few chunks, so small master memory and few master requests. Cost: small files occupy one chunk on few servers and can become hot spots.
5. A time-limited grant making one replica the primary for a chunk; it orders concurrent mutations without involving the master, and expires safely if the primary fails.
6. RS(6,3): 1.5×, any 3. RS(10,4): 1.4×, any 4.
7. Rebuilding one fragment requires reading $k = 10$ surviving fragments, versus one surviving replica.
8. It reads the other five data fragments of its local group plus that group's local parity, six fragments in all.
9. $(2 \times 10^8 + 2 \times 10^8) \times 150 = 6 \times 10^{10}$ B, about 60 GB.
10. $3 \times 10^{11} / 10,000 = 30$ MB, because at most 10,000 parts are allowed (and 30 MB exceeds the 5 MiB floor).
11. Fixed boundaries are at fixed offsets, so every block shifts; CDC boundaries depend on local content and re-synchronize after the insertion.

15.12 Interview questions

Basic

Q1. When would you use object storage rather than a block volume? Answer. For large, immutable, independently addressed data read sequentially or by many clients: media, backups, logs, datasets. It offers unlimited capacity, high durability and parallel throughput at the lowest price, but tens of milliseconds of first-byte latency and no in-place updates. Databases and anything needing low-latency random I/O stay on block storage.

Q2. How would PhotoShare let users upload photos without loading the API servers? Answer. The API authenticates the user, writes a pending photo row, and returns a short-lived presigned PUT URL for a server-chosen key. The phone uploads directly; an upload event triggers thumbnail jobs and activates the row. Videos use multipart upload. Keep expiries short; validate size and type.

Intermediate

Q3. Explain replication versus erasure coding and when you would choose each. Answer. Replication: simple, fast, cheap repair (read one copy), 3× overhead. RS(k,m): overhead $(k+m)/k$ (1.4× for RS(10,4)), tolerates any m losses, but repair reads k fragments and small objects encode poorly. Replicate hot data, small objects and metadata; erasure-code large warm and cold data, often by re-encoding after it is sealed.

Q4. Walk through a GFS write and explain the role of the lease. Answer. The client asks the master which replica holds the chunk's lease, pushes data along a chain of all replicas, then sends the write to the primary. The primary assigns a serial order, applies it, forwards it to the secondaries and replies when all apply. The lease (60 s, renewable) lets the primary order mutations without the master and expires safely if it dies.

Q5. A team writes a million files per hour into one HDFS directory and the cluster slows down. Why, and what do you do? Answer. Every create is a NameNode metadata operation and each small file costs heap. Pack records into larger files (Parquet, hourly compaction), spread directories, use federation, or move to an object store with hashed prefixes.

Advanced

Q6. Design the durability scheme for a 50 PB archive with eleven-nines durability and minimal cost. Answer. Use a wide erasure code such as RS(10,4) or an LRC, with each stripe's fragments spread across racks and, for zone failure, across three zones (or a geo-level XOR as in f4). Compute loss probability with the formula of §15.6 using a pes-

simistic AFR and realistic repair time, then add margin for correlated failures. Budget repair bandwidth, scrub checksums, keep versioning or an offline copy against bugs and deletion, and tier by age.

Q7. How does an object store provide strong read-after-write consistency at scale? Answer. Make each key's metadata update a single atomic commit in a linearizable, replicated index partition, after data is durable. Caches in front of the index must not serve stale entries: invalidate or validate them, for example against a component that records the latest change per key, as AWS describes with its witness. Concurrent writers still race; offer conditional writes for compare-and-swap.

15.13 Practical exercises

1. Extend the RS program to GF(2^8) using log and antilog tables and verify that RS(10,4) recovers all $\binom{14}{4} = 1,001$ four-loss patterns.
2. Using the §15.6 formula, tabulate $P_{\text{loss/yr}}$ for RS(6,3), RS(10,4) and 3× replication with $T = 6$, 24 and 168 hours.
3. Write a lifecycle policy for PhotoShare: originals to infrequent access after 60 days, thumbnails kept hot, abort incomplete uploads after 7 days. Estimate the first-year saving for 5 TB/day of new photos.

15.14 Design challenges

1. **Video archive.** Design storage for a service ingesting 2 PB of video per month, with hot playback of the newest 30 days and rare access afterwards. Choose redundancy per tier, a chunking and upload protocol, metadata design, and a lifecycle policy; estimate raw capacity, repair traffic and monthly cost.
2. **Training-data lake.** Thousands of GPU nodes read a 5 PB dataset of 50 billion small images each epoch. Choose a parallel file system or object storage, pack samples into shards, and keep metadata off the critical path (see Chapter 61).

15.16 Open verification items

- S3 maximum object size: AWS pages state both “50 TB” and 48.8 TiB (10,000 × 5 GiB); confirm the current figure and announcement date (docs.aws.amazon.com was unreachable from the authoring environment).
- S3 conditional writes: `If-None-Match` (2024) and `If-Match` (late 2024) availability dates and scope.
- Table 15.4 prices, transition-request prices ($0.01 and $0.05 per 1,000), Deep Archive retrieval times and minimum durations: verify against the AWS pricing page as of 2026.
- Exact title and URL of the Google Cloud Colossus blog post [Hildebrand and Serenyi 2021].
- HDFS “about 150 bytes per namespace object” rule of thumb: confirm a primary source.
- Recovery-traffic magnitude in [Rashmi et al. 2013] (“on the order of a hundred terabytes per day”).
- Typical object-store first-byte latency range in Table 15.1.

Chapter 16 — Search Systems

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Type “wireless noise canceling headphones” into an online store and, within about a tenth of a second, a ranked list comes back from tens of millions of products. A B-tree index (§11.8) cannot do this: it finds rows whose key *equals* or *starts with* a value, so `WHERE description LIKE '%noise%'` reads every row, and even then the database has no notion of which match is *best*.

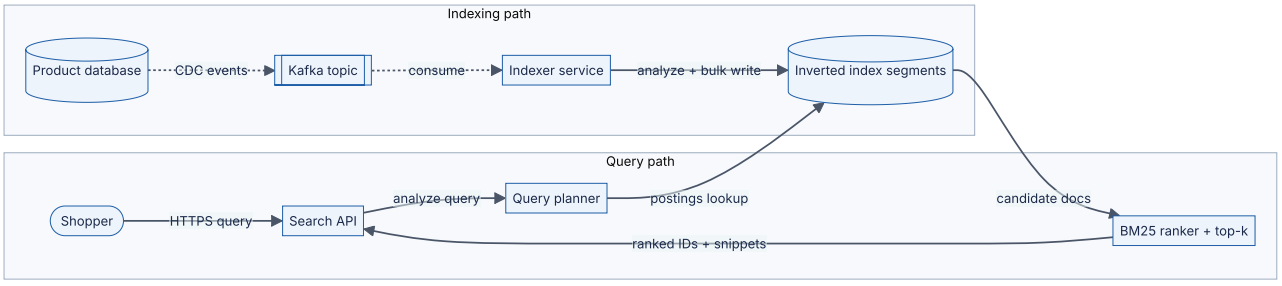
Search systems solve three problems that ordinary databases do not:

1. **Finding documents by the words inside them**, quickly, across billions of words. The answer is the **inverted index** (§16.3), together with the text analysis that decides what counts as a “word” (§16.4).
2. **Ordering matches by relevance**, so the most useful result comes first. The answer is a scoring function, today usually **BM25** (§16.5).
3. **Doing both at scale and in near real time**, while documents are being added, changed and deleted. The answer is immutable index segments that are merged in the background (§16.6), partitioned and replicated across nodes (§16.7). Elasticsearch and OpenSearch package all of this (§16.8), and an indexing pipeline keeps the index in step with the source of truth (§16.10).

Autocomplete (§16.9) has a latency budget so tight that it gets its own data structures, and §16.11 bridges to semantic and hybrid retrieval (Chapters 74–75). These ideas are stable: Brin and Page’s 1998 Google prototype already had an inverted index, position “hit lists” and a ranking function combining text scores with PageRank [Brin and Page 1998].

The running example is product search for an online electronics store. Figure 16.1 shows its two halves.

Figure 16.1 — The two paths of a search system.



Reading the diagram. The left subgraph is the **indexing path**. The product database is the source of truth; change data capture (CDC) publishes every insert, update and delete as an event to a Kafka topic. Those dotted arrows are asynchronous: the shopper never waits for them. The indexer consumes events, runs text analysis and writes to the index in bulk. The right subgraph is the **query path**, which is synchronous (solid arrows) from the shopper's HTTPS request to the ranked response. The query is analyzed with the *same* rules as the documents, the planner looks up postings lists, and the ranker scores candidates and keeps the top k. There are two storage boundaries, the product database and the index, and they are eventually consistent with each other; the lag between them is the **freshness** of search (§16.10). Failure points: if Kafka or the indexer stalls, search keeps serving but grows stale; if the index is unavailable, search fails even though the database is healthy. The two paths scale independently: indexing by adding partitions and indexer consumers, querying by adding replicas (§16.7).

16.1 Learning objectives

After this chapter you should be able to:

- Explain how an inverted index, postings lists, positions and skip pointers answer keyword, Boolean and phrase queries, and estimate an index's size with delta and variable-byte compression.
- Design an analysis chain (tokenizer, lowercasing, stemming or lemmatization, stop words, n-grams, synonyms) and predict how each choice changes recall, precision and index size.
- Compute TF-IDF and BM25 scores by hand, explain the roles of k_1 and b, and apply field boosting.
- Describe how Lucene builds indexes from immutable segments, handles deletes with tombstones, and merges segments, and estimate merge write amplification.
- Compare document and term partitioning, compute scatter–gather tail latency, and explain query-then-fetch, deep-pagination cost and the global-versus-local IDF problem.
- Describe the Elasticsearch/OpenSearch cluster model: node roles, shards, replicas, the translog, refresh, flush and near-real-time search.
- Design an autocomplete service with a trie or FST holding precomputed top-k completions and meet a 100 ms end-to-end budget.
- Build a near-real-time indexing pipeline with CDC and Kafka, and reason about its freshness latency and refresh-interval trade-offs.

16.2 Prerequisites

- B-trees and secondary indexes — §11.7–§11.8 (the inverted index is a different answer to the same "avoid a full scan" problem).
- Log-structured storage, LSM trees and compaction — §13.7–§13.9 (Lucene segments are an LSM-like design; this chapter cross-references rather than repeats).
- Partitioning and replication — §14.3 and §14.6–§14.7 (search clusters apply them to indexes).
- Percentiles and fan-out amplification — §4.8 (scatter–gather latency builds directly on p^N).
- Logarithms — §4.4 (IDF and merge-tier arithmetic use them).
- Tries — §17.11 gives the data structure; this chapter applies it to autocomplete.
- Python 3.10 or later to run the listings; all use only the standard library.

16.3 Inverted indexes

16.3.1 From the index at the back of a book to an inverted index

> DEFINITION
>
> **Definition — Inverted index.** A mapping from each distinct **term** (a normalized word or token) to a **postings list**: the sorted list of identifiers of the documents that contain the term, optionally with the term's frequency and positions in each document. The set of all terms is the **dictionary** (or **vocabulary**, or **lexicon**).

First-principles explanation

Open a textbook at the back. The index lists "Bloom filter … 211, 340, 512". Nobody reads the whole book to find Bloom filters; you look up the word and jump to the pages. The book's body maps *page → words*. The index at the back is that mapping turned inside out: *word → pages*. That is all an inverted index is. The "forward" direction (document → terms) is how documents are written; the "inverted" direction (term → documents) is how they are searched.

Three refinements make it a search index: page numbers become small-integer **document identifiers (docIDs)**; each list is kept **sorted** by docID so lists combine cheaply; and each entry can carry the **term frequency** (tf) and **positions** of the word, for ranking and phrase matching.

Why does this exist?

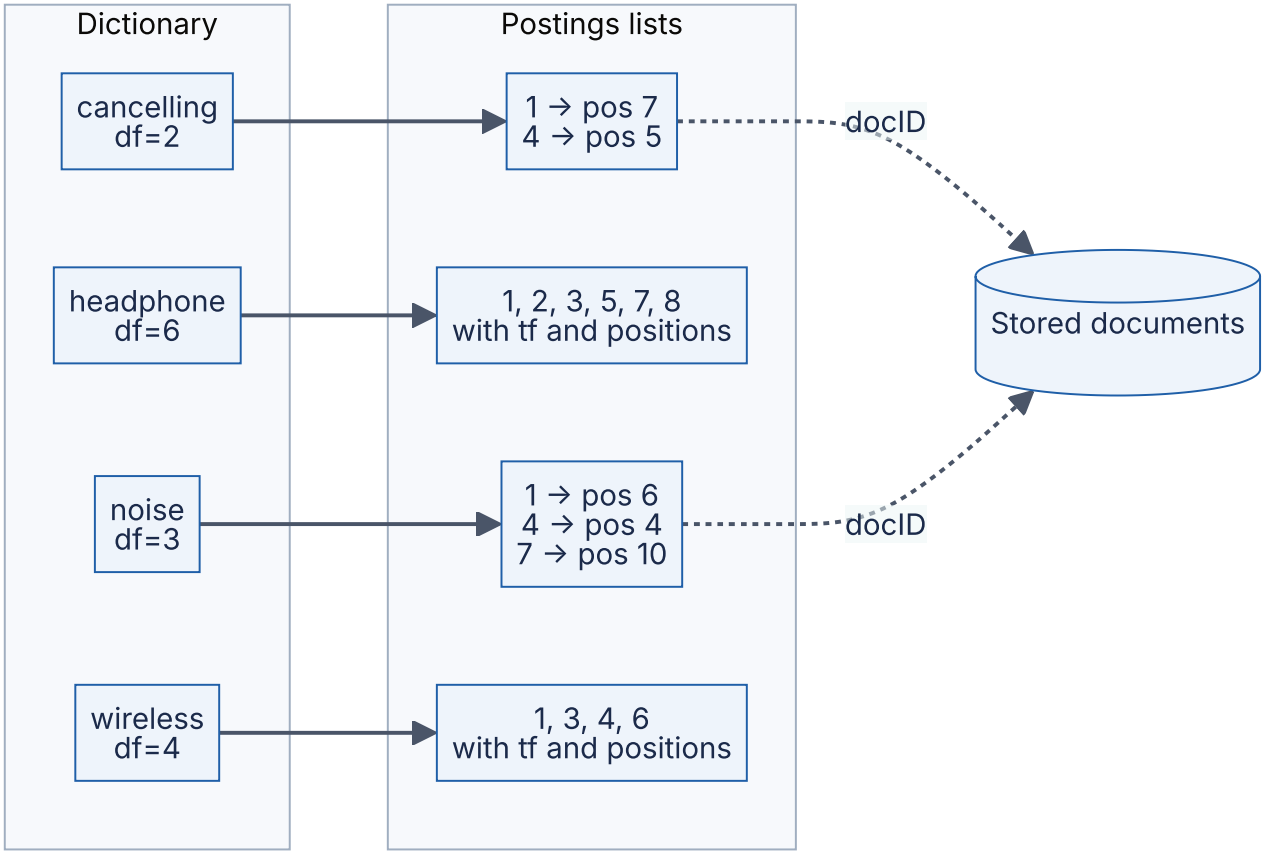
Consider answering “documents containing *noise* and *headphones*” by scanning. A catalog of 100 million documents averaging 2.4 KB of text is 240 GB. Reading 240 GB at a generous 10 GB/s of memory bandwidth takes 24 s per query on one core, before any matching work. An inverted index instead reads two postings lists. If *noise* appears in 1 million documents and *headphones* in 100,000, the engine touches about 1.1 million entries; at roughly 2.4 bytes per compressed entry (§16.3.5) that is about 2.6 MB, read in well under a millisecond. The index trades storage and indexing work for a 10,000-fold reduction in query work.

How it works internally

1. **Analyze** each document into terms with positions (§16.4).
2. **Assign** a docID; Lucene assigns them in insertion order within each segment, so postings are naturally sorted (§16.6).
3. **Append** the docID (with tf and positions) to the postings list of each distinct term.
4. **Store** the dictionary in a structure supporting exact and prefix lookup; Lucene uses a block tree indexed by a finite-state transducer (§16.9.3).
5. **Compress** postings (§16.3.4) and write them sequentially.

Architecture diagram

Figure 16.2 — Dictionary, postings lists and positions.



Reading the diagram. The left subgraph is the dictionary: one entry per distinct term with its **document frequency** (df, the number of documents containing it). Each solid arrow is a pointer, in practice a file offset, from a dictionary entry to its postings list. The right subgraph shows postings for the body field of this chapter's eight-product example (§16.5.4): *noise* occurs in documents 1, 4 and 7, at positions 6, 4 and 10. The dotted arrows show the last step of a query: docIDs are turned into displayable results by fetching stored fields, a separate storage structure. The dictionary is small and usually memory-resident; postings are large and read sequentially; stored documents are read only for the final top results. Failure points are corruption of any of the three structures, which is why Lucene checksums every file. Scaling is by partitioning documents across shards, each with its own complete dictionary and postings (§16.7).

16.3.2 Query evaluation with postings lists

Because postings are sorted, Boolean operators become list operations:

- **AND** (*noise* AND *wireless*) is an **intersection**: walk both lists in step, advancing whichever pointer holds the smaller docID, and output docIDs found in both. Cost is $O(L_1 + L_2)$ for lists of lengths L_1 and L_2.
- **OR** is a **union**, also a linear merge; ranked retrieval is usually OR-like, with scoring sorting candidates. **NOT** is a list difference.

- A **phrase query** (“noise canceling”) first intersects the lists, then checks positions: a document matches only if *canceling* occurs at position $p+1$ for some position p of *noise*. Positional data typically makes the index two to four times larger, which is why some fields are indexed without positions (in Elasticsearch, `index_options: docs` or `freqs`).

Process the **rarest term first**: an intersection is never larger than its shortest list.

16.3.3 Skip pointers

Intersecting a list of 200,000 docIDs with one of 1,000 by linear merge costs about 200,000 comparisons, almost all of them spent stepping through the long list past docIDs that cannot match. **Skip pointers** are shortcuts stored every s entries of a postings list: “the entry s positions ahead holds docID X”. When the target docID is beyond X, the iterator jumps s entries at once.

Lucene exposes this as an iterator operation, `advance(target)`: move to the first docID $\geq$ target. Its postings formats store multi-level skip data so `advance` can take long jumps, then shorter ones, then scan within one compressed block [Lucene Docs: postings format]. The skip interval trades jump distance against scan length. Manning et al. suggest $\sqrt{L}$ for a list of length L [Manning et al. 2008, §2.3], but that heuristic assumes lists of similar length. When a short list of m targets drives a long list of length L, the total cost is roughly L/s skip-follows plus $m \cdot s/2$ in-block steps, minimized at $s = \sqrt{2L/m}$.

```
        """Intersect two sorted postings lists (AND query), with and without skip point-
ers,
        counting comparisons. The skip version drives from the shorter list and calls
advance(target),
        the operation Lucene's postings iterators expose."""
        import math
        import random

        def intersect_linear(a, b):
            """Textbook merge: step whichever pointer holds the smaller docID."""
            i = j = comparisons = 0
            out = []
            while i < len(a) and j < len(b):
                comparisons += 1
                if a[i] == b[j]:
                    out.append(a[i]); i += 1; j += 1
                elif a[i] < b[j]:
                    i += 1
                else:
                    j += 1
            return out, comparisons

        class SkipPostings:
            """A postings list with a skip pointer every `step` entries."""
            def __init__(self, doc_ids, step=None):
                self.ids = doc_ids
                self.step = step or max(1, int(math.sqrt(len(doc_ids))))
                self.pos = 0
                self.comparisons = 0

            def advance(self, target):
                """Move to the first docID >= target; return it (or None when ex-
hausted)."""
                ids, s = self.ids, self.step
                nxt = (self.pos // s + 1) * s                    # next skip-pointer po-
sition
                while nxt < len(ids) and ids[nxt] <= target:     # follow skips while
they do not overshoot
                    self.comparisons += 1
                    self.pos, nxt = nxt, nxt + s
                while self.pos < len(ids) and ids[self.pos] < target:   # then scan in-
side one block
                    self.comparisons += 1
                    self.pos += 1
                return ids[self.pos] if self.pos < len(ids) else None

        def intersect_with_skips(short, long_list, step=None):
            it = SkipPostings(long_list, step)
            out = []
            for doc in short:                                    # drive from the rarer
term
                it.comparisons += 1
                found = it.advance(doc)
                if found is None:
                    break
                if found == doc:
```

```
                    out.append(doc)
            return out, it.comparisons

        if __name__ == "__main__":
            random.seed(7)
            N = 1_000_000
            common = sorted(random.sample(range(N), 200_000))   # e.g. "wireless": 20%
of docs
            rare = sorted(random.sample(range(N), 1_000))       # e.g. "anc": 0.1% of
docs
            r1, c1 = intersect_linear(common, rare)
            assert r1 == sorted(set(common) & set(rare))
            print(f"matches={len(r1)}  linear merge: {c1:,} comparisons")
            for step in (447, 128, 20):                         # sqrt(L), Lucene's block
size, sqrt(2L/m)
                r2, c2 = intersect_with_skips(rare, common, step)
                assert r2 == r1
                print(f"skip every {step:>3}: {c2:>7,} comparisons  ({c1 / c2:.0f}x
fewer)")
```

Output (Python 3.13):

```
matches=184  linear merge: 200,611 comparisons
skip every 447: 121,210 comparisons  (2x fewer)
skip every 128:  53,587 comparisons  (4x fewer)
skip every  20:  20,909 comparisons  (10x fewer)
```

What to notice:

- The intersection is **driven by the rare list**: 1,000 calls to `advance`, not 200,000 steps.
- The $\sqrt{L} = 447$ heuristic helps only 2× here because each `advance` then scans about 224 entries inside a block. Spacing tuned to the list-length ratio, $\sqrt{2 \times 200{,}000/1{,}000} = 20$, gives 10×. Multi-level skip lists, as in Lucene, get coarse and fine jumps without choosing one spacing.
- In a real engine the bigger win is **decoding**: a skipped compressed block is never decompressed.

16.3.4 Compression: delta encoding and variable-byte codes

A docID stored as a 32-bit integer costs 4 bytes. Postings lists hold one entry per (term, document) pair, so they dominate index size. Two observations make them highly compressible.

Delta (gap) encoding. A sorted list such as 824, 829, 215406 can be stored as its first value followed by differences: 824, 5, 214577. A frequent term has small gaps (a term in 20% of documents has an average gap of 5), and small numbers need few bits. Rare terms have large gaps but short lists, so they contribute little to total size.

Variable-byte (VByte) codes. Encode each gap in as many bytes as it needs, using 7 data bits per byte and the eighth bit as a flag. In Lucene's `VInt` convention the low-order 7 bits come first and a high bit of 1 means "more bytes follow" [Lucene Docs: DataOutput.writeVInt]. Manning et al. describe the same code with the flag set on the *last* byte instead [Manning et al. 2008, §5.3.1]; the two are equivalent in size.

FORMULA

Variable-byte length of an integer

$$\text{bytes}(g) = \max\left(1, \left\lceil \frac{\lfloor \log_2 g \rfloor + 1}{7} \right\rceil\right)$$

Symbol	Meaning	Units
g	The integer to encode, here a docID gap ($g \geq 1$)	count
$\lfloor \log_2 g \rfloor + 1$	Number of significant bits in g	bits
$\text{bytes}(g)$	Encoded length, 7 payload bits per byte	bytes

Table 16.1 — Variable-byte length by gap size.

Gap range	Significant bits	VByte bytes	Saving versus 4-byte integer
1–127	1–7	1	75%
128–16,383	8–14	2	50%
16,384–2,097,151	15–21	3	25%
2,097,152–268,435,455	22–28	4	0%

WORKED EXAMPLE

Worked example — encoding 824, 829, 215406.

1. Gaps: 824, 829 − 824 = 5, 215406 − 829 = 214577.
2. 824 has 10 significant bits (512 ≤ 824 < 1024), so $\lceil 10/7 \rceil = 2$ bytes. Split into 7-bit groups: $824 = 6 \times 128 + 56$. Low group first with the continuation bit set: $56 + 128 = 184$ = `10111000`; then `00000110` (6, no continuation).
3. 5 fits in one byte: `00000101`.
4. 214577 has 18 bits ($2^{17} = 131072 \le 214577 < 262144$), so 3 bytes. $214577 = 13 \times 16384 + 12 \times 128 + 49$, giving `10110001` (49 + 128), `10001100` (12 + 128), `00001101` (13).
5. Total: 6 bytes instead of 12.

Interpretation. Half the space is saved even here; frequent terms, whose gaps fit in one byte, save 75%. **Engineering implication.** The postings that make queries slow (common terms) compress best, so compression cuts I/O on the hot path, not just disk.

The listing below implements delta + VByte, checks the worked example, and measures the average bytes per posting on a synthetic collection of 200,000 documents whose term document frequencies follow Zipf’s law (a few very common terms, a long tail of rare ones).

```
        """Delta (gap) encoding + variable-byte (VByte) compression of a postings list,
        and a measurement of bytes per posting on a synthetic Zipf-distributed collec-
tion."""
        import random

        def vbyte_encode(n):
            """Lucene-style VInt: 7 data bits per byte, low-order group first,
            high bit = 1 means 'more bytes follow'."""
            out = bytearray()
            while n >= 0x80:
                out.append((n & 0x7F) | 0x80)
                n >>= 7
            out.append(n)
            return bytes(out)

        def vbyte_decode_all(data):
            nums, n, shift = [], 0, 0
            for byte in data:
                n |= (byte & 0x7F) << shift
                if byte & 0x80:
                    shift += 7
                else:
                    nums.append(n)
                    n, shift = 0, 0
            return nums

        def compress_postings(doc_ids):
            gaps = [doc_ids[0]] + [b - a for a, b in zip(doc_ids, doc_ids[1:])]
            return b"".join(vbyte_encode(g) for g in gaps)

        def decompress_postings(data):
            doc_ids, total = [], 0
            for gap in vbyte_decode_all(data):
                total += gap
                doc_ids.append(total)
            return doc_ids

        if __name__ == "__main__":
            ids = [824, 829, 215406]            # the example used in Manning et al.
(2008), ch. 5
            blob = compress_postings(ids)
            print("gaps:", [ids[0]] + [b - a for a, b in zip(ids, ids[1:])])
            print("bytes:", " ".join(f"{b:08b}" for b in blob), f"({len(blob)} bytes vs
{4*len(ids)} raw)")
            assert decompress_postings(blob) == ids

            # Synthetic collection: N docs, vocabulary with Zipfian document frequen-
cies.
            random.seed(16)
            N, M, total_postings_target = 200_000, 50_000, 10_000_000
            weights = [1 / r for r in range(1, M + 1)]                # Zipf, exponent
1
            scale = total_postings_target / sum(weights)
            raw_bytes = vb_bytes = postings = 0
            for w in weights:
                df = max(1, min(N, int(w * scale)))
```

```
                doc_ids = sorted(random.sample(range(N), df))
                vb_bytes += len(compress_postings(doc_ids))
                raw_bytes += 4 * df
                postings += df
            print(f"postings={postings:,}  raw={raw_bytes/1e6:.1f} MB  vbyte=
{vb_bytes/1e6:.1f} MB  "
                  f"bytes/posting={vb_bytes/postings:.2f}  ratio=
{vb_bytes/raw_bytes:.2f}")
```

Output (about 7 s):

```
gaps: [824, 5, 214577]
bytes: 10111000 00000110 00000101 10110001 10001100 00001101 (6 bytes vs 12 raw)
postings=8,946,910  raw=35.8 MB  vbyte=12.5 MB  bytes/posting=1.39  ratio=0.35
```

What to notice:

- Decoding has a data-dependent branch per byte, which is why production engines moved to **block** codes.
- On the Zipfian collection, docID postings shrink to **1.39 bytes each**, 35% of their raw size. Manning et al. report the same order for the Reuters RCV1 collection: about 100 million postings take 400 MB as 32-bit integers and 116 MB with variable-byte gaps [Manning et al. 2008, Table 5.6].

Lucene's postings formats (Lucene 5 through at least 9) group docID deltas and frequencies into blocks of 128 and store each block with **frame-of-reference bit packing**: every value uses the bit width of the block's largest value, decoded without branches; list tails use VInt [Lucene Docs: postings format]. Bit packing decodes several times faster than VByte, especially with SIMD [Lemire and Boytsov 2015]. Zobel and Moffat survey the wider family (Elias, Golomb, VByte) and its ratio-versus-speed trade-off [Zobel and Moffat 2006].

16.3.5 Estimating index size

FORMULA

Inverted index size (one copy)

$$S_{\text{index}} \approx \underbrace{N \cdot u \cdot (b_d + b_f)}_{\text{docIDs + frequencies}} + \underbrace{N \cdot L \cdot b_p}_{\text{positions}} + \underbrace{M \cdot b_t}_{\text{dictionary}}$$

Symbol	Meaning	Units
N	Number of documents	documents
u	Average number of *distinct* terms per document (postings per document)	postings/document
L	Average number of tokens per document (one position each)	tokens/document
b_d, b_f	Compressed bytes per docID gap and per term frequency	bytes
b_p	Compressed bytes per position gap	bytes
M	Number of distinct terms in the collection	terms
b_t	Dictionary bytes per term (term text + pointers + statistics)	bytes

WORKED EXAMPLE

Worked example — 100 million product and review documents. Assume $N = 10^8$, $L = 400$ tokens, $u = 200$ distinct terms per document, $M = 5 \times 10^7$ distinct terms (part numbers and misspellings make vocabularies large), $b_d = 1.4$ bytes (measured above), $b_f = 1$ byte, $b_p = 1.5$ bytes, $b_t = 20$ bytes. Sizes in SI units (1 GB = 10^9 bytes).

1. Postings: $N \cdot u = 10^8 \times 200 = 2 \times 10^{10}$.
2. DocIDs and frequencies: $2 \times 10^{10} \times (1.4 + 1) = 4.8 \times 10^{10}$ bytes = 48 GB.
3. Positions: $N \cdot L = 4 \times 10^{10}$ tokens × 1.5 bytes = 6×10^{10} bytes = 60 GB.
4. Dictionary: $5 \times 10^7 \times 20 = 10^9$ bytes = 1 GB.
5. Total inverted index ≈ 48 + 60 + 1 = **109 GB**.
6. Uncompressed for comparison (4-byte docID, tf and position): $2 \times 10^{10} \times 8 + 4 \times 10^{10} \times 4 = 160 + 160 = 320$ GB, about 3× larger.
7. The raw text is 4×10^{10} tokens × about 6 bytes = 240 GB, so the positional index is about 45% of the text and the non-positional part about 20%.

Interpretation. Positions cost more than docIDs and frequencies combined. **Engineering implication.** Elasticsearch also stores the original JSON (`_source`), **doc values** (a column store for sorting and aggregations) and **norms** (per-field length factors); budget roughly the index again for these, then multiply by $1 + r$ for r replicas: about $2 \times (109 + 110) \approx 440$ GB with one replica, before merge headroom (§16.6). Dropping positions from fields never used in phrases is the largest single saving.

Real-world industry applications

INDUSTRY EXAMPLE

Early Google: barrels and hit lists. Brin and Page's prototype partitioned its forward index into 64 "barrels" by word ID and sorted each barrel to produce the inverted index. Each posting carried a compact "hit list" (two bytes per hit, including capitalization and font size), and "fancy" hits from titles and anchor text were kept separately so queries could consult short, high-value lists first [Brin and Page 1998]. That idea survives as field-specific and tiered indexes. *Evidence: Primary* — [Brin and Page 1998]

Failure scenarios

Table 16.2 — Inverted index failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Query on a common term is slow	Postings list of tens of millions of entries is fully decoded and scored	Slow-query log; per-term latency	Add top-*k* pruning (§16.5.6); cache results	Block-max skipping; avoid stop-word-only queries on huge fields
Index far larger than estimated	Positions and n-gram fields indexed everywhere	Per-field disk usage API	Reindex with `index_options: freqs` where phrases are unused	Review mappings before launch
Corrupted segment after disk fault	Bit rot or torn write	Checksum mismatch on open	Recover shard from a replica or snapshot	Replicas on separate failure domains; checksums (Lucene has them)

Common misconceptions

COMMON MISTAKE

Mistake — "An inverted index is just a secondary index on a text column." A B-tree maps one value per row; an inverted index maps *many* terms per document, keeps term statistics for ranking and positions for phrases, and is built and compressed in bulk. That is why relational databases ship separate full-text index types (PostgreSQL's GIN, for example).

16.4 Tokenization and analysis

16.4.1 The analysis chain

DEFINITION

Definition — Analysis. The process that converts raw text into the terms stored in (or looked up from) an inverted index. An **analyzer** is a pipeline of zero or more **character filters** (rewrite the raw character stream), exactly one **tokenizer** (split the stream into tokens with positions and offsets) and zero or more **token filters** (modify, remove or add tokens).

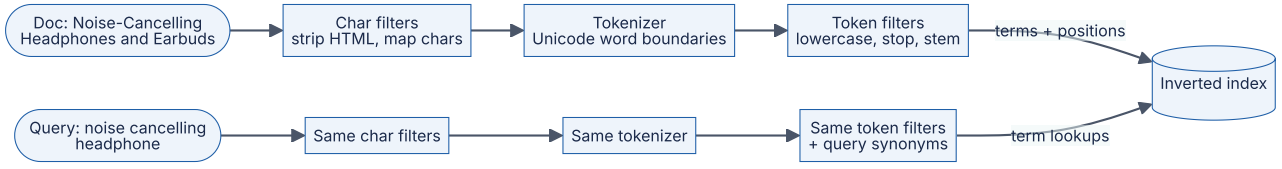
First-principles explanation

An inverted index matches terms *exactly*: `Headphones` and `headphone` are different keys, though a shopper does not care. Analysis decides which strings count as "the same word", as a librarian filing "Colour", "color" and "COLORS" under one card does by hand. Every decision moves the balance between two quality measures. **Recall** is the fraction of relevant documents that are returned; **precision** is the fraction of returned documents

that are relevant. Aggressive normalization (stemming, synonyms, folding accents) raises recall and risks precision: “university” and “universe” both stem to “univers” under the Porter stemmer. Conservative analysis does the opposite.

How it works internally

Figure 16.3 — An analysis chain applied at index time and at query time.



Reading the diagram. Two inputs enter the same pipeline: a document at index time (top) and a query at search time (bottom). Character filters run first on raw text (stripping HTML, mapping “&” to “and”); the tokenizer then splits text into tokens with positions; token filters normalize them. The index stores terms with positions; the query side only looks terms up. All steps are synchronous, in-process transformations; the only storage boundary is the index. The critical failure point is **asymmetry**: if the two pipelines diverge, for example because the index was built with stemming and the query analyzer was changed later, queries look up terms that were never stored and silently return nothing. Changing index-time analysis therefore requires a full reindex (§16.10.2); query-time-only filters such as synonyms can change without one. Analysis is CPU-bound and scales with indexer nodes.

Table 16.3 — Analysis chain components and their trade-offs.

Component	Example	Raises	Risks
Char filter	Strip HTML; map “½” to “1/2”	Clean tokens	Losing meaningful symbols
Standard tokenizer	Unicode word boundaries (UAX #29)	Language-neutral splitting	“C++”, “U.S.A.”, “e-mail” split oddly
Lowercase	“Wi-Fi” → “wi”, “fi”	Recall	“US” (country) vs “us” (pronoun)
ASCII folding	“café” → “cafe”	Recall for unaccented queries	Precision in languages where accents matter
Stop words	Drop “the”, “of”	Index size, speed	Queries like “The Who”, “to be or not to be”
Stemming	“running” → “run”	Recall	Over-stemming (“universe” ~ “university”)
Synonyms	“tv” → “television”	Recall	Drift (“apple” fruit vs company)
Edge n-grams	“head” → h, he, hea, head	Prefix matching	Index 3–10× larger

16.4.2 Tokenizers and normalization

A **whitespace tokenizer** splits on spaces and keeps punctuation attached ("head-phones,"). Lucene's **standard tokenizer** implements the Unicode word-break rules of UAX #29. Specialized tokenizers handle emails, URLs and paths, and `keyword` fields (SKUs, IDs, tags) keep the whole value as one token. **Unicode normalization** (NFC/NFKC) makes "é" as one code point equal to "e" plus a combining accent; normalization bugs are a classic cause of "the product is indexed but search cannot find it".

16.4.3 Stemming versus lemmatization

Stemming chops suffixes by rule. The Porter stemmer [Porter 1980] applies several dozen suffix-rewriting rules in five steps and maps "connection", "connected" and "connecting" to "connect". The "S" stemmer removes only plural endings [Harman 1991]; Lucene ships it as a minimal English stemmer, and this chapter's code uses it. **Lemmatization** maps a word to its dictionary form (lemma) using a vocabulary and part-of-speech information: "better" → "good", "mice" → "mouse", "was" → "be".

Table 16.4 — Stemming versus lemmatization.

	Stemming	Lemmatization
What it is	Rule-based suffix stripping	Dictionary + morphology lookup
Output	A stem, possibly not a word ("univers")	A real word (lemma)
Speed	Very fast, no dictionary	Slower; needs POS tagging for accuracy
Recall	High (aggressive)	High for irregular forms
Precision	Can conflate unrelated words	Better
Languages	Per-language rule sets (Snowball)	Needs a lexicon per language
Choose when	Large English corpora, speed matters	Morphologically rich languages, precision matters

Manning et al. observe that stemming helps recall but hurts precision, and its net effect on English retrieval quality is modest; for languages with richer morphology (Finnish, Hungarian, Arabic) normalization matters much more [Manning et al. 2008, §2.2.4].

16.4.4 Stop words

Stop words ("the", "a", "of") have the longest postings lists, so dropping them once saved much space. Modern engines usually *keep* them: their small gaps compress to a byte, BM25's IDF already gives them near-zero weight (§16.5.3), and dropping them breaks phrases and queries such as "The Who". Elasticsearch's standard analyzer keeps

them by default. If you remove them, keep the position gaps (as this chapter's analyzer does) so phrase matching stays correct.

16.4.5 n-grams and edge n-grams

A **character n-gram** is a substring of length n. Indexing all trigrams of "headphone" (hea, ead, adp, dph, …) lets the engine match substrings, misspellings and languages without spaces. An **edge n-gram** keeps only prefixes (h, he, hea, head, …), which supports search-as-you-type (§16.9.4). Both multiply the number of postings: a word of length ℓ produces $\ell - n + 1$ n-grams, so a trigram field is several times larger than a word field and its postings lists for common grams are very long.

16.4.6 Synonyms

Synonyms map equivalent terms ("tv" ⇔ "television"). At **index time** they enlarge the index and every change needs a reindex; at **query time** they cost slightly more per query but can be updated freely, so most teams apply them there. Multi-word synonyms ("ny" ⇔ "new york") produce expansions of different lengths, which Lucene represents as a token *graph*; its synonym-graph filter is meant for query time.

16.4.7 Language issues

- **No word separators.** Chinese, Japanese and Thai need dictionary-based segmenters (such as Lucene's Kuromoji for Japanese) or overlapping character bigrams, which need no dictionary but index more terms.
- **Compounds.** German "Kopfhörerverstärker" (headphone amplifier) needs decompounding so that "Kopfhörer" finds it.
- **Script rules.** Arabic needs letter-variant and diacritic normalization; Turkish has dotted and dotless "i", so naive lowercasing is wrong.
- **Mixed-language catalogs.** Give each language its own field and analyzer (`title.en`, `title.de`) rather than forcing one analyzer onto all text.

An Elasticsearch analyzer is declared in the index settings and attached to fields in the mapping:

```
        {
          "settings": {
            "analysis": {
              "filter": {
                "product_synonyms": { "type": "synonym_graph", "synonyms": ["tv, televi-
sion", "anc, noise cancelling"] }
              },
              "analyzer": {
                "product_index":  { "tokenizer": "standard", "filter": ["lowercase",
"asciifolding", "porter_stem"] },
                "product_search": { "tokenizer": "standard", "filter": ["lowercase",
"asciifolding", "product_synonyms", "porter_stem"] }
              }
            }
          },
          "mappings": {
            "properties": {
              "title": { "type": "text", "analyzer": "product_index",
"search_analyzer": "product_search" },
              "sku":   { "type": "keyword" }
            }
          }
        }
```

What to notice: the index and search analyzers share tokenizer and normalization but the synonym graph is applied only at search time; `sku` is a `keyword` field, indexed as a single unanalyzed token for exact matching.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **GitHub code search.** Source code defeats word analyzers: users search for punctuation (`foo(`), want no stemming or stop-word removal, and use regular expressions. GitHub's engine (Blackbird, written in Rust) therefore indexes character n-grams and answers a query by intersecting the postings lists of the query's n-grams, then verifying candidate documents; GitHub reported an index of about 25 TB built from 115 TB of source content [Clem 2023]. Trade-off: n-gram postings are numerous and long, which GitHub offset by indexing each unique file content only once and by sharding. *Evidence: Primary* — [Clem 2023]

Failure scenarios

Table 16.5 — Analysis failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Known document not found	Index and query analyzers differ	`_analyze` API on both strings	Align analyzers; reindex	One analyzer definition shared by both sides; tests
Irrelevant matches after a release	Aggressive stemmer or bad synonym	Relevance test set regression	Roll back query-time synonyms	Offline relevance evaluation gate
Index size jumps 5×	n-gram filter added to a large field	Disk usage alert	Move n-grams to a dedicated subfield	Size test on a sample before deploy

Common misconceptions

COMMON MISTAKE

Mistake — "Better analysis is always more normalization." Every normalization merges distinct strings. For SKUs, error codes, names and code, normalization destroys meaning. Analyze each field according to how people search it, and keep an unanalyzed `keyword` subfield for exact matching.

16.5 Ranking: TF-IDF and BM25

16.5.1 What a ranking function does

DEFINITION

Definition — Relevance score. A number computed for each (query, document) pair that estimates how well the document satisfies the query. A **ranking function** computes it; the engine returns the k highest-scoring documents.

First-principles explanation

A sensible librarian asked for "noise canceling headphones" reasons three ways. A book mentioning *noise canceling* ten times is more on topic than one mentioning it once, but not ten times more (**term frequency, with diminishing returns**). *Headphones* appears in half the catalog, so matching it says little, while rare *canceling* is informative (**inverse document frequency**). And a leaflet mentioning *noise* once is more focused than an encyclopedia mentioning it once (**length normalization**). BM25 writes these three intuitions as one formula.

The theoretical justification is the **probability ranking principle**: if documents are ranked by their probability of relevance to the query, the ranking is optimal for any measure that rewards putting relevant documents first [Robertson 1977]. BM25 approximates that probability from term statistics alone [Robertson and Zaragoza 2009].

16.5.2 TF-IDF

Karen Spärck Jones observed in 1972 that a term's value for retrieval falls as the number of documents containing it rises [Spärck Jones 1972]. Combined with term frequency, this gives the classic **TF-IDF** weight, the basis of the vector space model in which documents and queries are vectors of term weights compared by cosine similarity (§4.9.2).

FORMULA

TF-IDF weight of term t in document d

$$w_{t,d} = \mathrm{tf}_{t,d} \times \log_{10} \frac{N}{\mathrm{df}_t} \qquad \mathrm{score}(q,d) = \sum_{t \in q} w_{t,d}$$

Symbol	Meaning	Units
$\mathrm{tf}_{t,d}$	Occurrences of term t in document d	count
N	Documents in the collection	documents
df_t	Documents containing t	documents
$w_{t,d}$	Weight of t in d	dimensionless

WORKED EXAMPLE

Worked example — TF-IDF on the product catalog. The body field of the eight-product catalog (§16.5.4) has $N = 8$. *noise* occurs in 3 documents and *headphone* in 6.

1. $\mathrm{idf}(\textit{noise}) = \log_{10}(8/3) = \log_{10} 2.667 = 0.426$.
2. $\mathrm{idf}(\textit{headphone}) = \log_{10}(8/6) = 0.125$.
3. A document containing *noise* once scores 0.426 for that term; one containing *noise* 10 times scores 4.26.

Interpretation. IDF makes *noise* 3.4× more valuable than *headphone*, as intended, but raw tf grows without limit (keyword stuffing wins) and nothing corrects for length. **Engineering implication.** Lucene's TF-IDF variant (with $\sqrt{\mathrm{tf}}$ and length factors) was the default until Lucene 6 and Elasticsearch 5.0 switched to BM25 [Elastic Docs: similarity].

16.5.3 BM25

BM25 ("Best Matching 25", the 25th weighting scheme in the Okapi experiments at City University London) comes from the probabilistic relevance framework [Robertson and Zaragoza 2009]. It keeps IDF, makes term frequency **saturate**, and normalizes by document length relative to the average.

FORMULA

BM25 inverse document frequency (Lucene form)

$$\mathrm{IDF}(t) = \ln\left(1 + \frac{N - n_t + 0.5}{n_t + 0.5}\right)$$

Symbol	Meaning	Units
N	Documents in the collection (or shard; see §16.7.5)	documents
n_t	Documents containing term t (document frequency)	documents
$\mathrm{IDF}(t)$	Weight of a match on t	dimensionless

The classic Robertson–Spärck Jones form, $\ln \frac{N - n_t + 0.5}{n_t + 0.5}$, becomes *negative* for terms in more than half the documents; Lucene adds 1 inside the logarithm so that every match contributes a small positive amount.

FORMULA

BM25 score

$$\mathrm{score}(q, d) = \sum_{t \in q} \mathrm{IDF}(t) \cdot \frac{f_{t,d}\,(k_1 + 1)}{f_{t,d} + k_1\left(1 - b + b \cdot \frac{|d|}{\mathrm{avgdl}}\right)}$$

Symbol	Meaning	Units
$f_{t,d}$	Frequency of term t in document (field) d	count
$\lvert d\rvert$	Length of d in terms after analysis	terms
avgdl	Average length of that field across the collection	terms
k_1	Term-frequency saturation parameter; Lucene default 1.2 (typical 1.2–2.0)	dimensionless
b	Length-normalization strength, 0 (none) to 1 (full); default 0.75	dimensionless
$\mathrm{score}(q, d)$	Relevance score; only comparable within one query	dimensionless

Two properties follow from the formula. As $f_{t,d} \to \infty$ the fraction approaches $k_1 + 1$, so a term can never contribute more than $(k_1 + 1) \cdot \mathrm{IDF}$: repetition has diminishing returns. And

the denominator grows with $|d|/\text{avgdl}$, so the same tf in a longer document scores less; b controls how strongly.

Table 16.6 — BM25 term-frequency factor ($k_1 = 1.2$, $b = 0.75$) versus raw tf.

tf	Raw TF-IDF factor	BM25, $\|d\|$ = 0.5 avgdl	BM25, $\|d\|$ = avgdl	BM25, $\|d\|$ = 2 avgdl
1	1	1.257	1.000	0.710
2	2	1.600	1.375	1.073
5	5	1.913	1.774	1.549
10	10	2.047	1.964	1.818
∞	∞	2.200	2.200	2.200

Reading down a column shows saturation: 1 to 10 occurrences raises the BM25 factor by less than 2.6×, against 10× for raw tf. Reading across a row shows length normalization: the same tf is worth less in a longer document.

WORKED EXAMPLE

Worked example — BM25 for *noise* in two product descriptions. From the catalog in §16.5.4: $N = 8$ body fields, $n_{noise} = 3$, avgdl = 68/8 = 8.5 terms. Document 4 (earbuds) has $|d| = 7$; document 7 (kids' headphones) has $|d| = 12$. Each contains *noise* once. $k_1 = 1.2$, $b = 0.75$.

1. IDF: $\ln(1 + \frac{8 - 3 + 0.5}{3 + 0.5}) = \ln(1 + 1.5714) = \ln 2.5714 = 0.9445$.
2. Length factor, document 4:
   $k_1(1 - b + b \cdot 7/8.5) = 1.2 \times (0.25 + 0.6176) = 1.2 \times 0.8676 = 1.0412$.
3. TF part, document 4: $\frac{1 \times 2.2}{1 + 1.0412} = \frac{2.2}{2.0412} = 1.0778$.
4. Score, document 4: $0.9445 \times 1.0778 = 1.018$.
5. Length factor, document 7: $1.2 \times (0.25 + 0.75 \times 12/8.5) = 1.2 \times 1.3088 = 1.5706$; TF part $2.2/2.5706 = 0.8558$; score $0.9445 \times 0.8558 = 0.808$.
6. Saturation check for document 4: with tf = 2 the TF part would be $4.4/3.0412 = 1.447$, with tf = 5 it would be $11/6.0412 = 1.821$, never exceeding 2.2.

Interpretation. The same single mention of *noise* is worth 26% more in the short, focused earbuds description than in the longer kids' description, and repeating it five times would raise its weight by only 69%. The listing below reproduces 1.0179 and 0.8083. **Engineering implication.** BM25 resists keyword stuffing and long-document bias out of the box, which is why it is the default in Lucene, Elasticsearch, OpenSearch and Solr. Tune k_1 and b per field only against a relevance test set; for very short fields such as titles, a lower b is common because length differences carry little meaning.

> NOTE
>
> **Lucene’s scores versus the textbook formula.** Lucene 8 removed the constant factor $(k_1 + 1)$ from the numerator because it does not change the ranking; Elasticsearch preserves the classic score values by applying the constant as a boost, which is why `explain` output in Elasticsearch shows a factor of 2.2 [Lucene MIGRATE notes for 8.0]. Lucene also stores document length in a lossy one-byte **norm**, so its scores differ slightly from exact arithmetic.

16.5.4 A complete engine in one listing

The listing below implements the analysis chain of §16.4 (tokenize, lowercase, stop words keeping position gaps, S-stemmer), a positional inverted index over two fields, BM25 with per-field boosts, and phrase matching.

```
        """A tiny search engine: analysis, a positional inverted index, BM25 with field
boosts.
        Standard library only. Run: python3 search_engine.py"""
        import math
        import re
        from collections import defaultdict

        STOP_WORDS = {"a", "an", "and", "the", "for", "with", "of", "in", "to", "is",
"are"}

        def s_stem(token):
            """Harman's 'S' stemmer: strips only plural endings (like Lucene's
EnglishMinimalStemFilter)."""
            if len(token) > 3 and token.endswith("ies") and not token.endswith(("eies",
"aies")):
                return token[:-3] + "y"
            if len(token) > 3 and token.endswith("es") and not token.endswith(("aes",
"ees", "oes")):
                return token[:-1]
            if len(token) > 3 and token.endswith("s") and not token.endswith(("us",
"ss")):
                return token[:-1]
            return token

        def analyze(text):
            """Tokenize on non-alphanumerics, lowercase, drop stop words, stem. Keeps
positions."""
            out = []
            for pos, raw in enumerate(re.findall(r"[a-z0-9]+", text.lower())):
                if raw not in STOP_WORDS:
                    out.append((s_stem(raw), pos))
            return out

        class InvertedIndex:
            def __init__(self, fields):

```

What to notice:

- **Body-only BM25 ranks the earbuds above the headphones** that exactly match the query. Document 4's description is shorter (7 terms versus 10), and *headphone* is so common (in 6 of 8 bodies, IDF 0.33) that matching it barely helps. Lexical scoring has no idea that headphones are what the shopper wants.
- **Boosting the title field 2×** fixes the order: the title "Wireless noise canceling headphones" matches all four terms, adding $2 \times 3.588 = 7.18$ to document 1. Field structure is one of the strongest relevance signals available.
- The stop word "with" was removed, but positions were kept, so *noise* in document 4 is at position 4, not 3; phrase queries stay correct, and word order matters ("canceling noise" matches nothing).
- A real engine never scores every matching document this way; see §16.5.6.

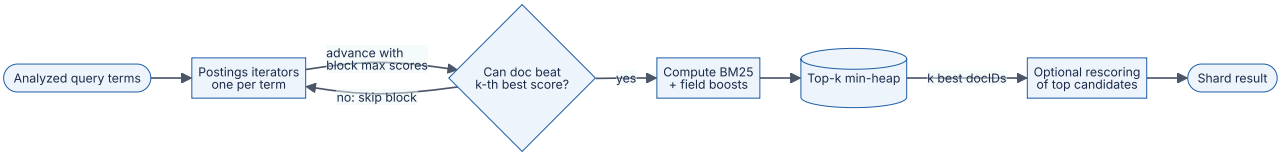
16.5.5 Field boosting and beyond

Field boosting weights each field's score, as in Elasticsearch's `multi_match` with `"fields": ["title^2", "body"]`. Summing per-field scores double-counts a term that appears in both fields, each saturating separately; **BM25F** combines weighted term frequencies across fields *before* saturation [Robertson et al. 2004], as Elasticsearch's `combined_fields` query does. Text relevance is rarely the whole ranking: **function scoring** adds signals such as $\log(1 + \text{sales})$, and **learning to rank** reorders a few hundred BM25 candidates with a trained model (Chapter 81).

16.5.6 Retrieving the top *k* efficiently

Scoring every document that matches any query term is wasteful: an OR query containing *headphone* may match millions of documents, but the user sees ten. Because each term's contribution is bounded by $(k_1 + 1) \cdot \text{IDF}(t)$, an engine can compute an upper bound on any document's score and skip documents that cannot beat the current k-th best score. **WAND** and its refinement **Block-Max WAND** store the maximum score per postings block and skip whole blocks [Ding and Suel 2011]. Lucene 8 added block-max WAND, and Elasticsearch 7 accordingly stopped counting total hits exactly by default (`track_total_hits` defaults to 10,000), since an exact count would force every match to be visited [Elastic Docs: track_total_hits].

Figure 16.4 — Ranked query pipeline inside one shard.



Reading the diagram. Each query term opens an iterator over its postings list. Before fully scoring a candidate, the WAND decision compares the sum of per-block maximum scores with the score of the current k-th best document held in a min-heap; if the bound is too low, whole blocks are skipped (the loop back to the iterators). Survivors are scored exactly and offered to the heap, an in-memory structure of size k. An optional rescoring stage applies more expensive signals (phrase proximity, a learned model) to only the top few hundred. All steps are synchronous and CPU-bound within one shard; the storage boundary is the postings files, usually served from the operating system page cache. Failure points are queries whose terms are all very common (little skipping possible) and very large k (deep pagination, §16.7.4). Scaling is by splitting the index into more shards, each running this pipeline in parallel.

Real-world industry applications

INDUSTRY EXAMPLE

Wikipedia's CirrusSearch. Wikimedia runs on-wiki search for Wikipedia and its sister projects with CirrusSearch, a MediaWiki extension backed by Elasticsearch. Pages are indexed with per-language analysis chains, and ranking combines text relevance with signals such as incoming links and page popularity, with rescoring profiles configurable per wiki [MediaWiki: CirrusSearch]. *Evidence: Primary* — [MediaWiki: CirrusSearch]

Failure scenarios

Table 16.7 — Ranking failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Accessories outrank the product searched for	Text match ignores intent; short bodies win	Click-through and relevance judgments	Boost title; add category signals	Offline evaluation set (NDCG)
Keyword stuffing by sellers	Unbounded tf in a custom scorer	Manual review, anomaly scores	Switch to BM25; cap field length	BM25 saturation; quality signals

Common misconceptions

COMMON MISTAKE

Mistake — "A BM25 score of 12 means a better match than a score of 6 on another query." BM25 scores depend on the query's terms, their IDF and the collection statistics. They rank documents *within* one query and have no absolute meaning; never threshold them globally or compare them across queries or indexes. Normalize, or use rank positions, when fusing result lists (§16.11).

16.6 Index construction and segment merging

16.6.1 Why indexes are built from immutable segments

DEFINITION

Definition — Segment. A self-contained, immutable mini-index (its own dictionary, postings, stored fields, norms and doc values) covering a subset of documents. A Lucene index is a set of segments plus a **commit point** file (`segments_N`) listing which segments are live; a search runs over every live segment and combines the results.

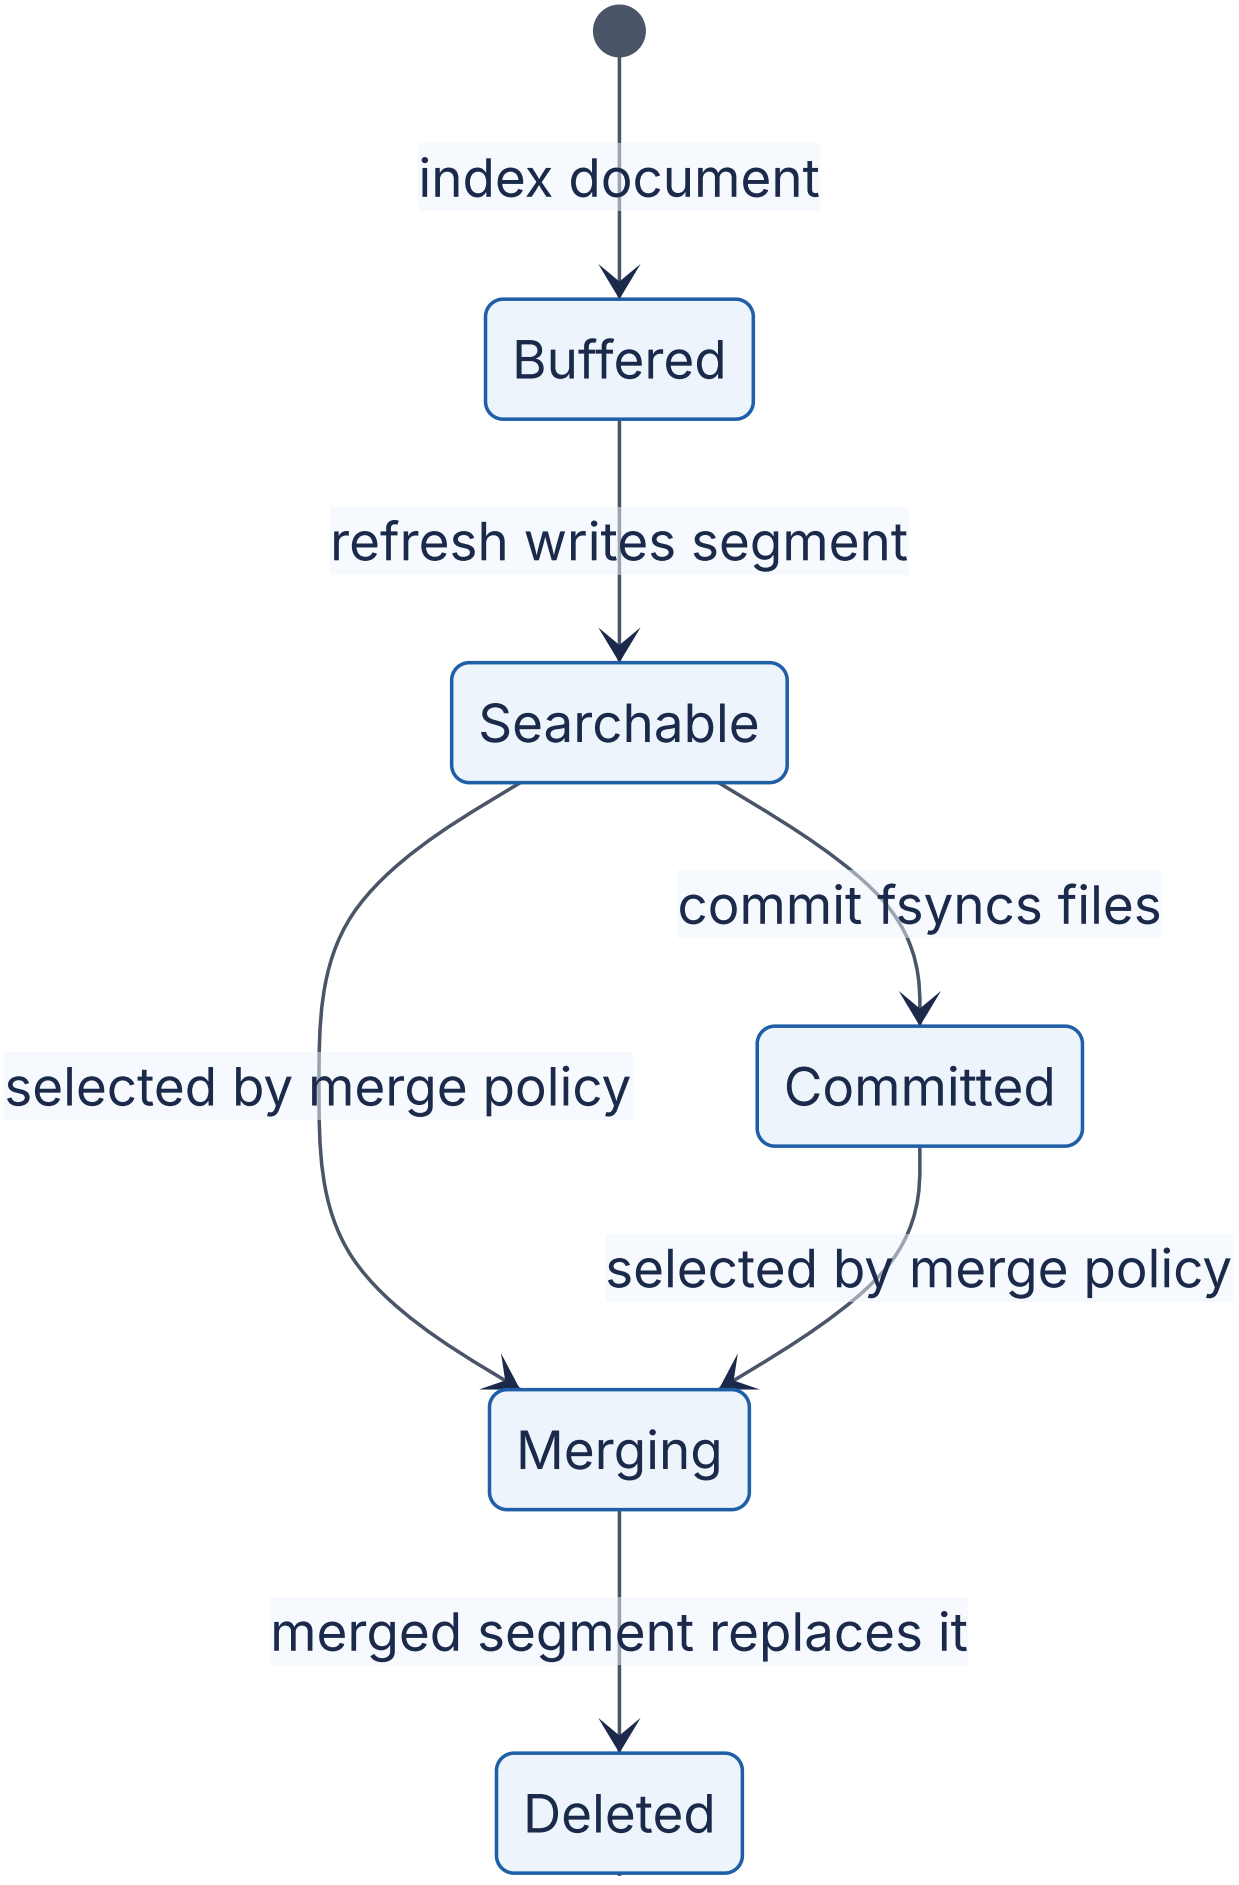
First-principles explanation

Compressed, sorted postings are excellent to read and terrible to update: inserting a docID mid-list means rewriting it. So search engines do what log-structured databases do (§13.7–§13.8): buffer new documents in memory, write the buffer out as a new small segment, and **merge** small segments into larger ones in the background, with segments playing the role of SSTables. Manning et al. describe the batch ancestors, blocked sort-based and single-pass in-memory indexing [Manning et al. 2008, ch. 4]. Immutable segments can be cached without invalidation, read without locks, copied as plain files for backup or replication, and compressed aggressively.

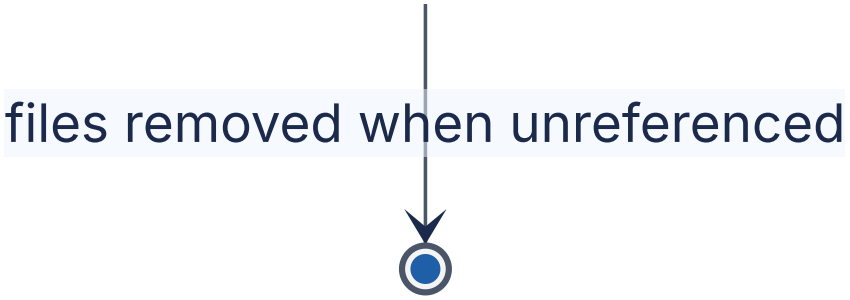
How it works internally

1. **Buffer.** The index writer analyzes incoming documents into an in-memory buffer. Documents in the buffer are *not* searchable.
2. **Refresh (flush to a segment).** The buffer is written as a new segment and a new searcher is opened that includes it. In Lucene terms this is opening a near-real-time reader; Elasticsearch calls it a **refresh** and by default does it every second (§16.8.4). The segment may sit only in the operating system's page cache: it is searchable but not yet durable.
3. **Commit.** Periodically, segment files are fsynced and a new `segments_N` file is written atomically. Only committed segments survive a crash without replay; Elasticsearch covers the gap with its translog (§16.8.3).
4. **Merge.** A background merge scheduler picks groups of segments, merges their postings into one new segment (dropping deleted documents), then swaps it in and deletes the old files once no reader uses them.

Figure 16.5 — Lifecycle of a Lucene segment.



index document
Buffered
refresh writes segment
Searchable
commit fsyncs files
selected by merge policy
Committed
selected by merge policy
Merging
merged segment replaces it
Deleted



Reading the diagram. A document enters the in-memory buffer (not yet visible). A refresh writes the buffer out as a segment that searches can see, a cheap operation because it need not wait for the disk. A commit fsyncs segment files and records them in the commit point, making them crash-durable; this is the expensive storage boundary. Either a searchable or a committed segment can be chosen for merging; once the merged segment is in place, the originals are marked deleted and their files removed when the last reader using them closes. All transitions are asynchronous background work relative to queries. Failure points: a crash loses searchable-but-uncommitted segments (recovered from the translog in Elasticsearch); a merge that runs out of disk fails and must be retried. Merging is throttled so it does not starve queries of I/O.

16.6.2 Deletes and updates as tombstones

Immutable segments cannot remove a document. Instead Lucene records deletions in a per-segment **live-docs bitset** (one bit per document) written as a separate small file: a **tombstone**. Searches skip documents whose bit is cleared. An **update** is a delete of the old version plus an add of the new one, which lands in a new segment. The space and the CPU spent iterating past deleted postings are reclaimed only when the segment is merged.

Consequences: deleted documents still count in term statistics until merged away, so replicas with different merge histories can score slightly differently; and update-heavy fields (prices, stock) generate many deletes, so keep volatile fields out of the text index where possible.

16.6.3 Merge policy

A **merge policy** decides which segments to merge. Lucene's default, `TieredMergePolicy`, groups segments into size tiers, allows about 10 segments per tier, merges up to 10 similar-sized segments at a time, favors merges that reclaim many deletes, and by default stops producing segments larger than about 5 GB [Lucene Docs: TieredMergePolicy]. The analysis is the same as size-tiered compaction in LSM stores (§13.9): each byte is rewritten once per tier it climbs.

FORMULA

Write amplification of tiered merging

$$W \approx 1 + \log_m \frac{S_{\max}}{S_{\text{flush}}}$$

Symbol	Meaning	Units
W	Bytes written to disk per byte of new index data	dimensionless
m	Merge factor: segments merged together per tier	count
$S_{\max}$	Maximum merged segment size	bytes
S_{flush}	Typical size of a newly flushed segment	bytes

WORKED EXAMPLE

Worked example — merge cost at a 1-second refresh. An index receives 2,000 documents/s; each adds about 1 KB to the index; refresh every 1 s gives $S_{\text{flush}} = 2$ MB. $S_{\max} = 5$ GB, $m = 10$.

1. $S_{\max}/S_{\text{flush}} = 5,000/2 = 2,500$.
2. $\log_{10} 2,500 = 3.40$, so $W \approx 4.4$.
3. Write bandwidth: $2,000 \times 1\ \text{KB} \times 4.4 = 8.8$ MB/s, plus the translog.
4. With a 30-second refresh, $S_{\text{flush}} = 60$ MB, ratio 83, $\log_{10} 83 = 1.92$, $W \approx 2.9$: one-third less merge I/O.

Interpretation. Frequent refreshes create many tiny segments that are rewritten several times. **Engineering implication.** For bulk loads and write-heavy indexes, lengthen or disable refresh (§16.10.1). For read-only indexes (yesterday's logs), **force-merge** to one segment once: queries then search one dictionary instead of dozens.

The following simulation of an idealized tiered policy confirms the formula: with three tiers above the flush size and $m = 10$, every unit of data is written exactly four times.

```
        """Simulate a simplified tiered merge policy and measure write amplification:
        every refresh flushes one small segment; whenever `merge_factor` segments of the
same tier
        exist they are merged into one segment of the next tier, until the size cap is
reached."""
        import math

        def simulate(flushes, merge_factor=10, max_tier=3):
            tiers = [0] * (max_tier + 1)      # number of live segments in each tier
            written = 0                       # units written: flushes + merge output
            for _ in range(flushes):
                tiers[0] += 1
                written += 1                  # the flush itself writes one unit
                t = 0
                while t < max_tier and tiers[t] == merge_factor:
                    tiers[t] = 0
                    tiers[t + 1] += 1
                    written += merge_factor ** (t + 1)    # merged segment size in units
                    t += 1
            return written / flushes, sum(tiers)

        if __name__ == "__main__":
            for flushes in (1_000, 100_000):
                wa, live = simulate(flushes)
                print(f"flushes={flushes:>7,}  write amplification={wa:.2f}  live
segments={live}")
            print("predicted 1 + log10(max/min) =", 1 + math.log10(10 ** 3))
```

Output:

```
flushes=  1,000  write amplification=4.00  live segments=1
flushes=100,000  write amplification=4.00  live segments=100
predicted 1 + log10(max/min) = 4.0
```

What to notice: once segments reach the cap they stop merging, so the number of live segments grows linearly with data (100 capped segments after 100,000 flushes); that is why large indexes are split into shards and time-based indexes rather than grown without bound.

COMMON MISTAKE

Mistake — “Deleting documents frees disk space immediately.” A delete sets a bit. Disk is reclaimed only when a merge rewrites the segment, and a merge temporarily needs space for both old and new segments. Clusters that are nearly full can fail to merge, accumulate deletes, and degrade; keep at least 15–20% free disk on data nodes and watch Elasticsearch’s disk watermarks.

16.7 Distributed search

16.7.1 Document partitioning versus term partitioning

When an index outgrows one node, or one node cannot serve the query rate, the index is partitioned. Search engines use the word **shard** for a partition (§14.6); this chapter uses the two interchangeably. There are two ways to cut an inverted index [Manning et al. 2008, §20.3].

- **Document partitioning** (local index): each shard holds *all* terms for a subset of documents, a complete small index. Every query goes to every shard, and a coordinator merges the per-shard top-k lists.
- **Term partitioning** (global index): each shard holds the *complete* postings lists for a subset of terms. A query visits only the shards owning its terms, but a multi-term query must ship long postings lists between nodes to intersect or score them.

Figure 16.6 — Document partitioning versus term partitioning.

Reading the diagram. In the upper subgraph the query fans out synchronously to every document shard; each shard runs the complete pipeline of Figure 16.4 on its own documents and returns only its top k (a few kilobytes), which a coordinator merges. In the lower subgraph the query goes only to the shards that own its terms, but each returns an entire postings list, potentially megabytes, which must be intersected and scored centrally. Each shard is its own storage boundary. Failure points: under document partitioning a slow or dead shard affects every query (mitigated by replicas); under term partitioning a hot term overloads one shard, and a dead shard makes every query containing its terms incomplete. Document partitioning scales by adding shards and replicas; term partitioning scales poorly for multi-term queries because network transfer grows with postings length.

Table 16.8 — Document versus term partitioning.

	Document partitioning	Term partitioning
What it is	Each shard indexes a subset of documents	Each shard owns all postings of a subset of terms
Query fan-out	All shards	Only shards owning query terms
Network per query	Small (top-k per shard)	Large (full postings lists)
Load balance	Even (random document assignment)	Skewed (Zipfian term popularity)
Indexing a document	Writes to one shard	Writes to many shards (one per term)
Tail latency	Max of S shard latencies	Fewer shards, but long transfers
Used by	Lucene-based engines, Google (as published), Earlybird	Research systems; rarely in production
Choose when	Almost always	Very high query rate of single-term lookups

Document partitioning wins in practice because it is simple, balanced and fault-tolerant; Dean's retrospective describes Google's serving system as replicated document-partitioned shards behind fan-out servers [Dean 2009].

16.7.2 Replicas

Each shard has r **replicas** on other nodes and zones, for **availability** and **query throughput** (any copy can answer). Replicas do not speed up indexing: every copy indexes every write. If each query costs c CPU-seconds on each of S shards at peak rate λ, the cluster needs about $\lambda S c / U$ cores at utilization U: 2,000 queries/s × 10 shards × 4 ms ÷ 0.5 = 160 cores, or 10 sixteen-core nodes holding, say, 20 shard copies.

16.7.3 Scatter–gather and tail latency

A document-partitioned query is a **scatter-gather**: a coordinator scatters the query to one copy of each of S shards and gathers their answers. The response time is the *maximum* of S shard latencies, so the fan-out amplification of §4.8.4 applies directly.

FORMULA

Scatter-gather tail latency

$$P(\text{query fast}) = p^S \qquad q_{\text{shard}} = q_{\text{query}}^{1/S}$$

Symbol	Meaning	Units
p	Probability one shard answers within threshold T	dimensionless
S	Number of shards the query waits for	count
$P(\text{query fast})$	Probability all S shards answer within T	dimensionless
q_{query}	Target percentile for the whole query (e.g. 0.99)	dimensionless
q_{shard}	Percentile each shard must meet at T	dimensionless

WORKED EXAMPLE

Worked example — 20 and 100 shards. Each shard's latency is log-normal with median 8 ms and p99 25.6 ms (simulated below). Assume independence.

1. $S = 20$: $P(\text{all} \le 25.6\text{ ms}) = 0.99^{20} = 0.818$; 18% of queries wait longer than the shard p99.
2. For the *query* p99 to be 25.6 ms, each shard needs $0.99^{1/20} = 0.99950$, its p99.95 at 25.6 ms.
3. $S = 100$: $0.99^{100} = 0.366$. The query median becomes the shard's $0.5^{1/100} =$ p99.3, which is 27.4 ms, more than three times the shard median, and the query p99 is about 51 ms.

Interpretation. Adding shards makes every shard's work smaller but makes the query wait for the unluckiest of more shards. **Engineering implication.** Use the fewest shards that meet size and throughput needs (§16.8.2), and use tail-tolerant techniques: **hedged requests** to a second replica after a delay [Dean and Barroso 2013], **adaptive replica selection** that routes to the replica with the best recent latency and queue length (on by default in Elasticsearch since 7.0, based on the C3 algorithm [Suresh et al. 2015]), and per-shard **timeouts with partial results**, accepting slightly incomplete answers rather than slow ones.

```
        """Scatter-gather tail latency: a query waits for the slowest of S shards.
        Monte Carlo check of P(all fast) = p**S, and the latency percentiles of max(S
shard latencies)."""
        import math
        import random

        def shard_latency_ms(rng):
            # Log-normal per-shard latency: median 8 ms, a heavy-ish right tail (p99 ~
25.6 ms).
            return 8.0 * math.exp(rng.gauss(0.0, 0.5))

        def percentile(sorted_vals, q):
            return sorted_vals[min(len(sorted_vals) - 1, int(q * len(sorted_vals)))]

        if __name__ == "__main__":
            rng = random.Random(42)
            trials = 20_000
            single = sorted(shard_latency_ms(rng) for _ in range(200_000))
            t99 = percentile(single, 0.99)
            print(f"one shard: p50={percentile(single, 0.50):.1f} ms  p99={t99:.1f} ms")
            print(" S   P(all<shard p99) sim  0.99**S   query p50   query p99")
            for S in (1, 10, 50, 100, 200):
                maxes = sorted(max(shard_latency_ms(rng) for _ in range(S)) for _ in
range(trials))
                fast = sum(m <= t99 for m in maxes) / trials
                print(f"{S:>3}   {fast:>18.3f}  {0.99 ** S:>7.3f}   {percentile(maxes,
0.5):>6.1f} ms"
                      f"   {percentile(maxes, 0.99):>6.1f} ms")
```

Output:

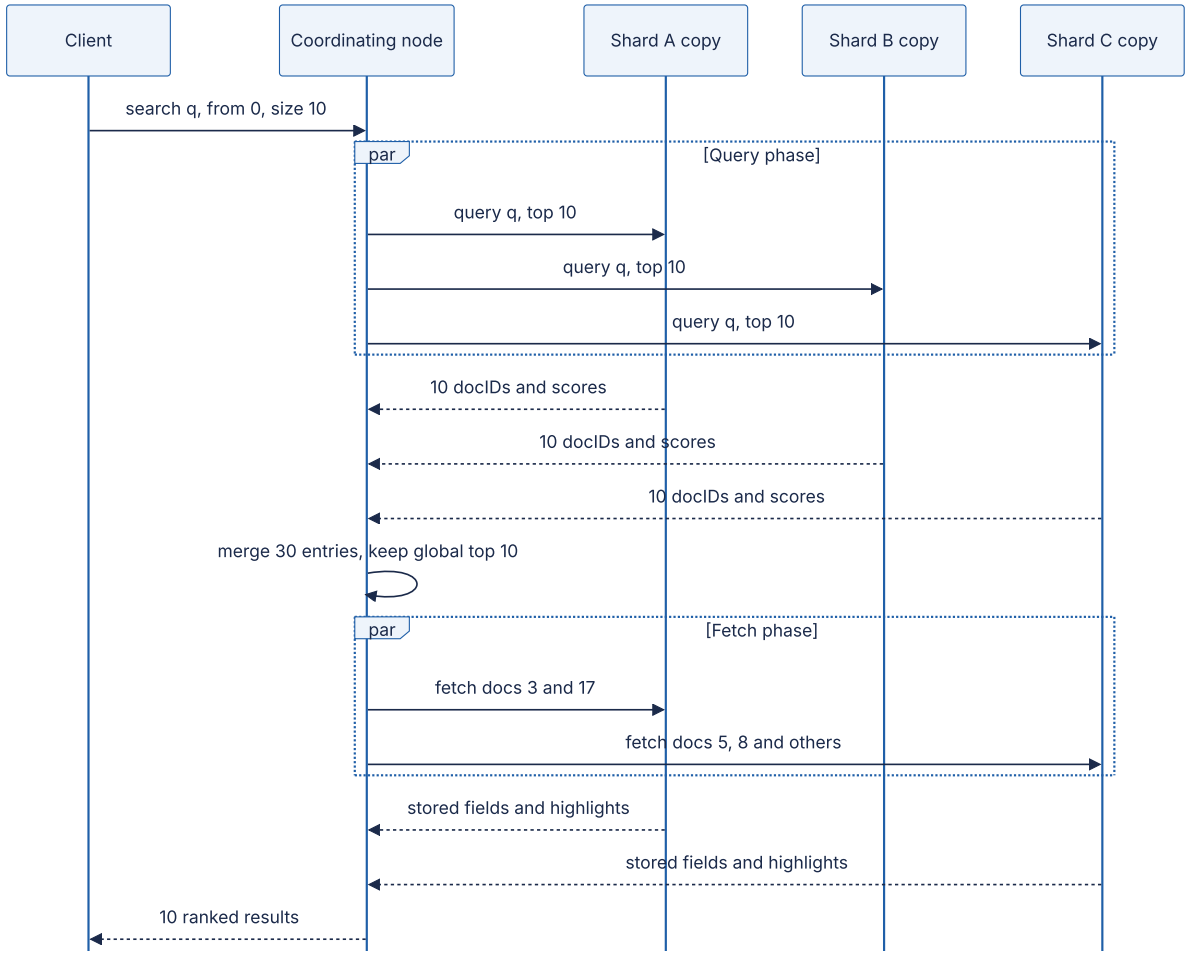
```
one shard: p50=8.0 ms  p99=25.6 ms
 S   P(all<shard p99) sim  0.99**S   query p50   query p99
  1               0.991    0.990      8.0 ms     25.2 ms
 10               0.904    0.904     16.9 ms     37.7 ms
 50               0.614    0.605     24.0 ms     46.9 ms
100               0.367    0.366     27.4 ms     51.1 ms
200               0.136    0.134     30.9 ms     56.3 ms
```

What to notice: the simulation matches 0.99^S; the query *median* at 100 shards (27.4 ms) is worse than a single shard's p99. Real shard latencies are also correlated (garbage-collection pauses, merges, a noisy neighbor), which makes the tail worse than the independent model.

16.7.4 Two-phase query-then-fetch

Shipping full documents from every shard would waste bandwidth, since most are discarded during the merge. Elasticsearch therefore runs a search in two phases [Elastic Docs: search_type].

Figure 16.7 — Query-then-fetch across three shards.



Reading the diagram. The client sends one request to any node, which acts as **coordinating node**. In the **query phase** it sends the query in parallel to one copy of every shard; each returns only docIDs and scores for its local top 10. The coordinator merges the 30 entries into a global top 10. In the **fetch phase** it asks only the shards that own those 10 documents for stored fields (`_source`) and highlighted snippets; shard B contributed nothing to the top 10, so it is not contacted. All calls are synchronous RPCs over the cluster transport protocol; each shard copy is a storage boundary. Failure points: a slow shard delays the query phase for everyone (§16.7.3); a shard copy that fails between phases forces a retry on another replica. The design scales because the expensive document payload is read for only k documents, not $S \times k$.

FORMULA

Deep pagination cost at the coordinator

$$E = S \cdot (from + size)$$

Symbol	Meaning	Units
S	Shards queried	count
from	Offset of the first requested result	results
size	Results per page	results
E	Entries every query phase must return and the coordinator must merge	entries

WORKED EXAMPLE

Worked example — page 500. $S = 20$ shards, 20 results per page.

1. Page 1: $E = 20 \times (0 + 20) = 400$ entries.
2. Page 500: $from = 499 \times 20 = 9,980$, so $E = 20 \times 10,000 = 200,000$ entries, 500× more, and each shard must also keep a heap of 10,000.

Interpretation. Deep pages cost in proportion to their depth. **Engineering implication.** Elasticsearch rejects requests with *from*+*size* above `index.max_result_window`, 10,000 by default. Use `search_after` with a sort tiebreaker (and a point-in-time snapshot) for deep scrolling, and the scroll or point-in-time APIs for exports.

16.7.5 Global versus local IDF

Each shard computes BM25 with its own N, n_t and avgdl. When documents are spread uniformly at random, local statistics are close to global ones. When they are not, scores from different shards are not comparable.

WORKED EXAMPLE

Worked example — skewed term distribution. Two shards hold 1,000,000 documents each. Custom routing by seller put most “anc” listings on shard B: shard A has 10 documents containing *anc*, shard B has 1,000.

1. Local IDF on A: $\ln(1 + 999,990.5/10.5) = 11.46$.
2. Local IDF on B: $\ln(1 + 999,000.5/1,000.5) = 6.91$.
3. Global IDF ($N = 2,000,000$, $n = 1,010$): $\ln(1 + 1,998,990.5/1,010.5) = 7.59$.

Interpretation. An *anc* match on shard A scores 66% higher than an identical match on shard B, purely because of where documents live, so shard A’s weak matches crowd out shard B’s strong ones. **Engineering implication.** Elasticsearch’s default `query_then_fetch` uses local statistics. `dfs_query_then_fetch` adds a preliminary round trip that collects term statistics from all shards and scores with global values, at the cost of extra latency [Elastic Docs: search_type]. Prefer random document routing so local statistics converge; use DFS for small or skewed indexes and in relevance tests.

Routing is the other side of the trade-off. By default Elasticsearch places a document on a shard by hashing its ID. A custom routing key (tenant ID, seller ID) places all of one tenant’s documents on one shard, so a tenant-scoped query hits one shard instead of S, removing fan-out at the cost of skew and the IDF effect above.

Real-world industry applications

INDUSTRY EXAMPLE

Twitter Earlybird. Twitter’s real-time search engine kept recent tweets in in-memory inverted indexes partitioned by document across many Earlybird servers, with a front-end (Blender) scattering each query and merging results. Indexing used a single writer and many concurrent readers per index, coordinated with memory barriers rather than locks, so that tweets became searchable within about 10 seconds of creation while queries averaged about 50 ms at billions of queries per day (2012 figures) [Busch et al. 2012]. *Evidence: Primary* — [Busch et al. 2012]

16.8 Elasticsearch and OpenSearch architecture

Elasticsearch wraps Lucene in a distributed system: a JSON-over-HTTP API, cluster membership, shard placement, replication and recovery. OpenSearch is a fork of Elasticsearch 7.10.2 created in 2021 after Elastic changed its license; the two share the architecture described here, though they have diverged in features since [OpenSearch Docs].

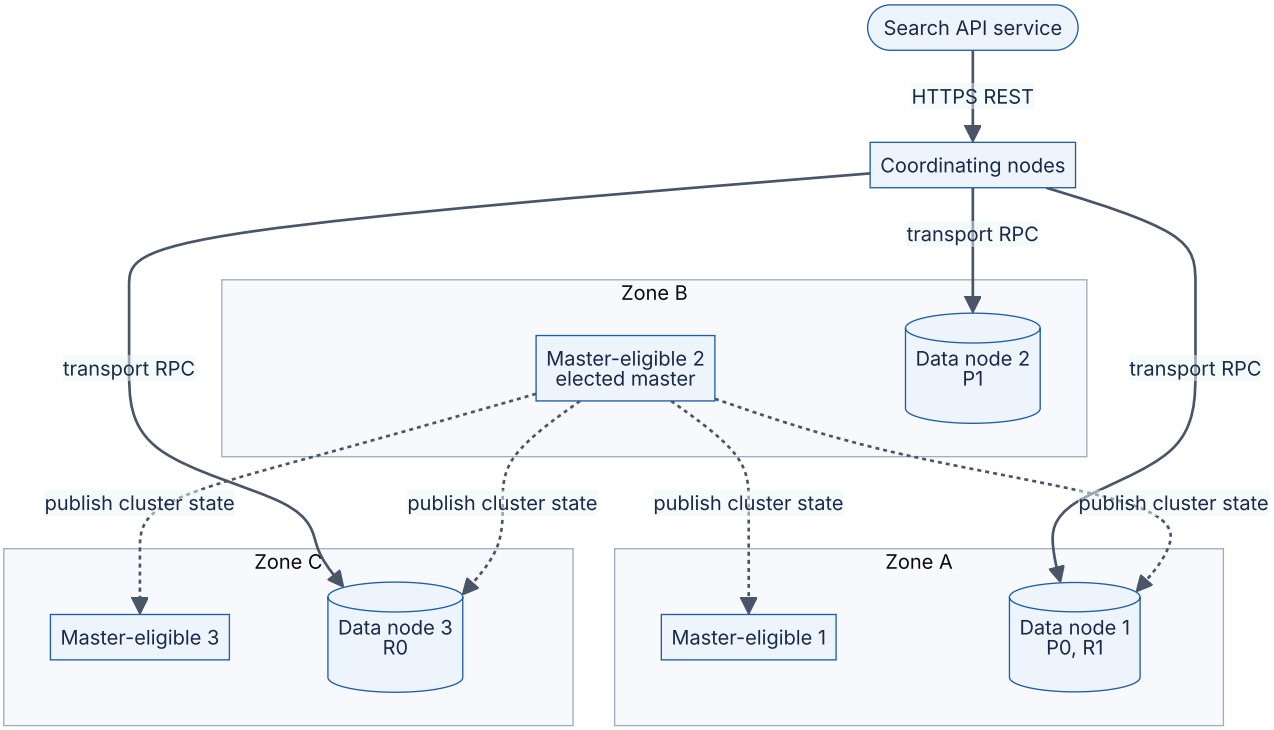
16.8.1 Cluster, nodes and roles

DEFINITION

Definition — Elasticsearch cluster. A set of nodes that share one cluster state (index definitions, mappings and the location of every shard copy). An **index** is a logical collection of documents divided into **primary shards**; each primary has zero or more **replica shards**; every shard is one Lucene index.

Nodes take one or more **roles** [Elastic Docs: node roles]: **master-eligible** nodes elect one elected master that owns and publishes the cluster state (a quorum-based protocol since 7.0, so three master-eligible nodes tolerate the loss of one); **data** nodes hold shards and execute queries and indexing (subdivided into hot, warm, cold and frozen tiers for time-based data); **ingest** nodes run preprocessing pipelines; and **coordinating-only** nodes route requests and merge results.

Figure 16.8 — A three-zone Elasticsearch cluster with two primaries and one replica each.



Reading the diagram. Clients call coordinating nodes over HTTPS; coordinating nodes talk to data nodes over Elasticsearch's binary transport protocol (synchronous RPCs, solid arrows). The index has two primary shards, P0 and P1, and one replica of each, R0 and R1; the allocator never places a primary and its replica on the same node and, with allocation awareness configured, not in the same zone. The elected master publishes cluster-state updates asynchronously (dotted arrows) to every node; it does not sit on the data path. Storage boundaries are the data nodes' local disks. Failure points: losing data

node 2 promotes R1 to primary and starts rebuilding a replica elsewhere; losing one master-eligible node leaves a quorum of two; losing a whole zone still leaves one copy of each shard. Scaling: add data nodes (shards rebalance automatically), add replicas for query throughput, and add coordinating nodes for heavy aggregations.

16.8.2 Shards, routing and sizing

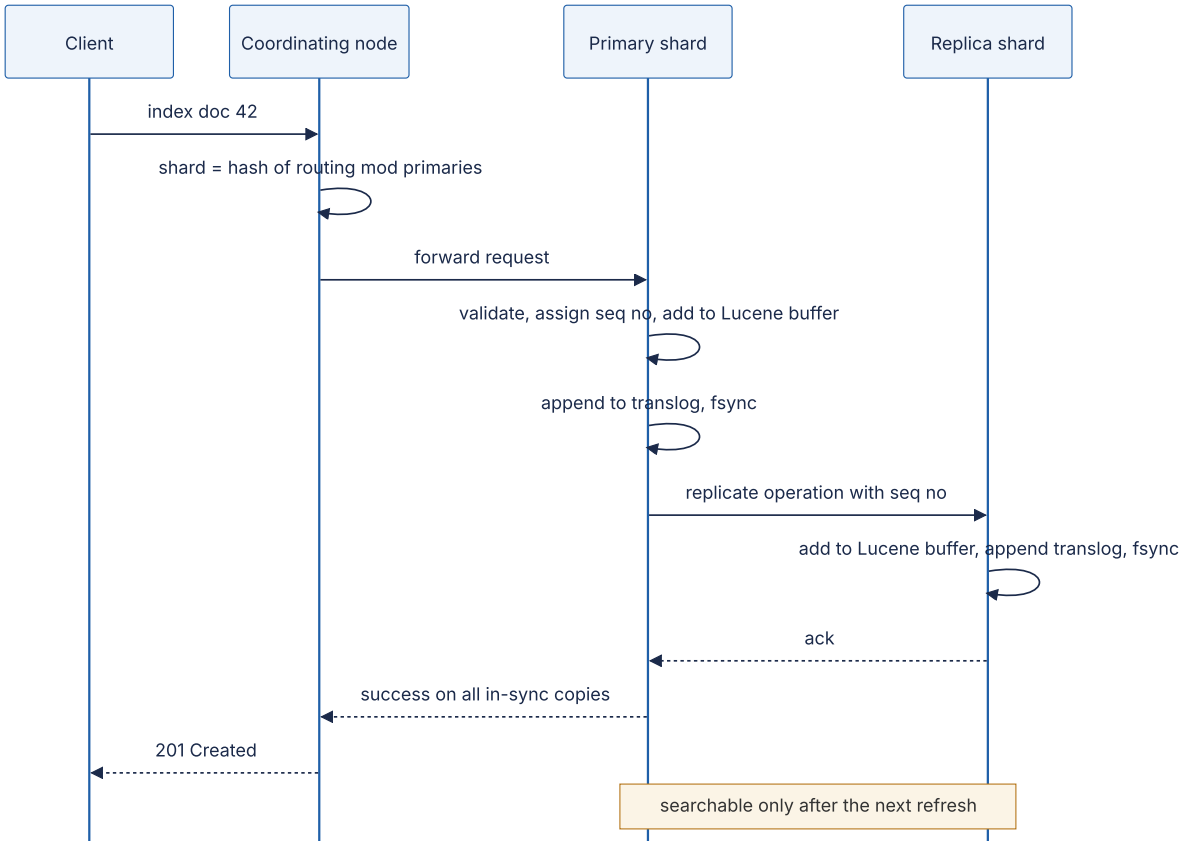
A document goes to shard $\text{hash}(\textit{routing}) \bmod N_{\text{primaries}}$, where routing defaults to the document ID and the hash is Murmur3 [Elastic Docs: _routing]. Because the formula depends on the number of primaries, that number is fixed when the index is created; changing it requires the split or shrink APIs (by integer factors) or a reindex. Replica count can be changed at any time. Since Elasticsearch 7.0 a new index has one primary and one replica by default.

Elastic's sizing guidance (as of 2025) is to aim for shards of roughly 10–50 GB and fewer than about 200 million documents each [Elastic Docs: size your shards]. Too-large shards recover slowly after node failure; too many small shards waste per-shard memory and inflate fan-out (§16.7.3). For the 440 GB catalog of §16.3.5 (about 220 GB of primary data), five primaries of roughly 44 GB fit the guidance. For logs and events, use **time-based indexes** with rollover and lifecycle policies, so old indexes can be force-merged, moved to cheaper tiers and deleted whole.

16.8.3 The write path: primary–backup replication and the translog

Elasticsearch uses primary–backup replication, modeled on Microsoft's PacificA protocol [Elastic Docs: data replication model].

Figure 16.9 — Indexing one document with one replica.



Reading the diagram. The coordinating node computes the shard and forwards the request to the node holding that shard's primary. The primary validates the document, assigns a sequence number (used to bring replicas back in sync after failures), indexes it into Lucene's in-memory buffer and appends it to the **translog**, a per-shard write-ahead log (§13.5) that by default is fsynced before the request is acknowledged (`index.translog.durability: request`). The primary then forwards the operation to all **in-sync** replicas in parallel and acknowledges only when they have all responded. Every arrow is synchronous; the disk boundary is the translog fsync on each copy. Failure points: a replica that fails to respond is reported to the master and removed from the in-sync set rather than blocking writes; a primary failure promotes an in-sync replica. The acknowledged document is durable but not yet visible to search; visibility comes at the next refresh. Indexing throughput scales with primaries, not replicas.

Table 16.9 — Refresh, flush and merge in Elasticsearch.

Operation	What it does	Default trigger	Makes data	Cost
Index (ack)	Buffer + translog fsync	Each request	Durable, not searchable	One fsync per request or bulk
Refresh	Write buffer as segment, reopen searcher	Every 1 s if the index was searched in the last 30 s	Searchable	New small segment; merge load
Flush	Lucene commit (fsync segments), trim translog	Translog size threshold	Durable without replay	Heavy fsync
Merge	Combine segments, drop deletes	Merge policy	Smaller, faster index	Background I/O and CPU

This split is what **near-real-time** means: a write is durable at acknowledgement (thanks to the translog) and searchable about one refresh interval later, without paying for a Lucene commit on every write [Elastic Docs: near real-time search]. A client that must read its own write can pass `refresh=wait_for`, which blocks the response until the next scheduled refresh.

16.8.4 Read path and memory

Queries rely on the operating system **page cache** for segment files (leave about half of RAM outside the JVM heap for it), the **shard request cache** for aggregations and the **node query cache** for filter bitsets. Elastic recommends a heap of at most half of RAM and below the roughly 31 GB compressed-pointer limit [Elastic Docs: heap size]; **doc values** serve sorting and aggregations from disk-based columns rather than heap.

Table 16.10 — Elasticsearch, OpenSearch and Solr compared (as of 2025).

	Elasticsearch	OpenSearch	Apache Solr
What it is	Lucene-based distributed engine by Elastic	Community fork of Elasticsearch 7.10.2 (Linux Foundation)	Apache Lucene project's search server
Coordination	Built-in quorum-based cluster coordination	Inherited from Elasticsearch	ZooKeeper (SolrCloud)
Replication	Document replication; stateless serverless offering	Document or segment replication	Replica types NRT, TLOG, PULL
Advantages	Feature velocity, ecosystem	Open-source license, AWS managed service	Mature, flexible configuration
Disadvantages	Licensing changes over time	Features lag or differ from Elasticsearch	Smaller operational ecosystem today
Choose when	You want the reference product and its tooling	You want Apache-licensed software or AWS OpenSearch Service	Existing Solr expertise or ZooKeeper-based operations

OpenSearch's **segment replication** copies segment files from primary to replicas instead of re-indexing each document on every replica, trading replica freshness for lower replica CPU [OpenSearch Docs: segment replication].

Failure scenarios

Table 16.11 — Distributed search and cluster failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Cluster status red	All copies of a primary lost	Cluster health API	Restore shard from snapshot; reindex from source	Replicas across zones; snapshots
Mapping explosion	Dynamic mapping of arbitrary JSON keys creates thousands of fields	Field count; cluster-state size	Reindex with strict mapping	`dynamic: strict`; field limits
Hot shard	Custom routing on a skewed key	Per-shard latency and CPU	Reroute; split shard	Random routing; routing partitions
Long GC pauses, node drops out	Heap too large or full	GC logs; node-left events	Reduce heap pressure; restart	Heap ≤ 50% RAM; circuit breakers
Stale results	Indexing pipeline lag	Freshness metric (§16.10.3)	Scale consumers	Alert on consumer lag

COMMON MISTAKE

Mistake — "Elasticsearch can be our primary database." It is durable per shard and replicated, but it has no multi-document transactions, near-real-time rather than immediate visibility, and mapping changes often require reindexing. Treat it as a derived, rebuildable view of a system of record (§16.10.2).

16.9 Typeahead and autocomplete

16.9.1 Requirements and the latency budget

DEFINITION

Definition — Autocomplete (typeahead). A service that, given the prefix a user has typed so far, returns a short ranked list (typically 5–10) of likely completions, usually popular past queries or entity names, on every keystroke or after a short pause.

First-principles explanation

Autocomplete is a friend finishing your sentences: useful only if the suggestion arrives before your next keystroke, 150–300 ms later. Nielsen's guideline is that about 0.1 s feels instantaneous [Nielsen 1993], so the whole round trip must fit in roughly 100 ms. That pushes design toward precomputation: answers for popular prefixes are computed offline and looked up, not searched.

Table 16.12 — End-to-end latency budget for one suggestion request.

Stage	Budget	Notes
Client event handling	≤ 5 ms	Plus an optional 30–50 ms debounce, outside the budget
Network round trip	30–50 ms	Reused HTTP/2 or HTTP/3 connection; nearby edge
Load balancer and gateway	2–5 ms	No per-request authentication call
Suggestion lookup	≤ 5 ms at p99	In-memory trie or FST; no disk
Serialization and render	~16 ms	One frame at 60 Hz
Total	**≈ 55–80 ms**	Leaves headroom under 100 ms

FORMULA

Autocomplete load and precomputed-index memory

$$\lambda_{ac} = \lambda_{search} \cdot c \cdot f \qquad M_{top\text{-}k} \approx P \cdot k \cdot b$$

Symbol	Meaning	Units
λ_{search}	Searches started per second	searches/s
c	Characters typed per search before selecting or submitting	characters
f	Fraction of keystrokes that send a request (after debounce and client caching)	dimensionless
λ_{ac}	Suggestion request rate	requests/s
P	Number of trie nodes (distinct prefixes) with stored suggestions	nodes
k	Suggestions stored per prefix	count
b	Bytes per stored suggestion reference	bytes
$M_{top\text{-}k}$	Memory for the precomputed lists	bytes

WORKED EXAMPLE

Worked example — sizing typeahead for the store. 50 million searches/day, peak-to-average ratio 2, $c = 8$, $f = 0.5$. The suggestion corpus is 10 million distinct past queries, giving an assumed $P = 6 \times 10^7$ trie nodes after prefix sharing; $k = 10$, $b = 4$ bytes (a query ID).

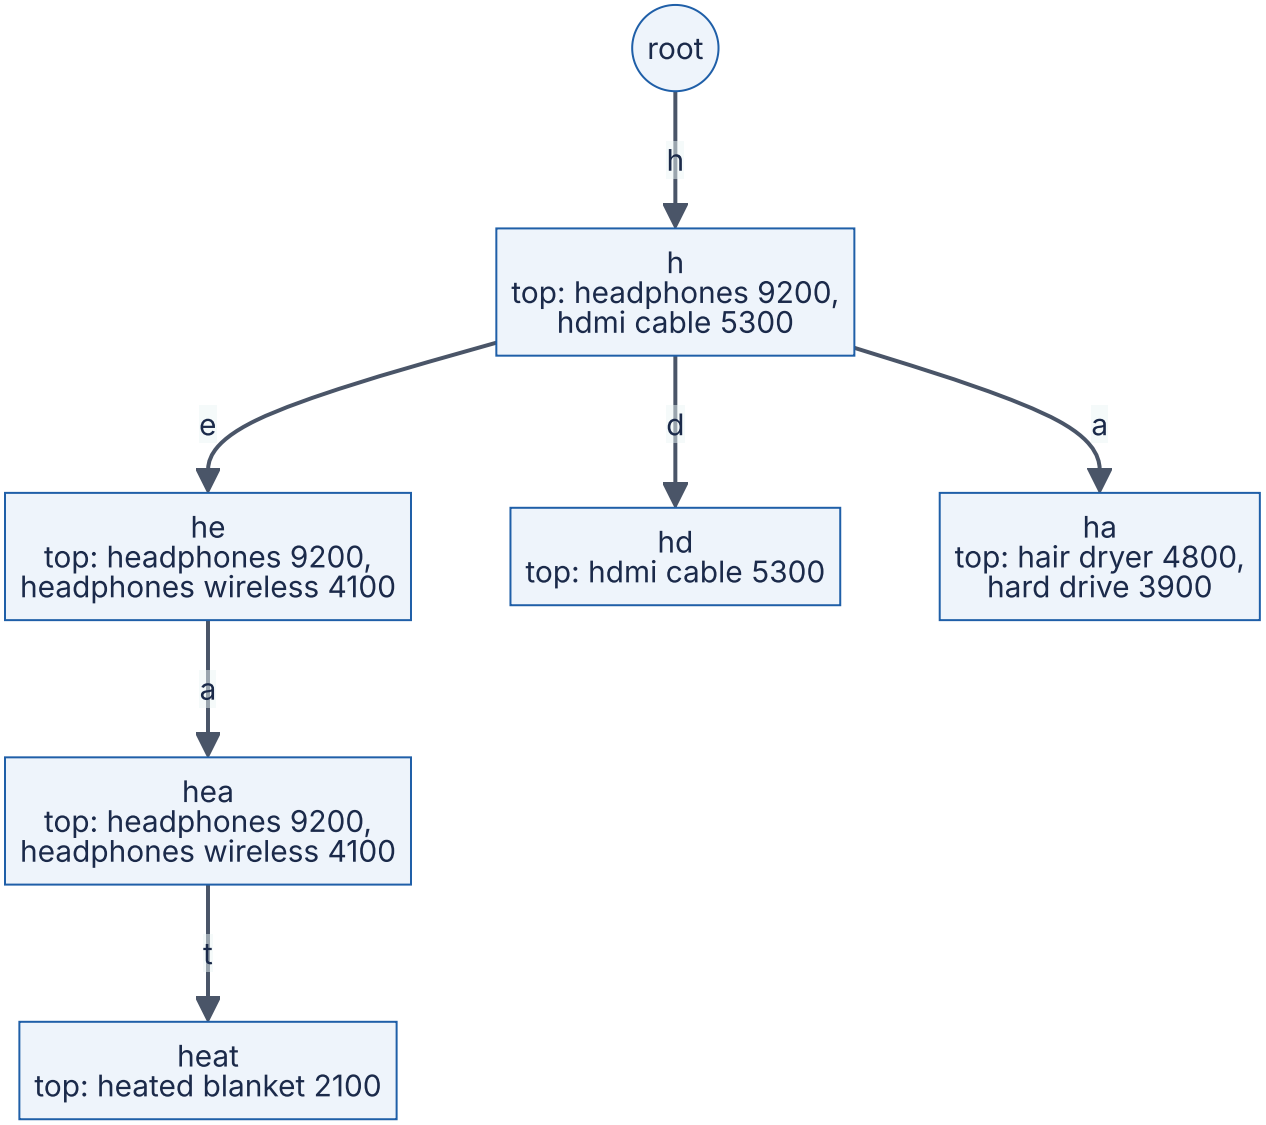
1. Average search rate: $5 \times 10^7 / 86,400 = 579$ searches/s; peak $\approx 1,157$/s.
2. Peak suggestion rate: $1,157 \times 8 \times 0.5 \approx 4,630$ requests/s, four times the search rate.
3. Memory for top-10 lists: $6 \times 10^7 \times 10 \times 4 = 2.4 \times 10^9$ bytes = 2.4 GB, plus the trie nodes themselves and the query strings (10 M × ~20 bytes = 200 MB).

Interpretation. Autocomplete usually generates more requests than search itself, but each is a memory lookup. **Engineering implication.** A few replicated in-memory nodes handle this load. Memory, not CPU, is the constraint, so cap precomputation at short prefixes (for example up to 10 characters), drop rare queries, and cache the responses for the most popular one- and two-character prefixes at the CDN or in the client.

16.9.2 Tries with precomputed top-*k*

A **trie** (§17.11) stores strings as paths from the root, one character per edge; all strings with a given prefix live under one node. Finding that node takes $O(\ell)$ steps for a prefix of length ℓ. The naive next step, walking the whole subtree to find the most popular completions, can touch millions of nodes for a one-letter prefix. The fix is to **store the top-*k* completions at every node**, computed bottom-up offline: a node's list is the best k among its own query (if one ends there) and its children's lists.

Figure 16.10 — A trie with top-2 completions stored at each node.



Reading the diagram. Each node is a prefix; edges are labeled with the next character. Each node stores its precomputed top-2 list with popularity counts from the query log. A lookup for “hea” follows three edges from the root and returns the list stored at that node with no further traversal. “heated blanket” lives under “heat” and appears in the lists of “he” and “hea” only when $k \geq 3$, because two headphone queries outrank it. The structure is read-only in memory; it is rebuilt offline and swapped in atomically. Failure points: an outdated build (stale trends) and memory exhaustion as the corpus grows. It scales by replication, and by partitioning on the first character or two of the prefix if one node cannot hold it.

```
        """Trie-based autocomplete with the top-k completions precomputed at every node.
        Lookup cost is O(len(prefix)) and independent of how many queries share the pre-
fix."""
        import heapq

        class Node:
            __slots__ = ("children", "count", "top")
            def __init__(self):
                self.children = {}      # char -> Node
                self.count = 0          # popularity if a query ends here, else 0
                self.top = []           # precomputed [(count, query)] best-first,
length <= k

        class Autocomplete:
            def __init__(self, k=3):
                self.root, self.k, self.nodes = Node(), k, 1

            def insert(self, query, count):
                node = self.root
                for ch in query:
                    if ch not in node.children:
                        node.children[ch] = Node()
                        self.nodes += 1
                    node = node.children[ch]
                node.count += count

            def build_top_k(self, node=None, prefix=""):
                """Post-order pass: a node's top-k = best k of (itself, children's top-k
lists)."""
                node = node or self.root
                candidates = [(node.count, prefix)] if node.count else []
                for ch, child in node.children.items():
                    self.build_top_k(child, prefix + ch)
                    candidates.extend(child.top)
                node.top = heapq.nlargest(self.k, candidates, key=lambda c: c[0])

            def suggest(self, prefix):
                node = self.root
                for ch in prefix.lower():
                    node = node.children.get(ch)
                    if node is None:
                        return []
                return [q for _, q in node.top]

            def suggest_by_dfs(self, prefix):
                """Without precomputation: walk the whole subtree. Returns (suggestions,
nodes visited)."""
                node = self.root
                for ch in prefix:
                    node = node.children.get(ch)
                    if node is None:
                        return [], 0
                found, stack, visited = [], [(node, prefix)], 0
                while stack:
                    n, p = stack.pop()
                    visited += 1
```

```
                    if n.count:
                        found.append((n.count, p))
                    stack.extend((c, p + ch) for ch, c in n.children.items())
                best = heapq.nlargest(self.k, found, key=lambda c: c[0])
                return [q for _, q in best], visited

        QUERY_LOG = {   # query -> times searched in the last 7 days (illustrative)
            "headphones": 9200, "headphones wireless": 4100, "headphone stand": 800,
            "headphones for kids": 1500, "head torch": 650, "heated blanket": 2100,
            "hdmi cable": 5300, "hard drive": 3900, "hair dryer": 4800, "hammock": 300,
        }

        if __name__ == "__main__":
            ac = Autocomplete(k=3)
            for q, c in QUERY_LOG.items():
                ac.insert(q, c)
            ac.build_top_k()
            for prefix in ("h", "he", "hea", "head", "headphones ", "x"):
                print(f"{prefix!r:>15} -> {ac.suggest(prefix)}")
            dfs, visited = ac.suggest_by_dfs("h")
            assert dfs == ac.suggest("h")
            print(f"trie nodes={ac.nodes}; DFS for 'h' visits {visited} nodes, precom-
puted lookup reads 1 node")
```

Output:

```
            'h' -> ['headphones', 'hdmi cable', 'hair dryer']
           'he' -> ['headphones', 'headphones wireless', 'heated blanket']
          'hea' -> ['headphones', 'headphones wireless', 'heated blanket']
         'head' -> ['headphones', 'headphones wireless', 'headphones for kids']
  'headphones ' -> ['headphones wireless', 'headphones for kids']
            'x' -> []
trie nodes=82; DFS for 'h' visits 81 nodes, precomputed lookup reads 1 node
```

What to notice: the build pass is one post-order traversal costing $O(\text{nodes} \cdot k \log k)$, done offline; the online lookup reads ℓ nodes regardless of corpus size; and a ten-query log already needs 82 nodes, which is why production systems compress the trie.

16.9.3 Finite-state transducers in Lucene

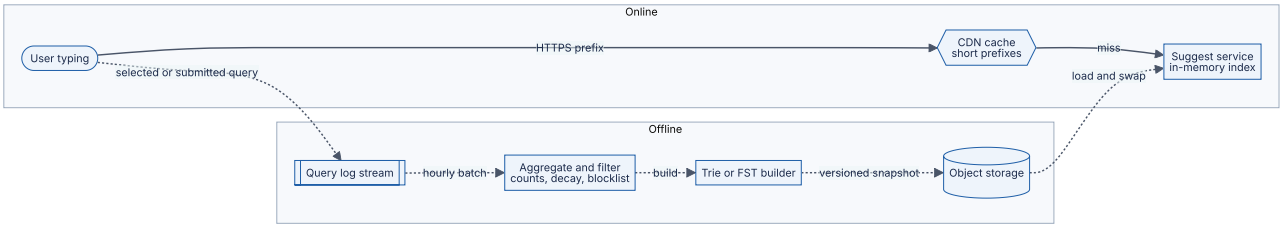
A trie shares common *prefixes* only. A **finite-state transducer (FST)** is a minimal automaton that shares both prefixes and suffixes (“-phones”, “-ing”) and attaches an output, such as a weight or an ordinal, to each accepted string. Minimal acyclic automata can be built incrementally from sorted input in linear time [Daciuk et al. 2000]. Lucene uses FSTs for its term-dictionary index, and Elasticsearch’s **completion suggester** (the `completion` field type) stores weighted suggestions in a per-segment FST held in memory, giving top-k lookups in microseconds with optional fuzzy matching and context filters [Elastic Docs: completion suggester]. Because the FST lives inside segments, suggestions update through normal indexing and refresh.

Table 16.13 — Autocomplete approaches.

Approach	How it works	Advantages	Disadvantages	Choose when
Trie with top-*k* per node	Offline build from query logs	Fastest; full control of ranking	Custom service; rebuilds	Very high traffic; query-log suggestions
FST completion suggester	Weighted FST per segment	Built in; compact; fuzzy	Prefix-only; weights static per document	Entity names in Elasticsearch
Edge n-gram field	Index every prefix as a term	Matches inner words, full query features	Index 3–10× larger; slower	Suggestions need filters and scoring
`search_as_you_type` field	Managed shingles and edge n-grams	Easy, infix-friendly	Same costs as edge n-grams	Small to medium catalogs

16.9.4 Serving architecture

Figure 16.11 — Autocomplete: offline build and online serving.



Reading the diagram. The offline subgraph runs asynchronously (dotted arrows): query logs are aggregated with time decay so trends surface, filtered against a blocklist of offensive or unsafe completions, built into a trie or FST, and published as a versioned snapshot to object storage. Online, the user's prefix goes over HTTPS to a CDN that caches responses for popular short prefixes; misses reach stateless suggest-service replicas that hold the whole structure in memory and swap in new snapshots atomically. The user's eventual query flows back into the log, closing the loop. Storage boundaries are the log, object storage and each replica's memory. Failure points: a bad snapshot (roll back to the previous version), a poisoned log (rate-limit and filter per user), and stale caches during breaking news (short TTLs). Scaling: add replicas; partition by prefix if memory runs out; personalize by blending global suggestions with the user's own recent queries at request time.

16.10 Near-real-time indexing

16.10.1 The refresh interval trade-off

DEFINITION

Definition — Near-real-time (NRT) search. A search system in which newly written documents become searchable after a short, bounded delay (typically one second to a minute) rather than immediately, because making them visible requires creating a new segment and reopening the searcher.

Each refresh creates a segment and a new searcher; refreshing more often gives fresher results but more tiny segments, more merging (§16.6.3) and lower indexing throughput.

Table 16.14 — Choosing a refresh interval.

Setting	Freshness	Indexing throughput	Merge load	Typical use
1 s (default)	~1 s	Lowest	Highest ($W \approx 4.4$ in §16.6.3)	Product, user-facing content
30 s	~30 s	Higher	Lower ($W \approx 2.9$)	Logs, metrics, analytics
`-1` (disabled) during bulk load, replicas 0	None until re-enabled	Highest	Lowest	Initial load or full reindex
`refresh=wait_for` on a request	Caller waits for next refresh	Unchanged	Unchanged	Read-your-writes for one client

Never call an explicit refresh after every write: it turns each document into its own segment and can collapse indexing throughput.

16.10.2 The indexing pipeline: CDC and Kafka

The source of truth is usually a relational database. Writing to the database *and* to the search index from application code (**dual writes**) loses updates whenever one write succeeds and the other fails, and can apply concurrent updates in different orders to the two stores [Kleppmann 2017, ch. 11]. The robust pattern is to derive the index from the database's own change log.

Figure 16.12 — Near-real-time indexing pipeline with CDC and Kafka.

Reading the diagram. The catalog service writes only to PostgreSQL, synchronously. Debezium reads the write-ahead log through logical decoding and publishes each committed change to Kafka asynchronously, keyed by product ID so that all changes to one product land in one partition, in order. The indexer consumes partitions, enriches each event into a complete search document (prices, stock, review counts from other stores), and writes in bulk through an **alias**, a stable name pointing at the current physical index. Each write carries an external version (for example the source log sequence number), so a replayed or reordered older event is rejected and the pipeline stays idempotent under at-least-once delivery (§22.15). Deletes arrive as delete events and become delete requests. Storage boundaries: the database, the Kafka log, the enrichment stores and the index. Failure points: indexer lag (search becomes stale, never wrong), poison events (send to a dead-letter topic), and Kafka retention shorter than a rebuild. Scaling: more Kafka partitions and indexer consumers. The lower path shows a full **rebuild**: a job replays the topic (or a snapshot plus the topic) into `products_v3` with refresh disabled; when it catches up, the alias is switched atomically from v2 to v3, a zero-downtime reindex used for analyzer or mapping changes.

16.10.3 Freshness budget

FORMULA

End-to-end freshness latency

$$T_{\text{fresh}} \approx T_{\text{cdc}} + T_{\text{queue}} + T_{\text{batch}} + T_{\text{index}} + T_{\text{refresh}}$$

Symbol	Meaning	Units
T_{cdc}	Commit to event published in Kafka	s
T_{queue}	Time the event waits for the indexer (consumer lag)	s
T_{batch}	Wait for a bulk request to fill or its timer to fire	s
T_{index}	Bulk request execution on primary and replicas	s
T_{refresh}	Wait for the next refresh: uniform in $[0, I]$, mean $I/2$	s
T_{fresh}	Commit in source database to searchable	s

WORKED EXAMPLE

Worked example — how fresh is a price change? T_{cdc} = 0.2 s, T_{queue} = 0.3 s at normal load, bulk requests flush every 1 s (mean wait 0.5 s, worst 1 s), T_{index} = 0.1 s, refresh interval I = 1 s (mean 0.5 s, worst 1 s).

1. Mean: 0.2 + 0.3 + 0.5 + 0.1 + 0.5 = 1.6 s.
2. Worst case without backlog: 0.2 + 0.3 + 1 + 0.1 + 1 = 2.6 s.
3. With I = 30 s: mean 1.1 + 15 = 16.1 s, worst 31.6 s.
4. During a backlog of 600,000 events drained at 5,000 events/s: T_{queue} grows by 120 s.

Interpretation. At default settings the pipeline, not Lucene, dominates freshness, and backlog dominates everything. **Engineering implication.** Publish freshness as a service-level objective (for example 99% of changes searchable within 5 s), measure it end to end by writing canary documents and timing when they become searchable, and alert on consumer lag.

COMMON MISTAKE

Mistake — "Kafka gives us exactly-once, so the index is always consistent." Consumers see events at least once and may restart from older offsets; enrichment lookups may read newer data than the event. Make every index write idempotent with external versions, design documents to be fully rebuilt from current source state, and reconcile periodically by comparing counts or checksums between source and index.

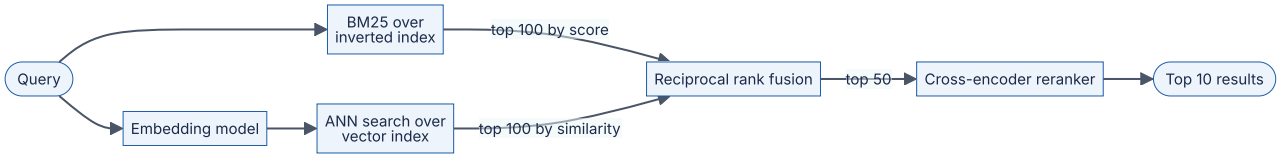
16.11 Beyond lexical matching: a bridge to semantic and hybrid search

BM25 matches *words*. It cannot know that "ANC earbuds" and "noise canceling in-ear headphones" describe the same thing unless synonyms are configured by hand, and the listing in §16.5.4 ranked earbuds above headphones because it understands nothing. **Semantic (dense) retrieval** encodes queries and documents as embedding vectors with a neural model and retrieves nearest neighbors by cosine similarity (§4.9.2), using approximate nearest neighbor (ANN) indexes such as HNSW. It captures meaning but can miss exact identifiers (part numbers, error codes) that BM25 matches perfectly.

Hybrid retrieval runs both and fuses the lists. Because BM25 scores and cosine similarities live on different scales (§16.5 misconception), fusion usually uses ranks: **reciprocal rank fusion** adds $1/(60 + \text{rank})$ from each list [Cormack et al. 2009]. A cross-encoder reranker may then reorder the top few dozen. Lucene, Elasticsearch and OpenSearch

now include vector fields and ANN search alongside inverted indexes, so one cluster can serve both (as of 2025).

Figure 16.13 — Hybrid retrieval (preview of Chapters 74–75).



Reading the diagram. The query takes two synchronous paths in parallel: lexical retrieval over the inverted index of this chapter, and an embedding model followed by ANN search over a vector index. Each returns its top 100 candidates; rank fusion merges them without comparing raw scores, and an optional reranker spends expensive model inference on only the top 50. The two indexes are separate storage boundaries that must be kept in step by the same indexing pipeline (§16.10.2), with embeddings computed at indexing time. Failure points: the embedding model adds latency and a GPU or CPU dependency on the query path; if it fails, falling back to BM25 alone keeps search available. Chapter 74 covers vector indexes and Chapter 75 covers hybrid retrieval, fusion and reranking in depth.

16.12 Summary and revision notes

SUMMARY

- An **inverted index** maps each term to a sorted postings list of docIDs (with tf and positions). AND is intersection, OR is union, phrases check positions; evaluate the rarest term first. **Skip pointers** (`advance(target)`) let a short list drive a long one; spacing near $\sqrt{2L/m}$ beats the $\sqrt{L}$ heuristic for unequal lists.
- **Compression:** delta-encode docIDs, then VByte (7 bits per byte) or block bit-packing (Lucene: blocks of 128). Measured ≈ 1.4 bytes per docID posting. Index size $\approx Nu(b_d + b_f) + NLb_p + Mb_t$; positions often cost more than docIDs; budget again as much for `_source` , doc values and norms, then multiply by replicas.
- **Analysis** (char filters → tokenizer → token filters) must match at index and query time. Stemming raises recall and risks precision; lemmatization is more precise and costlier; keep stop words but preserve positions; n-grams enable substring and prefix search at large size cost; apply synonyms at query time; analyze each language in its own field.
- **BM25:** IDF = $\ln(1 + (N - n + 0.5)/(n + 0.5))$; tf saturates at $k_1 + 1$ ($k_1 = 1.2$); length normalization via $b = 0.75$. Scores are comparable only within one query. Field boosts or BM25F add structure; WAND and Block-Max WAND skip blocks that cannot reach the top k.
- **Segments** are immutable; refresh makes them searchable, commit makes them durable; deletes are live-docs tombstones; updates are delete + add; tiered merging rewrites each byte about $1 + \log_m(S_{\max}/S_{\text{flush}})$ times.
- **Distributed search** uses document partitioning, replicas for availability and throughput, scatter–gather ($P = p^S$, so use few shards and tail-tolerant techniques), query-then-fetch, bounded pagination ($S(from + size)$), and local IDF unless `dfs_query_then_fetch` is used.
- **Elasticsearch/OpenSearch:** master-eligible, data, ingest and coordinating roles; shard = hash(routing) mod primaries; shards of about 10–50 GB; primary–backup replication with a fsynced translog; refresh every 1 s gives near-real-time visibility.
- **Autocomplete** must fit ≈ 100 ms end to end: precompute top-k per prefix in a trie or FST, serve from memory, cache short prefixes, rebuild offline from query logs with decay and blocklists.
- **NRT pipeline:** CDC → Kafka (keyed by document ID) → indexer with external versions → alias; freshness ≈ CDC + lag + batch + index + refresh; reindex by replay into a new index and alias swap.

16.13 Knowledge checkpoint

1. Why can a B-tree index not answer `LIKE '%noise%'` efficiently, and what does an inverted index store instead?
2. Encode the postings list 3, 130, 131 with delta + VByte. How many bytes?
3. When does a skip pointer help an intersection, and what spacing suits a 1,000-entry list driving a 1,000,000-entry list?
4. Give one risk each of stemming, stop-word removal and index-time synonyms.
5. What happens if the query analyzer applies a stemmer that the index analyzer did not?
6. Compute the BM25 IDF of a term in 1 of 8 documents.
7. What value does the BM25 term-frequency factor approach as tf grows, and why does that matter?
8. Why is an update in Lucene more expensive than an insert?
9. A cluster refreshes every 1 s with 1 MB flushes and a 5 GB segment cap, merge factor 10. Estimate write amplification.
10. A query fans out to 50 shards whose p99 is 30 ms. What fraction of queries wait longer than 30 ms?
11. Why does Elasticsearch limit `from + size` to 10,000 by default?
12. When does local IDF distort ranking, and what is the fix?
13. Why is the number of primary shards fixed at index creation?
14. Why is autocomplete precomputed rather than searched per keystroke?
15. Name two ways the indexing pipeline stays correct under at-least-once delivery.

Answers

1. A B-tree orders whole keys, so it helps only with equality or prefix predicates; an infix pattern forces a full scan. An inverted index stores term → sorted docIDs, so each word is a direct lookup.
2. Gaps 3, 127, 1 → each fits in 7 bits → 3 bytes (`00000011 01111111 00000001`), versus 12 bytes raw.
3. When one list is much shorter, so many entries of the long list can be jumped. $\sqrt{2 \times 10^6 / 10^3} \approx 45$.
4. Stemming: conflates unrelated words (“universe”/“university”). Stop words: breaks queries like “The Who”. Index-time synonyms: changes need a full reindex and inflate the index.
5. Query terms are stems that were never indexed in that form, so matches silently disappear.
6. $\ln(1 + 7.5/1.5) = \ln 6 = 1.79$.
7. $k_1 + 1$ (2.2 at default). It caps the benefit of repetition, defeating keyword stuffing.
8. It is a delete (tombstone bit in the old segment) plus a full re-index of the new version into a new segment, and the dead copy occupies space until merged.

9. $1 + \log_{10}(5,000/1) = 1 + 3.7 = 4.7$.
10. $1 - 0.99^{50} = 1 - 0.605 = 39.5\%$.
11. Every shard must return and the coordinator must merge $S \times (from + size)$ entries; deep pages are expensive and can exhaust memory. Use `search_after` instead.
12. When a term's documents are unevenly spread across shards (custom routing, small indexes); use `dfs_query_then_fetch` or random routing.
13. Routing computes hash(routing) mod number of primaries; changing it would move most documents. Split/shrink by integer factors or reindex.
14. The budget is ≈ 100 ms end to end, request rate exceeds search rate, and answers for a prefix change slowly, so a memory lookup of a precomputed list is cheaper and faster.
15. Key events by document ID for per-document ordering, and write with external versions so stale or replayed events are rejected; additionally reconcile periodically.

16.14 Interview questions

Basic

Q1. Explain how a search engine finds documents containing two words.

Answer. Text is analyzed into terms, and an inverted index maps each term to a sorted postings list of docIDs. The query is analyzed the same way, both postings lists are fetched, and they are intersected by walking them in docID order, starting from the shorter list and using skip pointers to jump through the longer one. Matching docIDs are scored (BM25) and the top k are returned, with stored fields fetched only for those.

Q2. What is BM25 and how does it improve on TF-IDF?

Answer. BM25 sums, over query terms, IDF times a term-frequency factor $f(k_1 + 1)/(f + k_1(1 - b + b|d|/\text{avgdl}))$. Unlike raw TF-IDF, term frequency saturates (repetition has diminishing returns, bounded by $k_1 + 1$), and document length is normalized against the average with strength b. Defaults $k_1 = 1.2$, $b = 0.75$ work well and are tuned per field against a relevance set.

Intermediate

Q3. Search results take up to 30 seconds to reflect product edits. Where do you look?

Answer. Decompose freshness into CDC lag, Kafka consumer lag, bulk batching, indexing time and refresh interval. Check whether the index has `refresh_interval: 30s` (common copy-paste from logging setups) or is search-idle; check consumer lag and whether a hot partition or slow enrichment lookups throttle the indexer; check for bulk rejections and

retries. Fix the dominant term, add an end-to-end canary freshness metric and alert on lag.

Q4. How many shards would you give a 300 GB product index serving 3,000 queries per second?

Answer. Size shards by data first: with 10–50 GB guidance, 6–10 primaries (say 8 of about 37 GB). Then size copies for throughput: measure per-shard query cost, e.g. 5 ms CPU; $3,000 \times 8 \times 5\ \text{ms} = 120$ core-seconds/s, so 240 cores at 50% utilization, about 15 sixteen-core nodes, so 8 primaries with enough replicas (for example 2 replicas, 24 copies) spread across three zones. Avoid many small shards: fan-out raises tail latency as p^S. Validate with a load test.

Advanced

Q5. Design search for a multi-tenant SaaS with 50,000 tenants of very different sizes.

Answer. Shared indexes with tenant ID filters are efficient for small tenants; route by tenant ID so a tenant's query hits one shard, using routing partitions (`routing_partition_size`) so large tenants spread over several shards. Give the largest tenants dedicated indexes to isolate load and allow custom analyzers. Watch the local-IDF problem: per-tenant statistics differ, so test relevance per tenant or accept local statistics. Enforce tenant filters in the search API, never in the client; cap per-tenant request rates; and use aliases with filters per tenant for migrations between shared and dedicated indexes.

Q6. Your 200-shard cluster's p99 latency is 400 ms while median shard latency is 10 ms. Diagnose and fix.

Answer. Scatter–gather means each query waits for the slowest of 200 shards: $0.99^{200} = 13\%$ of queries are fully fast at the shard p99. Look for correlated stalls (GC pauses, merges, hot nodes, uneven shard placement) using per-node latency. Fixes in order: reduce shard count by merging small indexes (shrink API, larger shards); enable or tune adaptive replica selection and add replicas so slow copies are avoided; hedge requests after the shard p95; set per-shard timeouts with partial results; and move heavy aggregations to separate coordinating nodes.

16.15 Practical exercises

1. **Extend the engine.** Add Boolean AND with skip-pointer intersection to the §16.5.4 listing, then add BM25F-style scoring (combine weighted tf across fields before saturation) and compare the ranking for "wireless noise canceling headphones".

2. **Measure compression.** Change the Zipf exponent in the §16.3.4 listing to 0.8 and 1.2 and report bytes per posting; then implement frame-of-reference bit packing for blocks of 128 gaps and compare size and decoding time with VByte.
3. **Analyzer laboratory.** Run Elasticsearch or OpenSearch locally and use the `_analyze` API to compare the standard, English and a custom analyzer on ten product titles containing hyphens, accents, model numbers and plurals.
4. **Refresh experiment.** Bulk-index one million synthetic documents with refresh intervals of 1 s, 30 s and disabled; record indexing throughput, segment counts over time and merge statistics, and compare with the write-amplification formula.
5. **Autocomplete from logs.** Feed a real or synthetic query log into the §16.9.2 trie with exponential time decay on counts and a blocklist; measure memory per million queries and lookup latency.

16.16 Design challenges

1. **Marketplace product search.** 200 million listings, 20,000 searches/s peak, prices and stock updated 5,000 times/s, freshness SLO of 5 s for stock. Decide what goes in the text index versus a fast-changing side store, shard and replica counts, the CDC pipeline and how stock filters are applied without reindexing documents for every change.
2. **Log search.** 2 TB/day of application logs, 30-day retention, most queries over the last hour. Design time-based indexes, rollover size, hot/warm tiers, refresh interval and force-merge policy, and compute the storage footprint with one replica.
3. **Global autocomplete.** 300 million users in 40 languages, suggestions within 100 ms p99 worldwide, trending queries reflected within 15 minutes, unsafe suggestions filtered. Design the build pipeline, per-language tries or FSTs, edge caching and the rollback mechanism.

16.18 Open verification items

- Lucene postings layout (blocks of 128 with frame-of-reference packing, multi-level skip data) is stated for Lucene 5–9; confirm against Lucene 10’s current postings format.
- `TieredMergePolicy` defaults (about 10 segments per tier, merge 10 at once, 5 GB maximum merged segment) — confirm current Lucene values.
- Lucene 8 removal of $(k_1 + 1)$ (LUCENE-8563) and Elasticsearch’s compensating 2.2 boost in `explain` — confirmed via issue tracker and forum summaries only.
- Manning et al. Table 5.6 figures (400 MB raw, 116 MB VByte for RCV1) quoted from memory.
- Earlybird “within 10 seconds” and “50 ms average” confirmed via search snippets, not full text.
- GitHub 25 TB / 115 TB figures from search summaries of the blog.
- Elastic Cloud Serverless “stateless” description and Elasticsearch BM25 switch version (5.0) — check docs.
- Workload numbers in worked examples (catalog size, query rates, $P = 6 \times 10^7$ trie nodes) are Illustrative.

Chapter 17 — Data Structures and Algorithms for Scale

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

A hash table, a sorted array and a B-tree will carry you a long way. Then the numbers grow. You need to know whether one of 3 billion usernames is taken without reading a disk. You need to count the distinct visitors to a site that gets 50 billion page views a day. You need the 100 most-shared links of the last hour in a stream of a million events per second. You need every driver within a kilometer of a rider, out of a million moving cars. And you need IDs for all of these things, generated on a thousand machines at once, without the machines talking to each other.

Exact answers cost memory, disk reads or coordination in proportion to the data. The structures in this chapter accept a small, *bounded* and *quantifiable* error, or a little randomness, in exchange for kilobytes of memory, constant-time operations and no coordination. A Bloom filter answers “have I seen this?” in about 10 bits per item at a 1% false-positive rate. A HyperLogLog counts a billion distinct items in 12 KB with 0.81% standard error. A Snowflake ID lets a thousand machines mint 4 billion IDs per second without talking to one another.

For each structure you get the idea, the mechanism, the sizing formula, a worked example and runnable Python that checks the formula against a measurement.

17.1 Learning objectives

After this chapter you should be able to:

- State the properties a non-cryptographic hash function must have, measure uniformity with a chi-square test, and explain how hash flooding works and how keyed hashes such as SipHash stop it.
- Size a Bloom filter for a target false-positive rate (bits per element and number of hash functions), predict its false-positive rate, and verify the prediction by measurement.
- Choose between Bloom, counting Bloom and cuckoo filters when deletions are needed.
- Explain how HyperLogLog estimates cardinality from leading zeros, compute its memory and standard error, and merge sketches across servers.

- Size a Count-Min sketch from an error target ε and confidence δ, and build a heavy-hitters (top-k) pipeline with a heap or the Space-Saving algorithm.
- Explain why skip lists give expected $O(\log n)$ search and why Redis uses them for sorted sets.
- Build a Merkle tree, produce and verify an inclusion proof, and explain how replicas use Merkle trees for anti-entropy.
- Encode a geohash, choose a precision for a search radius, and compare geohash, quadtrees, S2 and H3 for proximity search.
- Compare UUIDv4, UUIDv7, Snowflake, ULID and ticket servers, and compute the capacity and lifetime of a Snowflake bit layout.
- Use a trie for prefix lookup and reservoir sampling for uniform samples from a stream of unknown length.

17.2 Prerequisites

- Powers of two and logarithms — §4.3, §4.4 (every sizing formula here is a logarithm or an exponent).
- Probability essentials: complement, independence, expected value — §4.6 (false-positive rates and error bounds are probabilities).
- Cryptographic hash functions and the birthday bound — §10.4.1 (this chapter covers the fast, non-cryptographic kind and reuses the birthday bound for IDs).
- B-trees and indexes — §11.7, §11.8 (geospatial indexes reduce two dimensions to one so that a B-tree or sorted set can serve them).
- LSM trees, memtables and SSTables — §13.8 (the most common home of Bloom filters and skip lists).
- Partitioning by hash — §14.6 (hash quality decides partition balance).

17.3 Hash functions at scale

17.3.1 What a hash function must do

DEFINITION

Definition — Hash function. A deterministic function h that maps an input of any length to a fixed-size integer (for example 32, 64 or 128 bits), called the **hash** or **digest**. A **non-cryptographic hash function** is designed for speed and statistical uniformity on ordinary inputs. A **cryptographic hash function** additionally resists an adversary who tries to find collisions or preimages (§10.4.1).

First-principles explanation

Imagine a cloakroom with 1,000 numbered hooks. You want to hang each coat on a hook chosen by a rule, so that later you can go straight to the right hook instead of searching all of them. A good rule looks at the whole ticket and scatters tickets evenly: no hook gets 50 coats while others are empty. It must give the same hook for the same ticket every time. And it must be fast, because the queue is long. That rule is a hash function, and the hooks are **buckets**.

Every structure in this chapter starts with a hash: hash tables pick buckets, partitioned databases pick nodes (§14.6), Bloom filters pick bits, HyperLogLog reads output bits as coin flips. A poor hash passes its flaw to all of them.

Why does this exist?

At scale three demands sharpen. **Throughput**: a cache node may hash millions of keys per second. **Uniformity on structured input**: real keys look like `user:1`, `user:2`, and a weak hash maps near-identical keys to near-identical outputs. **Adversarial input**: an attacker who controls keys (HTTP parameters, JSON field names) can choose keys that all collide (§17.3.4).

How it works internally

MurmurHash3 and its relatives process the input in fixed-size blocks, repeatedly multiplying by large odd constants, rotating bits and XOR-ing into a running state; a **finalizer** then scrambles the state so that every input bit affects every output bit. Four properties matter:

1. **Determinism.** Same input and seed, same output, on every machine and run. A hash that changes between versions re-routes every key.
2. **Uniformity.** For realistic key sets, outputs are spread evenly over the output range, so `h(key) mod B` spreads evenly over B buckets.
3. **Avalanche.** Flipping one input bit flips each output bit with probability close to 1/2. This is what makes `user:1` and `user:2` land far apart.
4. **Speed.** A few CPU cycles per byte and low overhead for short keys.

A **seed** mixed into the initial state gives effectively independent hash functions from the same code; keyed hashes (§17.3.4) keep the seed secret.

17.3.2 MurmurHash3 and xxHash

MurmurHash3 (Austin Appleby, published with the SMHasher test suite) has 32- and 128-bit variants and is Apache Cassandra's default partitioner hash (`Murmur3Partitioner`) [Appleby: SMHasher; Apache Cassandra Docs]. **xxHash** (Yann Collet) offers XXH32, XXH64 and XXH3; its author reports higher throughput than MurmurHash3, especially on

long inputs [Collet: xxHash]. Both pass SMHasher's statistical tests, and neither is cryptographic.

Table 17.1 — Hash functions you will meet in system design.

Function	Output	Keyed / adversary-resistant?	Relative speed	Typical use
CRC32	32 bits	No; designed for error detection	Very fast (hardware instruction)	Checksums, some sharding (Redis Cluster uses CRC16)
FNV-1a	32/64 bits	No	Fast for short keys, weak mixing	Small in-process tables
MurmurHash3	32/128 bits	No (seeded, not secret)	Fast	Partitioners, Bloom filters, sketches
xxHash (XXH64, XXH3)	64/128 bits	No	Very fast	Checksums, sketches, deduplication
SipHash	64 bits	Yes, with a secret 128-bit key	Moderate	Hash tables exposed to untrusted keys
SHA-256, BLAKE2/BLAKE3	256 bits	Yes (cryptographic)	Slowest of these, still GB/s for BLAKE3	Content addressing, Merkle trees, integrity

Speeds are qualitative (as of 2025); benchmark on your hardware. This chapter's code uses BLAKE2b from Python's standard library for portability, not speed.

> RECOMMENDATION
>
> **Pick the hash by threat model, then by speed.** Untrusted keys in an in-memory table: SipHash or a bounded-worst-case structure. Keys from your own system (partitioning, sketches, filters): MurmurHash3 or xxHash. Integrity: a cryptographic hash. Never change a live system's partitioning hash without a migration plan.

17.3.3 Measuring uniformity

Mathematical foundations

Under a uniform hash, bucket counts are binomial, close to Poisson with mean n/B.

FORMULA

Expected bucket load and the chi-square uniformity test

$$\mu = \frac{n}{B}, \qquad \sigma \approx \sqrt{\frac{n}{B}}, \qquad \chi^2 = \sum_{i=1}^{B} \frac{(c_i - \mu)^2}{\mu}, \qquad \mathbb{E}[\chi^2] \approx B - 1, \quad \mathrm{sd}(\chi^2) \approx \sqrt{2(B-1)}$$

Symbol	Meaning	Units
n	Number of keys hashed	keys
B	Number of buckets	buckets
μ	Expected keys per bucket	keys/bucket
σ	Standard deviation of a bucket's count under a uniform hash	keys/bucket
c_i	Observed number of keys in bucket i	keys
χ^2	Chi-square statistic: total squared deviation from uniform	dimensionless

WORKED EXAMPLE

Worked example — what "uniform" looks like for 100,000 keys in 1,024 buckets.

1. Mean load: $\mu = 100,000/1,024 = 97.7$ keys per bucket.
2. Spread: $\sigma \approx \sqrt{97.7} = 9.9$. About 95% of buckets should hold between $97.7 - 2 \times 9.9 = 78$ and $97.7 + 2 \times 9.9 = 118$ keys.
3. The fullest of 1,024 buckets is typically about 3.2 standard deviations above the mean: $97.7 + 3.2 \times 9.9 \approx 129$ keys.
4. The chi-square statistic for a uniform hash should be near $B - 1 = 1,023$, with standard deviation $\sqrt{2 \times 1,023} = 45$. Values above about $1,023 + 3 \times 45 = 1,158$ suggest non-uniformity.

Interpretation. Even a perfect hash leaves a 30% spread between emptiest and fullest bucket. *Engineering implication.* Provision partitions for the fullest one, not the average; the relative spread $1/\sqrt{\mu}$ is one reason systems use many virtual nodes per server (§14.8).

Code example

The program implements MurmurHash3 (x86, 32-bit) and compares it with a deliberately bad hash on 100,000 structured keys.

```
        def murmur3_32(data: bytes, seed: int = 0) -> int:
            """MurmurHash3 x86_32 (Appleby), pure Python. Returns an unsigned 32-bit
int."""
            c1, c2, mask = 0xCC9E2D51, 0x1B873593, 0xFFFFFFFF
            h = seed & mask
            n_blocks = len(data) // 4
            for i in range(n_blocks):                       # body: 4-byte little-endian
blocks
                k = int.from_bytes(data[4 * i:4 * i + 4], "little")
                k = (k * c1) & mask
                k = ((k << 15) | (k >> 17)) & mask          # rotl32(k, 15)
                k = (k * c2) & mask
                h ^= k
                h = ((h << 13) | (h >> 19)) & mask          # rotl32(h, 13)
                h = (h * 5 + 0xE6546B64) & mask
            tail, k = data[4 * n_blocks:], 0                # tail: remaining 1-3 bytes
            for i, byte in enumerate(tail):
                k |= byte << (8 * i)
            if tail:
                k = (k * c1) & mask
                k = ((k << 15) | (k >> 17)) & mask
                k = (k * c2) & mask
                h ^= k
            h ^= len(data)                                  # finalization ("fmix32")
            h ^= h >> 16
            h = (h * 0x85EBCA6B) & mask
            h ^= h >> 13
            h = (h * 0xC2B2AE35) & mask
            h ^= h >> 16
            return h

        def additive_hash(data: bytes) -> int:
            """A deliberately bad hash: sum of byte values."""
            return sum(data)

        def bucket_stats(hash_fn, keys, buckets):
            counts = [0] * buckets
            for key in keys:
                counts[hash_fn(key) % buckets] += 1
            expected = len(keys) / buckets
            chi2 = sum((c - expected) ** 2 / expected for c in counts)
            return max(counts), sum(1 for c in counts if c == 0), chi2

        print(f"murmur3_32('hello') = {murmur3_32(b'hello'):#010x}")   # reference:
0x248bfa47

        # 100,000 realistic, highly structured keys: "user:0" ... "user:99999"
        keys = [f"user:{i}".encode() for i in range(100_000)]
        B = 1024                                            # expected ~97.7 keys per
bucket
        for name, fn in [("additive", additive_hash), ("murmur3", murmur3_32)]:
            mx, empty, chi2 = bucket_stats(fn, keys, B)
            print(f"{name:9s} max bucket = {mx:6d}  empty buckets = {empty:4d}  chi-
square = {chi2:12.0f}")
```

Output (Python 3.13):

```
murmur3_32('hello') = 0x248bfa47
additive  max bucket =   5520  empty buckets =  888  chi-square =      3598840
murmur3   max bucket =    132  empty buckets =    0  chi-square =         1105
```

What to notice:

- The implementation matches the reference value `0x248bfa47` for `"hello"` (and matched the C library on further test strings).
- MurmurHash3's fullest bucket (132) is close to the predicted ~129, and its chi-square (1,105) is within two standard deviations of 1,023: statistically indistinguishable from uniform.
- The additive hash leaves 888 buckets empty: the byte sums of `user:NNNNN` take fewer than 150 distinct values (553–790), so one bucket holds 5,520 keys.
- With a power-of-two B, `mod` keeps only low bits, which is safe only for hashes that mix well into them.

17.3.4 Hash flooding and keyed hashes

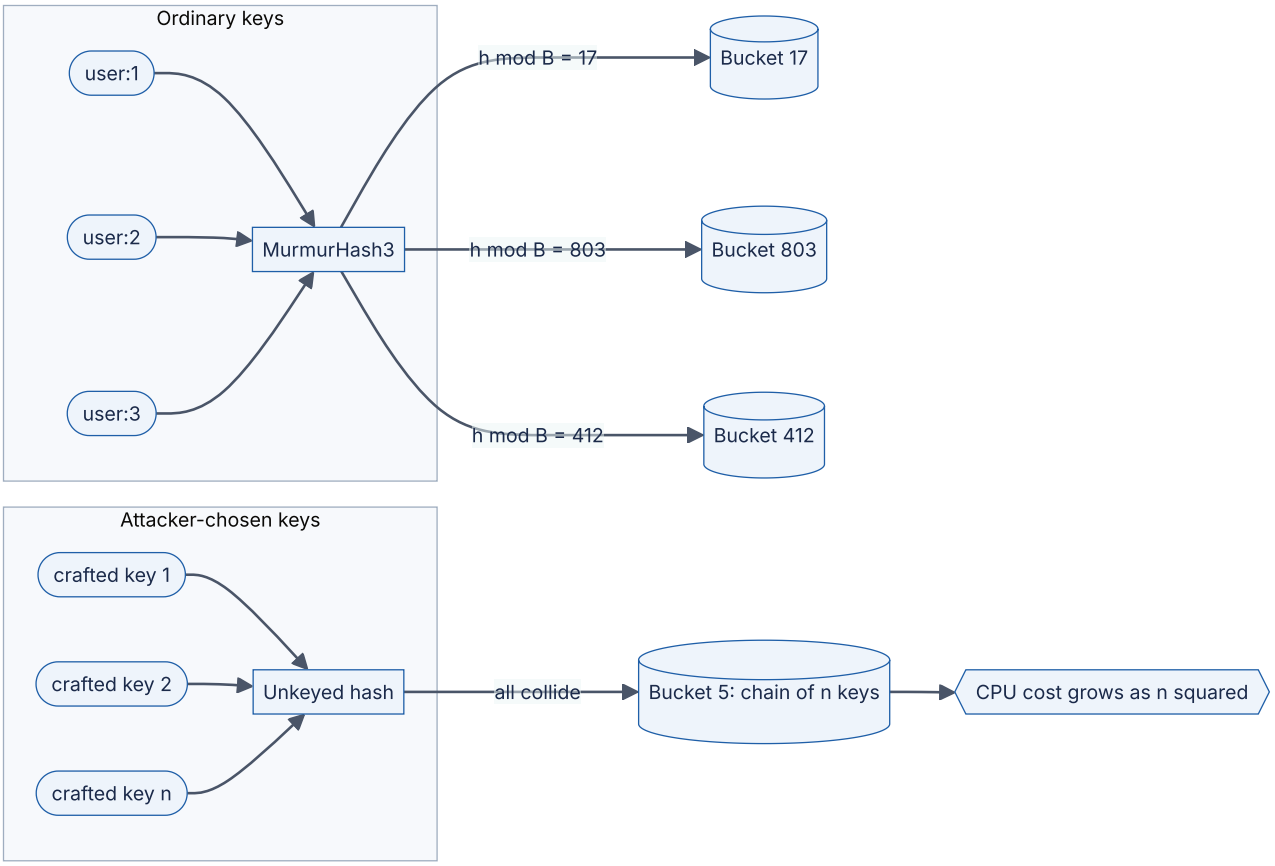
A chained hash table does $O(1)$ work per operation *on average*. If every key lands in one bucket, each insert walks a chain of all earlier keys, and inserting n keys costs $\sum_{i=1}^{n} i \approx n^2/2$ comparisons. Crosby and Wallach showed in 2003 that attackers can exploit this **algorithmic complexity attack** by sending inputs crafted to collide [Crosby & Wallach 2003]. In December 2011, Klink and Wälde demonstrated it against the hash tables that web frameworks in PHP, Java, Python, Ruby and ASP.NET used to store HTTP form parameters [Klink & Wälde 2011]. A single request with many colliding parameter names could occupy a CPU core for a long time. This is **hash flooding**.

> WORKED EXAMPLE
>
> **Worked example — the cost of 100,000 colliding keys.**
>
> 1. Uniform hash: about $100,000 \times 1 = 10^5$ bucket operations.
> 2. All keys colliding: about $n^2/2 = (10^5)^2/2 = 5 \times 10^9$ key comparisons.
> 3. At an optimistic 10^9 comparisons per second per core, that is 5 s of CPU for one request; at a more realistic 10^8 per second for string comparisons in an interpreted runtime, 50 s.
>
> *Interpretation.* One request of a few megabytes costs you seconds of CPU.
> *Engineering implication.* Any hash table filled from untrusted input needs a secret-keyed hash or a bounded worst case.

Three defenses are used in practice:

1. **Keyed hashes.** SipHash is a fast pseudorandom function keyed with a 128-bit secret chosen at process start, so attackers cannot predict collisions [Aumasson & Bernstein 2012]. Python uses it for `str` and `bytes` since 3.4 [PEP 456]; Rust's `HashMap` uses a SipHash variant. Consequence: Python's `hash()` differs between processes, so never use it for partitioning or persistence.
2. **Bounded worst case.** Since Java 8, `HashMap` turns long bucket chains into balanced trees, $O(\log n)$ per operation [JEP 180].
3. **Input limits.** Cap parameters, JSON keys and headers per request.

Figure 17.1 — Uniform hashing versus hash flooding.



Reading the diagram. Upper group: three structured keys pass through MurmurHash3 and, thanks to avalanche, land in unrelated buckets, so operations stay constant-time. Lower group: an attacker who knows an unkeyed hash precomputes keys that all map to bucket 5; every insert walks the whole chain and total work grows quadratically (the hexagon is the external effect, CPU exhaustion). Arrows are synchronous in-process calls; buckets are in-memory storage. The failure point is the hash function, not capacity, so adding servers does not help; the fixes are an unpredictable bucket choice (secret SipHash key) or bounded per-bucket cost (tree bins).

17.3.5 From hashes to partitions

With `hash mod N`, changing N moves almost every key (a key stays only if `h mod N` equals `h mod (N+1)`, about $1/(N+1)$ of keys). **Consistent hashing** places nodes and keys on a ring so a membership change moves only about $1/N$ of keys; jump and rendezvous hashing are alternatives. Chapter 14 owns this topic (§14.8; walk-through in §3.3.2). It assumes a uniform underlying hash.

Failure scenarios

Table 17.2 — Hash-function failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
One partition gets 5× the traffic of others	Weak hash on structured keys, or `mod` of a power of two keeping poorly mixed low bits	Per-partition request and size metrics; chi-square on a key sample	Re-hash with a better function (requires data migration)	Use MurmurHash3/xxHash; test with real key samples
CPU pinned by a few requests	Hash flooding of an unkeyed table	Profiling shows time inside hash-table insert; requests with thousands of parameters	Rate-limit offending clients; restart with patched runtime	Keyed hash (SipHash), tree bins, parameter-count limits
Keys "move" after a deploy	Language runtime's built-in `hash()` is randomized per process or changed between versions	Cache hit ratio collapses after a deploy; data written under one hash not found	Roll back; rebuild index	Use an explicitly specified, versioned hash for anything persisted or shared
Different services disagree on a key's partition	One service hashes UTF-8 bytes, another UTF-16, or seeds differ	Cross-service lookups miss	Fix encoding and seed; backfill	Specify encoding, algorithm, seed and byte order in the interface contract

Common misconceptions

> COMMON MISTAKE
>
> **"A 64-bit hash never collides, so I can use it as a unique ID."** By the birthday bound (§10.4.1), collisions among random 64-bit values become likely at about $2^{32} \approx 4.3$ billion items. A fingerprint is fine for sharding or deduplication hints, but anything that must be unique needs either a collision check or a much larger space (§17.10).

COMMON MISTAKE

"Cryptographic hashes are always better." They are slower and solve a different problem; for bucketing ordinary keys they are no more uniform than MurmurHash3. Use them where an adversary benefits from a collision.

17.4 Bloom filters and cuckoo filters

17.4.1 The membership problem

DEFINITION

Definition — Bloom filter. A probabilistic data structure for set membership, introduced by Burton Bloom in 1970, that stores a set of n items in an array of m bits using k hash functions [Bloom 1970]. A query answers either "definitely not in the set" or "probably in the set". It never gives a **false negative** (saying "no" for an item that was added), and gives a **false positive** (saying "yes" for an item that was not added) with a probability p that depends on m, n and k.

First-principles explanation

Picture a bouncer with a terrible memory but a stamp pad. Each guest who enters stamps three positions on a wall chart, chosen by the letters of their name. Asked "Was Alice here?", the bouncer checks Alice's three positions. If any is blank, she was certainly never here. If all are stamped, she was *probably* here, though other guests' stamps might happen to cover her positions. The chart is tiny, never forgets an entrant, and occasionally vouches for a stranger.

A Bloom filter is useful wherever "definitely not" lets you skip something expensive and an occasional "maybe" costs only a little wasted work.

Why does this exist?

Bloom's 1970 paper used a small in-memory filter so a hyphenation program could skip a disk-resident dictionary for most words [Bloom 1970]. The same shape recurs at scale:

- An LSM-tree database (§13.8) keeps many immutable files; a per-file filter in memory says "not in this file" for most of them.
- A crawler must not refetch any of billions of URLs; an exact URL set would take hundreds of gigabytes.
- A CDN should not write an object to disk on its first request, because most objects are never requested again.

In each case the filter turns most memory- or I/O-heavy exact lookups into a check of a few bits.

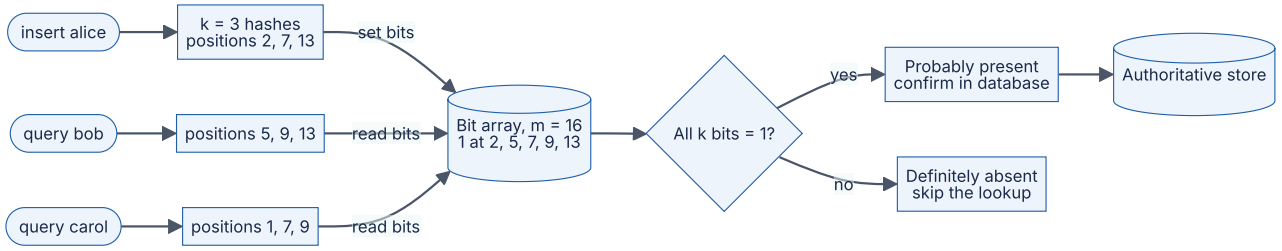
17.4.2 How it works internally

1. **Create** an array of m bits, all 0, and choose k independent hash functions $h_1, \ldots, h_k$, each mapping an item to a position in $[0, m)$.
2. **Insert** item x: compute $h_1(x), \ldots, h_k(x)$ and set those k bits to 1. Bits already set stay set.
3. **Query** item y: compute the same k positions. If any bit is 0, answer "definitely not present". If all are 1, answer "probably present".
4. **Never delete** by clearing bits: a bit may belong to several items, so clearing it creates false negatives (§17.4.6 covers deletable variants).

You do not need k unrelated hash functions: two hashes combined as $g_i(x) = h_a(x) + i \cdot h_b(x) \mod m$ give the same asymptotic false-positive rate [Kirsch & Mitzenmacher 2006], so one 128-bit hash split in two suffices. Filters with identical m, k and hashes merge by bitwise OR into a filter of the **union**.

Architecture diagram

Figure 17.2 — Inserting and querying a Bloom filter with k = 3.



Reading the diagram. Inserting `alice` sets bits 2, 7 and 13; an earlier insert set 5 and 9. A query for `bob` hits 5, 9 and 13, all set, so the filter says "probably present" although `bob` was never inserted: a false positive whose only cost is an unnecessary check against the authoritative store. A query for `carol` hits bit 1, which is 0, so the expensive lookup is skipped. All arrows are synchronous in-memory operations costing nanoseconds; the only I/O is the confirmation. Losing the filter never harms correctness (rebuild it from the data); undersizing it makes "maybe" frequent and erases the savings. Scale it by partitioning alongside the data it summarizes, one filter per file or shard.

17.4.3 Mathematical foundations

After inserting n items with k hashes into m bits, the probability that a particular bit is still 0 is $(1 - 1/m)^{kn} \approx e^{-kn/m}$, because each of the kn bit-settings misses that bit with probability $1 - 1/m$. A false positive needs all k positions of a new item to be 1. Treating the posi-

tions as independent gives the standard approximation [Bloom 1970; Broder & Mitzenmacher 2004].

FORMULA

Bloom filter false-positive rate

$$p \approx (1 - e^{-kn/m})^k$$

Symbol	Meaning	Units
p	Probability that a query for an item not in the set returns "probably present"	probability (0–1)
n	Number of items inserted	items
m	Size of the bit array	bits
k	Number of hash functions (bit positions per item)	count
$e^{-kn/m}$	Approximate fraction of bits still 0	fraction

WORKED EXAMPLE

Worked example — predicting the false-positive rate. You allocate $m = 10,000,000$ bits (1.25 MB) for $n = 1,000,000$ items with $k = 7$.

1. Exponent: $kn/m = 7 \times 10^6 / 10^7 = 0.7$.
2. Fraction of bits still 0: $e^{-0.7} = 0.4966$. So $1 - 0.4966 = 0.5034$ of the bits are 1, which is about half.
3. False-positive rate: 0.5034^7. Take logs: $7 \times \ln 0.5034 = 7 \times (-0.6864) = -4.805$; $e^{-4.805} = 0.0082$.

Interpretation. 82 in 10,000 absent-item queries return "maybe". *Engineering implication.* At 10,000 absent-key queries per second, each "maybe" costing a 10 ms disk read, the filter turns 10,000 disk reads per second into 82 for 1.25 MB of memory.

More hashes check more bits per query (lowering p) but set more bits per insert (raising it). Minimizing p over k gives:

FORMULA

Optimal number of hash functions

$$k^* = \frac{m}{n} \ln 2 \approx 0.693 \frac{m}{n}, \qquad p|_{k = k^*} = \left(\frac{1}{2}\right)^{k^*}$$

Symbol	Meaning	Units
k^*	Number of hash functions that minimizes p (round to an integer)	count
m/n	Bits per element	bits/item
$\ln 2$	Natural logarithm of 2, ≈ 0.693	dimensionless

WORKED EXAMPLE

Worked example — choosing k. With $m/n = 10$ bits per element: $k^* = 10 \times 0.693 = 6.93$, so use $k = 7$. At the optimum, exactly half of the bits are 1 ($e^{-k^* n/m} = e^{-\ln 2} = 1/2$) and $p = 0.5^{6.93} = 0.0082$, matching the previous example.

Interpretation. At the optimum the array is half full. *Engineering implication.* The fraction of 1 bits is a cheap health metric: alert when it passes about 0.5.

Usually you start from a tolerable p and solve for memory:

FORMULA

Bits per element for a target false-positive rate

$$\frac{m}{n} = \frac{-\ln p}{(\ln 2)^2} \approx 1.44 \log_2 \frac{1}{p}, \qquad k = -\log_2 p$$

Symbol	Meaning	Units
m/n	Bits of filter needed per inserted item	bits/item
p	Target false-positive rate	probability
$(\ln 2)^2$	≈ 0.4805	dimensionless
k	Matching number of hash functions (rounded)	count

WORKED EXAMPLE

Worked example — a username-availability filter for 1 billion accounts. You want “is this username taken?” answered in memory with a 1% false-positive rate.

1. Bits per element: $-\ln 0.01/0.4805 = 4.605/0.4805 = 9.585$ bits.
2. Total: 9.585×10^9 bits $= 1.198 \times 10^9$ bytes ≈ 1.2 GB (decimal).
3. Hash functions: $k = -\log_2 0.01 = 6.64$, so 7.
4. For 0.1%: $-\ln 0.001/0.4805 = 6.908/0.4805 = 14.38$ bits per element, 1.8 GB, $k = 10$.
5. Compare with an exact set: 1 billion usernames averaging 12 bytes, plus about 40 bytes of hash-table and object overhead each, is roughly 52×10^9 bytes = 52 GB.

Interpretation. Each 10× reduction in p costs a fixed $\ln 10/(\ln 2)^2 = 4.79$ extra bits per element, whatever the item size. *Engineering implication.* The filter fits in one server’s memory (or on every API node), where the exact set needs a cluster. “Taken” answers are confirmed against the database; “free” answers are always correct, and those are the ones that must be fast while the user types.

Table 17.3 — Bloom filter sizing at the optimal k.

Target p	Bits per element	Hash functions k	Memory for 10^9 items
10%	4.79	3	0.60 GB
1%	9.59	7	1.20 GB
0.1%	14.38	10	1.80 GB
0.01%	19.17	13	2.40 GB
0.001%	23.96	17	3.00 GB

The approximation assumes independent bit positions; it slightly underestimates the true rate for small filters [Bose et al. 2008], negligibly at millions of bits.

17.4.4 Implementation and measured validation

```
        import hashlib
        import math

        class BloomFilter:
            """Standard Bloom filter using Kirsch-Mitzenmacher double hashing."""

            def __init__(self, n_expected: int, fp_target: float):
                # m = -n ln p / (ln 2)^2 ; k = (m / n) ln 2
                self.m = math.ceil(-n_expected * math.log(fp_target) / math.log(2) ** 2)
                self.k = max(1, round(self.m / n_expected * math.log(2)))
                self.bits = bytearray((self.m + 7) // 8)

            def _positions(self, item: str):
                digest = hashlib.blake2b(item.encode(), digest_size=16).digest()
                h1 = int.from_bytes(digest[:8], "little")
                h2 = int.from_bytes(digest[8:], "little") | 1     # odd, so it never
sticks at h1
                return [(h1 + i * h2) % self.m for i in range(self.k)]

            def add(self, item: str) -> None:
                for pos in self._positions(item):
                    self.bits[pos >> 3] |= 1 << (pos & 7)

            def __contains__(self, item: str) -> bool:
                return all(self.bits[pos >> 3] & (1 << (pos & 7)) for pos in
self._positions(item))

        def predicted_fp(m: int, n: int, k: int) -> float:
            return (1 - math.exp(-k * n / m)) ** k

        n, probes = 100_000, 1_000_000
        print(f"{'target p':>9} {'m (bits)':>10} {'bits/item':>9} {'k':>3}
{'predicted':>10} {'measured':>10}")
        for target in (0.05, 0.01, 0.001):
            bf = BloomFilter(n, target)
            for i in range(n):
                bf.add(f"member-{i}")
            assert all(f"member-{i}" in bf for i in range(n))    # no false negatives,
ever
            fps = sum(f"stranger-{i}" in bf for i in range(probes))
            print(f"{target:9.3f} {bf.m:10d} {bf.m / n:9.2f} {bf.k:3d} "
                  f"{predicted_fp(bf.m, n, bf.k):10.5f} {fps / probes:10.5f}")

        # What happens if you insert 3x more items than the filter was sized for?
        bf = BloomFilter(n, 0.01)
        for i in range(3 * n):
            bf.add(f"member-{i}")
        fps = sum(f"stranger-{i}" in bf for i in range(probes))
        print(f"overfilled 3x: predicted {predicted_fp(bf.m, 3 * n, bf.k):.4f}, measured
{fps / probes:.4f}")
```

Output:

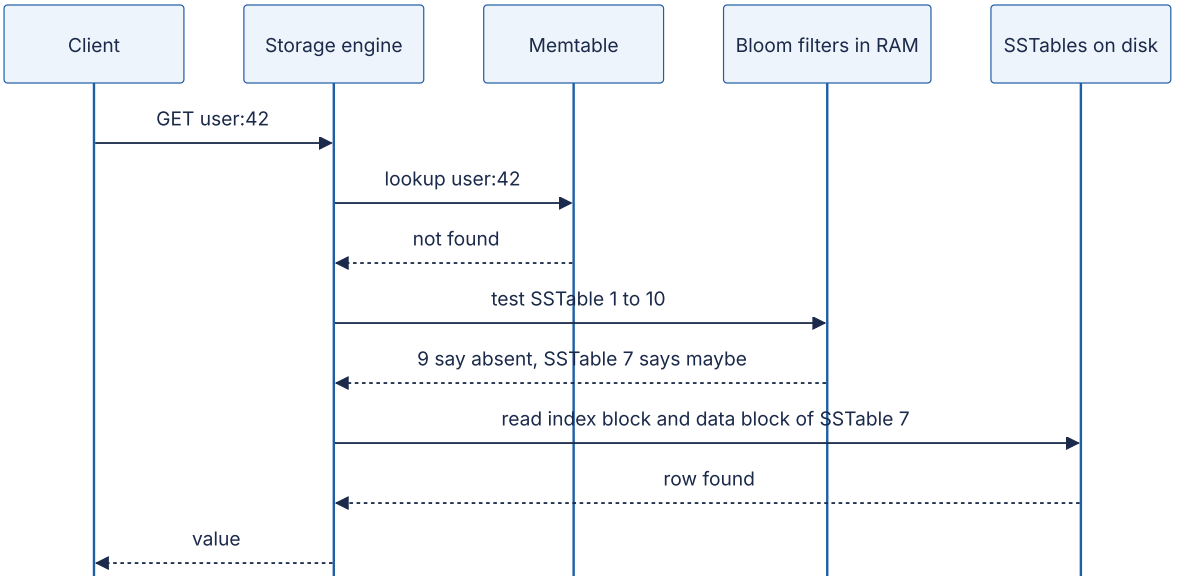
```
 target p   m (bits) bits/item   k  predicted   measured
    0.050     623523      6.24   4    0.05027    0.05044
    0.010     958506      9.59   7    0.01004    0.01018
    0.001    1437759     14.38  10    0.00100    0.00098
overfilled 3x: predicted 0.4360, measured 0.4376
```

What to notice:

- The sizing rule reproduces Table 17.3: 9.59 bits and $k = 7$ for 1%, 14.38 bits and $k = 10$ for 0.1%.
- Measured rates match predictions within sampling noise: with 10^6 probes at $p = 0.001$ you expect $1,000 \pm 32$ false positives, and 980 is inside that. (A 200,000-probe run measured 0.00117, 2.4 standard deviations high; use enough probes to resolve the rate.)
- The `assert` confirms the defining guarantee: every inserted item is found.
- Overfilling is the most common real failure: 3× the design load gives 44% false positives. Size for peak n or rebuild as n grows.

17.4.5 Bloom filters in system architecture

Figure 17.3 — Bloom filters on the read path of an LSM-tree storage engine.



Reading the diagram. After a memtable miss (§13.8), the engine would otherwise search every SSTable on disk. Instead it tests the key against each SSTable's RAM-resident filter (well under a microsecond each); nine say "absent" and are never touched, and only SSTable 7 costs disk reads. All calls are synchronous; the storage boundary separates RAM (memtable, filters) from disk (SSTables). For a missing key, ten files at $p = 1\%$ waste $10 \times 0.01 = 0.1$ reads instead of 10. Failure points: filters evicted from memory turn lookups back into disk reads, and range scans cannot use point filters (prefix Bloom filters

help within a known prefix). Scaling is automatic: each new SSTable carries its own filter. §13.10 covers the storage-engine side.

INDUSTRY EXAMPLE

Google Bigtable and Apache Cassandra. Bigtable lets clients enable Bloom filters per locality group so that most lookups for non-existent rows or columns never touch disk [Chang et al. 2006]. Cassandra keeps a Bloom filter per SSTable, tuned by the table option `bloom_filter_fp_chance` [Apache Cassandra Docs]. *Evidence: Primary* — [Chang et al. 2006; Apache Cassandra Docs]

INDUSTRY EXAMPLE

Akamai's "one-hit wonders". Akamai engineers reported that a large share of objects requested from their CDN servers are requested only once, so caching on first request wastes disk bandwidth and evicts useful content. Their servers record first requests in a Bloom filter and cache an object only on its second request [Maggs & Sitaraman 2015]. *Evidence: Primary* — [Maggs & Sitaraman 2015]

17.4.6 Counting Bloom filters

A **counting Bloom filter** replaces each bit with a small counter, typically 4 bits [Fan et al. 2000]. Insert increments the k counters, delete decrements them, and a query checks that all are non-zero, so the false-positive rate equals that of a bit filter with the same m and k. Costs: 4× the memory; counter overflow, which is astronomically unlikely with optimal k and 4-bit counters [Fan et al. 2000; Broder & Mitzenmacher 2004]; and false negatives if you delete an item that was never inserted. Fan and colleagues introduced it for the **Summary Cache** protocol, in which web proxies exchanged compact, constantly changing summaries of their cache contents.

17.4.7 Cuckoo filters

A **cuckoo filter** supports deletion with less memory than a counting Bloom filter and, at low false-positive rates, less than a plain Bloom filter [Fan et al. 2014].

DEFINITION

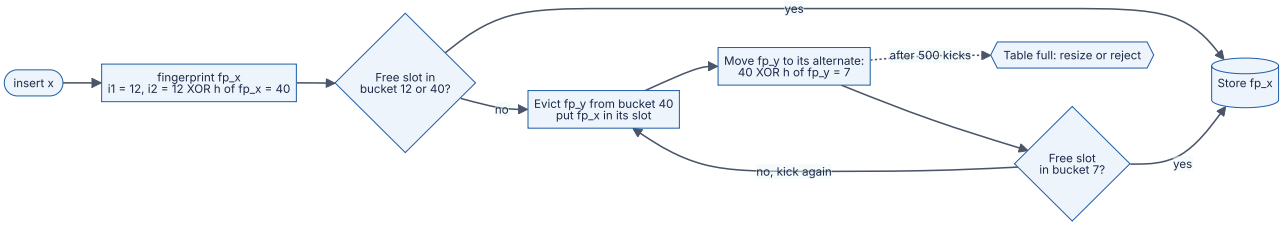
Definition — Cuckoo filter. A hash table of b-slot buckets that stores a short **fingerprint** of each item (an f-bit hash) in one of two candidate buckets. Membership checks two buckets for a matching fingerprint; deletion removes one copy of the fingerprint.

How it works internally

The name comes from the cuckoo bird, which lays its egg in another bird's nest and pushes an existing egg out.

1. For item x, compute a fingerprint $ = $ an f-bit hash of x, and the first bucket $i_1 = h(x) \mod B$.
2. Compute the alternate bucket $i_2 = i_1 \oplus h(fp)$. This is **partial-key cuckoo hashing**: because XOR is its own inverse, $i_1 = i_2 \oplus h(fp)$, so you can find an entry's other bucket from the fingerprint alone, without the original item.
3. **Insert**: if either bucket has a free slot, store fp there. Otherwise pick one of the two buckets, evict a random fingerprint from it, store fp in its place, and move the evicted fingerprint to *its* alternate bucket, repeating up to a limit (for example 500 kicks). If the limit is reached, the table is full.
4. **Lookup**: return true if either bucket contains fp.
5. **Delete**: remove one copy of fp from whichever bucket holds it.

Figure 17.4 — Inserting into a full cuckoo filter by relocation.



Reading the diagram. If either candidate bucket has room, the insert ends at once, the common case below about 90% load. Otherwise the filter displaces `fp_y` and moves it to its alternate bucket, computed from `fp_y` alone, repeating until a slot frees up. All steps are synchronous memory operations. Insert latency climbs as the table fills, and the dotted edge marks the failure point: after the kick limit the filter is full and must be rebuilt larger, since original items are not stored. Lookups and deletes always touch exactly two buckets.

Mathematical foundations

A lookup compares against up to $2b$ stored fingerprints, each matching by chance with probability 2^{-f}.

FORMULA

Cuckoo filter false-positive bound and space cost

$$\varepsilon \le \frac{2b}{2^f}, \qquad f \ge \log_2 \frac{2b}{\varepsilon}, \qquad \text{bits per item} = \frac{f}{\alpha} \approx \frac{\log_2(1/\varepsilon) + \log_2(2b)}{\alpha}$$

Symbol	Meaning	Units
ε	False-positive rate	probability
b	Slots per bucket (4 is the common choice)	slots
f	Fingerprint length	bits
α	Load factor reached before inserts fail (≈ 0.95 for $b = 4$)	fraction

WORKED EXAMPLE

Worked example — cuckoo versus Bloom at 1% and 0.1%. Take $b = 4$ and $\alpha = 0.95$, so $\log_2(2b) = 3$.

1. At $\varepsilon = 1\%$: $\log_2 100 = 6.64$; cuckoo needs $(6.64 + 3)/0.95 = 10.1$ bits per item. Bloom needs 9.59.
2. At $\varepsilon = 0.1\%$: $\log_2 1000 = 9.97$; cuckoo needs $(9.97 + 3)/0.95 = 13.7$ bits. Bloom needs 14.38.
3. Crossover: cuckoo wins when $1.44x > (x + 3)/0.95$, where $x = \log_2(1/\varepsilon)$, i.e. $1.37x > x + 3$, so $x > 8.1$ and $\varepsilon < 0.4\%$. Fan and colleagues' **semi-sorting** optimization saves one bit per item, which moves the crossover to about 3% [Fan et al. 2014].

Interpretation. Bloom filters pay 44% over the minimum $\log_2(1/\varepsilon)$; cuckoo filters pay 2–3 bits plus load-factor loss. *Engineering implication.* For low rates or deletion, prefer a cuckoo filter; for rates of 3% or more on append-only sets, a Bloom filter is smaller, simpler, and degrades gracefully when overfilled instead of refusing inserts.

Code example

```
        import hashlib
        import random

        class CuckooFilter:
            """Cuckoo filter (Fan et al. 2014): b slots per bucket, f-bit fingerprints,
            partial-key cuckoo hashing. Supports delete. num_buckets must be a power of
two."""

            def __init__(self, num_buckets: int, bucket_size: int = 4, fp_bits: int = 8,
max_kicks: int = 500):
                assert num_buckets & (num_buckets - 1) == 0
                self.nb, self.b, self.f, self.max_kicks = num_buckets, bucket_size,
fp_bits, max_kicks
                self.buckets = [[] for _ in range(num_buckets)]
                self.count = 0
                self.victim = None          # (bucket, fp) left homeless by a failed in-
sert
                self.rng = random.Random(7)

            def _hash(self, data: bytes) -> int:
                return int.from_bytes(hashlib.blake2b(data, digest_size=8).digest(),
"little")

            def _fingerprint_and_index(self, item: str):
                h = self._hash(item.encode())
                fp = (h >> 32) & ((1 << self.f) - 1) or 1       # fingerprint 0 is re-
served for "empty"
                return fp, (h & 0xFFFFFFFF) % self.nb

            def _alt_index(self, index: int, fp: int) -> int:
                # i2 = i1 XOR hash(fp): applying it twice returns the original bucket
                return (index ^ self._hash(fp.to_bytes(4, "little"))) % self.nb

            def add(self, item: str) -> bool:
                if self.victim is not None:
                    return False                                 # full: refuse further
inserts
                fp, i1 = self._fingerprint_and_index(item)
                i2 = self._alt_index(i1, fp)
                for i in (i1, i2):
                    if len(self.buckets[i]) < self.b:
                        self.buckets[i].append(fp)
                        self.count += 1
                        return True
                i = self.rng.choice((i1, i2))                    # both full: evict
("kick") a victim
                for _ in range(self.max_kicks):
                    j = self.rng.randrange(self.b)
                    fp, self.buckets[i][j] = self.buckets[i][j], fp
                    i = self._alt_index(i, fp)
                    if len(self.buckets[i]) < self.b:
                        self.buckets[i].append(fp)
                        self.count += 1
                        return True
```

```
                self.victim = (i, fp)                                   # keep the homeless
fingerprint
                self.count += 1                                         # so nothing is ever
lost
                return False

            def __contains__(self, item: str) -> bool:
                fp, i1 = self._fingerprint_and_index(item)
                i2 = self._alt_index(i1, fp)
                if self.victim is not None and self.victim[1] == fp and self.victim[0]
in (i1, i2):
                    return True
                return fp in self.buckets[i1] or fp in self.buckets[i2]

            def delete(self, item: str) -> bool:
                fp, i1 = self._fingerprint_and_index(item)
                i2 = self._alt_index(i1, fp)
                if self.victim is not None and self.victim[1] == fp and self.victim[0]
in (i1, i2):
                    self.victim = None
                    self.count -= 1
                    return True
                for i in (i1, i2):
                    if fp in self.buckets[i]:
                        self.buckets[i].remove(fp)
                        self.count -= 1
                        return True
                return False

        cf = CuckooFilter(num_buckets=2 ** 15, bucket_size=4, fp_bits=8)   # 131,072
slots
        capacity = cf.nb * cf.b
        inserted = 0
        while cf.add(f"member-{inserted}"):
            inserted += 1
        inserted += 1                                                   # the failed item is
held as the victim
        print(f"filter full at load factor {inserted / capacity:.3f}")
        assert all(f"member-{i}" in cf for i in range(inserted))  # no false negatives

        probes = 500_000
        fps = sum(f"stranger-{i}" in cf for i in range(probes))
        bound = 2 * cf.b / 2 ** cf.f
        print(f"false-positive rate: measured {fps / probes:.4f}, bound 2b/2^f =
{bound:.4f}")
        print(f"bits per stored item: {cf.f * capacity / inserted:.2f}")

        for i in range(0, inserted, 2):                                 # delete every second
member
            assert cf.delete(f"member-{i}")
        still_there = all(f"member-{i}" in cf for i in range(1, inserted, 2))
        print(f"after deleting half: count = {cf.count}, all survivors found =
{still_there}")
```

Output:

```
filter full at load factor 0.963
false-positive rate: measured 0.0298, bound 2b/2^f = 0.0312
bits per stored item: 8.30
after deleting half: count = 63135, all survivors found = True
```

What to notice:

- With $b = 4$ the table reached 96.3% load before the first failure, consistent with Fan and colleagues' ~95%.
- The measured rate (2.98%) sits under the bound $8/256 = 3.1\%$, which assumes every slot is full.
- Deletion works, but deleting a never-inserted item could remove another item's matching fingerprint; delete only known members.
- The `victim` slot, as in the reference implementation, keeps the last displaced fingerprint so a failed insert never causes a false negative.

Alternatives and trade-offs

Table 17.4 — Approximate membership filters compared.

	Bloom	Counting Bloom	Cuckoo	Static filters (XOR, ribbon)
What it is	Bit array, *k* hashes	Bloom with 4-bit counters	Fingerprints in 2 candidate buckets	Fingerprints placed by solving equations over a fixed set
Delete	No	Yes (only items present)	Yes (only items present)	No; rebuild
Bits per item at 1%	9.6	~38	~10 (~9 with semi-sorting)	~8–9.8
Lookup memory accesses	*k* (scattered)	*k*	2 buckets	~3
Behavior when overfilled	Degrades smoothly (*p* rises)	Degrades; counters may overflow	Inserts fail	Must know the set in advance
Union of two filters	Bitwise OR	Add counters	Not directly	Not directly
Choose when	Append-only sets, simplicity, mergeability	Deletion with modest memory pressure	Deletion; low *p*	Immutable sets, e.g. per-file filters

XOR filters [Graf & Lemire 2020] and RocksDB's ribbon filters are built once for a known set, which suits immutable per-file filters. Quotient filters are another fingerprint design supporting deletes and merges.

Failure scenarios

Table 17.5 — Bloom and cuckoo filter failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
False-positive rate far above target	More items inserted than the filter was sized for	Fraction of 1 bits > 0.5; measured "maybe then not found" ratio	Rebuild a larger filter from the source data	Size for peak n with headroom; scalable (layered) filters that add a new filter when one fills
False negatives appear	Bits cleared on delete, or counting-filter delete of a non-member	Items known to exist are reported absent	Rebuild from source	Never clear bits; delete only confirmed members
Disk reads spike after restart or memory pressure	Filters evicted from RAM or not yet loaded	Block-cache misses; read latency up	Pin filter blocks in memory	Budget filter memory explicitly (≈ 1.2 bytes/key at 1%)
Union gives garbage	Filters built with different m, k or hash seeds were OR-ed	Union reports nearly everything present	Rebuild with shared parameters	Version the parameters with the filter
Cuckoo insert fails in production	Table reached ~95% load	Insert error rate > 0	Allocate a larger filter and re-insert	Monitor load factor; resize at 80–90%

Common misconceptions

COMMON MISTAKE

"A Bloom filter tells me an item is in the set." Only *probably*; the useful answer is the negative one. Acting on a positive without confirmation means being wrong p of the time.

COMMON MISTAKE

"Bigger items need bigger filters." Filter size depends only on the number of items and the target false-positive rate, not on item size. A 2 KB URL and an 8-byte integer each cost 9.6 bits at 1%.

17.5 HyperLogLog

17.5.1 Counting distinct items from leading zeros

DEFINITION

Definition — HyperLogLog (HLL). A probabilistic algorithm that estimates the number of distinct items (the **cardinality**) in a multiset using m small registers, with relative standard error about $1.04/\sqrt{m}$, independent of the cardinality itself [Flajolet et al. 2007].

First-principles explanation

A friend flips coins in sessions and reports only the longest opening run of heads. Five heads in a row has probability $1/32$, so they probably ran about 32 sessions; twenty heads suggests about a million.

Read each item's hash as coin flips. The chance that its first 1-bit is at position r or later is $2^{-(r-1)}$, so if the largest such position over all items is R, there were about 2^R *distinct* items; duplicates hash identically and cannot raise the maximum. One maximum is very noisy, so HLL keeps many and averages them.

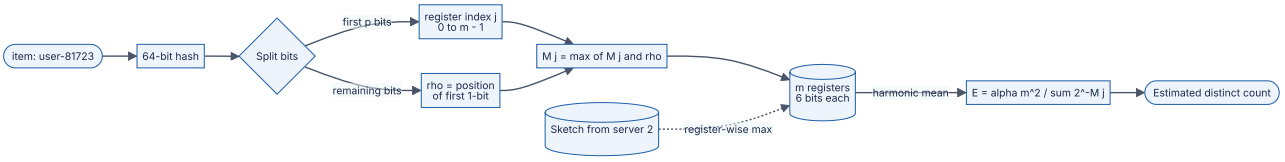
Why does this exist?

Exact distinct counting needs memory proportional to the distinct items: 1 billion 8-byte user IDs is at least 8 GB, per page, per day, per country. Summing per-server distinct counts double-counts users seen by two servers; HLL sketches merge without double counting.

How it works internally

1. Choose precision p; allocate $m = 2^p$ registers, all 0.
2. For each item, compute a 64-bit hash. The first p bits choose register j. In the remaining $64 - p$ bits, find ρ, the position of the leftmost 1-bit (1 if the first bit is 1).
3. Set $M[j] = \max(M[j], \rho)$.
4. Estimate with a bias-corrected **harmonic mean** of $2^{M[j]}$, which damps a few unusually large registers.
5. For small cardinalities, when many registers are still 0, switch to **linear counting**: $m \ln(m/V)$, where V is the number of zero registers.
6. **Merge** sketches by register-wise maximum, which equals the sketch of the combined stream.

Figure 17.5 — The HyperLogLog update and estimate path.



Reading the diagram. Each item is hashed once; the leading p bits pick a register and the first-1-bit position of the rest is the observation, kept only if it exceeds the register's maximum, so memory never grows. Updates are synchronous constant-time memory operations. The dotted edge is the asynchronous merge path: sketches from other servers or hours combine by register-wise max in a batch or query layer, with the same accuracy as one sketch. Failure points: a poor hash breaks the coin-flip assumption, and merging

sketches with different hashes or precisions gives nonsense. Scale by sharding the stream freely and merging later.

Mathematical foundations

FORMULA

HyperLogLog estimate and standard error

$$E = \alpha_m m^2 \left(\sum_{j=1}^{m} 2^{-M[j]} \right)^{-1}, \qquad \alpha_m \approx \frac{0.7213}{1 + 1.079/m}, \qquad \text{SE} \approx \frac{1.04}{\sqrt{m}}, \qquad \text{memory} = m \times 6 \text{ bits}$$

Symbol	Meaning	Units
E	Estimated number of distinct items	items
m	Number of registers, $m = 2^p$	registers
$M[j]$	Value of register j: the largest first-1-bit position seen	count
α_m	Bias-correction constant (valid for $m \geq 128$)	dimensionless
SE	Relative standard error of E	fraction
6 bits	Register width: enough to hold values up to 63, sufficient for a 64-bit hash	bits

WORKED EXAMPLE

Worked example — Redis's HyperLogLog. Redis uses $p = 14$.

1. Registers: $m = 2^{14} = 16,384$.
2. Standard error: $1.04/\sqrt{16,384} = 1.04/128 = 0.0081$, i.e. 0.81%.
3. Memory: $16,384 \times 6 = 98,304$ bits $= 12,288$ bytes $= 12$ KiB.
4. For 1 billion distinct users, one standard error is ±8.1 million, and about 95% of estimates fall within two standard errors, ±16.3 million.
5. An exact set of 1 billion 8-byte IDs needs at least 8 GB, about 650,000 times more memory.
6. Daily uniques for 1 million pages: about 12.3 GB dense, far less with the **sparse representation** most small sketches use.

Interpretation. Accuracy depends only on m; quadrupling memory halves the error ($p = 16$: 48 KiB, 0.41%). *Engineering implication.* 0.81% is invisible on dashboards; billing needs exact counts.

HyperLogLog++ [Heule et al. 2013], used by most production systems, adds a 64-bit hash (removing the large-range correction of the 32-bit original), empirical bias correction below about $5m$, and a sparse, higher-precision representation for small sets.

Code example

```
        import hashlib
        import math

        class HyperLogLog:
            """HyperLogLog (Flajolet et al. 2007) with 2^p registers and a 64-bit hash.
            Includes the linear-counting correction for small cardinalities."""

            def __init__(self, p: int = 14, salt: bytes = b""):
                self.p, self.m = p, 1 << p
                self.registers = bytearray(self.m)
                self.salt = salt
                self.alpha = 0.7213 / (1 + 1.079 / self.m)        # bias constant for m
>= 128

            def add(self, item: str) -> None:
                x = int.from_bytes(hashlib.blake2b(item.encode(), digest_size=8,
salt=self.salt).digest(), "big")
                j = x >> (64 - self.p)                            # first p bits choose
the register
                w = x & ((1 << (64 - self.p)) - 1)                # remaining 64 - p
bits
                rank = (64 - self.p) - w.bit_length() + 1         # position of the
leftmost 1-bit
                if rank > self.registers[j]:
                    self.registers[j] = rank

            def count(self) -> float:
                z = sum(2.0 ** -r for r in self.registers)
                estimate = self.alpha * self.m * self.m / z       # normalized harmonic
mean
                zeros = self.registers.count(0)
                if estimate <= 2.5 * self.m and zeros:            # small range: linear
counting
                    estimate = self.m * math.log(self.m / zeros)
                return estimate

            def merge(self, other: "HyperLogLog") -> None:
                self.registers = bytearray(max(a, b) for a, b in zip(self.registers,
other.registers))

        n, trials = 100_000, 50
        print(f"{'p':>3} {'registers':>9} {'memory':>9} {'predicted SE':>12} {'measured
RMS err':>16}")
        for p in (10, 12, 14):
            errors = []
            for t in range(trials):
                h = HyperLogLog(p, salt=t.to_bytes(4, "little"))
                for i in range(n):
                    h.add(f"user-{i}")
                errors.append((h.count() - n) / n)
            rms = math.sqrt(sum(e * e for e in errors) / trials)
            mem = h.m * 6 / 8                                     # 6-bit registers, as
in Redis
            print(f"{p:3d} {h.m:9d} {mem:7.0f} B {1.04 / math.sqrt(h.m):12.4f}
```

```
{rms:16.4f}")

        # Mergeability: two days of visitors with 50,000 in common
        day1, day2 = HyperLogLog(14), HyperLogLog(14)
        for i in range(0, 150_000):
            day1.add(f"user-{i}")
        for i in range(100_000, 250_000):
            day2.add(f"user-{i}")
        day1.merge(day2)
        print(f"union estimate {day1.count():,.0f} (true 250,000)")
```

Output:

```
  p registers    memory predicted SE measured RMS err
 10      1024     768 B       0.0325           0.0383
 12      4096    3072 B       0.0163           0.0162
 14     16384   12288 B       0.0081           0.0073
union estimate 248,111 (true 250,000)
```

What to notice:

- Each trial uses a different salt (an independent hash), so the RMS error over trials estimates the standard error, itself uncertain by about ±10% with 50 trials. Rows $p = 12$ and 14 match; $p = 10$ is 18% high, and a 200-trial run at $n = 20,000$ measured 0.0330 against 0.0325.
- The sketch for 100,000 distinct users is 12 KB whether the stream has 100,000 events or 100 billion.
- The merged sketch estimates the two-day union at 248,111, an error of −0.76%, without double-counting the 50,000 users present on both days.
- `salt` is a keyed BLAKE2b parameter. Every sketch that you intend to merge must use the same hash and salt.

INDUSTRY EXAMPLE

Redis **`PFADD`, `PFCOUNT`, `PFMERGE`.** Redis stores an HLL as a string of 16,384 6-bit registers (12 KB) with a sparse encoding for small sets, and documents a 0.81% standard error [Redis Docs: HyperLogLog; Sanfilippo 2014]. A typical pattern is one key per page per day, merged with `PFMERGE` into weekly keys. Google BigQuery exposes HyperLogLog++ through `HLL_COUNT` functions so partial sketches can be stored and merged later [Google Cloud Docs: BigQuery HLL functions]. *Evidence: Primary* — [Redis Docs: HyperLogLog; Google Cloud Docs]

Failure scenarios and misconceptions

What goes wrong	Why	Detection	Recovery	Prevention
Intersection estimate is meaningless	Computed as $\|A\| + \|B\| - \|A \cup B\|$; errors scale with the large sets	Negative or wildly varying estimates	Use exact counts or MinHash-based estimates for intersections	Only rely on HLL for unions and single-set counts
Merged count is far too high	Sketches built with different hashes, salts or precisions	Union exceeds sum of parts	Rebuild from raw data	Version the hash and p with the sketch
Small counts are biased	Raw estimator range below ~$5m$	Systematic error in tests with known small sets	Use HLL++ bias correction or linear counting	Use a library that implements HLL++

COMMON MISTAKE

"HLL counts events." It counts *distinct* items; adding a user a million times changes nothing. For per-item frequencies use Count-Min (§17.6).

COMMON MISTAKE

"Intersections work like unions." With two 10-million-user sets overlapping by 100,000, each count's standard error at $p = 14$ is about 81,000, so the inclusion–exclusion estimate's error exceeds the intersection itself.

17.6 Count-Min sketch and heavy hitters

17.6.1 The Count-Min sketch

DEFINITION

Definition — Count-Min sketch. A $d \times w$ array of counters with one hash function per row that estimates the frequency of any item in a stream. Each update increments one counter per row; each query returns the minimum of the item's d counters. The estimate never underestimates and, with probability at least $1 - \delta$, overestimates by at most εN, where N is the total of all updates [Cormode & Muthukrishnan 2005].

First-principles explanation

Imagine counting votes on a few small tally sheets, each assigning every candidate to one shared box by a different rule. Every box overcounts, but a candidate's box-mates differ between sheets, so the least-inflated box, the minimum, is close to the truth. More boxes

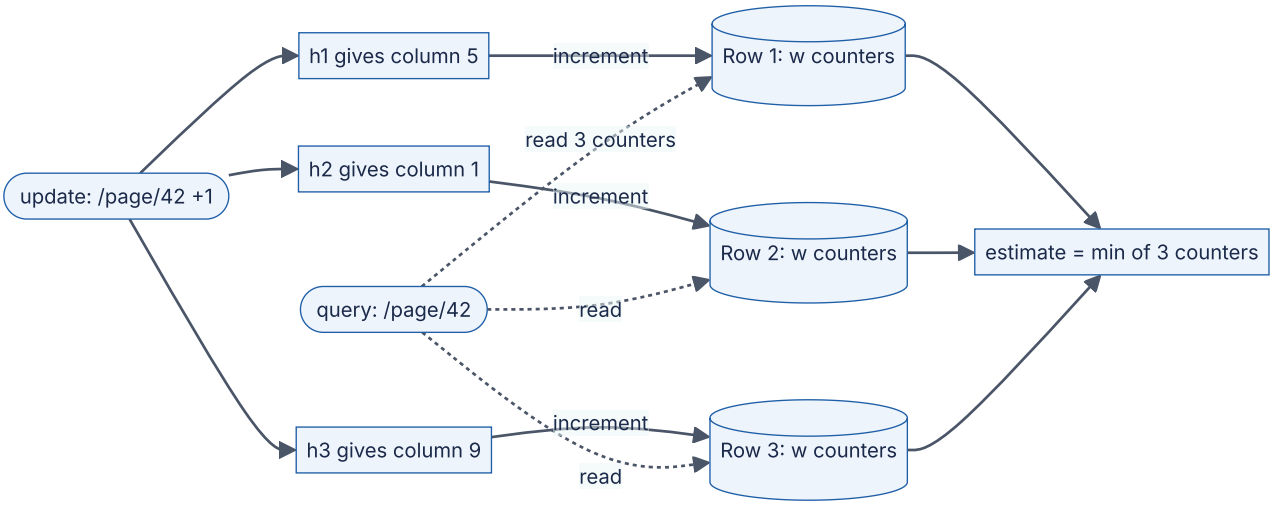
per sheet reduce inflation; more sheets reduce the chance that every box is badly inflated.

Why does this exist?

Per-item counts over millions of distinct keys (requests per IP, plays per song) need a hash map proportional to the key count, and attackers can create unbounded keys. The sketch has a fixed size, merges by adding arrays (same hashes) and carries a guaranteed bound.

Architecture diagram

Figure 17.6 — A Count-Min sketch with d = 3 rows.



Reading the diagram. An update increments one counter per row, *d* memory writes regardless of how many distinct items exist. A query (dotted, typically from a separate reader such as a rate limiter) reads the same *d* counters and returns the minimum; counters are shared storage cells, so estimates only err upward. Partitions keep their own sketches with identical hashes and a merger adds the arrays. Failure points: counter overflow (use 64-bit counters), merging sketches with different seeds, and error growing with *N* in a sketch that is never reset or decayed.

Mathematical foundations

FORMULA

Count-Min sizing and error bound

$$w = \lceil \frac{e}{\varepsilon} \rceil, \qquad d = \lceil \ln \frac{1}{\delta} \rceil, \qquad f_x \le \hat{f}_x \le f_x + \varepsilon N \text{ with probability } \ge 1 - \delta$$

Symbol	Meaning	Units
w	Counters per row (width)	counters
d	Rows, one hash function each (depth)	rows
ε	Error as a fraction of the stream total	fraction
δ	Probability that the error bound is exceeded for a given query	probability
N	Sum of all updates in the stream	events
f_x, $\hat{f}_x$	True and estimated count of item x	events
e	Euler's number, ≈ 2.718	dimensionless

WORKED EXAMPLE

Worked example — sizing a per-URL request counter. You want errors of at most 0.1% of traffic ($\varepsilon = 0.001$) with 99% confidence ($\delta = 0.01$).

1. Width: $w = \lceil 2.718/0.001 \rceil = 2,719$.
2. Depth: $d = \lceil \ln 100 \rceil = \lceil 4.605 \rceil = 5$.
3. Counters: $2,719 \times 5 = 13,595$; with 4-byte counters, 54.4 KB.
4. For a stream of $N = 10^6$ requests, each estimate is within $+1,000$ of the truth with probability 99%.
5. A day of $N = 10^{10}$ requests gives a bound of 10^7: a URL with 50,000 requests is lost in noise; one with 10^8 is within 10%.

Interpretation. The error is additive and proportional to the *whole stream*: accurate for heavy items, useless for rare ones. *Engineering implication.* Use it for heavy hitters, abusive-key rate limiting and frequency-based cache admission (TinyLFU, §20.9), and reset or decay it per window.

Conservative update increments only counters equal to the current minimum, reducing overestimation substantially while keeping the no-underestimate guarantee; such sketches no longer merge exactly by addition.

17.6.2 Heavy hitters and top-k

Heavy hitters exceed a frequency threshold (say 0.1% of traffic); **top-k** asks for the k most frequent items.

1. **Count-Min plus a min-heap.** After each update, if the item's estimate exceeds the heap minimum, replace that minimum. Memory: the sketch plus k entries.
2. **Space-Saving** [Metwally et al. 2005]. Keep k (item, count) counters. Increment a monitored item; otherwise take a free counter, or evict the smallest count $c_{\min}$ and give the newcomer $c_{\min} + 1$, an upper bound on its unseen occurrences.

FORMULA

Space-Saving guarantee

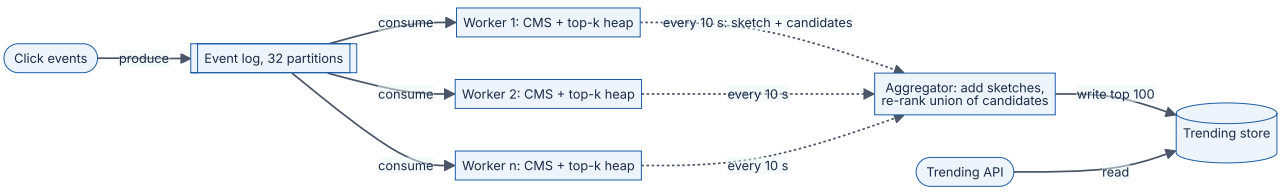
$$c_x - f_x \le c_{\min} \le \frac{N}{k}, \qquad f_x > \frac{N}{k} \Rightarrow x \text{ is monitored}$$

Symbol	Meaning	Units
k	Number of counters	counters
N	Stream length	events
c_x, f_x	Reported and true count of monitored item x	events
$c_{\min}$	Smallest counter value	events

WORKED EXAMPLE

Worked example — 100 counters over 1 million events. $N/k = 10^6/100 = 10,000$: every URL with over 10,000 requests (1% of traffic) is guaranteed monitored, and reported counts overestimate by at most 10,000. *Interpretation.* Error is relative to the stream; memory is k entries. *Engineering implication.* For a reliable top 10, monitor several times more than 10 counters so ranks 11–100 absorb churn.

Figure 17.7 — A distributed top-k pipeline.



Reading the diagram. Workers consume partitions of the event log (Chapter 30), each keeping a local Count-Min sketch and candidate heap. Every 10 seconds they ship sketches and candidates asynchronously (dotted) to an aggregator, which adds the

sketches, re-estimates candidates and writes the global top 100 to a store the API reads synchronously. An item moderately frequent everywhere can miss every local top-k; ship more candidates (top 1,000 for a global top 100) or partition the log by item key. Failure points: slow workers delay windows (event-time windows with lateness bounds, §29.8), and the aggregator must restart from the log. Scale by adding workers and partitions.

Code example

```
        import hashlib
        import heapq
        import math
        import random
        from collections import Counter

        class CountMinSketch:
            """Count-Min sketch (Cormode & Muthukrishnan 2005): d rows x w counters."""

            def __init__(self, epsilon: float, delta: float):
                self.w = math.ceil(math.e / epsilon)              # width from accuracy
                self.d = math.ceil(math.log(1 / delta))           # depth from confi-
dence
                self.table = [[0] * self.w for _ in range(self.d)]
                self.total = 0

            def _columns(self, item: str):
                digest = hashlib.blake2b(item.encode(), digest_size=16).digest()
                h1 = int.from_bytes(digest[:8], "little")
                h2 = int.from_bytes(digest[8:], "little")
                return [(h1 + r * h2) % self.w for r in range(self.d)]

            def add(self, item: str, count: int = 1) -> None:
                self.total += count
                for row, col in enumerate(self._columns(item)):
                    self.table[row][col] += count

            def estimate(self, item: str) -> int:
                return min(self.table[row][col] for row, col in

        for item in stream:
            cms.add(item)
        N = cms.total
        errors = [cms.estimate(x) - c for x, c in truth.items()]
        assert min(errors) >= 0                                    # never underesti-
mates
        print(f"w = {cms.w}, d = {cms.d}, counters = {cms.w * cms.d:,} vs distinct items
= {len(truth):,}")
        print(f"error bound eps*N = {eps * N:,.0f}; max error = {max(errors)}; "
              f"mean error = {sum(errors) / len(errors):.1f}; "
              f"items over bound = {sum(e > eps * N for e in errors)} of {len(er-
rors):,} (delta allows {delta:.0%})")

        tk = TopK(10, eps, delta)
        for item in stream:
            tk.add(item)
        true_top = [i for i, _ in truth.most_common(10)]
        print("CMS+heap top-10 recall:", len(set(i for _, i in tk.top()) &
set(true_top)) / 10)
        ss = space_saving(stream, 100)
        print("Space-Saving (100 counters) top-10 recall:", len(set(i for _, i in
ss[:10]) & set(true_top)) / 10)
        print("true top-3:", truth.most_common(3))
        print("Space-Saving top-3:", [(i, c) for c, i in ss[:3]])
```

Output:

```
w = 2719, d = 5, counters = 13,595 vs distinct items = 64,589
error bound eps*N = 1,000; max error = 2474; mean error = 61.1; items over bound = 1 of
64,589 (delta allows 1%)
CMS+heap top-10 recall: 1.0
Space-Saving (100 counters) top-10 recall: 1.0
true top-3: [('/page/1', 134738), ('/page/2', 63178), ('/page/3', 40195)]
Space-Saving top-3: [('/page/1', 134738), ('/page/2', 63178), ('/page/3', 40195)]
```

What to notice:

- Width 2,719 and depth 5 reproduce the worked example. The `assert` confirms that no estimate is below the truth.
- Only 1 of 64,589 items exceeded the $\varepsilon N = 1,000$ bound, far below the 1% that δ allows; the mean overestimate is 61.
- Both methods recover the true top 10 on this skewed (Zipf) stream, typical of real traffic; on a near-uniform stream there are no heavy hitters to find.
- Space-Saving's top three counts are exact because those items were never evicted. Production code uses a "stream-summary" structure for $O(1)$ eviction.

INDUSTRY EXAMPLE

Twitter Algebird and RedisBloom. Twitter's open-source Algebird library provides mergeable Count-Min sketches, HyperLogLog and Bloom filters for Hadoop, Scalding and Storm jobs: each partition builds a sketch and the framework adds them [Twitter: Algebird]. The RedisBloom module (in Redis Stack, and in Redis Open Source from Redis 8, as of 2025) provides `CMS.INCRBY` / `CMS.QUERY` and `TOPK.ADD` / `TOPK.LIST` [Redis Docs: Count-min sketch; Top-K]. *Evidence: Primary* — [Twitter: Algebird; Redis Docs]

COMMON MISTAKE

"Count-Min gives each item's count within ε percent." The bound is εN, a fraction of the *entire stream*; a rare item can be overestimated 100-fold. Report estimates only for items well above εN.

17.7 Skip lists

17.7.1 Probabilistic levels instead of rebalancing

DEFINITION

Definition — Skip list. An ordered linked list augmented with extra levels of "express" pointers. Each node is promoted to the next level with probability p (typically 1/2 or 1/4), so level i contains about a fraction p^i of the nodes. Search, insert and delete take expected $O(\log n)$ time [Pugh 1990].

First-principles explanation

A subway has local trains stopping everywhere and express trains stopping at every fourth station: ride the express to the last stop before your destination, then switch to the local. A skip list stacks several express lines and picks each station's express status by coin flip, so nothing needs rebalancing as stations are added.

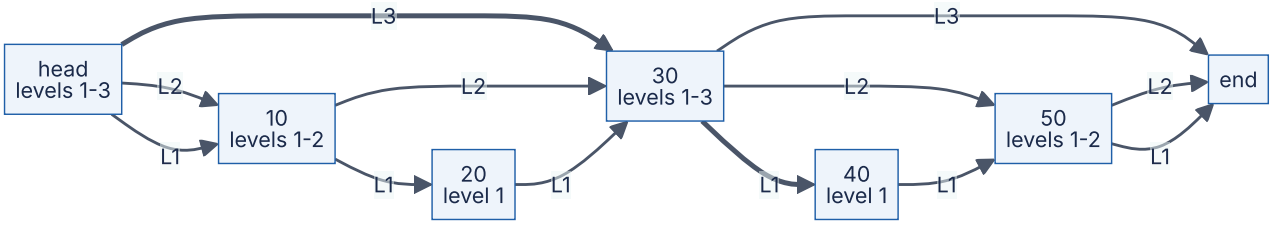
Why does this exist?

Balanced trees (red–black, AVL) guarantee $O(\log n)$, but their rotations are intricate and hard to make concurrent. Pugh showed that randomization gives the same *expected* cost with a far simpler algorithm: an insert changes only its predecessors' pointers [Pugh 1990].

How it works internally

1. **Search** for key x: start at the head's top level. Move right while the next key is less than x; when it is not, drop down a level. At level 0, the next node is x if x is present.
2. **Insert** x: search as above, remembering the last node visited on each level (the update path). Draw a random level ℓ: start at 1 and add a level while a coin with probability p comes up heads. Splice the new node in after the remembered node on each of levels $1..\ell$.
3. **Delete**: search, then unlink the node from each level it occupies.
4. **Range scan** $[a, b]$: search for a, then walk level 0 until passing b. This is why skip lists suit ordered data such as leaderboards and memtables.

Figure 17.8 — A skip list with three levels; the bold path finds 40.



Reading the diagram. Each box is one node, labeled with the levels it occupies; each arrow is a forward pointer labeled with its level (L1 links every node, L2 about a quarter to a half of them, L3 fewer still). Searching for 40 follows the bold path: at level 3 the head jumps straight to 30; the next L3 and L2 pointers from 30 overshoot (end, 50), so the search drops to level 1 and steps once to 40, two moves instead of four along the bottom list, a saving that grows with n. Everything is in memory and every step is a synchronous pointer read. Failure points: unlucky coin flips can slow one search (the guarantee is probabilistic), and pointer chasing causes CPU cache misses (§5.4), which is why on-disk indexes prefer B-trees. Concurrency scales well because an insert changes only a few predecessor pointers.

Mathematical foundations

FORMULA

Skip list levels, search cost and memory

$$L(n) = \log_{1/p} n, \qquad \mathbb{E}[\text{search path}] \le \frac{L(n)}{p} + \frac{1}{1-p}, \qquad \mathbb{E}[\text{pointers per node}] = \frac{1}{1-p}$$

Symbol	Meaning	Units
n	Number of elements	elements
p	Probability of promoting a node to the next level	probability
$L(n)$	Expected number of levels in use	levels
Search path	Forward moves plus level drops during one search	steps
Pointers per node	Average forward pointers stored per element	pointers

WORKED EXAMPLE

Worked example — choosing p for one million elements.

1. $p = 1/2$: $L = \log_2 10^6 = 19.9$ levels; search path $\le 19.9/0.5 + 1/0.5 = 41.9$ steps; 2.00 pointers per node.
2. $p = 1/4$: $L = \log_4 10^6 = 6/\log_{10} 4 = 6/0.602 = 9.97$ levels; search path $\le 9.97/0.25 + 1/0.75 = 41.2$ steps; 1.33 pointers per node.

Interpretation. Both give about 40 steps, but $p = 1/4$ stores a third fewer pointers.
Engineering implication. That is why Redis uses $p = 1/4$.

Code example and measured validation

```
        import math
        import random

        class Node:
            __slots__ = ("key", "forward")
            def __init__(self, key, level):
                self.key, self.forward = key, [None] * level

        class SkipList:
            """Pugh's skip list with promotion probability p (Redis uses p = 0.25, max
level 32)."""

            def __init__(self, p: float = 0.25, max_level: int = 32, seed: int = 0):
                self.p, self.max_level = p, max_level
                self.head = Node(None, max_level)
                self.level = 1
                self.pointers = 0                                # total forward point-
ers allocated
                self.rng = random.Random(seed)

            def _random_level(self) -> int:
                lvl = 1
                while self.rng.random() < self.p and lvl < self.max_level:
                    lvl += 1
                return lvl

            def insert(self, key) -> None:
                update, x = [self.head] * self.max_level, self.head
                for i in reversed(range(self.level)):            # descend, remembering
the last node per level
                    while x.forward[i] and x.forward[i].key < key:
                        x = x.forward[i]
                    update[i] = x
                lvl = self._random_level()
                self.level = max(self.level, lvl)
                node = Node(key, lvl)
                self.pointers += lvl
                for i in range(lvl):                             # splice in at each of
its levels
                    node.forward[i], update[i].forward[i] = update[i].forward[i], node

            def search(self, key):
                """Return (found, number of key comparisons)."""
                x, steps = self.head, 0
                for i in reversed(range(self.level)):
                    while x.forward[i] and x.forward[i].key < key:
                        x, steps = x.forward[i], steps + 1
                    steps += 1                                   # the comparison that
stopped us
                x = x.forward[0]
                return (x is not None and x.key == key), steps

            def range(self, lo, hi):
                """All keys in [lo, hi]: find lo in O(log n), then walk level 0."""
```

```
                x = self.head
                for i in reversed(range(self.level)):
                    while x.forward[i] and x.forward[i].key < lo:
                        x = x.forward[i]
                x, out = x.forward[0], []
                while x and x.key <= hi:
                    out.append(x.key)
                    x = x.forward[0]
                return out

        for p in (0.5, 0.25):
            for n in (10_000, 100_000, 1_000_000):
                sl = SkipList(p=p, seed=42)
                keys = list(range(n))
                random.Random(1).shuffle(keys)
                for k in keys:
                    sl.insert(k)
                probe = random.Random(2).sample(range(n), 2_000)
                avg = sum(sl.search(k)[1] for k in probe) / len(probe)
                L = math.log(n, 1 / p)
                bound = L / p + 1 / (1 - p)                    # Pugh's expected-cost
bound
                print(f"p={p:<4} n={n:>9,}  levels={sl.level:2d}  log_1/p(n)={L:5.1f}  "
                      f"avg comparisons={avg:5.1f}  Pugh bound={bound:5.1f}  "
                      f"pointers/node={sl.pointers / n:4.2f} (expect {1 / (1 -
p):4.2f})")
        print("range(500, 505):", sl.range(500, 505))
```

Output (about 40 s in CPython):

```
p=0.5  n=   10,000  levels=14  log_1/p(n)= 13.3  avg comparisons= 27.5  Pugh bound= 28.6
pointers/node=1.98 (expect 2.00)
p=0.5  n=  100,000  levels=17  log_1/p(n)= 16.6  avg comparisons= 32.7  Pugh bound= 35.2
pointers/node=2.00 (expect 2.00)
p=0.5  n=1,000,000  levels=20  log_1/p(n)= 19.9  avg comparisons= 38.4  Pugh bound= 41.9
pointers/node=2.00 (expect 2.00)
p=0.25 n=   10,000  levels= 7  log_1/p(n)=  6.6  avg comparisons= 23.8  Pugh bound= 27.9
pointers/node=1.33 (expect 1.33)
p=0.25 n=  100,000  levels= 9  log_1/p(n)=  8.3  avg comparisons= 31.9  Pugh bound= 34.6
pointers/node=1.34 (expect 1.33)
p=0.25 n=1,000,000  levels=11  log_1/p(n)= 10.0  avg comparisons= 37.4  Pugh bound= 41.2
pointers/node=1.33 (expect 1.33)
range(500, 505): [500, 501, 502, 503, 504, 505]
```

What to notice:

- The number of levels in use tracks $\log_{1/p} n$, and the measured search path stays below Pugh's bound at every size.
- Going from 10^4 to 10^6 elements (100×) adds only about 11–14 comparisons: logarithmic growth.
- Pointers per node match $1/(1-p)$ exactly, confirming the memory saving of $p = 1/4$.

INDUSTRY EXAMPLE

Redis sorted sets and LSM memtables. A large Redis sorted set is a hash table (member → score) plus a skip list ordered by (score, member) with $p = 1/4$ and up to 32 levels; each forward pointer stores a *span* so `ZRANK` sums spans along the search path in $O(\log n)$. Small sets use a compact listpack [Redis Docs: Sorted sets; Redis source `t_zset.c`]. LevelDB and RocksDB use a skip list as the default memtable, for concurrent inserts and ordered flushing to SSTables [RocksDB Wiki: MemTable]; Java's `ConcurrentSkipListMap` is a lock-free sorted map on the same idea. *Evidence: Primary* — [Redis Docs; RocksDB Wiki]

COMMON MISTAKE

"Skip lists guarantee O(log n)." Only in expectation over the coin flips; slow searches are exponentially unlikely, unless an adversary can predict your random generator.

17.8 Merkle trees

17.8.1 Hash trees for verification and anti-entropy

DEFINITION

Definition — Merkle tree (hash tree). A tree in which every leaf holds the hash of a data block and every interior node holds the hash of its children's hashes. The **root hash** summarizes the entire data set: changing any block changes the root [Merkle 1987].

First-principles explanation

Two libraries want to confirm their 1-million-book catalogs match without reading every entry over the phone. Each writes a summary per shelf, then per aisle from shelf summaries, then per floor, then for the building. They compare building summaries; on a mismatch they compare floors, then only aisles on mismatched floors, and so on. Work grows with the number of *differences* times the tree depth, not with catalog size.

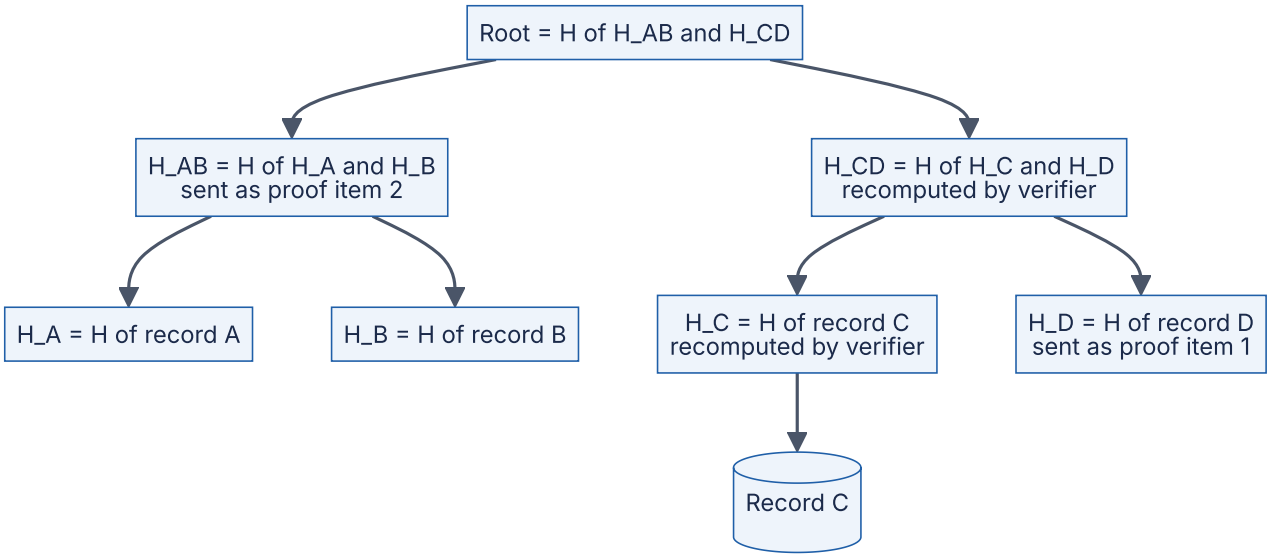
Why does this exist?

Merkle introduced hash trees so one signature over a root could authenticate many values [Merkle 1987]. Distributed systems use them for **verification** (prove a record belongs to a data set with a trusted root) and **anti-entropy** (find where replicas differ by exchanging a few hashes).

How it works internally

1. Hash each record into a leaf: a cryptographic hash such as SHA-256 if forgery matters, a cheaper one if only accidental divergence does.
2. Hash adjacent pairs level by level up to the root, prefixing leaf and interior inputs with different bytes (`0x00`, `0x01`, as in Certificate Transparency [RFC 6962]) so interior nodes cannot pose as leaves.
3. **Inclusion proof** for record *i*: the sibling hash at each level on the path from leaf *i* to the root. A verifier recomputes the root from the record and the siblings and compares it with the trusted root.
4. **Anti-entropy**: two replicas compare roots; if they differ, they compare children and descend only into subtrees whose hashes differ, until they reach the divergent leaves.

Figure 17.9 — A Merkle tree over four records and the inclusion proof for record C.



Reading the diagram. Leaves hash records, parents hash children, the root summarizes all. To prove C is present, the server sends C plus the two siblings marked as proof items, H_D and H_{AB}; the verifier recomputes H_C, H_{CD} and the root and compares it with a root obtained through a trusted channel (signed log head, block header), all synchronously and locally. Records live in storage; hashes can be cached or stored beside them. Failure points: a stale or untrusted root, and rebuild cost after many updates (incremental trees rehash only the changed leaf's path). Proofs grow logarithmically: 30 hashes for a billion records.

FORMULA

Merkle proof size and anti-entropy cost

$$h = \lceil \log_2 n \rceil, \qquad \text{proof size} = h \times H_{\text{bytes}}, \qquad \text{hashes compared} \le 1 + 2\,k\,h$$

Symbol	Meaning	Units
n	Number of leaves (records or key ranges)	leaves
h	Tree height	levels
H_{bytes}	Size of one hash (32 for SHA-256)	bytes
k	Number of divergent leaves between two replicas	leaves

WORKED EXAMPLE

Worked example — 1,048,576 records on two replicas.

1. Height: $h = \log_2 2^{20} = 20$.
2. Inclusion proof: $20 \times 32 = 640$ bytes, compared with sending all leaf hashes ($2^{20} \times 32$ B = 33.6 MB) or the data itself.
3. Anti-entropy with $k = 2$ divergent records: at most $1 + 2 \times 2 \times 20 = 81$ hash comparisons out of about 2.1 million tree nodes.

Interpretation. Both costs grow with $\log n$, and anti-entropy cost with the number of differences. *Engineering implication.* Replicas can run anti-entropy continuously at negligible network cost when mostly in sync.

```
        import hashlib

        def h(data: bytes) -> bytes:
            return hashlib.sha256(data).digest()

        def leaf_hash(record: bytes) -> bytes:
            return h(b"\x00" + record)          # domain separation: leaves and interior
nodes
        def node_hash(left: bytes, right: bytes) -> bytes:
            return h(b"\x01" + left + right)    # can never be confused (cf. RFC 6962)

        def build(records):
            """Return all levels, leaves first. An odd node is promoted unchanged."""
            level = [leaf_hash(r) for r in records]
            levels = [level]
            while len(level) > 1:
                nxt = [node_hash(level[i], level[i + 1]) for i in range(0, len(level) -
1, 2)]
                if len(level) % 2:
                    nxt.append(level[-1])
                levels.append(nxt)
                level = nxt
            return levels

        def proof(levels, index):
            """Sibling hashes from leaf to root: the audit path for one record."""
            path = []
            for level in levels[:-1]:
                sibling = index ^ 1
                if sibling < len(level):
                    path.append((sibling < index, level[sibling]))   # (sibling is on
the left?, hash)
                index //= 2
            return path

        def verify(record, path, root):
            acc = leaf_hash(record)
            for sibling_is_left, sib in path:
                acc = node_hash(sib, acc) if sibling_is_left else node_hash(acc, sib)
            return acc == root

        def diff(a, b, level=None, index=0, found=None):
            """Anti-entropy: descend only into subtrees whose hashes differ. Returns
(leaf indexes, hashes compared)."""
            if found is None:
                level, found = len(a) - 1, ([], [0])
            found[1][0] += 1

                return found
            if level == 0:
                found[0].append(index)
                return found
            for child in (2 * index, 2 * index + 1):
                if child < len(a[level - 1]):
                    diff(a, b, level - 1, child, found)
            return found
```

```
        records = [f"key-{i}=value-{i}".encode() for i in range(1 << 20)]       #
1,048,576 records
        replica_a = build(records)
        records_b = list(records)
        for i in (12_345, 777_777):                                              # two
divergent records
            records_b[i] = b"stale"
        replica_b = build(records_b)

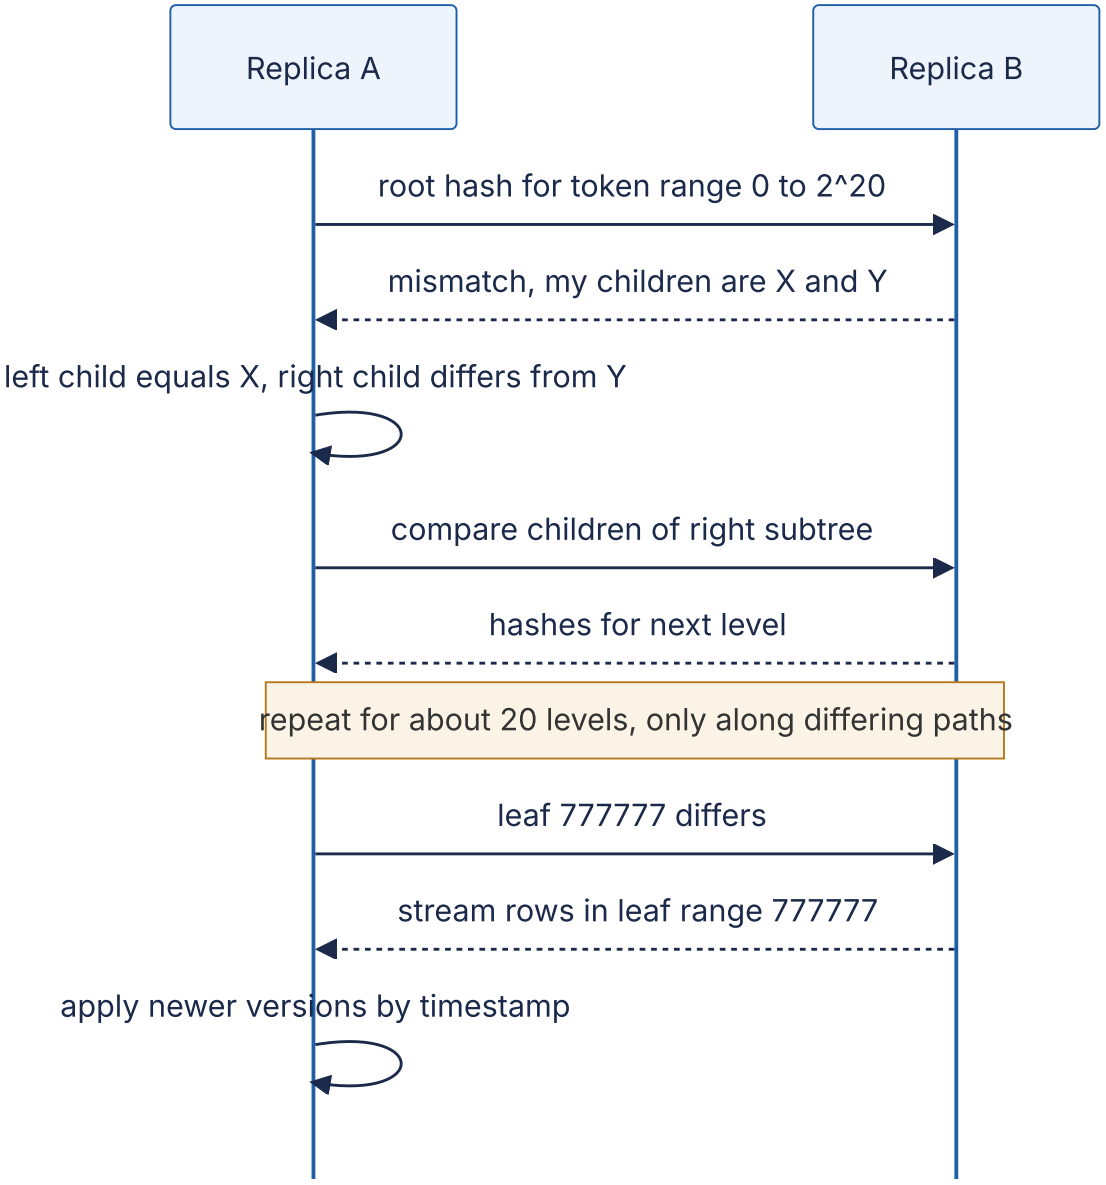
        root = replica_a[-1][0]
        p = proof(replica_a, 424_242)
        print(f"tree height = {len(replica_a) - 1}, proof length = {len(p)} hashes =
{32 * len(p)} bytes")
        print("valid record verifies:", verify(records[424_242], p, root))
        print("tampered record verifies:", verify(b"key-424242=forged", p, root))
        leaves, compared = diff(replica_a, replica_b)
        print(f"roots equal: {replica_a[-1][0] == replica_b[-1][0]}; divergent leaves:
{leaves}; "
              f"hashes compared: {compared[0]} of {sum(len(l) for l in replica_a):,}")
```

Output:

```
tree height = 20, proof length = 20 hashes = 640 bytes
valid record verifies: True
tampered record verifies: False
roots equal: False; divergent leaves: [12345, 777777]; hashes compared: 79 of 2,097,151
```

What to notice: the proof is exactly 20 hashes (640 bytes); a forged record fails verification against the same proof; and the anti-entropy walk finds both divergent records after 79 comparisons, just under the bound of 81.

Figure 17.10 — Merkle-tree anti-entropy between two replicas.



Reading the diagram. Replica A starts a background repair of one key range by sending its root; B returns its children; A finds only the right subtree differs and descends there, about 20 levels along differing paths only. At the leaves the replicas stream the divergent rows and keep the newer versions (§27.14). Each message is synchronous request/response, but repair is asynchronous to client traffic. Trees are built by scanning local data, an I/O-heavy step. Failure points: tree building competes with client reads; coarse leaves cause “overstreaming” of whole ranges for one changed row; and trees built at different moments show spurious differences for in-flight writes. Systems repair ranges incrementally on a schedule.

INDUSTRY EXAMPLE

Dynamo, Cassandra, Git and Certificate Transparency. Dynamo keeps a Merkle tree per key range and uses it to repair replicas after failures [DeCandia et al. 2007]. Cassandra's `nodetool repair` builds Merkle trees over token ranges, compares them and streams mismatched ranges [Apache Cassandra Docs: Repair]. Git names every file, directory and commit by the hash of its content, so equal commit hashes imply identical histories [Chacon & Straub 2014]. Certificate Transparency logs give logarithmic proofs of inclusion and append-only growth (§10.5) [RFC 6962]. *Evidence: Primary* — [DeCandia et al. 2007; Apache Cassandra Docs; Chacon & Straub 2014; RFC 6962]

Chapter 27 (§27.13) places Merkle-tree anti-entropy alongside read repair and hinted handoff in leaderless replication.

17.9 Geospatial indexing

17.9.1 Why location needs its own index

"Find all drivers within 1 km" looks like `WHERE lat BETWEEN ... AND lon BETWEEN ...`, but a B-tree orders keys along one dimension: an index on `lat` (or `(lat, lon)`) returns a strip around the planet, filtered afterwards by longitude. The fix is a **space-filling curve**: divide the map into **cells** whose IDs are close when the cells are close, index points by cell ID, look up a few cells per query and filter candidates by exact distance.

17.9.2 Geohash

DEFINITION

Definition — Geohash. A string encoding of a latitude/longitude cell, published by Gustavo Niemeyer in 2008, formed by alternately bisecting the longitude and latitude ranges, interleaving the resulting bits (longitude first) and writing every 5 bits as one base-32 character [Niemeyer 2008]. Each additional character subdivides the cell into 32 smaller cells, so a geohash that is a prefix of another names a cell containing it.

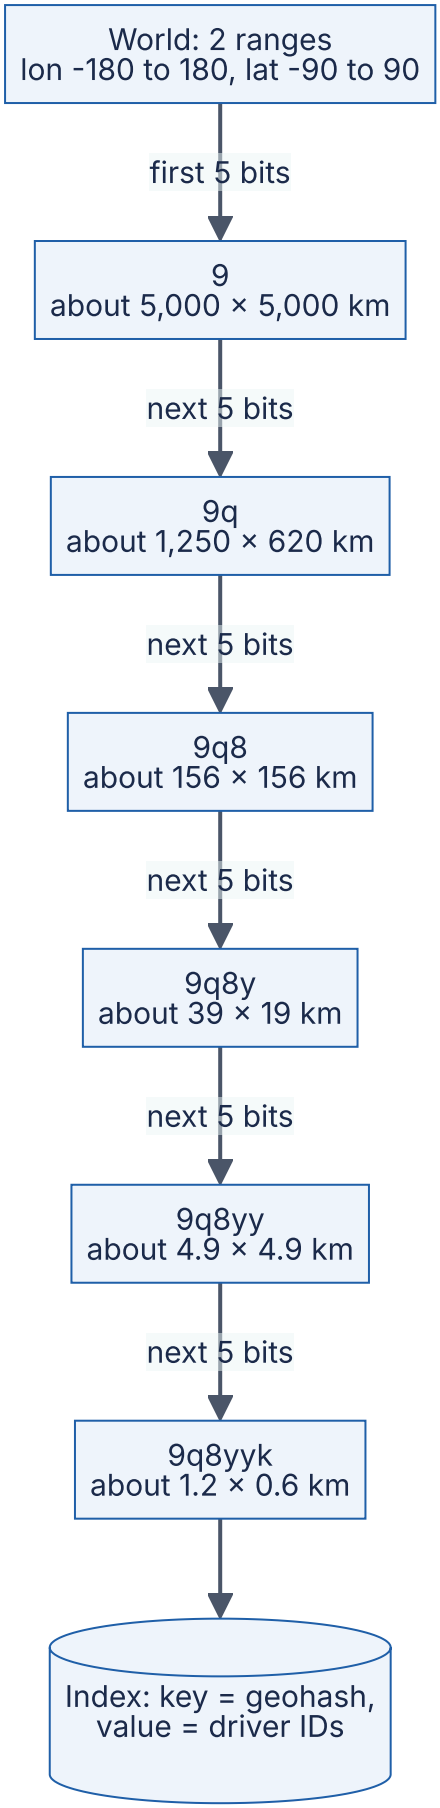
How it works internally

1. Start with longitude range $[-180, 180]$ and latitude range $[-90, 90]$.
2. Take the longitude midpoint. If the point is east of it, emit bit 1 and keep the upper half; otherwise emit 0 and keep the lower half.
3. Do the same with latitude, and keep alternating.

4. Group bits in fives and map each group to the alphabet `0123456789bcdefghjkmnpqrstuvwxyz` (the letters a, i, l and o are omitted to avoid confusion with digits).

The interleaving traces a **Z-order (Morton) curve**. A long shared prefix means nearby points, but not conversely: points a meter apart across a major boundary (the equator, the prime meridian) can share no prefix. Proximity search must always examine neighboring cells, never a prefix alone.

Figure 17.11 — Geohash refinement: each character narrows the cell.



World: 2 ranges
lon -180 to 180, lat -90 to 90
first 5 bits
9
about 5,000 × 5,000 km
next 5 bits
9q
about 1,250 × 620 km
next 5 bits
9q8
about 156 × 156 km
next 5 bits
9q8y
about 39 × 19 km
next 5 bits
9q8yy
about 4.9 × 4.9 km
next 5 bits
9q8yyk
about 1.2 × 0.6 km
Index: key = geohash,
value = driver IDs

Reading the diagram. Each arrow appends one character, shrinking the cell's area 32-fold (sizes at the equator; widths shrink by $\cos(\text{latitude})$). Because a longer geohash extends a shorter one, a range scan over keys starting `9q8yy` in any ordered store (B-tree, sorted set, LSM tree) returns every point in that 4.9 km cell: a 2-D query becomes 1-D range scans. Encoding is pure computation; the only storage is the index. The failure point is the boundary effect; the scaling decision is precision, trading cells scanned against false candidates per cell.

FORMULA

Geohash cell size

$$b_{\text{lon}} = \lceil \frac{5L}{2} \rceil, \quad b_{\text{lat}} = \lfloor \frac{5L}{2} \rfloor, \quad W = \frac{360^\circ}{2^{b_{\text{lon}}}} \times 111.32 \cos\varphi \text{ km}, \quad H = \frac{180^\circ}{2^{b_{\text{lat}}}} \times 110.57 \text{ km}$$

Symbol	Meaning	Units
L	Geohash length	characters
b_{lon}, b_{lat}	Bits spent on longitude and latitude	bits
W, H	Cell width (east–west) and height (north–south)	km
φ	Latitude of the cell	degrees
111.32, 110.57	Approximate km per degree of longitude at the equator and of latitude	km/degree

WORKED EXAMPLE

Worked example — a 6-character cell in San Francisco ($\varphi = 37.77^\circ$).

1. Bits: $5 \times 6 = 30$, so $b_{\text{lon}} = 15$, $b_{\text{lat}} = 15$.
2. Width: $360/32,768 = 0.010986^\circ$; $\times 111.32 = 1.223$ km at the equator; $\times \cos 37.77^\circ = 0.7905$ gives 0.967 km.
3. Height: $180/32,768 = 0.005493^\circ \times 110.57 = 0.607$ km.

Interpretation. The cell is about 970 m × 610 m, not square. *Engineering implication.* The 3 × 3 block around a point reaches at least 610 m in every direction: enough for a 500 m radius, **not** for 1 km. The program below measures the consequence.

Table 17.6 — Geohash precision (cell size at the equator, computed by the program below).

Length	Bits	Width	Height	Typical use
1	5	5,009 km	4,976 km	Continent
2	10	1,252 km	622 km	Large country region
3	15	157 km	156 km	Metropolitan region
4	20	39.1 km	19.4 km	City
5	25	4.9 km	4.9 km	District; 1–2 km searches
6	30	1.2 km	0.61 km	Neighborhood; ~500 m searches
7	35	153 m	152 m	Block
8	40	38 m	19 m	Building
9	45	4.8 m	4.8 m	Doorway (beyond typical GPS accuracy)
10	50	1.2 m	0.59 m	Below GPS accuracy

Code example: geohash encoding and a proximity search

```
        import math
        import random
        from collections import defaultdict

Output:

```
encode(57.64911, 10.40744, 11) = u4pruydqqvj
len bits  cell width (equator)  cell height
  1    5            5,009.4 km   4,975.6 km
  2   10            1,252.3 km     622.0 km
  3   15              156.5 km     155.5 km
  4   20               39.1 km      19.4 km
  5   25                4.9 km       4.9 km
  6   30                1.2 km     607.38 m
  7   35              152.87 m     151.84 m
  8   40               38.22 m      18.98 m
  9   45                4.78 m       4.75 m
 10   50                1.19 m       0.59 m
P=6 3x3   cell 9q8yyk: 966 m x 611 m; 9 cells -> 6,470 candidates, 3,601 within 1 km,
recall 0.942 (brute force finds 3,822)
P=5 3x3   cell 9q8yy: 3,864 m x 4,887 m; 9 cells -> 130,946 candidates, 3,822 within 1
km, recall 1.000 (brute force finds 3,822)
P=6 cover cell 9q8yyk: 966 m x 611 m; 25 cells -> 17,908 candidates, 3,822 within 1 km,
recall 1.000 (brute force finds 3,822)
```

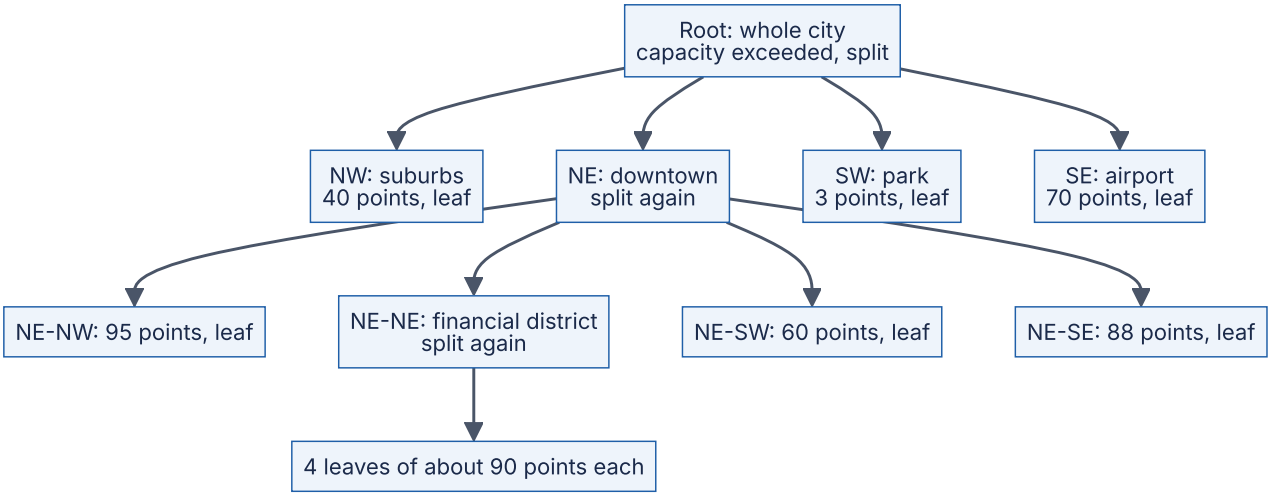
What to notice:

- The encoder reproduces the widely used reference geohash `u4pruydqqvj` for (57.64911, 10.40744), and the precision table reproduces Table 17.6.
- **The 3 × 3 trick at 6 characters silently misses 5.8% of drivers within 1 km**, exactly as the worked example predicted: the cells are only 611 m tall.
- Dropping to 5 characters restores full recall but scans 130,946 candidates, 65% of all drivers, because each cell is now about 4 km on a side.
- Covering the circle's bounding box with 25 six-character cells gives full recall with 17,908 candidates, 7× fewer. Rule: pick precision from the radius, then cover the area with as many cells as needed.
- Drivers are uniformly spread at about 1,220 per km² in this test, so the expected count within 1 km is $\pi \times 1^2 \times 1,220 \approx 3,830$; brute force found 3,822.

17.9.3 Quadtrees

A geohash grid is fixed, so a downtown cell may hold thousands of drivers and a lake cell none. A **quadtree** adapts [Finkel & Bentley 1974]: each node covers a rectangle holding up to a capacity (say 100 points) and splits into four children when it overflows. Dense areas grow deep, empty ones stay shallow, and queries descend only into nodes intersecting the search circle.

Figure 17.12 — An adaptive quadtree: dense areas split further.



Reading the diagram. The root split on overflow; three quadrants are leaves, downtown split again and its financial district a third time, so a query near the park reads one leaf while a downtown query descends three levels. The tree lives in memory and is walked synchronously by parent–child pointers. Failure points: moving points force constant reinsertion, splits and merges, complicating concurrency; a single in-memory tree is a single point of failure, so production systems shard by region and rebuild from the location stream after restart. For persistent indexes in ordinary databases, fixed cells (geohash, S2) fit B-trees better.

17.9.4 Google S2

S2 is Google's open-source spherical geometry library [S2 Geometry Docs]. It projects the sphere onto a cube's six faces, divides each face as a quadtree and orders cells along a **Hilbert curve**, whose consecutive cells always share an edge (the Z-curve jumps). A 64-bit **cell ID** encodes face, path and level (0–30); a cell's descendants form a contiguous ID range, so "points in this cell" is an integer range scan. A **region coverer** approximates any circle or polygon with a few cells at mixed levels.

FORMULA

Average S2 cell area at level L

$$\bar{A}_L \approx \frac{4\pi R^2}{6 \times 4^L} = \frac{510.1 \times 10^6 \text{ km}^2}{6 \times 4^L}$$

Symbol	Meaning	Units
$\bar{A}_L$	Average area of a level-L cell	km²
R	Earth's mean radius, ≈ 6,371 km	km
L	Cell level, 0 (a cube face) to 30	level

WORKED EXAMPLE

Worked example — which S2 level for a 1 km search? Level 12: $85.0 \times 10^6 / 4^{12} = 85.0 \times 10^6 / 16,777,216 = 5.07$ km², about 2.3 km across. Level 13: 1.27 km², about 1.1 km across. Level 30: 7.4×10^{-11} km² ≈ 0.74 cm². *Interpretation.* Each level quarters the area; 31 levels span a sixth of the planet to under a square centimeter. *Engineering implication.* Index points at a fine level and let the coverer choose coarse query cells, so one index serves every radius.

17.9.5 Uber H3

H3 is Uber's open-source hexagonal grid [H3 Docs; Brodsky 2018]. It projects the globe onto an icosahedron and tiles it with hexagons at 16 resolutions (0–15): 122 base cells, about 7× more cells per finer resolution, and 12 unavoidable pentagons per resolution. A hexagon's six neighbors all share an edge and are equidistant, whereas a square has edge and corner neighbors at different distances, so hexagons suit movement analysis, neighborhood smoothing and area pricing. The trade-off: seven children do not exactly tile their parent, so containment is approximate.

Table 17.7 — Selected H3 resolutions (average hexagon, from the H3 library version 4).

Resolution	Average area	Average edge length	Cells on Earth	Typical use
0	4,357,449 km²	1,281 km	122	Continental
5	252.9 km²	9.85 km	2,016,842	Regional demand
7	5.16 km²	1.41 km	98,825,162	City districts
8	0.737 km²	531 m	691,776,122	Neighborhood supply and demand
9	0.105 km²	201 m	4,842,432,842	Pickup zones, street blocks
10	0.0150 km²	75.9 m	33,897,029,882	Fine-grained locations
15	0.90 m²	0.58 m	about 5.7×10^{14}	Sub-meter (beyond GPS accuracy)

A k-ring query (`grid_disk` in H3 v4) returns a hexagon and all hexagons within k steps: 7 cells for $k = 1$ and 19 for $k = 2$ ($1 + 3k(k+1)$).

INDUSTRY EXAMPLE

Uber and Redis. Uber built H3 to analyze supply, demand and pricing by hexagon, using equidistant neighbors to smooth across adjacent areas, and open-sourced it in 2018 [Brodsky 2018; H3 Docs]. Redis's `GEOADD` / `GEOSEARCH` store each member's 52-bit interleaved geohash as its sorted-set score, so a radius search becomes range scans over covering cells plus a distance filter [Redis Docs: Geospatial]. *Evidence: Primary* — [Brodsky 2018; H3 Docs; Redis Docs]

17.9.6 Putting it together: a proximity service

Figure 17.13 — A nearby-drivers service built on a cell index.

Reading the diagram. Drivers report every 4 seconds; the location service computes each position's cell and moves the driver between cells in an in-memory geo index sharded by region. Updates are also appended asynchronously (dotted) to a location stream for analytics and for rebuilding a failed shard. A rider's request is synchronous: the query service covers the circle with cells, reads candidates, filters by exact distance and ranks by arrival time. Load: 1 million drivers every 4 s is 250,000 writes per second, hence memory and partitioning. Failure points: stale entries from dead apps (use a TTL), hot shards during events (finer cells or shard splits), and circles straddling shard boundaries (two-shard fan-out). Chapter 55 (§55.4, §55.5) develops the full design.

Table 17.8 — Geospatial indexes compared.

	Geohash	Quadtree	S2	H3	R-tree
Cell shape	Lat/lon rectangles	Adaptive rectangles	Spherical quadrilaterals	Hexagons (+12 pentagons)	Bounding boxes of data
Key	Base-32 string (prefix = parent)	Tree path	64-bit ID (range = parent)	64-bit ID	None (tree pages)
Adapts to density	No	Yes	No (coverer mixes levels)	No	Yes
Works in any ordered store	Yes	No (in memory)	Yes	Yes (exact match per cell)	No (specialized index)
Distortion	High near poles	Depends on projection	Low	Low	—
Neighbor queries	8 neighbors, boundary quirks	Tree walk	Edge neighbors	Uniform rings	Box overlap
Choose when	Simple prefix/range scans, Redis, Elasticsearch	In-memory dynamic points	Global coverage, polygons, ranges on integers	Movement analytics, aggregation, pricing	Polygons and shapes in PostGIS (GiST)

COMMON MISTAKE

"Searching the 3 × 3 block of geohash cells finds everything within the radius." Only if the cell's smaller side is at least the radius, and widths shrink with latitude; the measurement above lost 5.8% at 1 km. Derive precision from radius and latitude, or use a region coverer.

17.10 Unique ID generation

17.10.1 What an ID scheme must provide

Every row, message, order and event needs an identifier. On one database, an auto-increment column does the job. Across hundreds of services and partitioned databases, you need IDs that are:

1. **Unique** across all generators, forever.
2. **Generated without coordination** on the hot path, so that ID creation adds no network round trip and survives the loss of any central service.
3. **Roughly time-ordered** (**k-sortable**): later IDs sort later, keeping B-tree inserts at the index's right edge (§11.8, §13.6) and enabling pagination and recent-item range scans.
4. **Compact**: 64 bits fits a `BIGINT` and halves index size compared with 128 bits.
5. **Not leaking** information you would rather hide, such as exact creation time, order volume or which machine created the record.

No scheme maximizes all five. The rest of this section compares the main families.

17.10.2 UUIDv4 and UUIDv7

RFC 9562 (May 2024) defines the current 128-bit **UUID** versions and replaces RFC 4122 [RFC 9562]. **UUIDv4** is 122 random bits plus version and variant bits. **UUIDv7** starts with a 48-bit Unix millisecond timestamp, then the version, 12 bits of randomness or sub-millisecond counter, the variant and 62 random bits, so it sorts by creation time. Random UUIDv4 keys hit a random B-tree leaf on every insert; once the index exceeds memory, most inserts read a page and split pages all over the tree. UUIDv7 inserts land on the hot rightmost pages.

Collisions between random IDs are governed by the birthday bound (§10.4.1).

FORMULA

Birthday bound for random identifiers

$$P_{\text{collision}} \approx 1 - e^{-n^2/(2N)} \approx \frac{n^2}{2N} \text{ (when small)}, \qquad n_{50\%} \approx \sqrt{2N \ln 2} \approx 1.18\sqrt{N}$$

Symbol	Meaning	Units
n	Number of IDs generated within one collision domain	IDs
N	Number of possible values, $2^{\text{random bits}}$	values
$P_{\text{collision}}$	Probability that at least two IDs are equal	probability
$n_{50\%}$	Number of IDs at which a collision becomes a coin flip	IDs

WORKED EXAMPLE

Worked example — how safe are UUIDv4 and UUIDv7?

1. UUIDv4: $N = 2^{122} = 5.3 \times 10^{36}$. For one trillion IDs, $n^2/(2N) = 10^{24}/(1.06 \times 10^{37}) = 9.4 \times 10^{-14}$. A coin-flip collision needs $n_{50\%} = 1.18 \times \sqrt{5.3 \times 10^{36}} = 2.7 \times 10^{18}$ IDs.
2. UUIDv7 with all 74 non-timestamp bits random: only IDs created in the same millisecond can collide, so $N = 2^{74} = 1.9 \times 10^{22}$ per millisecond. At 1 million IDs per second (1,000 per ms): $10^6/(3.8 \times 10^{22}) = 2.6 \times 10^{-17}$ per millisecond; over a year of 3.16×10^{10} ms, 8.3×10^{-7}.

Interpretation. Both are safe for realistic systems. *Engineering implication.* The real risk is bad randomness (cloned VM random state, time-seeded generators); use the OS cryptographic source and keep a unique constraint.

17.10.3 Twitter Snowflake

In 2010, as Twitter moved storage from MySQL toward Cassandra, it needed roughly time-ordered 64-bit IDs generated at high rate without coordination. **Snowflake**, a small Thrift service, composed IDs from a timestamp, a machine number and a counter, with requirements of at least 10,000 IDs per second per process and 2 ms response time plus network latency [Twitter: Snowflake 2010].

Figure 17.14 — The Snowflake 64-bit ID layout.

Reading the diagram. Fields run from the most significant bit (left) to the least. The sign bit stays 0 so IDs are positive in signed 64-bit types. The 41-bit timestamp counts milliseconds since a custom epoch (Twitter's is 1288834974657, 4 November 2010 01:42:54.657 UTC [Twitter: Snowflake IdWorker]); in the high bits it makes IDs sort by time across machines, within clock skew. The 10-bit machine ID separates generators, so they never communicate; the only coordination is assigning machine IDs once, by configuration or a coordination service (§26.8). The 12-bit sequence counts IDs per millisecond per machine. Failure points: duplicated machine IDs, a clock moving backward, and exhausting 4,096 IDs in one millisecond (wait for the next).

FORMULA

Snowflake capacity and lifetime

$$\text{rate}_{\text{machine}} = 2^{S} \times 1000 \text{ IDs/s}, \qquad \text{rate}_{\text{cluster}} = 2^{M} \times \text{rate}_{\text{machine}}, \qquad \text{lifetime} = \frac{2^{T}}{1000 \times 3600 \times 24 \times 365.25} \text{ yea}$$

Symbol	Meaning	Units
T	Timestamp bits (millisecond resolution)	bits
M	Machine-ID bits	bits
S	Sequence bits	bits
rate	Maximum sustained ID generation rate	IDs/s
lifetime	Time from the epoch until the timestamp field overflows	years

WORKED EXAMPLE

Worked example — the 41/10/12 layout.

1. Per machine: $2^{12} = 4,096$ IDs per millisecond, or $4,096,000$ IDs/s.
2. Cluster: $2^{10} = 1,024$ machines × 4,096,000 = 4.19×10^{9} IDs/s.
3. Lifetime: $2^{41} = 2,199,023,255,552$ ms $= 2.199 \times 10^{12} / 3.156 \times 10^{10} = 69.7$ years. From Twitter's 2010 epoch, IDs run out in July 2080.
4. Instagram's variant uses 41 timestamp bits, 13 bits of logical shard ID and 10 sequence bits, generated inside PostgreSQL [Instagram Engineering 2012]: 8,192 shards × 1,024 IDs per millisecond each.

Interpretation. Moving a bit between fields doubles one limit and halves another. *Engineering implication.* Choose a late epoch, size machine bits for your largest fleet including short-lived containers, and document the layout: once clients store IDs it is a public contract.

Code example

```
        import datetime as dt
        import os
        import threading
        import time
        import uuid

        TWITTER_EPOCH_MS = 1288834974657           # 2010-11-04 01:42:54.657 UTC, from
Twitter's IdWorker
        TIMESTAMP_BITS, MACHINE_BITS, SEQUENCE_BITS = 41, 10, 12
        MAX_MACHINE = (1 << MACHINE_BITS) - 1      # 1023
        MAX_SEQUENCE = (1 << SEQUENCE_BITS) - 1    # 4095

        lifetime_ms = 1 << TIMESTAMP_BITS
        years = lifetime_ms / (1000 * 3600 * 24 * 365.25)
        end = dt.datetime.fromtimestamp((TWITTER_EPOCH_MS + lifetime_ms) / 1000,
dt.timezone.utc)
        print(f"lifetime: 2^41 ms = {lifetime_ms:,} ms = {years:.1f} years; Twitter-
epoch IDs run out {end:%Y-%m-%d}")

        # A clock that jumps back 5 ms
        fake = iter([1000, 1001, 996, 1002])
        g = Snowflake(1, epoch_ms=0, clock=lambda: next(fake))
        g.next_id(); g.next_id()
        try:
            g.next_id()
        except ClockMovedBackwards as e:
            print("clock step:", e)

        u = [uuid7() for _ in range(3)]
        print("uuid7:", u[0], "version", u[0].version, "| uuid4:", uuid.uuid4())
```

Output (IDs, dates and the rate vary by run and machine):

```
sample id: 2116059594966061194 -> (datetime.datetime(2026, 10, 30, 6, 48, 16, 583000,
tzinfo=datetime.timezone.utc), 37, 138)
this Python generator: 1,671,382 IDs/s
capacity: 4,096,000 IDs/s per machine, 4,194,304,000 IDs/s cluster
lifetime: 2^41 ms = 2,199,023,255,552 ms = 69.7 years; Twitter-epoch IDs run out 2080-
07-10
clock step: refusing to issue IDs for 5 ms
uuid7: 01a18b90-fa5a-78bc-a410-f69281e34317 version 7 | uuid4: 07ac5358-bdb5-42c6-bed7-
46d2df7a34d6
```

What to notice:

- 200,000 IDs from one generator are unique and strictly increasing, and decoding recovers the creation time, machine 37 and the sequence number.
- Even this Python generator manages about 1.7 million IDs per second; the real ceiling is 4,096 per millisecond.
- On a 5 ms backward clock step the generator refuses to issue IDs, as Twitter's `IdWorker` does [Twitter: Snowflake IdWorker]. Alternatives: wait out small steps, or reuse the last timestamp and borrow sequence numbers. Configure NTP to slew rather than step (§24.9).
- This `uuid7()` does not guarantee ordering among IDs created in the same millisecond. RFC 9562 §6.2 describes counter-based methods that do.

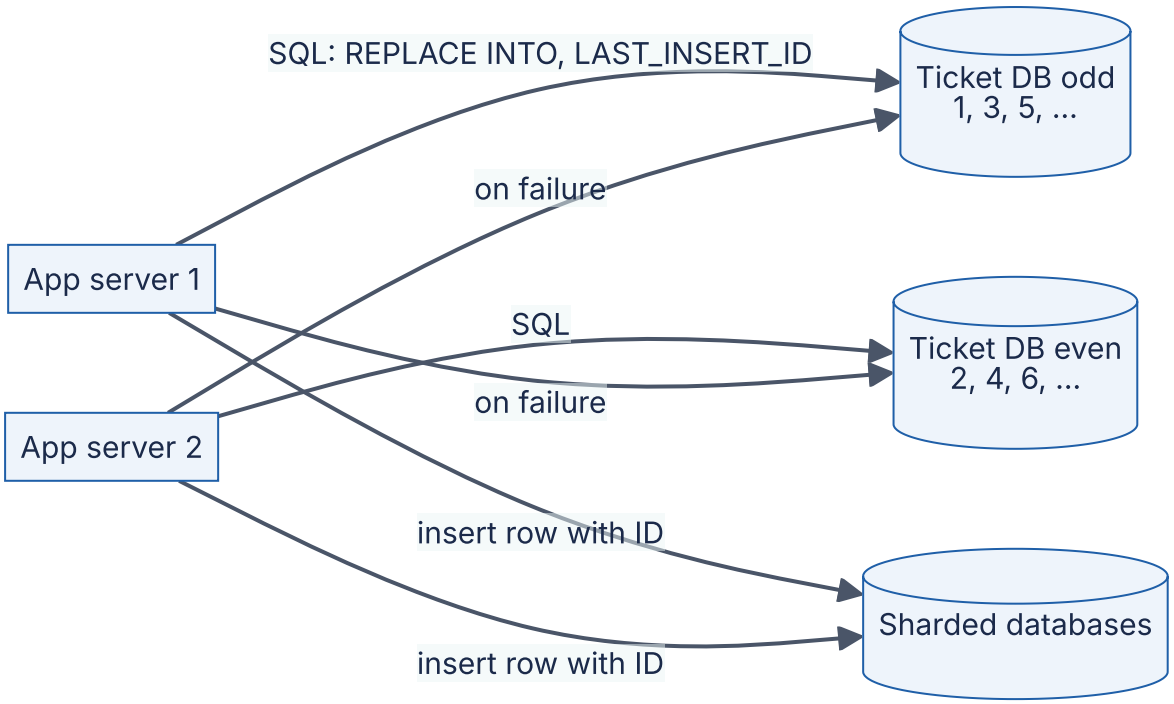
17.10.4 ULID

A **ULID** is 128 bits: a 48-bit millisecond timestamp and 80 random bits, written as 26 Crockford base-32 characters that sort in time order [ULID Spec], convenient for string keys (object paths, sort keys). Its timestamp lasts until the year 10889, and a monotonic mode increments the random part within a millisecond. UUIDv7 now offers the same properties in standard form.

17.10.5 Database sequences and ticket servers

Flickr scaled database sequences with **ticket servers**: dedicated MySQL instances that only hand out numbers via `REPLACE INTO Tickets64 (stub) VALUES ('a'); SELECT LAST_INSERT_ID();` on a one-row auto-increment table [Flickr: Ticket Servers 2010]. Two servers issue odd and even numbers (`auto_increment_increment = 2`, offsets 1 and 2), so either can fail without stopping ID generation.

Figure 17.15 — Flickr-style ticket servers.



Reading the diagram. App servers fetch an ID with one synchronous SQL round trip, then insert rows into the sharded databases. The ticket servers never communicate, since odd and even cannot collide; on failure clients switch servers (cross arrows), losing global ordering. Failure points: a round trip per ID and a write-path dependency whose capacity is one single-row MySQL update stream. Fetching **blocks** of, say, 1,000 IDs divides load by the block size at the cost of only rough ordering.

Table 17.9 — Unique ID schemes compared.

	UUIDv4	UUIDv7	Snowflake-style	ULID	Sequence / ticket server
Size	128 bits	128 bits	64 bits	128 bits (26 chars)	64 bits
Time-ordered	No	Yes (ms)	Yes (ms, within clock skew)	Yes (ms)	Yes per server; roughly with blocks
Coordination	None	None	Assign machine IDs once	None	Round trip per ID or block
Uniqueness	Probabilistic (122 bits)	Probabilistic per ms (74 bits)	Guaranteed if machine IDs unique and clock monotonic	Probabilistic per ms (80 bits)	Guaranteed
Leaks	Nothing	Creation time	Creation time, machine, volume	Creation time	Volume (sequential)
Index locality	Poor (random inserts)	Good	Good	Good	Best
Main failure mode	Bad randomness	Bad randomness	Duplicate machine ID; clock steps	Bad randomness	Ticket tier outage
Choose when	Unguessable public IDs; low insert rates	Default 128-bit key	Compact keys at very high rates	String keys that must sort	Small systems; strict ordering needed

COMMON MISTAKE

“Time-ordered IDs give a total order of events.” IDs from different machines are ordered only within clock skew (§24.9); for causal order use logical clocks or a single sequencer (§24.10).

COMMON MISTAKE

“Sequential IDs in URLs are harmless.” They reveal growth and invite enumeration. Authorization must stop access either way (§10.7.1), but an opaque public ID mapped to the internal key removes the leak.

17.11 Tries

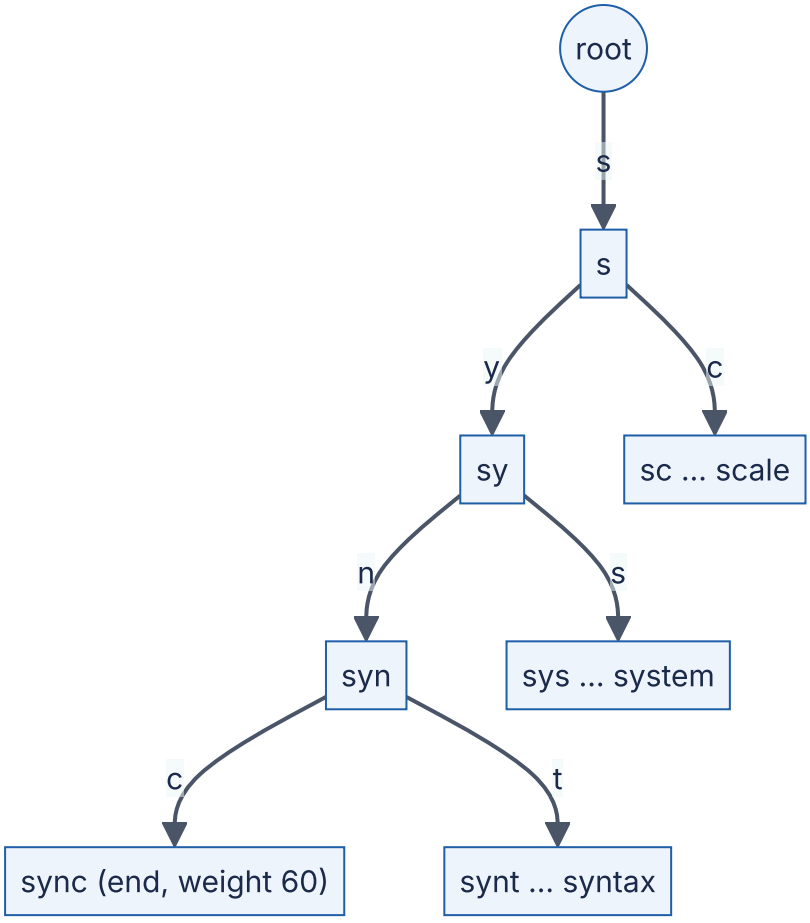
17.11.1 Prefix trees

DEFINITION

Definition — Trie (prefix tree). A tree in which each edge is labeled with a character and each node represents the string spelled by the path from the root; nodes that end a stored key are marked. Looking up a key or a prefix of length L takes $O(L)$ steps, independent of how many keys are stored [Fredkin 1960].

A trie answers the question a hash table cannot: “which stored keys *start with* this prefix?” Walk down L edges to the prefix node; its subtree holds every completion. **Radix trees** (Patricia tries) compress chains of single-child nodes into one edge labeled with a string, which cuts node count and pointer overhead dramatically. Tries are used for autocomplete, longest-prefix matching in IP routing tables, and as compact sorted dictionaries; Redis uses a radix tree internally for streams [Redis Docs: Streams]. Chapter 16 (§16.9) builds a production autocomplete on tries and finite-state transducers, including precomputed top-k completions at each node; this section gives only the structure.

Figure 17.16 — A trie holding sync, syntax, system and scale.



Reading the diagram. Each edge adds one character; the ellipses abbreviate chains of single-child nodes that a radix tree would store as one edge. A query for the prefix `syn` follows three edges and then enumerates the subtree: `sync` and `syntax`. All operations are in-memory pointer walks. The main failure point is memory: a naive trie with one node per character can use tens of bytes per character, so large dictionaries use radix trees, arrays of children, or succinct encodings. Tries scale by sharding on the first characters of the key, with care for skewed prefixes (many queries start with “s” and few with “x”).

```
        import heapq

        class TrieNode:
            __slots__ = ("children", "weight")
            def __init__(self):
                self.children, self.weight = {}, 0              # weight > 0 marks the
end of a stored word

        class Trie:
            def __init__(self):
                self.root, self.nodes = TrieNode(), 1

            def insert(self, word: str, weight: int) -> None:
                node = self.root
                for ch in word:
                    if ch not in node.children:
                        node.children[ch] = TrieNode()
                        self.nodes += 1
                    node = node.children[ch]
                node.weight += weight

            def top_k(self, prefix: str, k: int):
                """Walk to the prefix node (O(len(prefix))), then collect its subtree's
k heaviest words."""
                node = self.root
                for ch in prefix:
                    node = node.children.get(ch)
                    if node is None:
                        return []
                found, stack = [], [(node, prefix)]
                while stack:
                    cur, word = stack.pop()
                    if cur.weight:
                        found.append((cur.weight, word))
                    stack.extend((child, word + ch) for ch, child in
cur.children.items())
                return heapq.nlargest(k, found)

        t = Trie()
        for word, w in [("system", 90), ("systems", 40), ("syscall", 25), ("sync", 60),
                        ("synchronous", 30), ("syntax", 20), ("scale", 80), ("schema",
50)]:
            t.insert(word, w)
        print(t.top_k("sy", 3))
        print(t.top_k("syn", 5))
        print("nodes:", t.nodes, "for", sum(len(w) for w in ["system", "systems",
"syscall", "sync",
              "synchronous", "syntax", "scale", "schema"]), "characters")
```

Output:

```
[(90, 'system'), (60, 'sync'), (40, 'systems')]
[(60, 'sync'), (30, 'synchronous'), (20, 'syntax')]
nodes: 32 for 52 characters
```

What to notice: shared prefixes are stored once (32 nodes for 52 characters), and the cost of `top_k` is the prefix walk plus the size of the subtree. For a short prefix such as “s” in a large dictionary the subtree is huge, which is why production autocomplete stores pre-computed top-k lists at each node (§16.9).

17.12 Reservoir sampling and streaming algorithms

17.12.1 Reservoir sampling

DEFINITION

Definition — Reservoir sampling. An algorithm that maintains a uniform random sample of k items from a stream whose length n is not known in advance, using $O(k)$ memory and a single pass: after any number of items, every item seen so far is in the sample with probability k/n [Vitter 1985].

First-principles explanation and mechanism

You want 1,000 representative requests from a day of traffic for debugging, but you do not know how many requests the day will bring, and you cannot store them all. Sampling each request with a fixed probability gives the wrong sample size if traffic differs from your guess. Reservoir sampling (**Algorithm R**, which Knuth attributes to Alan Waterman) adjusts as it goes:

1. Put the first k items in the reservoir.
2. For the n-th item ($n > k$), draw a random integer j in $[0, n)$. If $j < k$, replace reservoir slot j with the new item; otherwise discard it.

FORMULA

Reservoir sampling inclusion probability

$$P(\text{item } i \text{ in sample after } n \text{ items}) = \frac{k}{i} \times \prod_{j=i+1}^{n} \left(1 - \frac{1}{j}\right) = \frac{k}{i} \times \frac{i}{n} = \frac{k}{n}, \qquad \mathbb{E}[\text{replacements}] \approx k \ln \frac{n}{k}$$

Symbol	Meaning	Units
k	Reservoir size	items
n	Items seen so far	items
i	Arrival position of a particular item ($i > k$)	position
$1 - 1/j$	Probability that item j does not evict this item: it is chosen with probability k/j and then evicts one of k slots	probability

WORKED EXAMPLE

Worked example — sampling traces. A service handles 600,000 requests per minute and keeps a reservoir of $k = 1,000$ per minute. Each request is kept with probability $1,000/600,000 = 1/600$. The expected number of reservoir writes per minute is about $1,000 + 1,000 \times \ln(600,000/1,000) = 1,000 + 1,000 \times 6.40 = 7,400$, not 600,000. *Interpretation.* Late items are rarely written, so the cost is dominated by drawing a random number per item. *Engineering implication.* Vitter's Algorithm Z [Vitter 1985] and Li's Algorithm L [Li 1994] compute how many items to *skip* before the next replacement, drawing about $O(k \log(n/k))$ random numbers instead of n; use them when random-number generation dominates.

Code example and measured validation

```
        import math
        import random
        from collections import Counter

        def reservoir_sample(stream, k, rng=random):
            """Algorithm R: a uniform sample of k items from a stream of unknown length,
in O(k) memory."""
            reservoir = []
            for n, item in enumerate(stream, start=1):
                if n <= k:
                    reservoir.append(item)                    # fill the reservoir
first
                else:
                    j = rng.randrange(n)                      # uniform in [0, n)
                    if j < k:                                 # happens with probabil-
ity k / n
                        reservoir[j] = item                   # evict a uniformly cho-
sen resident
            return reservoir

        def reservoir_sample_skip(stream, k, rng=random):
            """Algorithm L (Li 1994): same distribution, but jumps over items, so it
draws
            O(k log(n/k)) random numbers instead of n."""
            it = iter(stream)
            reservoir = [x for _, x in zip(range(k), it)]
            w = math.exp(math.log(rng.random()) / k)
            while True:
                skip = math.floor(math.log(rng.random()) / math.log(1 - w))
                for _ in range(skip):                         # discard without drawing
randomness
                    if next(it, None) is None:
                        return reservoir
                item = next(it, None)
                if item is None:
                    return reservoir
                reservoir[rng.randrange(k)] = item
                w *= math.exp(math.log(rng.random()) / k)

        # Validate uniformity: every one of n = 1,000 items should be chosen with proba-
bility k/n = 0.01
        n, k, trials = 1_000, 10, 50_000
        rng = random.Random(5)
        for name, fn in (("Algorithm R", reservoir_sample), ("Algorithm L",
reservoir_sample_skip)):
            counts = Counter()
            for _ in range(trials):
                counts.update(fn(range(n), k, rng))
            freqs = [counts[i] / trials for i in range(n)]
            expected = k * trials / n                         # 500 selections per item
            chi2 = sum((counts[i] - expected) ** 2 / expected for i in range(n))
            print(f"{name}: inclusion prob. min {min(freqs):.4f}  max {max(freqs):.4f}
"
                  f"(target {k / n:.4f}); first decile {sum(freqs[:100]) / 100:.4f}, "
```

```
                    f"last decile {sum(freqs[-100:]) / 100:.4f}; chi-square {chi2:.0f} on
{n - 1} dof")
```

Output:

```
Algorithm R: inclusion prob. min 0.0087  max 0.0115  (target 0.0100); first decile
0.0100, last decile 0.0100; chi-square 957 on 999 dof
Algorithm L: inclusion prob. min 0.0087  max 0.0113  (target 0.0100); first decile
0.0100, last decile 0.0100; chi-square 969 on 999 dof
```

What to notice: early and late items are equally likely to be chosen (first and last deciles both 0.0100), and the chi-square statistics (957 and 969 on 999 degrees of freedom) are what a uniform sample produces. The spread from 0.0087 to 0.0115 is ordinary sampling noise over 50,000 trials. The skip-based Algorithm L produces the same distribution with far fewer random draws. (The `None` sentinel in this sketch assumes the stream contains no `None` items.)

Two extensions are common. **Weighted reservoir sampling** keeps items with probability proportional to a weight, for example to oversample slow or failed requests [Efraimidis & Spirakis 2006]. **Distributed reservoir sampling** tags each item with a random key and keeps the k items with the smallest keys; because "smallest k keys" merges across partitions, each partition samples independently and a coordinator merges the results.

17.12.2 The streaming toolbox

Every structure in this chapter is a **streaming algorithm**: one pass, memory far smaller than the data, and an answer whose error you can state in advance. Most are also **mergeable**, which is what makes them fit distributed systems: compute per partition, combine centrally.

Table 17.10 — Streaming and probabilistic structures at a glance.

Question	Structure	Memory	Error	Mergeable	Section
Have I seen *x*?	Bloom / cuckoo filter	~10 bits per item at 1%	False positives only	Bloom: OR	§17.4
How many distinct items?	HyperLogLog	12 KB for 0.81%	$\pm 1.04/\sqrt{m}$ relative	Register max	§17.5
How often did *x* occur?	Count-Min sketch	$\lceil e/\varepsilon \rceil \times \lceil \ln(1/\delta) \rceil$ counters	$+\varepsilon N$, probability $1-\delta$	Add arrays	§17.6
Which items are most frequent?	Space-Saving; CMS + heap	k counters	$\leq N/k$	Approximately	§17.6.2
What is the p99?	HDR histogram, t-digest, KLL sketch	KBs	Bounded relative or rank error	Yes	§4.8, Chapter 40
Give me a fair sample	Reservoir sampling	k items	Exact distribution	Smallest-k random keys	§17.12.1
Do two replicas differ?	Merkle tree	Hash per range	Exact (with cryptographic hash)	—	§17.8

17.13 Summary and revision notes

SUMMARY

- **Hashing.** Good non-cryptographic hashes (MurmurHash3, xxHash) are deterministic, uniform and avalanche well. Test uniformity with chi-square ($\approx B - 1$ for a good hash). Use keyed SipHash for tables filled from untrusted input (hash flooding), cryptographic hashes for integrity. Consistent hashing is in §14.8.
- **Bloom filters.** $p \approx (1 - e^{-kn/m})^k$; optimal $k = (m/n) \ln 2$, where half the bits are set; $m/n = -\ln p/(\ln 2)^2$: 9.6 bits at 1%, +4.8 bits per 10× lower p. No false negatives; no deletes; OR merges. Overfilling 3× pushed a 1% filter to 44%.
- **Deletion.** Counting Bloom filters (4-bit counters, 4× memory) or cuckoo filters (fingerprints in two buckets, ~95% load, $\varepsilon \leq 2b/2^f$, smaller than Bloom below about 3% with semi-sorting).
- **HyperLogLog.** Leading zeros of hashes estimate cardinality; $m = 2^p$ registers, SE $= 1.04/\sqrt{m}$; Redis: 12 KB, 0.81%. Merge by register-wise max; unions are accurate, intersections are not. HLL++ adds 64-bit hashing, bias correction and sparse storage.
- **Count-Min.** $w = \lceil e/\varepsilon \rceil$, $d = \lceil \ln(1/\delta) \rceil$; never underestimates; error $\leq \varepsilon N$ with probability $1 - \delta$, relative to the whole stream. Heavy hitters: CMS + heap, or Space-Saving with error $\leq N/k$.
- **Skip lists.** Random levels with probability p; expected $O(\log n)$; $1/(1-p)$ pointers per node. Redis sorted sets ($p = 1/4$, spans for rank) and LSM memtables.
- **Merkle trees.** Root hash summarizes data; inclusion proofs of $\lceil \log_2 n \rceil$ hashes; anti-entropy cost grows with differences × depth (Dynamo, Cassandra, Git, Certificate Transparency).
- **Geospatial.** Map 2-D to 1-D cells. Geohash: interleaved bits, base-32, prefix = containment, boundary quirks; choose precision from radius and latitude or cover the area. Quadtrees adapt to density. S2: cube + Hilbert curve + 64-bit IDs, area /4 per level. H3: hexagons, aperture 7, uniform neighbors.
- **IDs.** UUIDv4 (random, poor index locality), UUIDv7 (time-ordered, RFC 9562), Snowflake (41/10/12 bits: 4.1 M IDs/s per machine, 69.7 years), ULID, ticket servers. Time-ordered IDs are ordered only within clock skew.
- **Streaming.** Tries answer prefix queries in $O(L)$. Reservoir sampling keeps a uniform k-sample with probability k/n in one pass. Prefer mergeable sketches in distributed systems: compute per partition, combine centrally.

17.14 Knowledge checkpoint

1. Why does the sum-of-bytes hash perform so badly on keys such as `user:12345`?

2. What is hash flooding, and name two defenses.
3. A Bloom filter has $m = 8 \times 10^6$ bits, $n = 10^6$ items and $k = 6$. What is its false-positive rate?
4. How many bits per element and how many hash functions do you need for $p = 0.1\%$?
5. Why can you not delete from a standard Bloom filter?
6. In a cuckoo filter, why is the alternate bucket computed as $i_1 \oplus h(fp)$ rather than from the original item?
7. What are the memory and standard error of a HyperLogLog with $p = 12$?
8. Why can HyperLogLog sketches be merged without double counting?
9. Size a Count-Min sketch for $\varepsilon = 0.0001$ and $\delta = 0.001$.
10. With Space-Saving and $k = 500$ counters over $N = 10^7$ events, what is the maximum overestimate?
11. What are the expected levels and pointers per node of a skip list with $p = 1/4$ and $n = 4^{10}$?
12. How many hashes are in a Merkle inclusion proof for 10^9 records?
13. How large is a 6-character geohash cell at latitude 60°?
14. Why do H3 hexagons suit neighborhood smoothing better than square cells?
15. How long do 41-bit millisecond timestamps last, and how many IDs per second can one Snowflake machine issue?
16. Why do random UUIDv4 primary keys slow down inserts into a large B-tree?
17. What is the probability that the 10th item of a stream is in a reservoir of size 5 after 1,000 items?

Answers

1. The sum takes fewer than 150 distinct values for these keys, so they crowd into a few buckets; there is no avalanche.
2. An attacker sends keys that all collide in an unkeyed hash table, making inserts $O(n)$ each and total work $O(n^2)$. Defenses: a keyed hash with a secret per-process key (SipHash), tree-structured buckets (Java 8), and limits on parameter counts.
3. $kn/m = 0.75$; $1 - e^{-0.75} = 0.5276$; $0.5276^6 = 0.0216$, about 2.2%.
4. $6.908/0.4805 = 14.4$ bits per element; $k = 10$.
5. A bit may have been set by several items; clearing it for one would cause false negatives for others.
6. Because only the fingerprint is stored. XOR with the fingerprint's hash is its own inverse, so either bucket can compute the other from the fingerprint alone during relocation.
7. $m = 4,096$ registers × 6 bits = 3,072 bytes; SE $= 1.04/64 = 1.63\%$.
8. Registers keep maxima, and the maximum is idempotent and order-independent: a register-wise max equals the sketch of the combined stream.
9. $w = \lceil 2.718/0.0001 \rceil = 27,183$; $d = \lceil \ln 1000 \rceil = 7$; 190,281 counters.
10. $N/k = 10^7/500 = 20,000$.
11. $\log_4 4^{10} = 10$ levels; $1/(1 - 0.25) = 1.33$ pointers per node.

12. $\lceil \log_2 10^9 \rceil = 30$ hashes (960 bytes with SHA-256).
13. Width $1.223 \times \cos 60^\circ = 0.61$ km; height 0.61 km, about 610 m × 610 m.
14. All six neighbors share an edge and are equidistant from the center, so a k-ring is a uniform neighborhood; squares have edge and corner neighbors at different distances.
15. 2^{41} ms = 69.7 years; $4,096 \times 1,000 = 4,096,000$ IDs per second.
16. Each insert targets a random leaf page; once the index exceeds memory, most inserts need a disk read and cause page splits across the tree. Time-ordered keys append near the rightmost pages, which stay cached.
17. $k/n = 5/1,000 = 0.5\%$, the same as every other item.

17.15 Interview questions

Basic

Q1. How would you check username availability for 1 billion users as the user types? Answer. Put a Bloom filter of all usernames in memory on each API node: at 1% false positives that is 9.6 bits per name, about 1.2 GB, with $k = 7$. A “definitely absent” answer is shown immediately; a “maybe taken” answer is confirmed against the database (a unique index on the username column), which also handles races at sign-up time. Rebuild or grow the filter as the user base grows, and add new names to it on sign-up.

Q2. How would you count daily unique visitors per page for a site with 10 million pages? Answer. One HyperLogLog per page per day (Redis `PFADD`), 12 KB dense at 0.81% error, much less for small pages thanks to the sparse encoding. Weekly and monthly uniques come from `PFMERGE`, not from summing daily counts. Exact counts are needed only for billing-grade metrics.

Q3. Why might you choose UUIDv7 over UUIDv4 for primary keys? Answer. UUIDv7 is time-ordered, so inserts go to the right edge of the B-tree index, keeping hot pages in memory and reducing page splits; it also allows rough time-range queries and pagination by ID. UUIDv4 is better when IDs must reveal nothing, including creation time.

Intermediate

Q4. Design a “trending hashtags in the last 10 minutes” feature for 500,000 tweets per second. Answer. Partition the stream (by hashtag, so each tag’s counts land on one worker). Each worker keeps per-minute Count-Min sketches and a Space-Saving or CMS-plus-heap candidate list. Every few seconds workers send their top candidates to an aggregator, which sums the last ten one-minute windows and ranks by a velocity score (current versus baseline rate) rather than raw counts, so permanently popular tags do not

dominate. With $\varepsilon = 10^{-5}$ the per-window error is $10^{-5} \times 3 \times 10^{7} = 300$ mentions, small next to trending tags with tens of thousands. Discuss spam filtering and late events.

Q5. Your geohash-based "nearby restaurants" search misses results near cell edges. Why, and how do you fix it? Answer. Points close to the query point but across a cell boundary have different prefixes, and a 3 × 3 block covers less than the radius when cells are smaller than the radius. Fix: choose precision from the radius and latitude, compute the full set of cells covering the circle's bounding box, scan all of them, then filter by exact distance. Or use S2's region coverer.

Q6. Two replicas of a 2 TB key-value store may have diverged after a network partition. How do you find and fix the differences efficiently? Answer. Build a Merkle tree per token range on each replica, compare roots, and descend into differing subtrees; at the leaves, stream only the differing ranges and resolve conflicts with the system's rule (timestamps, vector clocks, §27.14). Cost scales with the number of differences times tree depth. Leaf granularity trades tree size against overstreaming. Throttle tree building, which requires scanning data.

Advanced

Q7. An LSM-based store's read latency for missing keys doubled after a data-size increase. What could be wrong with the Bloom filters? Answer. Possibilities: filters sized by an outdated n or a configured bits-per-key too low for the new number of SSTables (expected wasted reads = files × p); filter blocks evicted from the block cache because total filter memory grew (≈ 1.2 bytes per key at 1%), so filters themselves now cost disk reads; or many more levels/files after compaction changes. Check filter-useful and filter-miss metrics and block-cache hit ratio, pin filter and index blocks, lower p for the deepest level, or use a partitioned filter.

Q8. Design ID generation for a multi-region payments platform producing 2 million IDs per second. Answer. A Snowflake-style 64-bit layout with an explicit region field: for example 41 bits of milliseconds from a 2026 epoch (69.7 years), 3 bits of region, 7 bits of worker within the region, 12 bits of sequence (2^{10} generators × 4.1 M/s gives ample headroom). Assign worker IDs through a lease in a coordination service so that two processes never share one, and refuse to issue IDs while a lease is lost. Handle clock steps by waiting out small ones and failing over large ones. Expose IDs externally only through opaque tokens if volume should stay private. Keep a unique constraint on storage as a final defense.

Q9. A product manager wants "users who visited both page A and page B this month" from your HyperLogLog sketches. What do you say? Answer. HLL estimates unions well, but an intersection via inclusion–exclusion has an absolute error on the order of the errors of the large sets: with 10 M users each and a 100,000-user overlap at 0.81%, the noise exceeds the answer. Options: MinHash-based sketches (estimate the

Jaccard similarity, then multiply by the union), exact computation in a batch job over the raw logs, or theta sketches that support set operations with stated error.

17.16 Practical exercises

1. **Hash uniformity.** Replace `murmur3_32` in §17.3.3 with Python's FNV-1a and with CRC32 (`zlib.crc32`). Compare chi-square values on `user:N` keys and on 100,000 random UUID strings.
2. **Bloom filter health.** Extend the §17.4.4 program to print the fraction of 1 bits as you insert from 0 to 3× the design capacity, and plot it against the measured false-positive rate.
3. **Scalable Bloom filter.** Implement a filter that adds a new, larger Bloom filter with a tighter p each time the current one reaches capacity, so the overall false-positive rate stays below a target.
4. **HyperLogLog bias.** Run the §17.5 program for n from 100 to 200,000 with $p = 12$ and plot the relative error. Find where the raw estimator is biased and where linear counting takes over.
5. **Conservative update.** Modify the Count-Min sketch to use conservative update and compare mean and maximum error on the Zipf stream.
6. **Geohash versus H3.** Repeat the proximity search with H3 (`pip install h3`) at resolution 8 using `grid_disk`, and compare candidate counts with the geohash covering approach.

17.17 Design challenges

1. **Web crawler frontier.** Design deduplication of URLs for a crawler that discovers 5 billion URLs per day and keeps 100 billion known URLs. Size the filter (or filters), decide how to handle false positives (missed pages) versus false negatives (impossible by design), and explain how the filter is partitioned across crawler nodes.
2. **Real-time analytics.** A product analytics service ingests 2 million events per second and must answer, within 5 seconds of an event: unique users per feature per hour, the top 50 features by usage, and p99 latency per endpoint. Choose a sketch for each, size it, show how per-partition sketches are merged, and state the error each answer carries.
3. **Nearby search at global scale.** Design the location index for a delivery app with 3 million active couriers in 800 cities, updates every 5 seconds, and queries for the 20 nearest couriers within 3 km. Compare geohash, S2 and H3 for this use, choose a cell size, estimate write load and memory per shard, and describe how the system behaves when a stadium event concentrates 20,000 couriers in a few cells.
