17.19 Open verification items

- Twitter’s 2010 “Announcing Snowflake” blog post (author, exact date, URL) could not be fetched; layout, epoch and requirements were verified against the archived GitHub repository (tag `snowflake-2010`) instead.
- Flickr ticket-servers post: confirm author (believed Kay Kremerskothen) and date (February 2010).
- Akamai one-hit-wonder share and the second-request caching rule: confirm wording in Maggs & Sitaraman (2015).
- Counting Bloom filter overflow bound (4-bit counters suffice): confirm statement in Fan et al. (2000).
- Redis sorted-set constants ($p = 1/4$, 32 levels) and listpack thresholds: confirm against current `t_zset.c` / `redis.conf` (as of 2025). RedisBloom bundling in Redis 8: confirm.
- RocksDB ribbon filters and default skip-list memtable: confirm current RocksDB wiki.
- Niemeyer (2008) geohash: no formal publication; confirm citation form.
- xxHash versus MurmurHash3 speed claims: author benchmarks only.

Part IV — Scalability and Performance

Chapter 18 — Scalability

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3.5 h

A system that works for a thousand users does not automatically work for ten million. Somewhere between the two, a CPU saturates, a connection limit is reached, a lock becomes hot or a bill becomes absurd. **Scalability** is the discipline of growing capacity *predictably*: knowing which resource runs out next, what more of it costs, and how long it takes to add. Chapter 2 sketched QuickBite, our hypothetical food-delivery platform, and estimated its load at 2 million daily active users (§2.11). This chapter carries QuickBite from a 1,000-user pilot to 10 million users, one architecture per stage. Along the way you learn the two basic moves (bigger machines or more machines), why the second move requires stateless services, how to find what stops scaling, how autoscalers decide, and how to write a capacity plan with explicit headroom.

Several topics are only summarized here because other chapters own them: load-balancing algorithms (Chapter 19), caching (Chapter 20), replication and sharding (Chapter 14), queueing mathematics (§4.10–§4.13) and the estimation handbook (Chapter 89).

18.1 Learning objectives

After this chapter you should be able to:

- Explain the limits and cost curve of vertical scaling, and name the situations in which it is the right answer.
- State the preconditions for horizontal scaling and design a stateless service by externalizing session and other state.
- Use the resource model and the Universal Scalability Law to predict where adding nodes stops paying off.
- Configure target-tracking autoscaling, choose its signal and target, and size headroom for warm-up delay.
- Check a connection-pool configuration against a database’s connection limit before the autoscaler breaks it.
- Choose a database-scaling option from a decision table and place a design on the X, Y and Z axes of the scale cube.
- Produce a capacity plan with peak-to-average ratios, N+1/N+2 or zone-level redundancy, a growth forecast and lead times.

18.2 Prerequisites

- The resource model, service demand and the utilization law — §2.6 (used to find bottlenecks).
- Back-of-the-envelope estimation and the QuickBite assumptions — §2.7 and §2.11 (the running example).
- Queueing delay versus utilization — §4.10 (why target utilization is below 100%).
- Little's Law — §4.11 (connection and concurrency sizing).
- Amdahl's Law and the Universal Scalability Law — §4.12–§4.13 (applied here, not re-derived).
- Statelessness, cookies and sessions — §8.3.2 and §8.10 (externalized state).
- Connection pooling and PgBouncer — §14.13 (connection budgets).

Units: KB, MB, GB are powers of ten; RPS means requests per second; all QuickBite figures are teaching assumptions, not measurements of a real company.

18.3 Vertical scaling

18.3.1 Scaling up

DEFINITION

Definition — Scalability. The ability of a system to handle a growing workload by adding resources, with throughput rising roughly in proportion to the resources added and latency staying within its objective. A system is *not* scalable for a workload if adding resources yields little or no extra throughput, or if the cost per unit of work rises sharply.

DEFINITION

Definition — Vertical scaling (scaling up). Increasing the capacity of a single node by giving it more or faster CPU cores, memory, storage or network bandwidth, for example by moving a database from an 8-core to a 64-core machine.

First-principles explanation

A bakery with one oven is falling behind. The first fix is obvious: buy a bigger oven. Nothing else changes. The recipes, the staff and the shop layout all stay the same. That is vertical scaling. It works until no bigger oven exists, until the biggest ovens cost far more per loaf than two smaller ones, or until the baker, not the oven, is the limit.

Why does this exist?

Vertical scaling is the cheapest move in *engineering effort*. The software is unchanged, so there is no new failure mode, no data distribution and no coordination protocol to design. A single relational database primary (Chapter 11) holds all its data in one place and gives you transactions and joins for free. Keeping it on one node as long as possible is often the most valuable architectural decision a young product makes.

How it works internally

1. Measure which resource is saturated (§2.6). Scaling up the wrong resource buys nothing.
2. Move to a larger node. In the cloud this is usually a stop, resize and restart, or a failover to a pre-built larger replica. On owned hardware it means adding memory or replacing the server.
3. Re-tune software limits that were sized for the old machine: thread pools, buffer pool size (§13.4), `max_connections`, file-descriptor limits. A 64-core database with a 16-thread pool is still a 16-thread database.
4. Re-measure. The bottleneck may now be a lock, a single-threaded component or memory bandwidth (§5.9, §5.10).

The limits of vertical scaling

Table 18.1 — Where vertical scaling stops.

Limit	What happens	Example
Hardware ceiling	No larger node exists	As of 2026, general-purpose cloud instances top out at a few hundred vCPUs and a few TB of memory
Serial code	Extra cores sit idle	A single-threaded event loop or a global lock caps throughput (Amdahl, §4.12)
Coherency inside the node	Throughput flattens or falls	Cache-line contention and NUMA traffic between sockets (§5.10)
Availability	One node is one failure domain	Resizing needs a restart or failover; the node is a single point of failure
Cost	Price per unit of throughput rises	Large nodes deliver less throughput per dollar (below)
Blast radius	Every user shares the node	One bad query affects everyone

The cost curve

Two effects shape the cost of scaling up. First, **price per core**. Within one cloud instance family, price is roughly proportional to size as of 2026: twice the vCPUs costs about twice

as much. Beyond the largest standard size, specialized high-memory or multi-socket machines carry a premium, and on owned hardware high-end multi-socket servers have long cost more per unit of performance than commodity ones Barroso et al. 2018. Second, **throughput per core** falls as the node grows, because contention and coherency inside the node grow with core count. Combining a linear price with USL throughput (§4.13) gives a simple model of the cost curve.

FORMULA

Relative cost per unit of throughput on one node

$$k(N) = \frac{N}{C(N)} = 1 + \alpha(N - 1) + \beta N(N - 1)$$

Symbol	Meaning	Units
N	Cores (or vCPUs) in the node; price assumed proportional to N	count
$C(N)$	USL relative capacity: throughput at N cores divided by throughput at 1 core	dimensionless
α	Contention coefficient inside the node	dimensionless
β	Coherency coefficient inside the node	dimensionless
$k(N)$	Cost per unit of throughput relative to a 1-core node	dimensionless (×)

The formula is just the USL denominator: if price grows with N and throughput with $C(N)$, the ratio is what is left. It assumes linear pricing; on owned hardware or specialized instances, multiply by the price premium as well.

WORKED EXAMPLE

Worked example — Is the 192-core database node worth it? A load test of QuickBite's order database at several core counts fits $\alpha = 0.02$ and $\beta = 0.00005$ (assumed values for the exercise).

1. $N = 8$: $C = 8/(1 + 0.14 + 0.0028) = 8/1.1428 = 7.00$; $k = 1.14$.
2. $N = 32$: $C = 32/(1 + 0.62 + 0.0496) = 32/1.6696 = 19.17$; $k = 1.67$.
3. $N = 96$: $C = 96/(1 + 1.90 + 0.456) = 96/3.356 = 28.61$; $k = 3.36$.
4. $N = 192$: $C = 192/(1 + 3.82 + 1.8336) = 192/6.6536 = 28.86$; $k = 6.65$.

Interpretation. Doubling from 96 to 192 cores doubles the price and adds less than 1% throughput. Each unit of throughput on the 192-core node costs 6.65 times as much as on a single core, and twice as much as on the 96-core node. **Engineering implication.** Scale up while $k(N)$ is still close to linear (here, up to roughly 32 cores). Past the knee, spend effort on removing contention (shorter transactions, fewer hot rows) or on scaling out. Fit α and β from measurements at several sizes (§23.10); a two-point test cannot reveal the knee (§4.13).

When vertical scaling is the right answer

- **The workload needs a single coherent copy of state**, such as a transactional database primary, a lock manager or an in-memory matching engine. Splitting it would add coordination that costs more than the bigger node.
- **You are below the knee of the cost curve.** Going from 4 to 16 cores typically costs little in efficiency.
- **Time matters more than elegance.** Resizing takes minutes to hours; sharding takes months. Scaling up buys time to build the horizontal design properly.
- **The team is small.** One large node has far fewer moving parts to operate than ten small ones.
- **Per-node software licences** are not a factor, or favor fewer, larger nodes.

INDUSTRY EXAMPLE

Stack Overflow. Stack Overflow has publicly described serving its very large Q&A traffic with a small number of servers, including a handful of SQL Server machines with very large memory and on the order of ten web servers, preferring to scale up and to optimize code rather than to distribute the database. *Evidence: Primary* — [Craver 2016]

COMMON MISTAKE

"Vertical scaling is old-fashioned; real systems scale out." Most successful systems scaled up first and still run their most coherent component (often the primary database) on one large node. The mistake is not scaling up; it is scaling up *past the knee* without a plan for what comes next.

18.4 Horizontal scaling

18.4.1 Scaling out

DEFINITION

Definition — Horizontal scaling (scaling out). Increasing capacity by adding more nodes that share the workload, for example by running 20 identical application servers behind a load balancer instead of one. Removing nodes when load falls is **scaling in**.

First-principles explanation

The bakery opens a second shop with its own oven and staff, then a third. Each shop is ordinary and cheap, and the chain can keep opening shops. But now customers need to be sent to a shop with spare capacity, every shop needs the same recipes, and anything that must be shared (the one supplier of flour, the single account book) becomes the new limit.

Why does this exist?

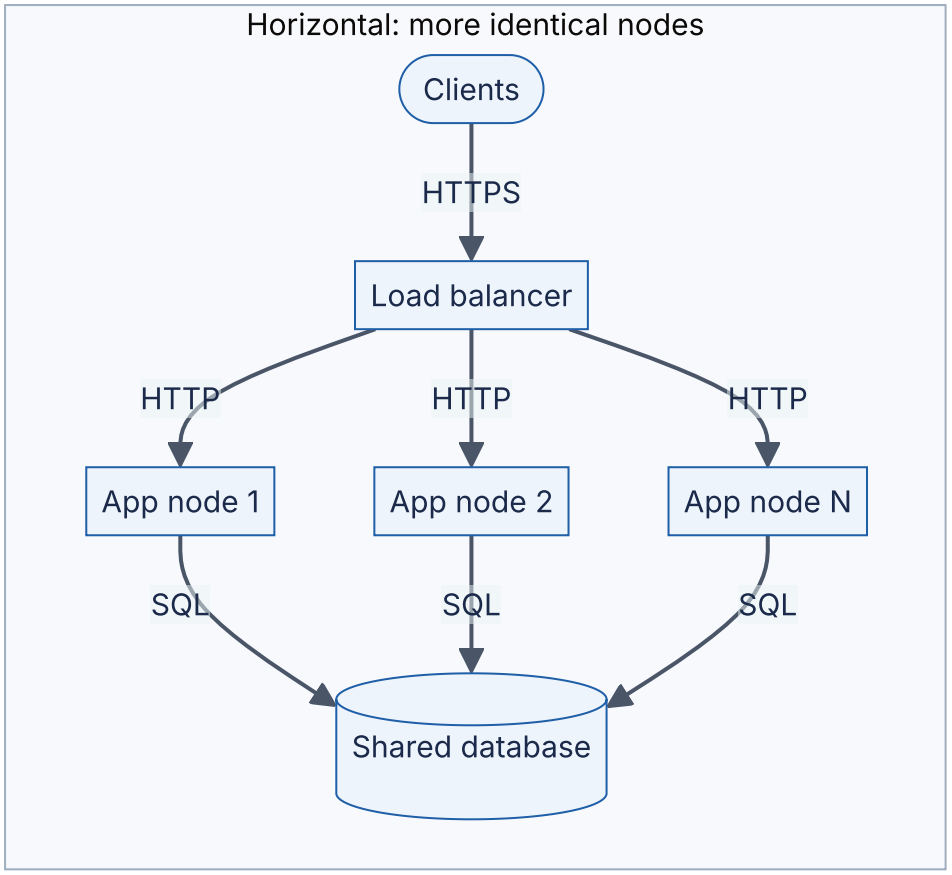
Horizontal scaling removes the hardware ceiling, keeps cost per unit of throughput nearly constant while the work is independent, and turns failures from outages into reduced capacity: losing one of 20 nodes removes 5% of capacity. Barroso, Hölzle and Ranganathan argue that warehouse-scale computers are built from large numbers of commodity servers for exactly these reasons: cost efficiency and tolerance of individual failures through software Barroso et al. 2018.

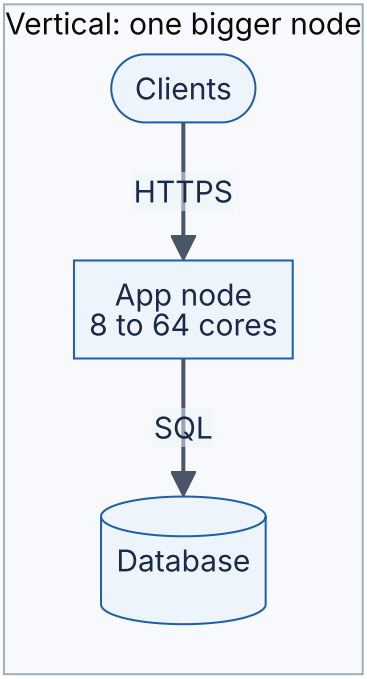
How it works internally

1. **Make nodes interchangeable.** Any node can serve any request, which requires that no node holds state that others need (§18.5).
2. **Distribute the load.** A load balancer, DNS or the client spreads requests across nodes (§18.6, Chapter 19).
3. **Detect and remove failed nodes.** Health checks stop traffic to a node that fails (§19.5).

4. **Add and remove nodes automatically** from a template (a machine image or container image) as load changes (§18.8).
5. **Push shared state down to a tier that scales differently**: a database, cache or partitioned store (§18.9).

Figure 18.1 — Vertical versus horizontal scaling.





Reading the diagram. On the left, clients reach one large node over HTTPS; capacity grows only by enlarging it, and it is a single failure point. On the right, a load balancer spreads HTTP requests over *N* identical nodes, and the others absorb a failed node's share. All arrows are synchronous. The storage boundary in both is the database, and on

the right all *N* nodes converge on it: scaling out the application tier *moves* the bottleneck to the shared tier (§18.7), which scales separately (§18.9).

Advantages, disadvantages and alternatives

Table 18.2 — Vertical and horizontal scaling compared.

	Vertical scaling	Horizontal scaling
What it is	Bigger node	More nodes
How it works	Resize, restart or fail over	Load balancer plus identical, replaceable nodes
Advantages	No code change; transactions and joins stay local	No hardware ceiling; failures reduce capacity instead of causing outages
Disadvantages	Ceiling; single failure domain; cost knee	Needs stateless design, distribution, coordination for shared state
Performance	Lowest latency (no network hops between parts)	Near-linear throughput while work is independent
Operational complexity	Low	Medium (fleet, deploys, autoscaling) to high (distributed data)
Cost	Linear, then superlinear past the knee	Roughly linear, plus coordination overhead
Choose when	Coherent state; below the knee; urgent relief	Stateless tiers; growth beyond one node; high availability

In practice you use both: scale out the stateless tiers, scale up the stateful tier until it reaches its knee, then partition it (Chapter 14).

Failure scenarios

Table 18.3 — Horizontal scaling failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Throughput flat after adding nodes	Bottleneck is a shared tier	Per-tier utilization; USL fit	Scale or relieve the shared tier	Find the bottleneck before scaling (§18.7)
Users lose sessions on scale-in	State held in node memory	Logouts after deploys or scale-in	Move state out	Stateless design (§18.5)
New nodes overloaded on arrival	Cold caches, JIT warm-up	High p99 on young nodes	Slow-start traffic ramp	Warm-up and readiness probes (§18.8)
Database connection limit hit	Every node opens its own pool	`too many clients` errors	Pooler; smaller pools	Connection budget (§18.8.5)

COMMON MISTAKE

"Adding nodes always adds capacity." Only while the work is independent. With contention or coherency, throughput flattens and then falls (§4.13). Measure the gain from each added node (§18.7).

18.5 Stateless vs stateful services

18.5.1 What "stateless" really means

DEFINITION

Definition — Stateless service. A service whose instances keep no client-specific or request-spanning data in local memory or disk that another instance would need. Any instance can serve any request, and an instance can be killed at any moment without losing anything except the requests it is processing (§8.3.2).

DEFINITION

Definition — Stateful service. A service whose instances hold data that must survive between requests and that clients or other instances depend on: a database, a cache node, a WebSocket server holding live connections, or an application server keeping sessions in memory.

First-principles explanation

Chapter 8 used two waiters: one memorizes your order, the other pins it to a shared board. The second waiter is stateless *because the board exists*. State did not disappear; it moved to a place built to hold it. "Stateless" is therefore a property of one tier, bought by making another tier stateful on purpose.

Why does this exist?

Every scaling move in this chapter (adding nodes, removing nodes, replacing a failed node, rolling out a new version, shifting traffic between zones) is trivial for a stateless tier and hard for a stateful one. Concentrating state in a few tiers that are designed for it (databases, caches, session stores) leaves the large, expensive compute tier free to scale elastically.

How it works internally: where state goes

Table 18.4 — Externalizing state from an application server.

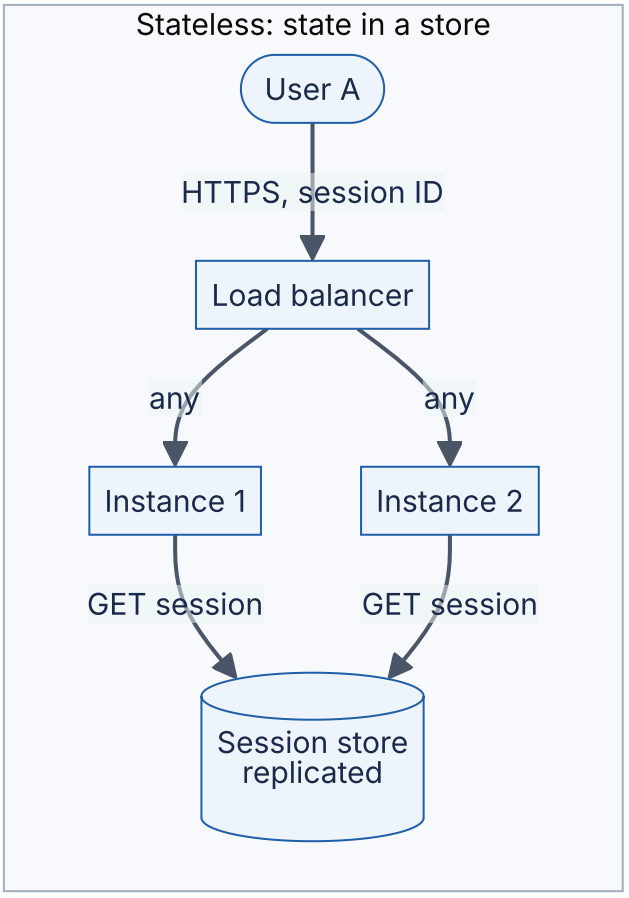
State in the server	Where it moves	Cost per request	See
Login session	Shared session store keyed by session ID, or a signed token in the client	~0.5–1 ms store lookup, or signature check	§8.10, §8.13
Shopping cart, draft order	Database or session store	One read or write	Chapter 11
Cached query results	Shared cache tier	~0.5 ms network round trip	Chapter 20
Uploaded files in progress	Object storage, multipart or presigned upload	Direct client upload	§15.8
Scheduled jobs, timers	Queue or job scheduler	Asynchronous	Chapter 30
Rate-limit counters	Shared counter store	One atomic increment	§22.8
Local disk logs	Log shipping to a central store	Asynchronous	Chapter 40

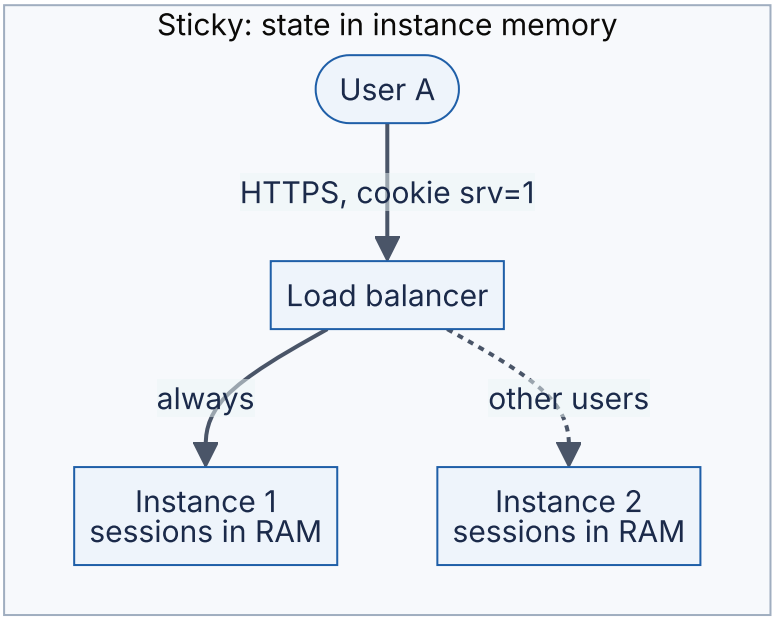
Some local state is harmless: a **read-only cache** that can be rebuilt (a menu cache with a TTL), compiled code and configuration loaded at start. The test is simple: *if this instance vanished now, would any user or other instance notice anything beyond a retry?* If not, the instance is stateless for scaling purposes.

Sticky sessions

Session affinity, also called **sticky sessions**, makes the load balancer send all requests from one client to the same instance, usually with a cookie or a hash of the client address (§19.6). It lets a stateful server *look* stateless to the load balancer.

Figure 18.2 — Sticky sessions versus an externalized session store.





Reading the diagram. On the left, the load balancer pins User A to instance 1 by a cookie, and A's session lives only in instance 1's memory. If scale-in, a deploy or a crash removes instance 1, A is logged out; heavy users stay stuck on an overloaded instance. On the right, any instance can serve any request and fetches the session synchronously from a replicated session store (storage boundary) in about a millisecond. The store becomes a

critical dependency that must be replicated (Chapter 20), but instances can be added, drained or killed freely, and scale independently of session capacity.

Table 18.5 — Ways to handle session state.

	Sticky sessions	Shared session store	Client-side token (signed cookie, JWT)
How it works	LB pins client to instance	Instances look up session by ID	Client carries signed state
Advantages	No code change; fastest local access	Instances disposable; revocation is one delete	No server lookup; no store to run
Disadvantages	Session loss on instance loss; uneven load; blocks scale-in	Extra hop; store must be highly available	Size limits; revocation is hard before expiry
Choose when	Short-term migration of a legacy app	Default for server-rendered and API sessions	Short-lived access tokens (§8.13)

Affinity is not always a smell. It is a legitimate **performance** optimization when the state is a rebuildable cache, for example routing a user to the instance that already holds their data warm, provided correctness never depends on it. Long-lived connections such as WebSockets are inherently stateful at the connection level; they are scaled with connection-aware techniques (§9.9).

Failure scenarios

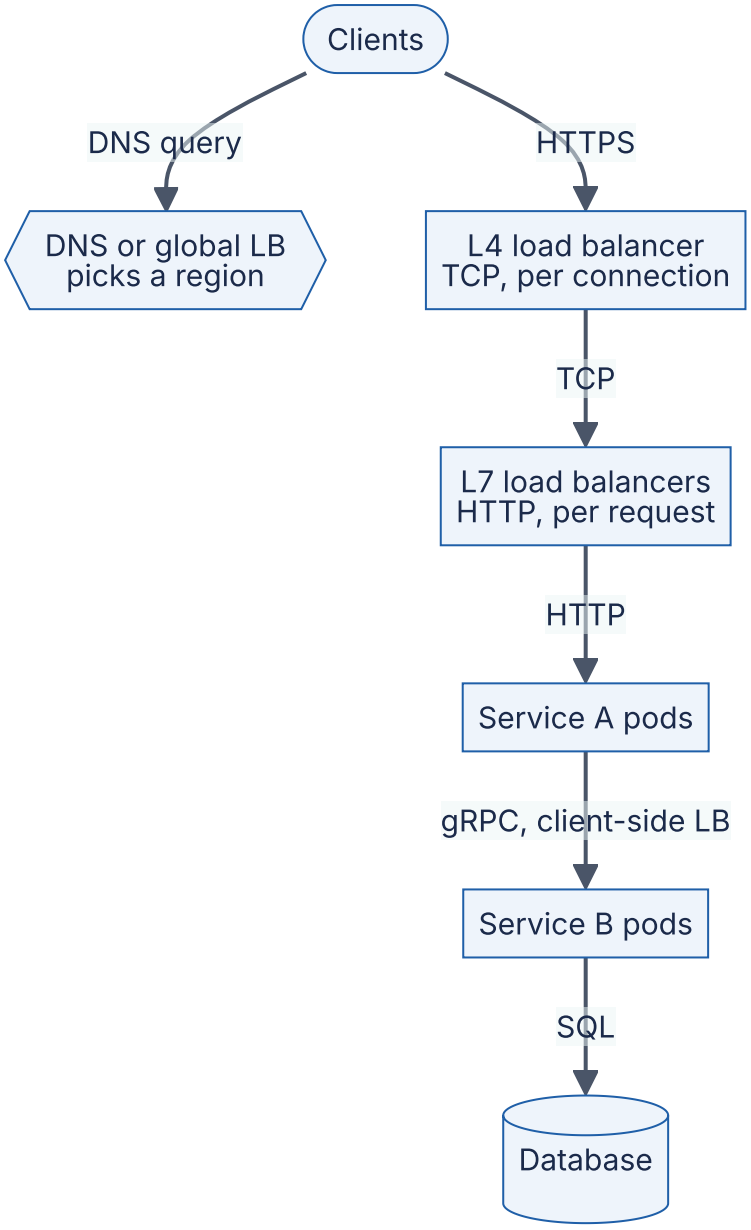
The classic state-related failures (mass logout on deploy, sessions lost at scale-in, a session-store outage that logs everyone out, a hot instance under affinity) appear in Table 8.1 and Table 18.3. All share one prevention: decide where each piece of state lives *before* the tier needs to scale, and replicate that place.

> COMMON MISTAKE
>
> **"Stateless means the system has no state."** It means *this tier* keeps none between requests. The engineering work is choosing where state lives and making that place durable, available and fast enough.

18.6 Load distribution

Horizontal scaling needs something to spread requests across nodes. This section is a map; Chapter 19 is the territory.

Figure 18.3 — Layers of load distribution.



Reading the diagram. DNS or global server load balancing (hexagon) steers each client to a region, at the granularity of DNS answers and their TTLs (§19.9). A **layer-4 load balancer** spreads TCP connections without reading requests; a **layer-7 load balancer** routes each HTTP request by path, header or cookie (§19.3). Inside, **client-side load balancing** lets service A pick a pod of service B from a registry (§19.10). All arrows are synchronous. Failure points: the load balancers, made redundant with pairs, anycast or ECMP (§19.8), and stale DNS answers. Each layer scales horizontally; the database at the bottom does not, by this mechanism.

The algorithm matters most when requests differ in cost. Round robin suits uniform requests; least-outstanding-requests and **power of two choices** avoid piling work on a slow node; consistent hashing keeps related requests together for cache locality (§14.8, §19.4).

Good algorithms approximate one shared queue in front of all servers, which beats separate queues (Figure 4.4).

18.7 Bottleneck identification

18.7.1 Where scaling stops

DEFINITION

Definition — Scaling bottleneck. The resource that limits throughput as load or node count grows: the resource with the largest service demand per unit of capacity (§2.6). For a horizontally scaled system, it is usually a resource that *all* nodes share and that cannot itself be scaled out by adding application nodes.

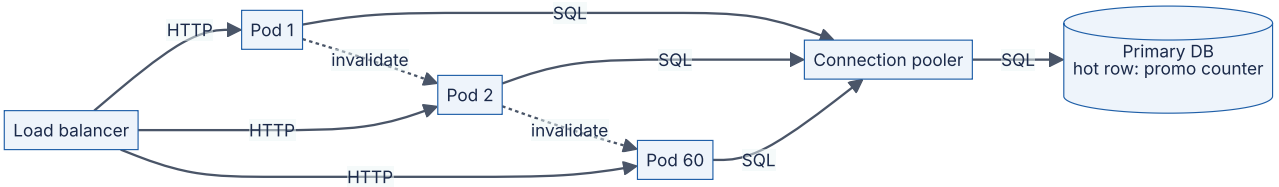
First-principles explanation

Adding checkout lanes to a supermarket helps until every lane waits for the single price-check clerk. The clerk was always there; with two lanes she was idle most of the time, and with twenty she is the whole story. Horizontal scaling multiplies the parts you replicate and leaves untouched the parts you share, so the shared parts eventually dominate.

How it works internally

1. **List the resources on the request path** using the resource model of Table 2.7: CPU, memory, disk, network and software resources (locks, pools, single-threaded components).
2. **Classify each as per-node or shared.** Per-node resources (application CPU) grow with N; shared ones (the database primary, a global counter, a leader, a license server, a third-party rate limit) do not.
3. **Compute utilization at the target load** with the utilization law $U = XD/c$ (§2.6). The largest is the bottleneck now.
4. **Ask what grows with N.** Connection counts, health-check traffic, cache-invalidation fan-out and membership gossip all grow with node count, sometimes as N^2. These are the coherency terms of the USL.
5. **Fit the USL** to load-test throughput at several node counts (§4.13, §23.10) [Gunther 2007]. Its coefficients tell you whether you face contention (α), coherency (β) or neither.
6. **Relieve, then repeat.** The bottleneck moves.

Figure 18.4 — The shared-resource funnel.



Reading the diagram. Sixty pods scale out freely behind the load balancer (synchronous HTTP) but converge, through a pooler, on one primary database and one hot row: a promotion counter that every order updates under a lock, a *contention* cost (USL α). The dotted arrows are asynchronous cache invalidations between pods; their number grows with pod pairs, a *coherency* cost (USL β). Storage boundary: the database. Failure point: the hot row saturates while pod CPUs look idle. Adding pods worsens both costs.

Mathematical foundations

The USL itself is in §4.13. For a capacity decision you need one derived quantity: what the *next* node buys.

FORMULA

Marginal throughput of the N-th node

$$\Delta X(N) = X_1\,[C(N) - C(N-1)] \qquad E(N) = \frac{C(N)}{N}$$

Symbol	Meaning	Units
X_1	Throughput of one node (measured)	requests/s
$C(N)$	USL relative capacity at N nodes (§4.13)	dimensionless
$\Delta X(N)$	Extra throughput gained by adding node N	requests/s
$E(N)$	Scaling efficiency: fraction of linear scaling achieved	dimensionless (0–1)

WORKED EXAMPLE

Worked example — How many pods can QuickBite usefully run? A load test of the order API, where every order updates a promotion counter row and pods broadcast invalidations, fits $\alpha = 0.03$ and $\beta = 0.0002$. One pod sustains $X_1 = 800$ RPS. The product team wants 15,000 RPS for a national promotion.

1. Peak concurrency: $N^* = \sqrt{(1 - 0.03)/0.0002} = \sqrt{4,850} = 69.6$ pods.
2. Maximum throughput:
   $C(70) = 70/(1 + 0.03 \times 69 + 0.0002 \times 70 \times 69) = 70/(1 + 2.07 + 0.966) = 70/4.036 = 17.34$, so
   $X_{max} \approx 17.34 \times 800 = 13,875$ RPS.
3. Marginal gain at 40 pods: $C(40) = 16.116$ and $C(39) = 16.008$, so
   $\Delta X(40) = 800 \times 0.108 \approx 87$ RPS, about one-ninth of what the first pod delivered.
4. Efficiency at 40 pods: $E(40) = 16.116/40 = 0.40$. You pay for 40 pods and get the work of 16.

Interpretation. No number of pods reaches 15,000 RPS; the system peaks at about 13,900 RPS near 70 pods and degrades beyond. **Engineering implication.** Stop scaling out and remove the shared costs: split the counter into per-shard sub-counters that are summed periodically (§14.10), and replace pod-to-pod invalidation with a TTL or a pub/sub channel (§20.10). Re-test and re-fit; if α falls to 0.005 and β to 0.00001, N^* rises to about 315 pods.

WARNING / TRADE-OFF

The autoscaler cannot see the knee. A CPU-based autoscaler adds pods whenever pods are busy. Past N^*, extra pods add contention, latency rises, pods stay busy, and the autoscaler adds still more. Cap `maxReplicas` below the measured knee and alert when the cap is reached.

COMMON MISTAKE

“Low utilization everywhere means we can scale.” If latency rises with load while every hardware dashboard is calm, the bottleneck is a software resource: a lock, a pool or a single-threaded component (§2.6).

18.8 Scaling application servers

18.8.1 Preconditions

A stateless application tier scales out only if four things are true:

1. **Instances are disposable**: built from an immutable image, configured from the environment, holding no state (§18.5).
2. **Readiness is explicit.** A **readiness probe** tells the load balancer when a new instance can take traffic, separately from a **liveness probe** that says whether it should be restarted.
3. **Shutdown is graceful.** On a termination signal the instance stops accepting new requests, finishes in-flight ones within a deadline (**connection draining**), closes pools and exits.
4. **Dependencies can take the extra load.** Each new instance opens connections and sends queries to shared tiers (§18.8.5).

18.8.2 Autoscaling and its signals

DEFINITION

Definition — Autoscaling. Automatically changing the number of instances of a service in response to a measured or forecast signal, within configured minimum and maximum bounds. **Reactive** autoscaling responds to current metrics; **scheduled** autoscaling follows a calendar; **predictive** autoscaling acts on a forecast.

A thermostat is the right analogy: it measures the room, compares it with a set point and switches the heating on or off. Like a thermostat, an autoscaler reacts *after* the temperature changes and the heater takes time to warm up, so the set point must leave room for that delay.

Table 18.6 — Autoscaling signals.

Signal	Good for	Weakness
CPU utilization	CPU-bound stateless services	Misses I/O-bound services whose threads wait idle; noisy
Requests per second per instance	Uniform request cost; needs a measured per-instance capacity	Breaks when the request mix changes
In-flight requests (concurrency)	I/O-bound services; follows Little's Law ($L = \lambda W$)	Rises when a dependency slows, which more instances may not fix
Queue depth or consumer lag per worker	Asynchronous workers (Chapter 30)	Needs a target derived from the latency objective
Latency (p95, p99)	Guard rail and alerting	Lagging, nonlinear, and caused by dependencies as often as by load
Schedule	Known daily or weekly peaks	Misses surprises
Forecast	Ramps faster than reaction time	Wrong when the forecast is wrong

The best primary signal is one that is **proportional to load and inversely proportional to instance count**: doubling the instances should halve it. CPU and per-instance request rate usually qualify; latency usually does not.

18.8.3 Target tracking

Target tracking keeps a per-instance metric near a set point by resizing the fleet in proportion to the error. It is the algorithm of the Kubernetes Horizontal Pod Autoscaler (HPA) and of AWS target-tracking policies [Kubernetes Docs: HPA], [AWS Docs: EC2 Auto Scaling].

FORMULA

Target-tracking replica count (Kubernetes HPA)

$$n_{desired} = \lceil n_{current} \times \frac{m_{current}}{m_{target}} \rceil \quad \text{if } \left|\frac{m_{current}}{m_{target}} - 1\right| > \tau$$

Symbol	Meaning	Units
$n_{current}$	Current number of replicas	pods
$n_{desired}$	Replica count the autoscaler requests, clamped to [min, max]	pods
$m_{current}$	Current per-replica metric, averaged over replicas	metric units (e.g. % CPU, RPS)
m_{target}	Target per-replica metric	same units
τ	Tolerance band within which no action is taken (default 0.1 as of 2026)	dimensionless

WORKED EXAMPLE

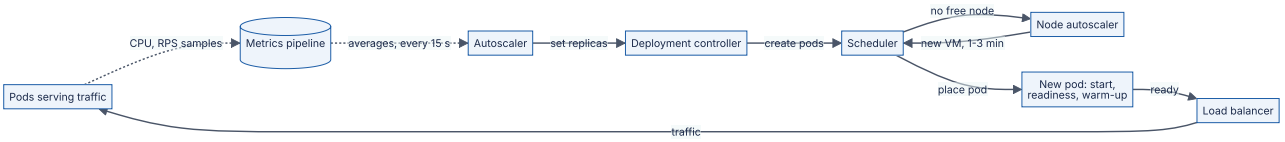
Worked example — Two HPA decisions for QuickBite.

CPU target. 10 replicas average 90% CPU against a 60% target. Ratio $= 90/60 = 1.5$, outside the ±0.1 band. $n_{desired} = \lceil 10 \times 1.5 \rceil = 15$. After scaling, the same load spread over 15 pods averages $90 \times 10/15 = 60\%$, exactly the target.

Request-rate target. 14 pods average 650 RPS against a target of 500 RPS per pod (assuming a measured 830 RPS per pod at the p99 objective, so 500 is about 60%). Ratio $= 1.3$; $n_{desired} = \lceil 14 \times 1.3 \rceil = \lceil 18.2 \rceil = 19$. If instead they averaged 530 RPS, the ratio 1.06 is inside the band and nothing happens.

Interpretation. The rule is proportional: double the per-pod metric, double the pods. The tolerance stops it reacting to noise. **Engineering implication.** Choose m_{target} from a load test, not from intuition: it is the per-instance throughput at which latency still meets the objective, times a safety factor for reaction time (next section).

Figure 18.5 — The autoscaling control loop.



Reading the diagram. Pods report metrics asynchronously (dotted) to a metrics pipeline, the storage boundary for recent samples. The autoscaler reads averages periodically (every 15 s by default in Kubernetes) and sets a new replica count; the deployment controller creates pods and the scheduler places them. If no node has room, a node autoscaler must first create a virtual machine, typically adding one to several minutes. The new pod pulls its image, starts and passes readiness before receiving traffic, often with cold caches. Failure points: stale metrics, image-registry outages, exhausted quotas. The sum of these delays is the **reaction time** that headroom must cover.

Flapping and scale-in

Scaling in too eagerly causes **flapping**: remove pods, utilization rises, add pods, repeat. Autoscalers therefore scale in slowly. The Kubernetes HPA, for example, uses by default the highest recommendation of the last five minutes when scaling down (a **stabilization window**) [Kubernetes Docs: HPA]. Scale up fast, scale down slowly: the cost of a few spare pods for five minutes is small; the cost of being under capacity during a rebound is an incident.

18.8.4 Warm-up and reaction time

A new instance is not useful the moment it is requested. Its delay is the sum of metric collection, the evaluation period, possibly provisioning a machine, pulling the image, starting the process, passing readiness, and **warm-up**: the period in which caches are empty, connection pools are filling and just-in-time compilers have not yet optimized hot code. During all of this the *existing* instances absorb the growing load.

FORMULA

Target utilization that survives reaction time

$$u_{target} \le \frac{u_{safe}}{1 + r \times T_{react}}$$

Symbol	Meaning	Units
u_{target}	Utilization set point for the autoscaler	fraction
u_{safe}	Highest utilization at which latency still meets the objective (from load tests and §4.10)	fraction
r	Fastest expected load growth, relative to current load	fraction per minute
T_{react}	Reaction time: metric delay + evaluation + provisioning + start + warm-up	minutes

The derivation is one line: during T_{react} load grows by a factor of about $1 + rT_{react}$ while capacity stays fixed, so utilization must start that factor below u_{safe}. It is a linear approximation, good when rT_{react} is below about 0.5.

WORKED EXAMPLE

Worked example — Choosing QuickBite's CPU target. Load tests show p99 stays within objective up to $u_{safe} = 0.85$. Dinner ramps grow load by up to $r = 15\%$ per minute. Reaction time: metric delay 0.5 min, evaluation 0.25 min, pod start and readiness 1 min, warm-up equivalent to 0.5 min of lost capacity, so $T_{react} = 2.25$ min.

1. $1 + rT_{react} = 1 + 0.15 \times 2.25 = 1.3375$.
2. $u_{target} \le 0.85/1.3375 = 0.636$. Choose **60%**.
3. If the cluster has no spare nodes and a node autoscaler adds 2 min: $T_{react} = 4.25$, $1 + 0.6375 = 1.6375$, $u_{target} \le 0.52$. Choose **50%**, which means about 20% more pods at all times.

Interpretation. Slow provisioning is paid for with permanently idle capacity. **Engineering implication.** Shorten T_{react} instead of lowering the target: keep a small buffer of spare nodes (low-priority placeholder pods that real pods can evict), use pre-initialized warm pools, slim images, and send a new instance a slowly increasing share of traffic (**slow start**) while it warms.

The simulation below checks the formula against a model of the HPA with startup and warm-up delays. Load doubles from 6,000 to 12,000 RPS over five minutes, a growth of 10–20% per minute.

```
        """Target-tracking autoscaler with startup delay and warm-up (Section 18.8).

        A simplified model of the Kubernetes HPA rule
            desired = ceil(current * current_metric / target_metric)
        applied every 15 s to CPU utilization. New pods serve nothing for STARTUP_S sec-
onds,
        then serve at half capacity for WARMUP_S seconds (cold caches, JIT compilation).
        Load ramps linearly from 6,000 to 12,000 RPS over five minutes.
        """
        import math

        POD_RPS = 1_000        # requests/s one warm pod handles at 100% CPU
        STARTUP_S = 60         # scheduling + image pull + process start + readiness
probe
        WARMUP_S = 60          # serving at half capacity while caches and JIT warm up
        SYNC_S = 15            # autoscaler evaluation period
        METRIC_LAG_S = 30      # age of the utilization sample the autoscaler sees
        TOLERANCE = 0.10       # no action while |ratio - 1| <= 10%
        RAMP_S = 300           # load doubles over five minutes, starting at t = 60 s

        def load(t):
            return 6_000 + 6_000 * min(max(t - 60, 0), RAMP_S) / RAMP_S

        def run(target):
            pods = [-10_000] * math.ceil(6_000 / (POD_RPS * target))   # start times;
all warm
            worst, overloaded = 0.0, 0
            for t in range(0, 1_200):
                cap = 0.0
                for start in pods:
                    age = t - start
                    if age >= STARTUP_S + WARMUP_S:
                        cap += POD_RPS
                    elif age >= STARTUP_S:
                        cap += POD_RPS / 2
                util = load(t) / cap
                worst = max(worst, util)
                overloaded += util > 1.0
                if t % SYNC_S == 0 and t >= METRIC_LAG_S:
                    # Average CPU over all pods as the autoscaler sees it; pods that are
                    # not ready count as idle, as the HPA assumes when scaling up.
                    seen = load(t - METRIC_LAG_S) / (len(pods) * POD_RPS)
                    ratio = seen / target
                    if abs(ratio - 1) > TOLERANCE:
                        desired = math.ceil(len(pods) * ratio)
                        if desired > len(pods):
                            pods += [t] * (desired - len(pods))
            return worst, overloaded, len(pods)

        print("target  peak util  seconds >100%  final pods")
        for target in (0.5, 0.6, 0.7, 0.8):
```

```
        worst, over, final = run(target)
        print(f"{target:5.0%}   {worst:8.0%}   {over:12d}   {final:9d}")
```

Output:

```
target  peak util  seconds >100%  final pods
  50%        74%              0          23
  60%        88%              0          19
  70%       102%              9          17
  80%       116%            184          15
```

What to notice:

- At an 80% target the fleet spends about three minutes above 100% utilization, during which queues grow without bound (§4.10). At 60% the worst moment is 88%, close to $u_{safe} = 0.85$. That is consistent with the formula, because this ramp starts at 20% per minute, a little faster than the 15% assumed in the worked example.
- The final pod counts differ by only 8 pods (23 versus 15), but the overload differs by minutes. Headroom is cheap insurance against reaction time.
- The model ignores backlog carried over from overloaded seconds, so real overload lasts longer than shown.

INDUSTRY EXAMPLE

Predictive autoscaling. Netflix described Scryer, a system that forecasts each service's traffic from historical daily and weekly patterns and scales capacity *ahead* of the predicted demand, with reactive autoscaling kept as a safety net for surprises. Cloud providers offer similar predictive scaling for virtual-machine groups. *Evidence: Primary* — [Netflix 2013], [AWS Docs: EC2 Auto Scaling]

18.8.5 Connection pools versus database limits

Every application instance keeps a **connection pool** to the database (§7.16, §14.13). Pool size is set per instance, but the database's connection limit is set per database. Horizontal scaling multiplies the first and leaves the second fixed. PostgreSQL runs one backend process per connection, reserves a few slots for superusers, and refuses the rest with `FATAL: sorry, too many clients already` [PostgreSQL Docs: Connections].

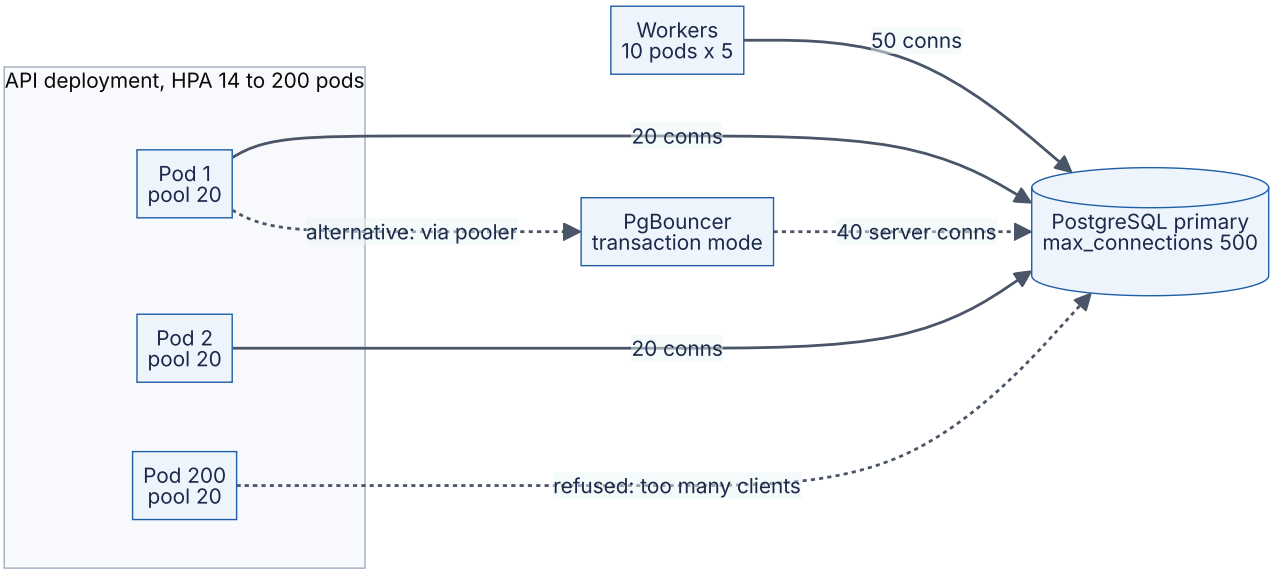
FORMULA

Connection budget

$$n_{max} \times p + \sum_{j} n_j p_j \leq M - R$$

Symbol	Meaning	Units
n_{max}	Maximum replicas of the scaled service (autoscaler `maxReplicas`)	pods
p	Maximum pool size per replica	connections
n_j, p_j	Replicas and pool size of every other client service j	pods, connections
M	Database `max_connections`	connections
R	Connections reserved for superusers, replication, monitoring and migrations	connections

Figure 18.6 — Two hundred pods against one connection limit.



Reading the diagram. The API deployment grows from 14 to 200 pods with pools of up to 20, and workers hold another 50 connections. All speak the PostgreSQL protocol synchronously to one primary whose `max_connections` of 500 is the hard limit (storage boundary). The dotted edge from pod 200 shows connections refused once the budget is spent. The dotted path through PgBouncer is the alternative: the pooler multiplexes client connections onto about 40 server connections (§14.13), decoupling pod count from database connections. Failure point: the limit is reached exactly when traffic peaks and the autoscaler is adding pods.

WORKED EXAMPLE

Worked example — QuickBite's promotion-night outage, on paper. PostgreSQL primary: $M = 500$. Reserved: 3 superuser slots plus 27 for replication, monitoring and migrations, so $R = 30$. Workers: $10 \times 5 = 50$. API pods: pool 20, HPA from 14 to 200 replicas.

1. Budget for the API: $500 - 30 - 50 = 420$ connections.
2. At the minimum of 14 pods: $14 \times 20 = 280$. Fits.
3. The autoscaler crosses $420/20 = 21$ pods during a normal dinner peak. Pod 22 cannot fill its pool; its readiness check fails or its requests error. CPU stays high, so the autoscaler adds more pods, which also fail.
4. At the maximum of 200 pods: $200 \times 20 = 4,000$ connections, 9.5 times the budget.
5. What the database actually needs, by Little's Law (§4.11): at peak about 4,000 queries/s that reach the database (most browse reads are served by the cache) at about 2 ms each, plus 60 order transactions/s at about 15 ms, gives $4,000 \times 0.002 + 60 \times 0.015 = 8 + 0.9 \approx 9$ busy connections on average. With 3× burst headroom, about 30.

Three fixes.

- **Shrink the pool:** $p = \lfloor 420/200 \rfloor = 2$. At 14 pods each pod then has 2 connections for about $9/14 = 0.64$ busy on average: workable, but a single slow query blocks half a pod's pool.
- **Cap the autoscaler:** `maxReplicas` = 21. Safe for the database, but caps the API tier at 21 pods even when the bottleneck is CPU.
- **Add a transaction-mode pooler** (§14.13): pods keep pools of 10 to PgBouncer (2,000 cheap client connections), and PgBouncer holds 40 server connections, comfortably above the 30 needed. Pod count and database connections are now independent.

Interpretation. The configuration that worked at 14 pods was a latent outage at 22. **Engineering implication.** Check the connection budget whenever you change `maxReplicas`, pool size or the number of client services, and put a pooler in front of PostgreSQL before the API tier autoscales. Size the *server* side of the pool from Little's Law, not from pod count.

Failure scenarios

Table 18.7 — Application-tier scaling failures.

What goes wrong	Why	Detection	Recovery	Prevention
Overload during ramps	Reaction time longer than the headroom covers	Utilization > u_{safe} while scaling	Shed load (§22.9)	Lower target; shorten T_{react}; scheduled scaling
Runaway scale-out	Bottleneck downstream keeps pods busy	Replicas at max; DB saturated	Cap replicas; fix bottleneck	`maxReplicas` below the knee
Connection exhaustion	Pods × pool > `max_connections`	`too many clients` errors	Lower pool; restart pooler	Connection budget; transaction pooler
Flapping	Scale-in too fast	Oscillating replica count	Lengthen stabilization	Scale down slowly
Cold-start storms	Many new pods with empty caches hit the DB at once	DB load spike after scale-out	Slow start	Warm caches; shared cache tier
Quota or capacity exhaustion	Cloud account or zone out of instances	Pending pods; API errors	Other instance types or zones	Quota reviews in the capacity plan

COMMON MISTAKE

"Autoscaling replaces capacity planning." An autoscaler only moves between `minReplicas` and `maxReplicas`, using nodes, quotas and database connections that someone had to plan. It handles hourly variation, not next year's growth.

18.9 Scaling databases (overview)

Once the application tier is stateless, the database is usually the bottleneck, because it is the tier that holds the shared, coherent state. Chapters 11–14 treat its scaling options in depth. This section is a decision aid: start from the symptom, try the cheapest option that addresses it, and escalate only when measurements say so.

Table 18.8 — Database scaling options: a decision table.

Option	Fixes this symptom	Adds read capacity	Adds write capacity	Adds storage	Cost and complexity	See
Query and index tuning	Slow queries, full scans	Yes	Yes	No	Low	§11.7–§11.10
Connection pooler	Too many connections; per-connection memory	Indirectly	Indirectly	No	Low	§14.13
Vertical scaling	Any resource saturated, below the cost knee	Yes	Yes	Yes	Low, until the knee	§18.3
Cache in front of the DB	Read-heavy, repetitive reads	Yes (large)	No	No	Medium: invalidation	Chapter 20
Read replicas	Read-heavy; analytics on the primary	Yes	No	No	Medium: replication lag	§14.3–§14.4
Functional split (Y axis)	Unrelated tables compete for one server	Yes	Yes	Yes	Medium: no cross-DB joins	§18.10
Storage engine choice	Write-heavy ingest; space amplification	Depends	Yes (LSM)	Depends	Medium	§13.7–§13.11
Partitioning or sharding (Z axis)	Writes or data beyond one primary	Yes	Yes	Yes	High: shard key, resharding, cross-shard queries	§14.6–§14.12
Distributed SQL (NewSQL)	Need SQL and transactions beyond one node	Yes	Yes	Yes	High: latency, cost	§12.11
NoSQL key-value or wide-column store	Simple access patterns at very high scale	Yes	Yes	Yes	Medium to high: data-model redesign	Chapter 12
Separate read model (CQRS, search index)	Queries the primary schema serves badly	Yes	No	Yes	Medium to high: asynchronous updates	§32.4, Chapter 16
Archiving and tiering	Table and index growth from old data	Indirectly	Indirectly	Frees space	Low to medium	§15.9

Three rules summarize the table. **Reads and writes scale differently:** caches and replicas multiply reads; only partitioning or a bigger primary multiplies writes, so measure the read-to-write ratio first (117:1 for QuickBite browsing, §2.11). **Cheap fixes first:** index-

ing, pooling, caching and a bigger node often buy an order of magnitude together, while sharding is a one-way door (§2.8) that costs months. **Plan the hard move early:** §18.11.4 turns this into a lead-time calculation.

18.10 The scale cube

18.10.1 Three axes of scaling

DEFINITION

Definition — Scale cube. A model by Martin Abbott and Michael Fisher that classifies every scaling technique along three independent axes [Abbott and Fisher 2015]: the **X axis**, cloning identical copies of a service or its data behind a load balancer; the **Y axis**, splitting by function, service or resource so that each part handles different work; and the **Z axis**, splitting by customer, requester or other key so that each part handles the same work for a subset of the data or users.

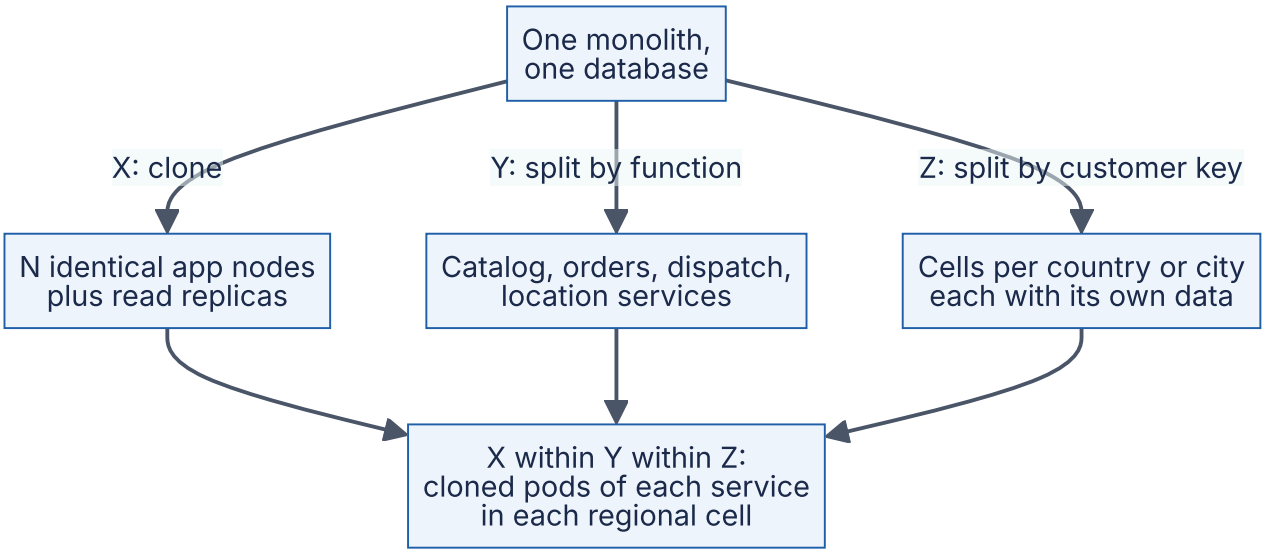
First-principles explanation

The bakery chain again. **X axis**: open more identical shops, each making everything. **Y axis**: split the work so one kitchen makes bread, another cakes, another sandwiches, each sized for its own demand. **Z axis**: give each city its own complete operation that serves only that city's customers. The axes combine: each city (Z) can have specialized kitchens (Y), each with several identical ovens (X).

Why does this exist?

Engineers tend to reach for one familiar technique. The cube forces the question "which kind of split solves *this* bottleneck?" Each axis relieves a different limit and costs something different.

Figure 18.7 — The scale cube applied to QuickBite.



Reading the diagram. The top node is the starting point: one deployable unit and one database. Arrows are design moves, not request flows, so no protocols apply. X clones the application and read-only data; the shared primary remains. Y splits by function into services, each with its own data store (a storage boundary per service). Z splits by a customer key such as country, so each cell holds only its customers' data and contains its own failures. Large systems end up at the bottom node, combining all three. Failure points differ by axis: X still shares the database, Y adds network calls, Z adds a routing layer and cross-cell operations.

Table 18.9 — The three axes compared.

	X axis: clone	Y axis: split by function	Z axis: split by key
What it is	Identical copies behind a load balancer	Different services for different work	Same service, different subsets of customers or data
Relieves	Compute and read capacity	Codebase size, team coupling, mixed workloads	Write capacity, data size, blast radius, data residency
Advantages	Simplest; no code change if stateless	Independent scaling and deployment	Near-linear scaling; failure isolation
Disadvantages	Shared data tier remains; caches duplicated	Network calls, distributed transactions	Routing layer; cross-cell queries and rebalancing
Operational complexity	Low	Medium to high	High
Examples	Stateless pods, read replicas	Microservices (Chapter 34), separate location service	Sharding (Chapter 14), cells (§33.12), regional stacks (Chapter 44)
Choose when	First, for stateless tiers	Parts of the system have very different load or owners	One primary or one failure domain is too big

WORKED EXAMPLE

Worked example — Which axis for which QuickBite bottleneck? At 2 million daily users (§2.11):

1. *Browse reads, 7,000 RPS.* Independent requests, read-only, cacheable. **X axis**: about 18 cloned API pods plus a menu cache (§18.11).
2. *Courier location writes, 5,000/s, about 83 times the order write rate.* A different workload from orders in rate, data shape and consistency. **Y axis**: a separate location service with its own in-memory store, as §2.8 decided.
3. *Order writes heading for the WAL limit of about 500/s* (§2.10) as QuickBite expands into several countries. **Z axis**: partition orders by country or city, which also satisfies data-residency rules and contains failures.

Interpretation. Each bottleneck has a natural axis, determined by whether the work is identical (X), different (Y) or identical on separable data (Z). **Engineering implication.** Name the axis explicitly in design reviews; “we will shard” and “we will add microservices” are answers to different problems.

INDUSTRY EXAMPLE

Cells and shuffle sharding at AWS. AWS publishes guidance on **cell-based architecture**: dividing a service into independent cells, each a complete copy of the stack serving a subset of customers, behind a thin routing layer [AWS 2023]. Its Builders’ Library also describes **shuffle sharding**, which assigns each customer to a random combination of nodes so that one customer’s harmful traffic affects few others [MacCárthaigh 2019]. Both are Z-axis splits, chosen as much to limit the blast radius of failures as to add capacity. *Evidence: Primary* — [AWS 2023], [MacCárthaigh 2019]

COMMON MISTAKE

“Z axis means database sharding.” Sharding a database is one Z-axis split. Abbott and Fisher’s Z axis can split the *whole stack* (application pods, caches and data) by customer, which also isolates failures. Conversely, splitting into microservices is a Y-axis move and adds no write capacity to a shared database.

18.11 Capacity planning

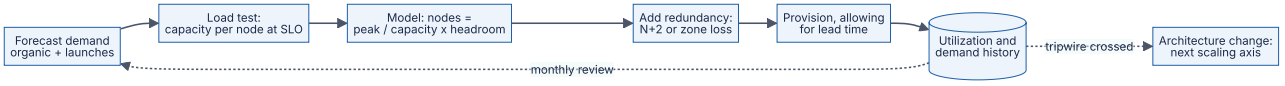
18.11.1 The planning loop

DEFINITION

Definition — Capacity planning. The recurring process of forecasting demand, translating it into the resources needed to serve it within the service-level objective with stated headroom and redundancy, and acquiring those resources before they are needed, allowing for the lead time to obtain them.

Capacity planning is the scalability counterpart of a household budget: forecast income and expenses, keep a reserve for emergencies, and order large purchases early enough to arrive on time. Google's SRE book lists its mandatory steps as an accurate forecast of organic demand that extends beyond the lead time for acquiring capacity, the inclusion of inorganic demand such as launches and marketing campaigns, and regular load testing to relate raw resources to service capacity [Beyer et al. 2016].

Figure 18.8 — The capacity planning loop.



Reading the diagram. This is a process, not a running system. Load tests convert requests per second into nodes; the per-node capacity c must be measured at the latency objective, not at saturation. The model adds queueing headroom, the redundancy step adds failure headroom, and provisioning starts early enough to cover lead time: minutes for cloud instances, weeks for quotas or reservations, months for hardware or a re-architecture. Utilization history (a storage boundary) feeds the next forecast (dotted). The second dotted exit matters most: when a tripwire (§2.7) fires, the answer is a design change, not more nodes.

18.11.2 Headroom and redundancy

FORMULA

Provisioned capacity with headroom

$$N = \lceil \frac{R_{peak}\,(1+g)^{L}}{c \times u_{target}} \rceil \qquad N_{total} = N + k \quad \text{or} \quad N_{total} = \lceil N \times \frac{Z}{Z-f} \rceil$$

Symbol	Meaning	Units
R_{peak}	Current design peak load	requests/s
g	Demand growth rate per period	fraction per month
L	Lead time to add capacity	months
c	Per-node throughput at which latency meets the objective (measured)	requests/s per node
u_{target}	Target utilization (queueing and reaction-time headroom, §18.8.4)	fraction
N	Nodes needed to serve the load with headroom	nodes
k	Spare nodes for failures and deploys (N+1: $k = 1$; N+2: $k = 2$)	nodes
Z, f	Failure domains (zones) used, and how many may fail at once	count
N_{total}	Nodes to provision	nodes

Three kinds of headroom hide in this formula: **queueing headroom** ($u_{target} < 1$, because latency grows as $1/(1-\rho)$, §4.10), **growth headroom** ($(1+g)^{L}$, because capacity takes time to arrive), and **failure headroom** (k or $Z/(Z-f)$). N+2 is the common rule for services: one spare for an unplanned failure, a second for the node that is down for maintenance or a deploy at the same moment [Beyer et al. 2016]. The zone form provisions so that losing f of Z zones leaves enough capacity *without any scaling action*, a property AWS calls **static stability** [Weiss and Furr 2020].

WORKED EXAMPLE

Worked example — QuickBite's API fleet at 2 million users. From §2.11: $R_{peak} = 6,667$ RPS (rounded to 7,000 in Chapter 2), $c = 1,000$ RPS per node, $u_{target} = 0.6$.

1. *Servers needed now:* $6,667/(1,000 \times 0.6) = 11.1$, so $N = 12$.
2. *N+2:* $N_{total} = 14$, the figure Chapter 2 used. Spread over 3 zones as 5, 5 and 4, losing a 5-node zone leaves 9 nodes: $6,667/9,000 = 74\%$ utilization. The service survives, but above its 60% target and with no room for a burst.
3. *Zone-safe,* $Z = 3$*,* $f = 1$*:* $N_{total} = \lceil 12 \times 3/2 \rceil = 18$, six per zone. Losing a zone leaves 12 nodes at $6,667/12,000 = 56\%$.
4. *With growth headroom:* demand grows $g = 8\%$ per month and new reserved capacity takes $L = 3$ months to arrange. $(1.08)^3 = 1.26$, so plan for $6,667 \times 1.26 = 8,398$ RPS: $N = \lceil 8,398/600 \rceil = 14$, and zone-safe $N_{total} = 21$.

Interpretation. Moving from N+2 to zone-level static stability costs 4 more nodes (29% more) and buys survival of a whole-zone outage within target. **Engineering implication.** Decide which failure the fleet must absorb without scaling, write it down in the capacity plan, and size for it; autoscalers may not be able to add capacity during a zone outage, when every other customer is trying to do the same.

18.11.3 Peak-to-average ratio and the cost of peaks

FORMULA

Peak-to-average ratio and average fleet utilization

$$PAR = \frac{R_{peak}}{R_{avg}} \qquad \bar{u} = \frac{R_{avg}}{N_{total} \times c}$$

Symbol	Meaning	Units
R_{avg}	Average load over a day (or week)	requests/s
PAR	Peak-to-average ratio	dimensionless
$\bar{u}$	Average utilization of a statically provisioned fleet	fraction

WORKED EXAMPLE

Worked example — How idle is a fleet sized for dinner? QuickBite's browse load averages $2,000,000 \times 30/86,400 = 694$ RPS and peaks at 6,667 RPS.

1. $PAR = 6,667/694 = 9.6$. This follows from the assumptions: 20% of the day's traffic in one hour is $0.2 \times 24 = 4.8$ times the daily average, and the burst factor of 2 doubles it.
2. Static, zone-safe fleet of 18 nodes: $\bar{u} = 694/(18 \times 1,000) = 3.9\%$.
3. With autoscaling between a floor of 6 nodes (two per zone) and 18, the fleet follows demand; if it averages 8 nodes, $\bar{u} = 694/8,000 = 8.7\%$, and the fleet costs less than half as much.

Interpretation. A fleet sized for a sharp peak, with queueing and failure headroom, is idle most of the day. Barroso and Hölzle reported that servers in large datacenters typically operate at 10–50% of their maximum utilization [Barroso and Hölzle 2007].
Engineering implication. The higher the PAR, the more autoscaling, scheduled scaling or sharing capacity with batch work pays off. A low PAR (a steady workload) favors reserved, statically sized capacity.

18.11.4 Forecasting and lead time

Forecasts combine **organic growth**, extrapolated from history (often as a compound monthly rate with daily and weekly seasonality), with **inorganic** steps: launches, marketing campaigns, new countries, and events such as holidays [Beyer et al. 2016]. The crucial output is not a number but a *date*: when will each component cross its usable capacity, and is that further away than the time needed to fix it?

FORMULA

Time until a component's capacity is exhausted

$$D(t) = D_0(1+g)^t \qquad t_{exhaust} = \frac{\ln(C_{usable}/D_0)}{\ln(1+g)} \qquad t_{start} = t_{exhaust} - L_{fix}$$

Symbol	Meaning	Units
D_0	Current peak demand on the component	operations/s
g	Compound growth rate per period	fraction per month
C_{usable}	Usable capacity: limit × target utilization	operations/s
$t_{exhaust}$	Periods until demand reaches usable capacity	months
L_{fix}	Lead time of the fix, including a safety margin	months
t_{start}	Latest month to start the fix	months

WORKED EXAMPLE

Worked example — When must QuickBite start partitioning orders? The order database's WAL disk caps it at about 500 orders/s (§2.6); at $u_{target} = 0.6$, $C_{usable} = 300$ orders/s. Today $D_0 = 56$ orders/s at 2 million users (the unrounded 55.6 of §2.11, which Chapter 2 rounds up to 60), growing 8% per month.

1. $C_{usable}/D_0 = 300/56 = 5.36$; $\ln 5.36 = 1.678$; $\ln 1.08 = 0.0770$.
2. $t_{exhaust} = 1.678/0.0770 = 21.8$ months.
3. Partitioning by region (§14.7) is estimated at 6 months of work plus a 3-month margin: $L_{fix} = 9$. So $t_{start} = 21.8 - 9 \approx 13$ months from now.
4. Sensitivity: at 12% monthly growth, $t_{exhaust} = 1.678/\ln 1.12 = 1.678/0.1133 = 14.8$ months, and the project must start in about 6 months.

Interpretation. The same headroom means two years at one growth rate and barely more than one at another. **Engineering implication.** Put t_{start} for every architectural limit into the capacity plan, recompute it monthly from measured growth, and treat crossing it as a tripwire (§2.7). Group commit (§13.5) could raise the limit about 4× (an assumed factor, §2.10) and push $t_{exhaust}$ out by $\ln 4/\ln 1.08 = 18$ months, a cheaper first move worth evaluating before partitioning.

INDUSTRY EXAMPLE

Intent-based capacity planning at Google. The SRE book describes Auxon, a tool in which teams state capacity *intent* (dependencies, service-level requirements, N+2 redundancy, budget) and a solver produces the resource allocation, replacing hand-maintained spreadsheets of machine counts. *Evidence: Primary* — [Beyer et al. 2016]

18.11.5 Worked capacity plan: QuickBite from 1,000 to 10 million users

The plan reuses Chapter 2's per-user assumptions: 30 browse requests and 0.25 orders per daily active user (DAU), 20% of daily traffic in the busiest hour, a burst factor of 2, one active courier per 100 DAU at peak sending a location every 4 s, and $c = 1,000$ RPS per API node at $u_{target} = 0.6$. Two zones are used for the first two stages and three thereafter, and no stage runs fewer than two API nodes. The program below computes every row of Table 18.10.

```
        """QuickBite capacity plan from 1k to 10M daily active users (Section 18.11).

        All inputs are teaching assumptions carried over from Chapter 2 (Table 2.10,
Section 2.11).
        """
        import math

        BROWSE_PER_DAU = 30      # browse requests per DAU per day
        ORDERS_PER_DAU = 0.25    # orders per DAU per day
        BUSY_HOUR_SHARE = 0.20   # share of daily traffic in the busiest hour
        BURST = 2.0              # burst factor above the busiest-hour average
        COURIERS_PER_DAU = 0.01  # couriers active at peak per DAU (20,000 at 2M DAU)
        UPDATE_INTERVAL_S = 4    # courier location update interval
        NODE_RPS = 1_000         # sustained RPS per API node (measured, Section 2.11)
        U_TARGET = 0.6           # target utilization per node

        def peak(daily):
            return daily * BUSY_HOUR_SHARE / 3_600 * BURST

        def api_nodes(rps, zones):
            work = max(1, math.ceil(rps / (NODE_RPS * U_TARGET)))
            if zones == 1:
                return work, work + 1                    # N+1 on one zone
            return work, math.ceil(work * zones / (zones - 1))  # survive one zone loss

        stages = [  # (name, DAU, zones)
            ("S1 pilot", 1_000, 2),
            ("S2 city", 20_000, 2),
            ("S3 region", 200_000, 3),
            ("S4 country", 2_000_000, 3),
            ("S5 multi-country", 10_000_000, 3),
        ]

        print(f"{'stage':17} {'DAU':>10} {'browse/s':>9} {'avg/s':>7} {'PAR':>4} "
              f"{'orders/s':>8} {'loc w/s':>8} {'work':>5} {'total':>5} {'avg

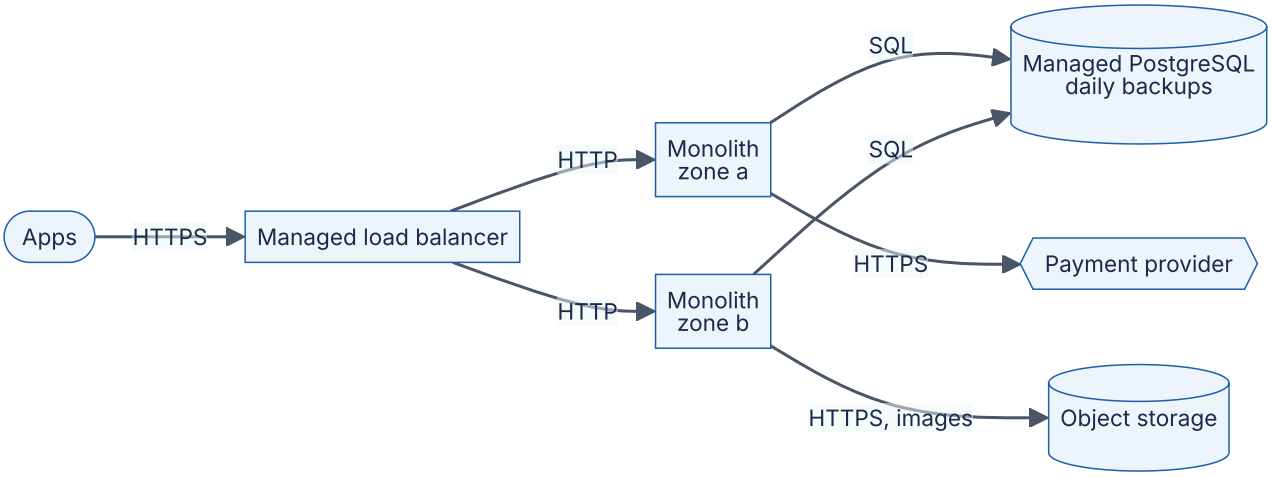
What to notice: the API fleet is never the hard part; at every stage the interesting limits are elsewhere (the order database, the location write path, availability). The minimum of two nodes dominates the first three stages, which is why their average utilization rounds to zero.

Table 18.10 — QuickBite capacity plan by stage.

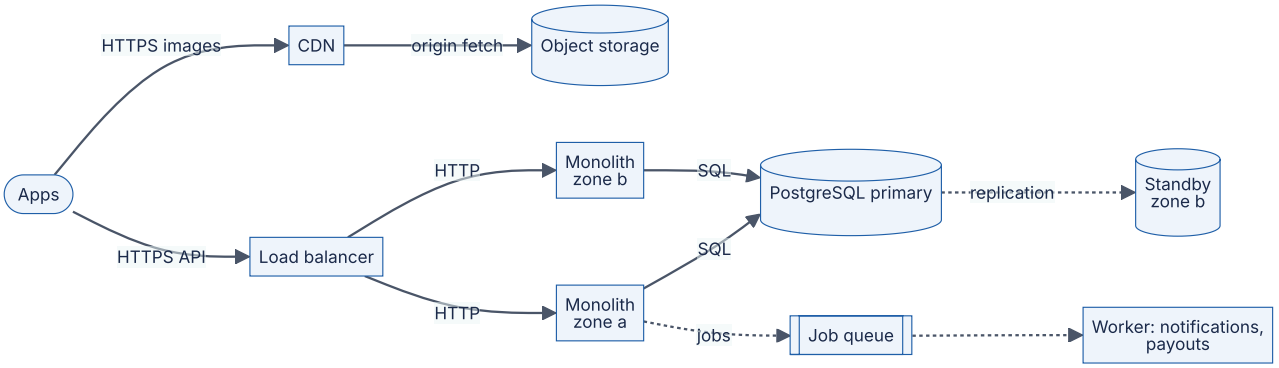
Stage	DAU	Peak browse RPS	Peak orders/s	Location writes/s	API nodes	What changes, and why
S1 pilot	1,000	3	0.03	2.5	2	Monolith; managed DB; second node only for availability
S2 city	20,000	67	0.6	50	2	Standby DB, CDN for images, job queue
S3 region	200,000	667	5.6	500	3 (autoscaled)	Cache, pooler, location moves to an in-memory store
S4 country	2,000,000	6,667	56	5,000	18 (autoscaled)	Y-axis location service, event log, read replicas
S5 multi-country	10,000,000	33,333	278	25,000	84 in 4 cells	Z-axis regional cells; orders partitioned by region

Figure 18.9 — Stage S1: 1,000 DAU.



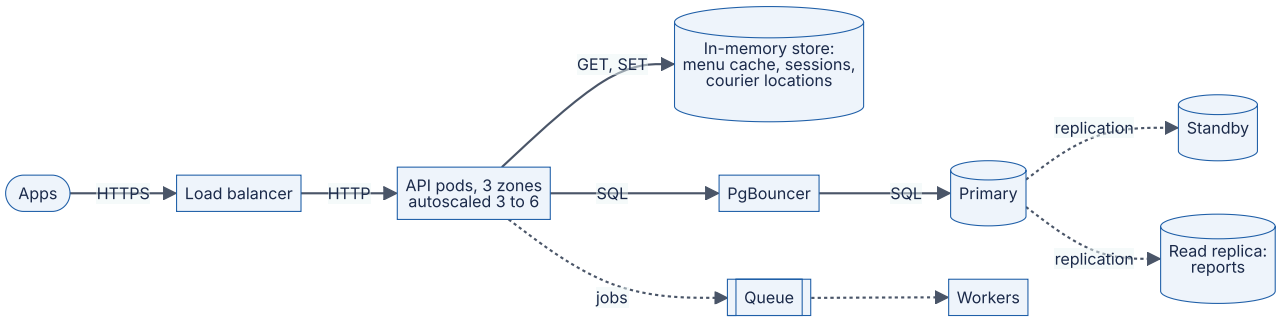
Reading the diagram. The three apps call a managed load balancer over HTTPS, which forwards synchronous HTTP to two copies of the modular monolith (§2.8) in different zones. Sessions live in the database from day one, so the nodes are stateless. One managed PostgreSQL instance with backups is the only database; images go to object storage; the payment provider is external. Failure point: the single database instance, acceptable for a pilot. Peak load (3 RPS) would fit on a laptop; the second node exists for deploys and failures, not capacity.

Figure 18.10 — Stage S2: 20,000 DAU (one city).



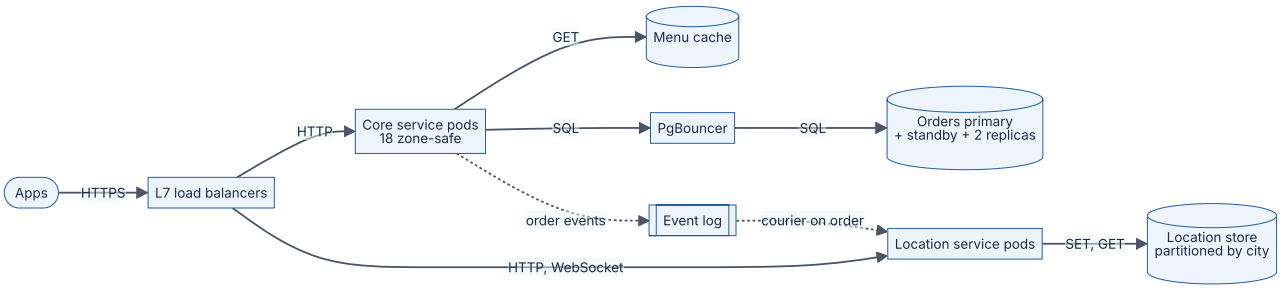
Reading the diagram. Paying customers arrive, so availability matters more than capacity. A CDN serves menu images. The database gains a standby in a second zone, fed by replication (dotted), with automatic failover (§14.4). Notifications and payouts move asynchronously to a job queue and worker, so a slow third party cannot hold an API request. Storage boundaries: object storage, primary and standby, the queue. The API tier is still two nodes at 67 RPS.

Figure 18.11 — Stage S3: 200,000 DAU (one region).



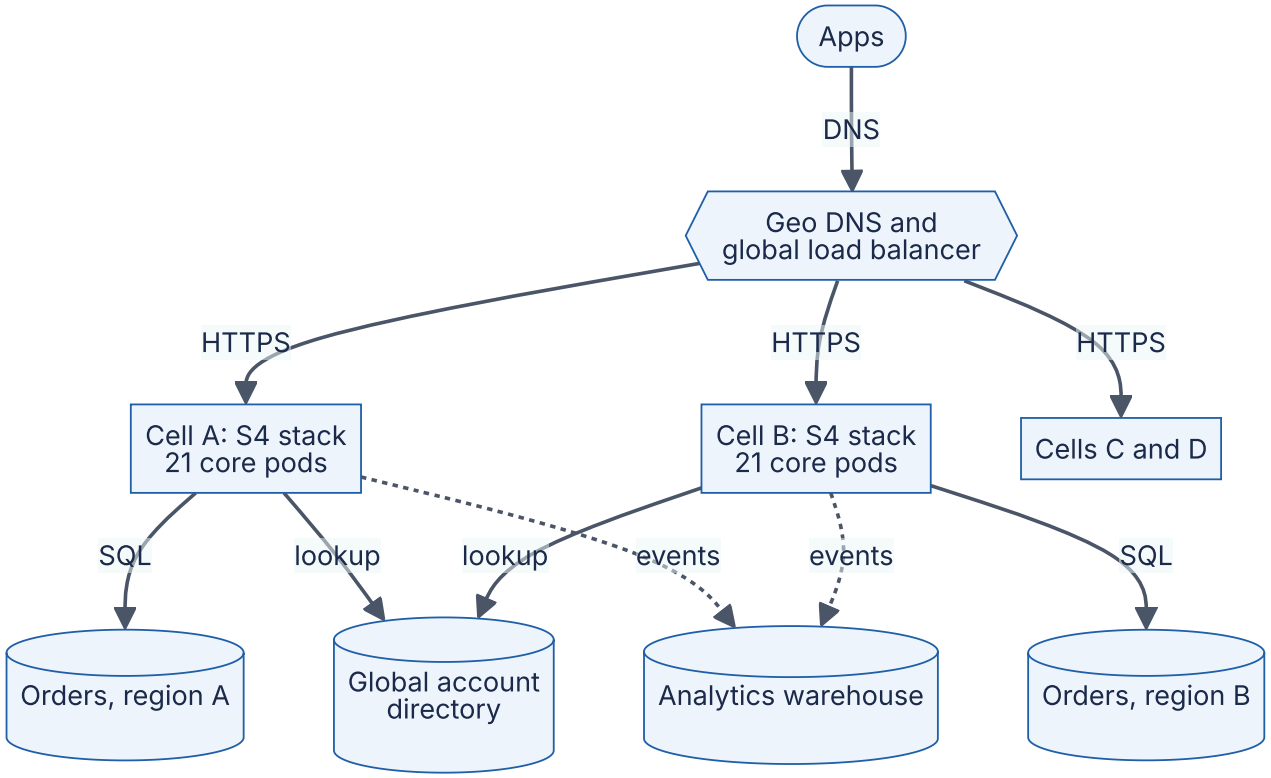
Reading the diagram. Menu queries are now the database's largest cost, so a replicated in-memory store caches menus with a TTL and holds sessions (Chapter 20). Courier locations, 500 writes/s of short-lived data, move there too. The API runs as autoscaled pods across three zones behind a transaction-mode pooler, which fixes the connection budget before autoscaling can break it (§18.8.5). A read replica serves reports. Failure point: the in-memory store is on the critical path for sessions, so it is replicated across zones.

Figure 18.12 — Stage S4: 2,000,000 DAU (one country).



Reading the diagram. This is Chapter 2's container view (Figure 2.7) sized by this chapter's arithmetic. The location path (5,000 writes/s) is a separate service with a store partitioned by city: a Y-axis split that also serves the 2,500 tracking reads/s. The core service runs 18 zone-safe pods (§18.11.2) and publishes order events asynchronously to a durable log that the location service consumes. The orders primary runs at about 11% of its WAL limit (56 of 500 orders/s), so it is not partitioned yet, but §18.11.4 has started the clock.

Figure 18.13 — Stage S5: 10,000,000 DAU (several countries).



Reading the diagram. Order writes would reach 278/s, 93% of one primary's usable 300/s, and expansion brings data-residency rules, so the system splits on the Z axis into four regional **cells**, each a complete S4 stack with its own orders database serving one region. Assuming four equal cells, each peaks at 8,333 browse RPS: $\lceil 8,333/600 \rceil = 14$ working pods, 21 zone-safe, 84 in total. Global DNS routes users to their cell; a small global account directory maps accounts to cells; events flow asynchronously to a global analytics warehouse. Failure is contained to one cell. Cross-cell operations, such as a traveler ordering abroad, become explicit exceptions (Chapter 44, §33.12).

Failure scenarios and misconceptions

Table 18.11 — Capacity planning failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Outage at a known peak	Planned for average load	Saturation at the same hour daily	Emergency scale-up; shed load	Plan with PAR and burst factors
Zone loss overloads survivors	Sized N+k, not zone-safe	Utilization jump on zone failure	Shed non-critical traffic	Static stability, $Z/(Z-f)$
Capacity arrives too late	Lead time ignored	Forecast crosses usable capacity before the fix is ready	Vertical stopgap	t_{start} tripwires
Wrong per-node capacity	c measured at saturation, or with an unrealistic request mix	p99 breach below planned load	Re-measure	Load test at the latency objective
Launch traffic unplanned	Inorganic demand missed	Marketing calendar surprises	Pre-scale; queue sign-ups	Include launches in forecasts

COMMON MISTAKE

“Plan for average load and let the autoscaler handle peaks.” QuickBite’s PAR is 9.6. An autoscaler with a two-minute reaction time cannot add 9× capacity in time for a dinner rush that ramps in minutes, and it is bounded by `maxReplicas`, quotas and database connections that only a plan provides. Use scheduled scaling for known peaks and the autoscaler for the surprises.

COMMON MISTAKE

“Headroom is waste.” Queueing headroom keeps latency within objective (§4.10), failure headroom keeps the service up when a zone fails, and growth headroom covers lead time. Waste is headroom nobody can justify; write the reason for each factor into the plan.

18.12 Summary and revision notes

SUMMARY

- **Vertical scaling** is the cheapest move in effort and keeps state coherent, but it hits a hardware ceiling, keeps one failure domain, and gets expensive past the knee: with linear pricing, cost per unit of throughput is $k(N) = N/C(N) = 1 + \alpha(N - 1) + \beta N(N - 1)$.
- **Horizontal scaling** removes the ceiling and turns failures into lost capacity, but needs interchangeable nodes, load distribution, and a shared tier that can take the combined load.
- **Stateless** means a tier keeps no state another instance needs; state moves to session stores, databases, caches and clients. Sticky sessions hide state rather than removing it.
- **Bottlenecks** in scaled-out systems are shared resources. Use the resource model (§2.6) and fit the USL; the marginal gain $\Delta X(N) = X_1[C(N) - C(N - 1)]$ shows when another node stops paying. Cap autoscalers below the knee.
- **Target tracking:** $n_{desired} = \lceil n \cdot m_{current}/m_{target} \rceil$ with a tolerance band; scale up fast, down slowly. Choose $u_{target} \le u_{safe}/(1 + rT_{react})$ and shorten reaction time with warm pools and spare nodes.
- **Connection budget:** $n_{max} p + \sum n_j p_j \le M - R$. Autoscaling multiplies pools; put a transaction pooler in front of PostgreSQL and size server connections by Little's Law.
- **Databases:** caches and replicas scale reads; only partitioning (or a bigger primary) scales writes. Try cheap fixes first (Table 18.8).
- **Scale cube:** X clones, Y splits by function, Z splits by customer or key. Each relieves a different bottleneck.
- **Capacity planning:** $N = \lceil R_{peak}(1 + g)^L/(c\,u_{target}) \rceil$, then N+2 or zone-safe $\lceil NZ/(Z - f) \rceil$. PAR reveals idle cost. Turn forecasts into dates: $t_{exhaust} = \ln(C_{usable}/D_0)/\ln(1 + g)$, and start fixes L_{fix} earlier.

18.13 Knowledge checkpoint

1. Give two reasons vertical scaling stops being the right answer.
2. With linear pricing and USL coefficients $\alpha = 0.02$, $\beta = 0.00005$, what is the relative cost per unit of throughput at 32 cores?
3. What test tells you whether an application instance is stateless?
4. Why do sticky sessions make scale-in harder?
5. 12 pods average 75% CPU with a 50% target. How many pods does the HPA request?

6. Why do autoscalers scale down more slowly than they scale up?
7. u_{safe} = 0.8, load grows at 10% per minute, reaction time is 3 minutes. What is the highest safe target?
8. A database has `max_connections` = 300 and 20 reserved. Pods have pools of 10. What is the largest safe `maxReplicas` with no other clients?
9. Which database-scaling options add write capacity?
10. Classify: read replicas; a separate payments service; one database per country.
11. Why is N+2 not the same as zone-safe for 14 nodes in 3 zones?
12. Peak 9,000 RPS, average 1,500 RPS. What is the PAR, and what does it suggest?
13. Usable capacity is 4 times current demand and demand grows 5% per month. When is it exhausted?

Answers

1. Any two of: no larger node exists; cost per unit of throughput rises past the knee; a single node is one failure domain; serial code or in-node coherency leaves added cores idle.
2. $k(32) = 1 + 0.02 \times 31 + 0.00005 \times 32 \times 31 = 1 + 0.62 + 0.0496 = 1.67$.
3. If it vanished now, would any user or other instance notice anything beyond a retry? If not, it is stateless.
4. Removing an instance destroys the sessions pinned to it, so scale-in either logs users out or must wait for sessions to expire.
5. $\lceil 12 \times 75/50 \rceil = 18$.
6. To avoid flapping: removing capacity too early causes a rebound that needs it back, and under-capacity is costlier than a few minutes of spare pods.
7. $0.8/(1 + 0.1 \times 3) = 0.8/1.3 = 0.615$, so about 60%.
8. $\lfloor (300 - 20)/10 \rfloor = 28$ pods.
9. A bigger primary, a functional split onto separate databases, partitioning or sharding, distributed SQL, and write-optimized or partitioned NoSQL stores. Caches and read replicas do not.
10. X axis; Y axis; Z axis.
11. N+2 tolerates any two node failures, but 14 nodes in 3 zones put 5 in one zone; losing that zone removes 5. Zone-safe sizing provisions $Z/(Z - f)$ times the needed nodes.
12. PAR = 6. A statically sized fleet would be idle most of the day; autoscaling or scheduled scaling pays off.
13. $\ln 4 / \ln 1.05 = 1.386/0.0488 = 28.4$ months.

18.14 Interview questions

Basic

Q1. What is the difference between vertical and horizontal scaling, and when would you choose each? Answer. Vertical adds resources to one node: no code change, transactions stay local, but there is a ceiling, one failure domain and a rising cost per unit of throughput past the knee. Horizontal adds nodes: no ceiling and graceful degradation, but it needs stateless nodes, load distribution and a shared tier that can keep up. Scale the stateless tiers out from the start; scale the database up until its knee, then partition.

Q2. How do you make a service stateless? Answer. Move every piece of request-spanning state to a tier built for it: sessions to a replicated session store or signed tokens, carts and drafts to the database, cached data to a shared cache, uploads to object storage, timers to a queue. Keep only rebuildable local caches. Add readiness probes and graceful shutdown so instances can be added and removed safely.

Intermediate

Q3. Your API autoscales from 10 to 100 pods during a sale, and the database starts refusing connections. What happened and how do you fix it? Answer. Pods times pool size exceeded `max_connections` minus reserved slots. Short term: lower pool sizes or cap replicas. Proper fix: a transaction-mode pooler such as PgBouncer, with server connections sized by Little's Law (transaction rate × hold time × headroom), and a connection-budget check whenever replicas or pools change. Also verify that the database itself is not the real bottleneck.

Q4. How do you choose the autoscaling metric and target? Answer. Pick a metric proportional to load and inversely proportional to replicas: CPU for CPU-bound services, in-flight requests for I/O-bound ones, backlog per worker for queues. Load-test to find the per-pod throughput at which p99 meets the objective (u_{safe}), then lower the target by the load growth expected during the reaction time: $u_{safe}/(1 + rT_{react})$. Add scheduled scaling for known peaks.

Advanced

Q5. Adding servers no longer increases throughput. How do you investigate? Answer. Measure throughput at several node counts and fit the USL. A large α points to a shared, serialized resource (a hot row, a global lock, a single primary); a significant β points to coordination that grows with node pairs (invalidation broadcasts, gossip, distributed locks). Confirm with per-resource utilization (USE, §2.6) and profiling. Fix the shared cost by partitioning or removing it; cap the autoscaler below the knee meanwhile.

Q6. Walk through a capacity plan for a service growing from one city to several countries. Answer. Convert users to peak rates (busy-hour share, burst factor); measure per-node capacity at the latency objective; compute nodes at a target utilization; add N+2 or zone-safe redundancy and growth over lead time. For each shared component, compute when demand crosses usable capacity and subtract the fix's lead time. Map each limit to an axis: X for stateless tiers, Y for very different workloads such as location updates, Z (cells, partitions) for write limits and data residency.

18.15 Practical exercises

1. Run the autoscaler simulation with a 2-minute load ramp and with `STARTUP_S = 180`. Find the highest target that avoids overload in each case and compare it with the formula in §18.8.4.
2. Extend the capacity-plan program to compute PgBouncer server connections per stage, assuming 2 ms per query and that 40% of browse requests miss the cache.
3. Load-test any small web service at 1, 2, 4, 8 and 16 workers, fit the USL coefficients and report N^*.

18.16 Design challenges

1. **Ticket on-sale.** A concert-ticket service sees 100 times its normal load for 10 minutes when sales open. Design the scaling strategy: what is pre-scaled, what autoscales, what queues users, and how the inventory database avoids a hot row.
2. **QuickBite in a new continent.** Extend the S5 design to a continent with strict data-residency laws and a different payment provider. Decide what is global, what is per cell, and how a traveler's account works across cells.

Chapter 19 — Load Balancing

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Chapter 18 made the case for horizontal scaling: run many identical, stateless copies of a service instead of one big machine. That decision creates a new problem the moment you make it. Clients know one name, `api.example.com`, but there are now forty servers behind it. Something must pick a server for every connection or request, notice when a server dies, and keep doing so while servers come and go. That something is a **load balancer**, and it sits on the critical path of almost every request in a modern system.

Load balancing looks simple ("send each request to the next server") and hides some of the most instructive ideas in system design. A balancer that ignores load can push slow servers into collapse while fast ones idle. A balancer that chases the least-loaded server can stampede it. A balancer that remembers which server holds a user's session cannot also spread load perfectly. And a balancer is itself a server that can fail, so you must balance the balancers. This chapter works through each of these problems with the mechanism, the arithmetic and a simulation that you can run.

19.1 Learning objectives

After this chapter you should be able to:

- Distinguish layer 4 from layer 7 load balancing, and choose between TLS termination, re-encryption and passthrough, and between NAT, full-proxy and direct server return forwarding.
- Implement round robin, smooth weighted round robin, least connections, EWMA-based least response time and power of two choices, and predict how each behaves on heterogeneous servers.
- State the maximum-load results for one and two random choices, and use a simulation to compare p99 queue lengths across algorithms, including with stale load information.
- Explain consistent hashing with bounded loads and Maglev hashing, build a Maglev lookup table and measure its disruption when a backend fails.
- Configure active and passive health checks, compute detection time and the requests lost during it, and avoid flapping and ejection cascades.
- Weigh session affinity methods (cookies, source-IP hashing, consistent hashing) against their costs.

- Design redundant load balancer tiers with VRRP, anycast and ECMP, compute failover times, and drain connections safely.
- Explain where DNS-based global server load balancing fits and where it falls short, and compare proxy, client-side, sidecar and lookaside load balancing.
- Compare NGINX, HAProxy, Envoy, AWS ALB/NLB and Google Maglev for a given workload.

19.2 Prerequisites

- IP routing, BGP and anycast — §7.5 (anycast and ECMP are how balancers themselves are made redundant).
- DNS resolution, TTLs and DNS-based load balancing — §7.6.4, §7.6.5 (global load balancing starts in DNS).
- TCP handshakes, TLS 1.3 and HTTP/2 multiplexing — §7.7, §7.9, §7.10 (they decide what a balancer can see and what a connection costs).
- Reverse proxies and NAT — §7.12, §7.13 (a load balancer is a reverse proxy or a NAT device with a selection policy).
- Queueing basics: utilization, M/M/1, shared versus separate queues, Little's Law — §4.10, §4.11 (every algorithm here is an attempt to approximate one shared queue).
- Percentiles and tail latency — §4.8.
- Consistent hashing and virtual nodes — §14.8 (this chapter builds on it and does not repeat the derivations).
- Stateless versus stateful services — §18.5.

19.3 Layer 4 versus layer 7 load balancing

19.3.1 What a load balancer is

> DEFINITION
>
> **Definition — Load balancer.** A component that receives traffic addressed to a single service endpoint, the **virtual IP address (VIP)** or service name, and distributes it across a **pool** of **backends** (also called *upstreams*, *targets* or *real servers*) according to a **balancing algorithm**, while excluding backends that are unhealthy.

DEFINITION

Definition — Layer 4 (L4) and layer 7 (L7) load balancing. An **L4 load balancer** makes its decision from transport-layer information (IP addresses, ports, protocol) and balances **connections or flows**: every packet of one TCP connection goes to the same backend. An **L7 load balancer** terminates the client connection, parses the application protocol (usually HTTP), and balances **requests**: two requests on one connection may go to different backends.

First-principles explanation

Picture a post office with twenty counters. An L4 balancer is a doorman who looks only at the envelope (sender, entrance) and sends each customer to a counter for the whole visit, however many errands they have. An L7 balancer is a receptionist who opens each letter, reads the errand, and sends each errand to the right counter. She is far more flexible, but opening letters takes time and trust: she must hold the keys to the envelopes (TLS keys).

Why does this exist?

Both exist because of a trade-off between **cost per byte** and **intelligence per request**. Network-level balancers carry terabits per second by touching only packet headers on commodity servers [Eisenbud et al. 2016]. Routing by path, retrying an idempotent `GET` elsewhere, or spreading gRPC calls that share one HTTP/2 connection needs the request itself. Large sites stack both: L4 in front for scale, L7 behind for routing (Figure 19.9).

How it works internally

An **L4 balancer** comes in two forms:

1. **Packet-forwarding L4** (Linux IPVS, Maglev, Meta's Katran, AWS Network Load Balancer). It does not terminate TCP. For the first packet of a flow it picks a backend by hashing the **5-tuple** (source IP, source port, destination IP, destination port, protocol) or by algorithm, records the choice in a **connection-tracking table**, and rewrites or encapsulates each packet toward that backend. The backend completes the TCP handshake with the client itself.
2. **Connection-terminating L4 proxy** (HAProxy `mode tcp`, NGINX `stream`). It accepts the client's TCP connection, opens a second TCP connection to a chosen backend, and copies bytes in both directions without parsing them.

An **L7 balancer** (NGINX `http`, HAProxy `mode http`, Envoy, AWS Application Load Balancer) always terminates:

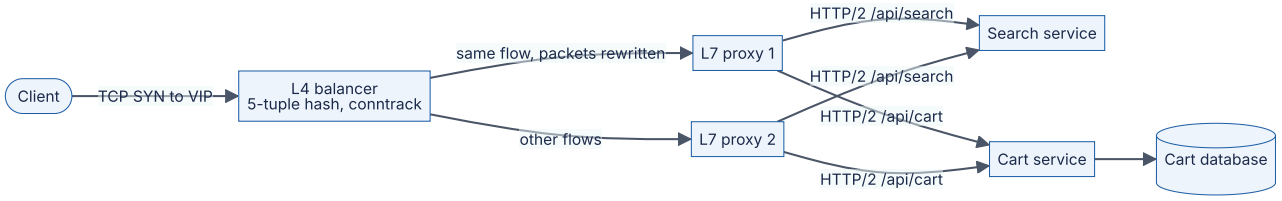
1. Accept the client TCP connection and, for HTTPS, complete the TLS handshake with the site's certificate (**TLS termination**).

2. Parse each HTTP request: method, path, `Host`, headers.
3. Apply **routing rules** (host- and path-based) to choose a pool, then the balancing algorithm to choose a backend in it.
4. Forward the request over a pooled, often long-lived connection to the backend, adding headers such as `X-Forwarded-For` (§7.12).
5. Stream the response back, optionally compressing, caching or retrying on failure.

TLS choices. With **termination**, the balancer decrypts and forwards plaintext inside the private network. With **re-encryption** (TLS bridging), it decrypts, inspects, and opens a new TLS connection to the backend, which zero-trust networks (§10.10) often require. With **passthrough**, an L4 balancer forwards encrypted bytes untouched and may route on the **Server Name Indication (SNI)** field, which travels unencrypted in the TLS ClientHello; it cannot see paths or headers, but certificates and keys stay on the backends.

Architecture diagram

Figure 19.1 — An L4 balancer forwards flows; an L7 balancer terminates connections and routes requests.



Reading the diagram. The client opens one TCP connection to the VIP. The L4 balancer hashes the 5-tuple, records the choice in its connection table, and sends every packet of the flow to the same L7 proxy. The proxy terminates TCP and TLS, reads each HTTP request, and routes `/api/search` and `/api/cart` to different services over pooled HTTP/2 connections. All arrows are synchronous. The cart database is the only storage boundary. Failure points: a lost L4 node breaks its flows unless peers can rebuild the mapping (§19.8); a lost L7 proxy breaks the connections it terminated. Scaling: add L4 nodes behind ECMP and L7 proxies behind the L4 tier.

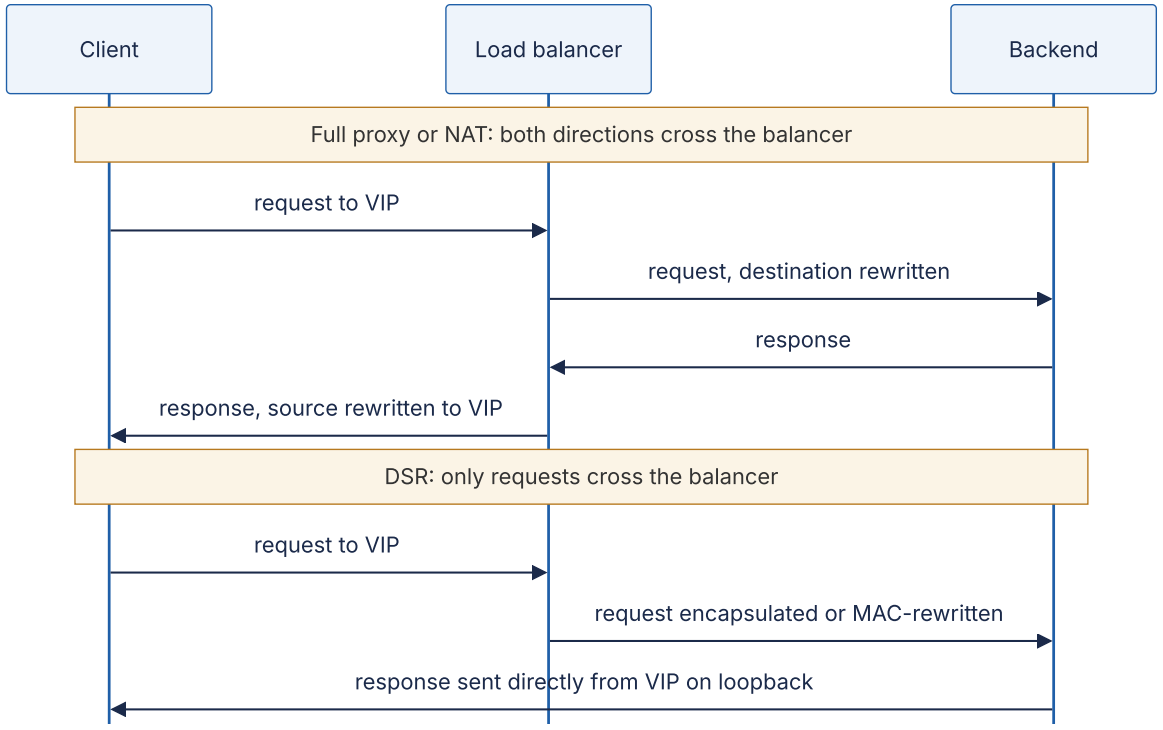
Forwarding modes and direct server return

A packet-forwarding balancer must decide how replies get back to the client.

DEFINITION

Definition — Direct server return (DSR). A forwarding mode in which the balancer delivers request packets to the backend but the backend sends responses **directly to the client**, using the VIP as its source address, bypassing the balancer on the return path.

Figure 19.2 — Full-proxy (NAT) forwarding versus direct server return.



Reading the diagram. In the upper half every byte, in both directions, passes through the balancer, which rewrites addresses each way; the backend learns the client's address only if the balancer passes it (PROXY protocol or `X-Forwarded-For`). In the lower half the balancer forwards only requests, by rewriting the destination MAC address (same layer-2 segment) or by wrapping the packet in an outer IP header (IP-in-IP, GRE, GUE). The backend holds the VIP on a loopback interface and replies from it straight to the client. All flows are synchronous. Failure points: with DSR the balancer never sees responses, so it cannot notice a backend that never answers, and tunnel headers shrink the usable MTU. Scaling: response bytes never load the balancer.

FORMULA

Balancer bandwidth by forwarding mode

$$B_{\text{proxy}} = R\,(s_{\text{req}} + s_{\text{resp}}), \qquad B_{\text{DSR}} = R\,s_{\text{req}}$$

Symbol	Meaning	Units
B_{proxy}	Bandwidth through the balancer when both directions cross it	bytes/second
B_{DSR}	Bandwidth through the balancer with direct server return	bytes/second
R	Request rate	requests/second
s_{req}, s_{resp}	Average request and response size on the wire	bytes

WORKED EXAMPLE

Worked example — a video-thumbnail service. $R = 100,000$ requests/s, $s_{\text{req}} = 2$ KB, $s_{\text{resp}} = 50$ KB (SI units).

1. Full proxy: $100,000 \times (2,000 + 50,000) = 5.2 \times 10^{9}$ bytes/s $= 41.6$ Gbit/s.
2. DSR: $100,000 \times 2,000 = 2 \times 10^{8}$ bytes/s $= 1.6$ Gbit/s.
3. Ratio: $41.6/1.6 = 26$.

Interpretation. With DSR, one balancer with a 10 Gbit/s NIC has room to spare; a full proxy needs at least five such NICs before any headroom. *Engineering implication.* For download-heavy L4 traffic, DSR is the cheapest scaling lever; it is unavailable at L7, because an L7 proxy must see the response to do its job.

Table 19.1 — Forwarding modes of an L4 balancer.

Mode	How it works	Client IP at backend	Return path	Constraints
Destination NAT	Rewrite destination IP; backend's gateway is the balancer	Preserved	Through balancer	Backends must route replies via the balancer
Full NAT / L4 proxy	Rewrite source and destination, or terminate TCP	Lost (use PROXY protocol)	Through balancer	Port exhaustion on the balancer's source IPs
DSR, L2 (MAC rewrite)	Rewrite destination MAC only	Preserved	Direct	Same layer-2 segment; VIP on loopback; ARP suppressed
DSR, tunnel	Encapsulate in IP-in-IP, GRE or GUE	Preserved	Direct	MTU and MSS clamping; backend decapsulates

These are the modes of Linux Virtual Server (LVS-NAT, LVS-DR and LVS-TUN), which IPVS implements in the kernel [Zhang 2000]. Maglev encapsulates packets to backends in GRE and relies on DSR [Eisenbud et al. 2016].

Advantages and disadvantages

Table 19.2 — Layer 4 versus layer 7 load balancing.

Aspect	Layer 4	Layer 7
What it is	Flow or connection balancer	Request balancer and reverse proxy
Unit of balancing	TCP connection or UDP flow	HTTP request or gRPC call
Sees	IPs, ports, protocol (and SNI if it peeks)	Method, path, headers, cookies, body
TLS	Passthrough (or termination in an L4 proxy)	Termination or re-encryption
Advantages	Very high throughput, protocol-agnostic, DSR possible, low added latency	Content routing, retries, per-request balancing, header rewriting, observability per request
Disadvantages	Long-lived connections pin load; no content routing	CPU for TLS and parsing; holds keys; more complex failure modes
Performance	Line rate on commodity servers (10 Gbit/s per Maglev machine)	Bounded by TLS handshakes and request parsing per core
Operational complexity	Routing integration (BGP, ECMP), tunnels	Configuration surface: routes, timeouts, retries
Choose when	Non-HTTP protocols, extreme volume, first tier of a stack	HTTP/gRPC services, microservices, canary routing

COMMON MISTAKE

"An L4 balancer cannot handle HTTPS." It can: with passthrough it forwards encrypted bytes and never needs keys, and with SNI it can even pick a pool per hostname. What it cannot do is route on anything *inside* the encrypted stream, such as the URL path.

COMMON MISTAKE

"Putting HTTP/2 behind an L4 balancer spreads load." It spreads *connections*. A client that multiplexes all its calls over one HTTP/2 connection sends all of them to one backend. This is the classic surprise when teams adopt gRPC behind a cloud L4 balancer (§8.8).

19.4 Load-balancing algorithms

A balancing algorithm answers one question per connection or request: *which backend?* Section 4.10.4 showed why the answer matters: one shared queue feeding all servers beats separate queues by a wide margin, because no server idles while work waits elsewhere. A load balancer cannot build one shared queue across machines; it must commit each request to one server's queue at arrival. Every algorithm below is a different approximation of the shared queue, trading information for cost.

19.4.1 Round robin and weighted round robin

DEFINITION

Definition — Round robin (RR). Send the k-th request to backend $k \bmod N$. **Weighted round robin (WRR)** gives backend i an integer weight w_i and sends it a share $w_i / \sum_j w_j$ of requests in each cycle.

First-principles explanation

A teacher handing out exam papers walks along the row giving one to each desk in turn. Nobody gets two before everyone has one, and the teacher needs no information about the students. That is round robin: perfectly fair in *count*, blind to *effort*. If some desks hold students who work twice as fast, you give them two papers per round: weighted round robin.

Why does this exist?

Round robin needs only a counter and no feedback from backends, so it is cheap and predictable; it is the default in NGINX, HAProxy, Envoy and AWS ALB. Weights handle the commonest exception: a mixed fleet.

How it works internally

A naive WRR repeats each backend w_i times in a row: with weights $a{:}\,5, b{:}\,1, c{:}\,1$ it sends `a a a a a b c`, five requests in a burst to `a`. NGINX uses **smooth weighted round robin**, which interleaves [NGINX source: ngx_http_upstream_round_robin.c]:

1. Each backend keeps a *current weight*, initially 0.
2. On each pick, add every backend's configured weight to its current weight.
3. Choose the backend with the largest current weight.
4. Subtract the total of all weights from the chosen backend's current weight.

Over one cycle of $\sum w_i$ picks each backend is chosen exactly w_i times, and the chosen backend is pushed to the back of the line each time, so picks are spread out.

Mathematical foundations

FORMULA

Weighted round-robin share

$$\lambda_i = \lambda \cdot \frac{w_i}{\sum_{j=1}^{N} w_j}, \qquad \rho_i = \frac{\lambda_i}{\mu_i}$$

Symbol	Meaning	Units
λ	Total request rate into the pool	requests/second
λ_i	Request rate sent to backend i	requests/second
w_i	Configured weight of backend i	dimensionless
N	Number of backends	count
μ_i	Capacity (service rate) of backend i	requests/second
ρ_i	Utilization of backend i	dimensionless

WORKED EXAMPLE

Worked example — a mixed fleet. Three backends with 8, 16 and 32 cores; each core serves 125 requests/s, so $\mu = 1,000$, $2,000$ and $4,000$ requests/s. Total load $\lambda = 5,600$ requests/s.

1. Unweighted RR: each gets $5,600/3 = 1,867$ requests/s. Utilizations: $1,867/1,000 = 1.87$ (overloaded, queue grows without bound), 0.93 and 0.47.
2. Weights $1 : 2 : 4$ (proportional to cores), $\sum w = 7$: $\lambda_i = 800$, $1,600$, $3,200$ requests/s.
3. Utilizations: $800/1,000 = 0.8$, $1,600/2,000 = 0.8$, $3,200/4,000 = 0.8$.

Interpretation. Total capacity is 7,000 requests/s, so the pool is at 80%, yet unweighted RR drives the smallest machine to 187% while the largest idles at 47%. *Engineering implication.* RR is only safe on homogeneous pools; with mixed instance types, set weights proportional to measured capacity, or use a load-aware algorithm.

Code example

```
        """Smooth weighted round robin, the algorithm NGINX uses for weighted up-
streams."""
        from collections import Counter

        class SmoothWRR:
            def __init__(self, weights: dict):
                self.weights = dict(weights)              # server -> configured weight
                self.current = {s: 0 for s in weights}    # server -> current weight
                self.total = sum(weights.values())

            def pick(self) -> str:
                # 1. Every server earns its weight.
                for s, w in self.weights.items():
                    self.current[s] += w
                # 2. The richest server wins (ties: first in insertion order).
                best = max(self.current, key=self.current.get)
                # 3. The winner pays the total, so it falls behind the others.
                self.current[best] -= self.total
                return best

        def naive_wrr(weights: dict) -> list:
            """Repeat each server w times in a row: correct shares, bursty order."""
            return [s for s, w in weights.items() for _ in range(w)]

        if __name__ == "__main__":
            w = {"a": 5, "b": 1, "c": 1}
            lb = SmoothWRR(w)
            seq = [lb.pick() for _ in range(7)]
            print("naive :", " ".join(naive_wrr(w)))
            print("smooth:", " ".join(seq))
            assert seq == ["a", "a", "b", "a", "c", "a", "a"]

            w2 = {"s1": 1, "s2": 2, "s3": 4}               # 8, 16 and 32 cores
            lb2 = SmoothWRR(w2)
            counts = Counter(lb2.pick() for _ in range(7_000))
            print("shares over 7,000 picks:", dict(counts))
            assert counts == {"s1": 1_000, "s2": 2_000, "s3": 4_000}
```

What to notice:

- The smooth sequence for weights 5, 1, 1 is `a a b a c a a`, the sequence documented in the NGINX source, instead of five `a`s in a row.
- Shares are exact over each cycle: 1,000, 2,000 and 4,000 picks out of 7,000.
- The algorithm is $O(N)$ per pick; NGINX accepts that because pools are small. Large pools use precomputed schedules or randomized weighted choice.

INDUSTRY EXAMPLE

Google: weighted round robin driven by backend reports. Google's SRE book describes datacenter load balancing in which clients weight backends using utilization and error rates that the backends report in their responses, after finding that plain round robin and "least-loaded" round robin left large utilization differences between the most and least loaded tasks. gRPC's `weighted_round_robin` policy, which takes weights from backend load reports, follows the same idea. *Evidence: Primary* — [Beyer et al. 2016, ch. 20; gRPC Docs: Load balancing]

19.4.2 Least connections

DEFINITION

Definition — Least connections. Send each new connection or request to the backend with the fewest **active** (in-flight) connections or requests, as counted by the balancer. *Weighted least connections* divides each count by the backend's weight. Envoy calls the request-counting variant **least request**; AWS ALB calls it **least outstanding requests**.

First-principles explanation

At a supermarket you do not join checkouts in turn; you join the shortest line. A fast cashier's line empties quickly, so she gets more customers without anyone measuring her speed. Least connections works the same way: the count of in-flight requests is a free, real-time signal that combines how much work a backend has and how fast it clears it.

How it works internally

1. The balancer increments a counter for a backend when it forwards a request (or opens a connection) and decrements it when the response completes (or the connection closes).
2. For each new request it scans for the minimum count, breaking ties randomly (ties in a fixed order send every tie to backend 0).
3. Weighted versions compare active_i / w_i.

The count is **local to one balancer**. With ten balancer instances, each sees only the connections it opened itself.

Mathematical foundations

FORMULA

Little's Law per backend (§4.11)

$$L_i = \lambda_i W_i \quad \Rightarrow \quad \lambda_i = \frac{L_i}{W_i}$$

Symbol	Meaning	Units
L_i	Average in-flight requests at backend *i* (its "connections")	requests
λ_i	Request rate sent to backend *i*	requests/second
W_i	Average time a request spends at backend *i*	seconds

WORKED EXAMPLE

Worked example — least connections finds the fast server. A pool has a fast backend (W = 50 ms) and a slow one (W = 200 ms, perhaps on a noisy host). Least connections keeps both at about the same count, say L = 20.

1. Fast: λ = 20/0.050 = 400 requests/s.
2. Slow: λ = 20/0.200 = 100 requests/s.
3. Split: 400/(400 + 100) = 80% to the fast backend, with no configuration.
4. Round robin at the same 500 requests/s sends 250 to each; the slow one then holds $250 \times 0.2 = 50$ in-flight requests (more, as its queue grows), $2.5\times$ the fast one.

Interpretation. Equalizing in-flight counts makes the rate to each backend inversely proportional to its latency. *Engineering implication.* Least connections is the robust default when request costs vary widely (search queries, report generation) or backends differ, and essential for long-lived connections (WebSockets, §9.6), where round robin balances connection *arrivals* but not connection *lifetimes*.

WARNING / TRADE-OFF

The fast-failure sinkhole. A backend that fails instantly (returns `503` in 1 ms because its database is down) has the fewest in-flight requests, so least connections sends it *more* traffic. The Google SRE book describes the same trap for "least-loaded" balancing [Beyer et al. 2016, ch. 20]. Pair load-aware algorithms with passive health checks that count errors (§19.5.1).

19.4.3 Least response time and EWMA

DEFINITION

Definition — Least response time. Choose the backend with the lowest recent latency, usually an **exponentially weighted moving average (EWMA)** of observed response times, often multiplied by the in-flight count so that both queue length and speed count.

An EWMA is a running average that forgets: every new sample pulls the estimate a fraction α of the way toward itself. It needs one number per backend, reacts to changes, and ignores old history.

FORMULA

Exponentially weighted moving average

$$S_k = \alpha x_k + (1-\alpha) S_{k-1}, \qquad S_k - x^* = (1-\alpha)^k (S_0 - x^*) \text{ after a step to } x^*, \qquad \alpha = 1 - e^{-\Delta t/\tau}$$

Symbol	Meaning	Units
S_k	Latency estimate after k samples	ms
x_k	The k-th observed latency	ms
α	Smoothing factor, $0 < \alpha \le 1$	dimensionless
x^*	New steady latency after a sudden change	ms
Δt, τ	Time since previous sample; decay time constant (time-based variant)	seconds

::: example **Worked example — how fast does the estimate notice a slowdown?** A backend's latency jumps from 20 ms to 200 ms (garbage-collection storm). $\alpha = 0.1$.

1. After k samples: $S_k = 200 - 180 \times 0.9^k$.
2. $k = 10$: $0.9^{10} = 0.349$, $S = 200 - 62.8 = 137$ ms.
3. $k = 22$: $0.9^{22} = 0.098$, $S = 200 - 17.7 = 182$ ms, within 10% of the truth.
4. At 100 requests/s to this backend, 22 samples arrive in 0.22 s; at 1 request/s, it takes 22 s.

Interpretation. Per-sample smoothing reacts at the speed of traffic, so a backend that gets little traffic (because it looked slow) updates slowly; the time-based form fixes the memory at τ. *Engineering implication.* Choose τ near the timescale of the problems to dodge (seconds for GC pauses), and decay idle estimates toward the pool average so a once-slow backend is retried.

INDUSTRY EXAMPLE

Twitter Finagle and Linkerd: power of two choices with peak EWMA. Finagle, Twitter's RPC library, offers a "peak EWMA" balancer: it tracks an EWMA of round-trip time that jumps *up* immediately on a slow response and decays slowly, multiplies it by the outstanding request count, and compares two randomly chosen backends. Linkerd, which grew out of Finagle, uses the same latency-aware power-of-two-choices approach. *Evidence: Primary* — [Twitter: Finagle documentation, Load balancers]

19.4.4 Power of two choices

DEFINITION

Definition — Power of two choices (P2C). For each request, pick **two** backends uniformly at random and send the request to the less loaded of the two (by in-flight count, EWMA latency or another load signal).

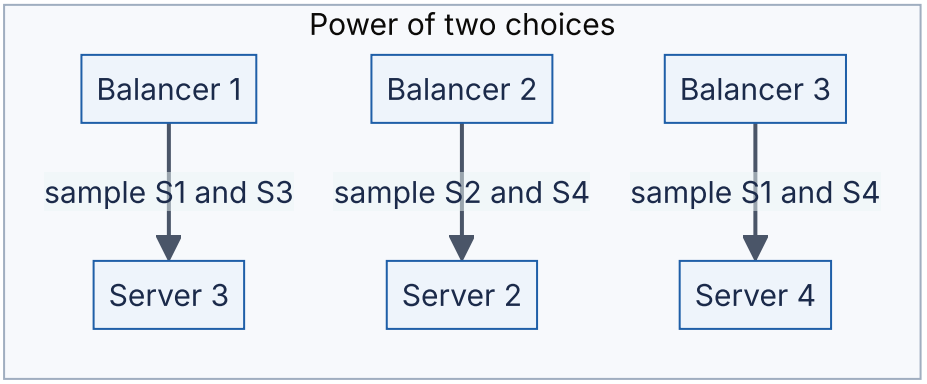
First-principles explanation

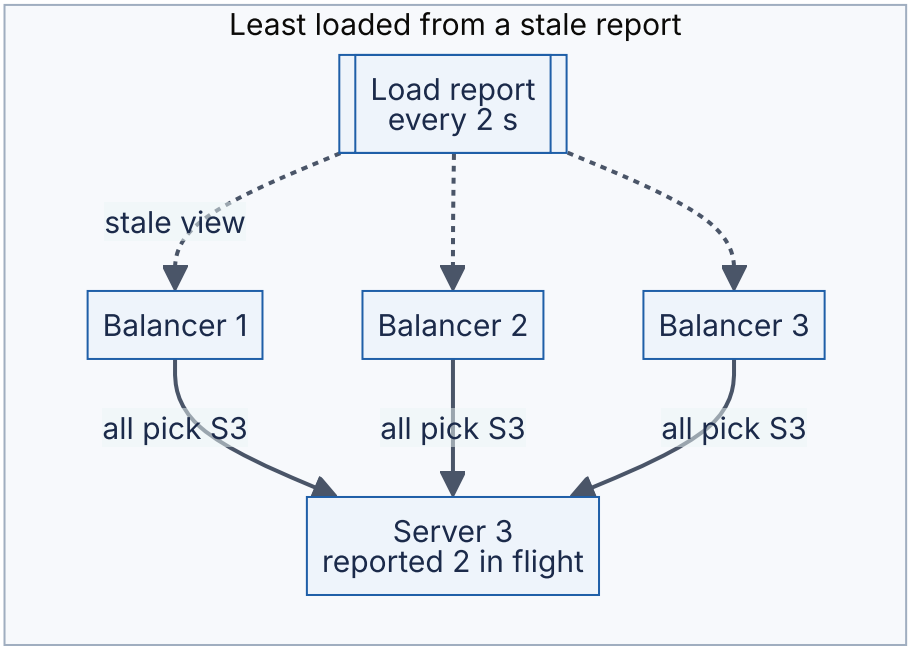
Return to the supermarket, but now the store is enormous, with 500 checkouts, and you cannot see all the lines. If you join a random line, sooner or later you join a terrible one. If you glance at just *two* random lines and join the shorter, you almost never join a terrible line, because both would have to be terrible. The surprise is how much that one extra glance buys: the worst line in the store shrinks *exponentially*.

Why does this exist?

Least connections needs a global, current view of every backend's load. That is cheap for one balancer and 10 backends, but not for 50 balancers and 5,000 backends: each balancer sees only its own traffic, and load reports arrive late. When many balancers all pick "the least loaded backend" from the same stale information, they all pick the *same* backend and swamp it, a **herd effect** (Figure 19.3). Random choice avoids herds but tolerates bad luck. Two random choices keep almost all the benefit of full information, avoid the herd, and cost two lookups [Mitzenmacher 2001].

Figure 19.3 — Herd behavior with stale load information, and how two random choices avoid it.





Reading the diagram. On the left, three balancers receive the same load report asynchronously (dotted) every 2 seconds. Server 3 looked idlest, so all three forward every new request to it (solid, synchronous) until the next report, by which time it is the busiest and the herd moves on. On the right, each balancer samples two random servers per request and picks the lighter, so choices scatter even with stale information. No storage is involved; the failure point is the shared stale view. P2C needs no coordination, so it scales to any number of balancers.

Mathematical foundations

The classic model is **balls into bins**: throw n balls into n bins, each ball choosing its bin(s) at random.

FORMULA

Maximum load with one and with d random choices [Azar et al. 1999]

one choice: $\text{max load} = \frac{\ln n}{\ln \ln n}(1 + o(1))$, $d \geq 2$ choices: $\text{max load} = \frac{\ln \ln n}{\ln d} + \Theta(1)$ (with high pr

Symbol	Meaning	Units
n	Number of balls (requests) and of bins (servers)	count
d	Number of random bins examined per ball	count
maxload	Largest number of balls in any bin	balls
$o(1)$, $\Theta(1)$	A term that vanishes as n grows; a bounded constant	—

WORKED EXAMPLE

Worked example — one million balls into one million bins.

1. $\ln n = \ln 10^6 = 13.82$; $\ln \ln n = \ln 13.82 = 2.63$.
2. One choice, leading term: $13.82/2.63 = 5.26$.
3. Two choices, leading term: $2.63/\ln 2 = 2.63/0.693 = 3.79$.
4. Measured (listing below): 9.0 with one choice, 4.0 with two, 3.0 with three.

Interpretation. The leading term underestimates the one-choice case at practical sizes (the $o(1)$ factor is large), but the shape is right: the worst bin with one choice grows almost like $\log n$, while with two choices it grows like $\log \log n$, which is below 5 for any n you will meet. Going from two choices to three helps far less than going from one to two. *Engineering implication.* Two samples are the sweet spot: almost all the benefit, no coordination, and no herd.

Mitzenmacher analyzed the dynamic version, the **supermarket model**: requests arrive as a Poisson stream at rate λn to n servers of rate 1, each joining the shorter of d random queues [Mitzenmacher 2001].

FORMULA

Queue-length tail in the supermarket model (large n)

$$s_i = \lambda^i \quad (d = 1), \qquad s_i = \lambda^{\frac{d^i - 1}{d - 1}} \quad (d \geq 2), \qquad \text{so for } d = 2\text{: } s_i = \lambda^{2^i - 1}$$

Symbol	Meaning	Units
s_i	Fraction of servers with at least i requests (queued or in service)	dimensionless
λ	Utilization: arrival rate per server divided by service rate	dimensionless
d	Number of queues sampled per request	count
i	Queue-length threshold	requests

WORKED EXAMPLE

Worked example — at 90% utilization. $\lambda = 0.9$.

1. Random ($d = 1$): $s_5 = 0.9^5 = 0.59$, so 59% of servers have 5 or more requests. $s_{10} = 0.9^{10} = 0.35$.
2. Two choices: $s_5 = 0.9^{2^5 - 1} = 0.9^{31} = 0.038$, so 3.8%. $s_{10} = 0.9^{1023} \approx 10^{-47}$: effectively never.

Interpretation. With one choice the tail decays geometrically; with two it decays **doubly exponentially**. *Engineering implication.* At high utilization the difference is between a long tail of overloaded servers and none, which is exactly what p99 latency measures.

Code example

```
        """Balls into bins: maximum load with d = 1, 2, 3 random choices."""
        import math
        import random

        def max_load(n: int, d: int, rng: random.Random) -> int:
            """Throw n balls into n bins; each ball goes to the least loaded of d random
bins."""
            bins = [0] * n
            for _ in range(n):
                if d == 1:
                    i = rng.randrange(n)
                else:
                    i = min((rng.randrange(n) for _ in range(d)), key=bins.__getitem__)
                bins[i] += 1
            return max(bins)

        if __name__ == "__main__":
            rng = random.Random(42)
            trials = 5
            print(f"{'n':>9} | {'d=1':>5} {'d=2':>5} {'d=3':>5} | "
                  f"{'ln n/ln ln n':>12} {'ln ln n/ln 2':>12} {'ln ln n/ln 3':>12}")
            for n in (1_000, 10_000, 100_000, 1_000_000):
                t = trials if n < 1_000_000 else 2
                row = [sum(max_load(n, d, rng) for _ in range(t)) / t for d in (1, 2,
3)]
                lnln = math.log(math.log(n))
                print(f"{n:>9,} | {row[0]:5.1f} {row[1]:5.1f} {row[2]:5.1f} | "
                      f"{math.log(n) / lnln:12.2f} {lnln / math.log(2):12.2f} {lnln /
math.log(3):12.2f}")
```

Output (Python 3.13):

```
        n |   d=1   d=2   d=3 | ln n/ln ln n ln ln n/ln 2 ln ln n/ln 3
    1,000 |   5.4   3.0   2.2 |         3.57         2.79         1.76
   10,000 |   6.6   3.0   3.0 |         4.15         3.20         2.02
  100,000 |   7.4   3.2   3.0 |         4.71         3.53         2.22
1,000,000 |   9.0   4.0   3.0 |         5.26         3.79         2.39
```

What to notice:

- Going from 10^3 to 10^6 bins, the one-choice maximum grows from 5.4 to 9.0; the two-choice maximum barely moves (3.0 to 4.0).
- The measured values sit above the leading terms by a roughly constant amount, the $\Theta(1)$ and $o(1)$ terms.

INDUSTRY EXAMPLE

Envoy and NGINX ship P2C. Envoy's default least-request balancer, when all hosts have equal weight, picks two random hosts and chooses the one with fewer active requests; the number of choices is configurable. NGINX supports `random two least_conn`, which its documentation recommends for setups in which several balancers serve the same backends (as of 2026). *Evidence: Primary* — [Envoy Docs: Load balancers; NGINX Docs: ngx_http_upstream_module]

19.4.5 Simulation: algorithms on heterogeneous servers

Real fleets are mixed. The simulation below has ten FIFO servers, five of rate 1 and five of rate 2 (capacity 15 requests per time unit), Poisson arrivals and exponential service. It records the **queue length each request finds** at its chosen server and its latency, and reports mean, p99 and maximum after a warm-up. The third experiment refreshes the load view only every 2 time units, modeling many balancers that share periodic load reports.

```
        """Compare load-balancing policies on heterogeneous servers.

        Ten FIFO servers: five 'slow' (1 request/s each) and five 'fast' (2 requests/s
each).
        Poisson arrivals, exponential service times. For each policy we record, for ev-
ery
        request, the queue length it finds at its chosen server (requests already there)
        and its latency (waiting + service). Times are in units of the slow server's
mean
        service time.
        """
        import random

```

What to notice:

- **Load-oblivious policies fail on mixed fleets.** At 60% load, random and round robin send 0.9 requests per time unit to each slow server (90% busy) while fast ones idle at 45%: p99 queue 19 for RR and 35 for random, against 1 to 4 for the others. At 85% they send 1.275 to servers that can do 1.0; those queues grow without bound, so the numbers only reflect the run length.

19.4.6 Consistent hashing for request routing

Hash-based balancing sends all requests with the same **key** (user ID, cache key, video ID) to the same backend, so its cache or local state is reused. **Consistent hashing** places backends and keys on a ring so that adding or removing one of N backends moves only

about $1/N$ of keys, where `hash mod N` would move nearly all; the derivations, code and alternatives (jump, rendezvous hashing) are in §14.8.

Two limits of the plain ring matter here. **Balance depends on keys, not arcs**: an even split of the key space still sends a hot key's traffic to one server. And **lookups cost** $O(\log M)$ over M ring points, while per-packet L4 balancers want $O(1)$. The next two techniques address these limits. Ring hashing is available in HAProxy (`hash-type consistent`), NGINX (`hash ... consistent`, Ketama) and Envoy (`RING_HASH`).

19.4.7 Consistent hashing with bounded loads

DEFINITION

Definition — Consistent hashing with bounded loads. A variant of consistent hashing in which every backend has a **capacity** of $\lceil (1+\varepsilon)\,m/n \rceil$ for m current items (requests, sessions) and n backends. An item goes to the first backend clockwise from its hash that is below capacity, so overflow from a full backend walks on to the next [Mirrokni, Thorup & Zadimoghaddam 2018].

First-principles explanation

Each customer has a favorite checkout (her hash). The store rules that no line may exceed the average by more than 25%; if her favorite is at the limit, she walks on to the next checkout under it. Most customers still get their favorite, and no line passes the cap even when one cashier is everyone's favorite.

Why does this exist?

Hash routing exists for locality, but popularity is skewed (§14.10): one viral video can draw a large share of requests and melt its server. Bounded loads keep most of the locality while making overload impossible by construction. When an item or backend is added or removed, the expected number of moved items exceeds the minimum by only a factor $O(1/\varepsilon^2)$ for $\varepsilon \le 1$, and $1 + O(\log c/c)$ for $c = 1+\varepsilon \ge 2$ [Mirrokni, Thorup & Zadimoghaddam 2018].

FORMULA

Bounded-load capacity

$$\text{cap} = \lceil (1 + \varepsilon) \frac{m}{n} \rceil$$

Symbol	Meaning	Units
cap	Maximum items any backend may hold	items
ε	Allowed overload above the average, $\varepsilon > 0$	dimensionless
m	Items currently assigned (for request routing: in-flight requests)	items
n	Number of backends	count

WORKED EXAMPLE

Worked example — 10,000 in-flight requests on 40 cache servers.

1. Average: $m/n = 10,000/40 = 250$ requests per server.
2. $\varepsilon = 0.25$: $\text{cap} = \lceil 1.25 \times 250 \rceil = \lceil 312.5 \rceil = 313$.
3. $\varepsilon = 1$: $\text{cap} = \lceil 2 \times 250 \rceil = 500$.
4. With Zipf-distributed popularity over 2,000 videos, the most popular video alone draws about $1/H_{2000} \approx 1/8.2 \approx 12\%$ of requests, roughly 1,200, nearly five servers' worth, where H_{2000} is the 2,000th harmonic number.

Interpretation. A plain ring must put all ~1,200 requests for the top video on one server ($\approx 5\times$ average); the bounded ring spills them across about four consecutive servers on the ring. *Engineering implication.* ε is a dial between cache locality (large ε) and balance (small ε); values between 0.25 and 1 are common starting points.

                    where.append(self.owner[i])
                return load, where

        if __name__ == "__main__":
            rng = random.Random(7)
            servers = [f"cache-{i}" for i in range(40)]
            # 10,000 in-flight requests for 2,000 objects with Zipf(1.0) popularity:
            # every request for the same object hashes to the same point.
            objects = [f"video:{i}" for i in range(2_000)]
            zipf_w = [1 / (r + 1) for r in range(len(objects))]
            requests = rng.choices(objects, weights=zipf_w, k=10_000)
            avg = len(requests) / len(servers)
            ring = Ring(servers)
            for eps in (None, 1.0, 0.25):
                load, where = ring.assign(requests, eps)
                first = sum(1 for k, s in zip(requests, where)
                            if s == ring.owner[bisect.bisect_right(ring.pos, h(k)) %
len(ring.pos)])
                label = "plain ring" if eps is None else f"bounded eps={eps}"
                print(f"{label:<18} max load {max(load.values()):5d}
({max(load.values()) / avg:4.2f}x avg)"
                      f"  on first-choice server {first / len(requests):6.1%}")

            # Membership change: add a 41st server, count requests that change server.
```

```
            bigger = Ring(servers + ["cache-40"])
            for eps in (None, 1.0, 0.25):
                _, before = ring.assign(requests, eps)
                _, after = bigger.assign(requests, eps)
                moved = sum(1 for a, b in zip(before, after) if a != b) / len(requests)
                print(f"add 41st server, eps={eps}: {moved:5.1%} of requests change
server")
```

Output (Python 3.13):

```
plain ring         max load  1534 (6.14x avg)  on first-choice server 100.0%
bounded eps=1.0    max load   500 (2.00x avg)  on first-choice server  83.2%
bounded eps=0.25   max load   313 (1.25x avg)  on first-choice server  72.5%
add 41st server, eps=None:  1.0% of requests change server
add 41st server, eps=1.0:  1.9% of requests change server
add 41st server, eps=0.25:  3.3% of requests change server
```

What to notice:

- The plain ring's busiest server holds 6.1 times the average because every request for a hot video lands on the same point. The cap is met exactly: 500 and 313.
- With $\varepsilon = 0.25$, 72.5% of requests still reach their first-choice server; the rest are hot-object overflow.
- Bounded loads cost some stability: adding a server moves 3.3% of requests instead of 1.0%, because changing n changes the cap and shifts overflow chains.
- For request routing, m is the number of in-flight requests, so the cap moves continuously with traffic; the code takes a static snapshot for clarity.

INDUSTRY EXAMPLE

Vimeo and HAProxy. Vimeo's video-delivery team found that plain consistent hashing across its cache servers overloaded the servers holding popular videos, implemented the bounded-loads algorithm in HAProxy, and reported a large drop in cache-tier bandwidth imbalance. HAProxy exposes it as `hash-balance-factor` (a value of 125 corresponds to $\varepsilon = 0.25$). Google has reported using the algorithm in Google Cloud Pub/Sub. *Evidence: Primary* — [Rodland 2016; HAProxy Docs: hash-balance-factor; Mirrokni & Zadimoghaddam 2017]

19.4.8 Maglev hashing

DEFINITION

Definition — Maglev hashing. A consistent-hashing scheme that builds a **lookup table** of prime size M in which every entry names a backend. Each backend has its own pseudo-random **preference permutation** of table positions; backends take turns claiming their next preferred empty position until the table is full. A packet's backend is `table[hash(5-tuple) mod M]` : one array read [Eisenbud et al. 2016].

First-principles explanation

Picture 3 students sharing 7 lockers. Each has a private, shuffled preference list; in rounds, each claims the first free locker on their list. Everyone gets almost the same number, and if one student leaves and the rounds are rerun, most lockers keep their owners, because the preference lists have not changed.

Why does this exist?

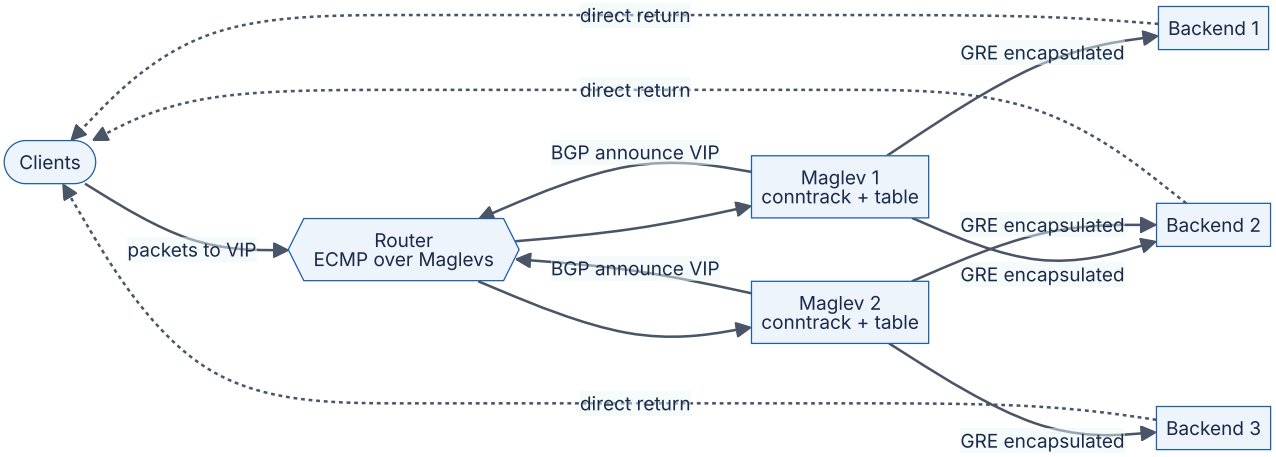
Google's Maglev is a software L4 balancer that has served Google's traffic since 2008, running on commodity Linux servers behind routers that spread packets across Maglev machines with ECMP [Eisenbud et al. 2016]. Two requirements shaped its hashing:

1. **Any Maglev machine must route any packet of a flow to the same backend**, even if the packet reaches a different Maglev machine after a router change, so the choice must be a deterministic function of the 5-tuple and the backend set.
2. **Per-packet cost must be tiny**: the paper reports a single machine saturating a 10 Gbit/s link with small packets, which leaves no room for a binary search per packet.

A ring gives (1) but $O(\log M)$ lookups and imperfect balance; Maglev hashing gives near-perfect balance and $O(1)$ lookup, at the price of slightly more than minimal disruption.

How it works internally

Figure 19.4 — Maglev: ECMP spreads packets over balancer machines; each machine maps flows to backends with the same lookup table.



Reading the diagram. Each Maglev machine announces the VIPs to the router by BGP, and the router spreads packets across them with ECMP (§19.8.3). A Maglev machine looks the flow up in its connection-tracking table; on a miss it reads `table[hash(5-tuple) mod M]`, records the result and forwards the packet in a GRE tunnel. Backends reply directly to clients (dotted: the asymmetric return path, still synchronous TCP). Tables are computed from configuration and connection state is soft, so there is no storage boundary. Failure point: if a Maglev machine dies, its flows rehash to machines with no connection entries, but those compute the same table, so most flows keep their backend. Scaling: add Maglev machines or backends.

The table is filled as follows:

1. For each backend i, compute offset_i and skip_i from two hashes of its name.
2. Its preference list is $\text{perm}_i[j] = (\text{offset}_i + j \cdot \text{skip}_i) \mod M$ for $j = 0, 1, \ldots, M-1$. Because M is prime and $1 \le \text{skip}_i < M$, this visits every position exactly once.
3. Set every entry empty. Loop over backends in turn: backend i walks its list from where it stopped to the first empty position, claims it, and the turn passes. Stop when all M entries are full.
4. To look up a packet, compute `table[hash(5-tuple) mod M]`.

Because each round gives every backend one entry, entry counts differ by at most one. Weights can be added by letting heavier backends take more turns. The paper chooses M much larger than the number of backends (it suggests $M > 100N$) so that a one-entry difference is a small fraction of each backend's share.

FORMULA

Maglev preference permutation

$$\text{offset}_i = h_1(\text{name}_i) \bmod M, \qquad \text{skip}_i = h_2(\text{name}_i) \bmod (M-1) + 1, \qquad \text{perm}_i[j] = (\text{offset}_i + j \cdot \text{skip}_i) \text{ ı}$$

Symbol	Meaning	Units
M	Lookup-table size, a prime	entries
h_1, h_2	Two independent hash functions	—
offset_i	Backend i's first preferred position	entry index
skip_i	Step between backend i's successive preferences, $1 \le \text{skip}_i \le M-1$	entries
$\text{perm}_i[j]$	Backend i's j-th preferred position	entry index

WORKED EXAMPLE

Worked example — filling a table of size 7. Backends B0 (offset 3, skip 4), B1 (offset 0, skip 2), B2 (offset 3, skip 1).

1. Preference lists: B0: $3, 0, 4, 1, 5, 2, 6$ (each step adds 4 mod 7). B1: $0, 2, 4, 6, 1, 3, 5$. B2: $3, 4, 5, 6, 0, 1, 2$.
2. Round 1: B0 claims 3. B1 claims 0. B2 wants 3 (taken), claims 4.
3. Round 2: B0's next is 0 (taken), then 4 (taken), claims 1. B1 claims 2. B2 claims 5.
4. Round 3: B0 tries 5, 2 (taken), claims 6. Table full: `[B1, B0, B1, B0, B2, B2, B0]` , counts 3, 2, 2.
5. B1 fails; rebuild with B0 and B2: B0 claims 3, B2 claims 4; B0 claims 0, B2 claims 5; B0 claims 1, B2 claims 6; B0 claims 2. Table: `[B0, B0, B0, B0, B2, B2, B2]` .
6. Compare: entries 0 and 2 (B1's) had to move. Entry 6 moved from B0 to B2 although B0 is still alive.

Interpretation. Balance is exact up to one entry, but disruption is not minimal: one of seven entries (14%) moved between survivors. *Engineering implication.* With realistic sizes the extra disruption is small (listing below), and Maglev's connection tracking hides it for established flows; only new flows, or flows that move to another Maglev machine, follow the new table.

```
        """Maglev lookup-table population (Eisenbud et al., NSDI 2016) and its disrup-
tion."""
        import hashlib
        from collections import Counter

        def _h(s: str, salt: str) -> int:
            return int.from_bytes(hashlib.md5((salt + s).encode()).digest()[:8], "big")

        def offset_skip(name: str, m: int):
            return _h(name, "offset") % m, _h(name, "skip") % (m - 1) + 1

        def populate(backends, m, params=None):
            """Return a lookup table of size m (m prime). params optionally maps a
            backend name to a fixed (offset, skip) pair, for hand-checkable examples."""
            perms = []
            for b in backends:
                off, skip = params[b] if params else offset_skip(b, m)
                perms.append((off, skip))
            nxt = [0] * len(backends)        # next preference index for each backend
            table = [None] * m
            filled = 0
            while True:
                for i, (off, skip) in enumerate(perms):     # one turn per backend
                    c = (off + nxt[i] * skip) % m
                    while table[c] is not None:              # preferred slot taken: try
next
                        nxt[i] += 1
                        c = (off + nxt[i] * skip) % m
                    table[c] = backends[i]
                    nxt[i] += 1
                    filled += 1
                    if filled == m:
                        return table

        if __name__ == "__main__":
            # Small example: M = 7, three backends with hand-picked offset and skip.
            p = {"B0": (3, 4), "B1": (0, 2), "B2": (3, 1)}
            print("B0..B2 table:", populate(["B0", "B1", "B2"], 7, p))
            print("B1 removed  :", populate(["B0", "B2"], 7, p))

            # Realistic size: M = 65,537 (prime), 100 backends; then backend-42 fails.
            M = 65_537
            names = [f"backend-{i}" for i in range(100)]
            before = populate(names, M)
            counts = Counter(before)
            print(f"entries per backend: min {min(counts.values())}, max
{max(counts.values())}, "
                  f"ideal {M / len(names):.1f}")
            after = populate([n for n in names if n != "backend-42"], M)
            changed = sum(1 for a, b in zip(before, after) if a != b)
            collateral = sum(1 for a, b in zip(before, after) if a != b and a != "back-
end-42")
```

```
        print(f"backend-42 removed: {changed / M:.2%} of entries changed "
              f"(minimum {counts['backend-42'] / M:.2%}); "
              f"{collateral / M:.2%} moved between surviving backends")
```

Output (Python 3.13):

```
B0..B2 table: ['B1', 'B0', 'B1', 'B0', 'B2', 'B2', 'B0']
B1 removed  : ['B0', 'B0', 'B0', 'B0', 'B2', 'B2', 'B2']
entries per backend: min 655, max 656, ideal 655.4
backend-42 removed: 1.66% of entries changed (minimum 1.00%); 0.66% moved between sur-
viving backends
```

What to notice:

- With 100 backends and $M = 65,537$, every backend owns 655 or 656 entries: imbalance 0.15%, far better than a ring with a few hundred vnodes per node (§14.8.4).
- Removing one backend changes 1.66% of entries: the unavoidable 1.00% plus 0.66% collateral movement between survivors, a trade Maglev accepts for $O(1)$ lookups and balance.
- Building the table is $O(M \log M)$ expected work and takes well under a second here; the paper's implementation rebuilds when backend health changes.

> INDUSTRY EXAMPLE
>
> **Open-source Maglev-style L4 balancers.** Meta's **Katran** is an L4 balancer built on the Linux kernel's XDP and eBPF facilities that uses a Maglev-style lookup table and IP-in-IP encapsulation toward backends. GitHub's **GLB Director** takes a different route: it uses rendezvous hashing to build a forwarding table in which every row lists a primary and a secondary backend, and a backend that receives a packet for a flow it does not know forwards it to the secondary ("second chance"), so connections survive backend set changes without shared connection state. *Evidence: Primary* — [Meta Engineering 2018 (Katran); Julienne 2018 (GLB)]

19.4.9 Choosing an algorithm

Table 19.3 — Load-balancing algorithms compared.

Algorithm	Load signal	State	Strength	Weakness	Choose when
Round robin	None	Counter	Simple, predictable	Overloads slow backends	Identical backends, uniform requests
Smooth weighted RR	Static weights	Weights	Handles known capacity differences	Weights go stale	Mixed instance types
Least connections	Local in-flight count	Count per backend	Adapts to speed and request cost	Herds with many balancers; fast-failure sinkhole	Single balancer tier, variable request cost, long-lived connections
Least response time (EWMA)	Observed latency	EWMA per backend	Avoids slow backends	Feedback oscillation; slow to retry	Latency-sensitive RPC
Power of two choices	In-flight or EWMA, two samples	Same as above	Near-optimal, no herding, $O(1)$	Slightly worse than perfect information	Many balancers or client-side balancing
Ring consistent hash	Key	Ring, $O(\log M)$	Locality, minimal movement	Hot keys overload one backend	Caches, sticky routing
Bounded-load hash	Key + in-flight count	Ring + counts	Locality with a load cap	More movement; needs load counts	Caches with skewed popularity
Maglev hash	5-tuple or key	Table of M entries	$O(1)$ lookup, even balance	Small extra disruption	L4 packet balancers

RECOMMENDATION

A default ladder. Start with round robin for identical stateless backends. Move to least request with P2C (Envoy's default, NGINX `random two least_conn`, HAProxy `leastconn` or `random(2)`) as soon as requests vary in cost or several balancers share backends. Use a hash, bounded if keys are skewed, only when locality pays for itself, and measure the cache hit ratio to prove it.

19.5 Health checks

19.5.1 Active and passive checks

DEFINITION

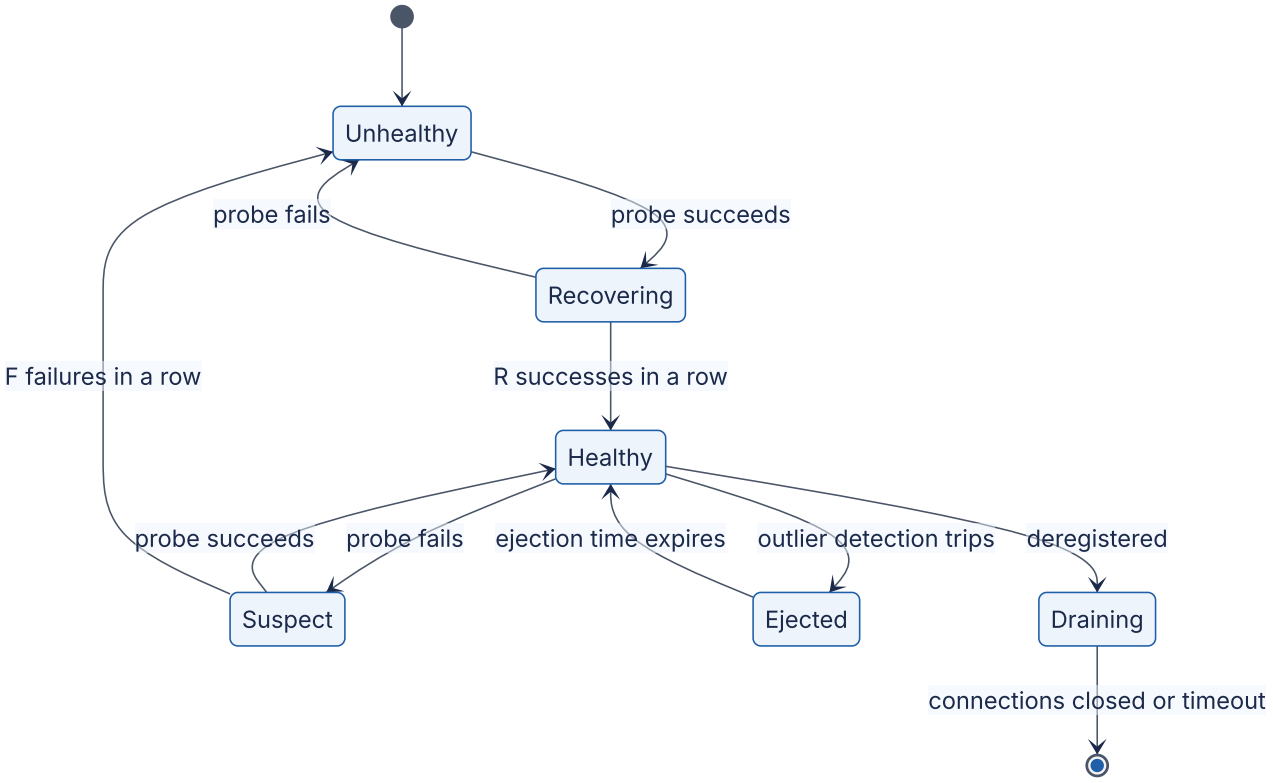
Definition — Health check. A mechanism by which a balancer decides whether a backend should receive traffic. An **active** check sends synthetic probes (a TCP connect, an HTTP `GET /healthz`, a gRPC health RPC) on a timer. A **passive** check, also called **outlier detection**, watches real traffic for errors, timeouts or latency and **ejects** misbehaving backends for a period.

A lifeguard does two things: every few minutes she scans the whole pool (active), and she reacts at once when she hears a shout (passive). Neither alone is enough. Active checks find dead backends even when no traffic flows, but are slow and test only what the probe touches. Passive checks react within milliseconds on busy services, but need traffic and cannot tell a broken backend from a bad request.

How it works internally

1. **Probe.** Every interval *I* (HAProxy default 2 s), send a probe with a timeout.
2. **Thresholds.** Mark a backend down after *F* consecutive failures (*fall*, HAProxy default 3) and up after *R* consecutive successes (*rise*, default 2) [HAProxy Docs]. AWS ALB target groups default to a 30 s interval, 2 failures and 5 successes (as of 2026).
3. **Outlier detection.** Envoy, by default, ejects a host after 5 consecutive `5xx` responses, for a base time of 30 s multiplied by the number of times it has been ejected, and never ejects more than 10% of a cluster at once (as of 2026) [Envoy Docs: Outlier detection]. NGINX open source marks a server unavailable for `fail_timeout` (10 s) after `max_fails` (1) failures.
4. **Fail open.** If too many backends look unhealthy, the checks are probably wrong. Envoy's **panic threshold** (default 50%) makes it ignore health and balance across all hosts; AWS ALB routes to all targets when all fail their checks.

Figure 19.5 — Health state of one backend as seen by the balancer.



Reading the diagram. A new backend starts unhealthy and must pass *R* probes before receiving traffic. One failed probe makes it *suspect* but keeps it in rotation; only *F* consecutive failures remove it. This **hysteresis** prevents flapping on one lost packet. Passive outlier detection can eject a backend immediately, for a time that grows with repeat offenses. *Draining* is the orderly exit (§19.8.4). Transitions are asynchronous (probe timers, response observations), and state is per balancer, so balancers may briefly disagree. Failure point: a probe that skips the real dependency path reports healthy while users fail. Scaling: probe traffic grows with balancers × backends.

FORMULA

Detection time and requests lost to a dead backend

$$T_{\text{detect}} \approx F \cdot I + T_o, \qquad N_{\text{lost}} \approx \frac{\lambda}{n} T_{\text{detect}}$$

Symbol	Meaning	Units
T_{detect}	Worst-case time from failure to removal	seconds
F	Consecutive failures required (fall threshold)	count
I	Probe interval	seconds
T_o	Probe timeout	seconds
N_{lost}	Requests sent to the dead backend meanwhile (without retries)	requests
λ, n	Total request rate; number of backends	requests/second; count

WORKED EXAMPLE

Worked example — active versus passive detection. 10 backends, $\lambda = 5,000$ requests/s, so 500 requests/s each. A backend's process hangs.

1. HAProxy defaults: $F = 3$, $I = 2$ s, timeout 2 s: $T_{\text{detect}} \approx 3 \times 2 + 2 = 8$ s; $N_{\text{lost}} \approx 500 \times 8 = 4,000$ requests.
2. ALB defaults: $F = 2$, $I = 30$ s, timeout 5 s: $T_{\text{detect}} \approx 65$ s; $N_{\text{lost}} \approx 32,500$ requests.
3. Passive, 5 consecutive errors (if the hang yields fast errors): ejection after 5 requests, about $5/500 = 10$ ms.

Interpretation. Active checks alone cost thousands of failed requests per incident; passive checks cut that by orders of magnitude on busy pools. *Engineering implication.* Use both, retry idempotent requests on another backend (§22.12), and tune active intervals for low-traffic pools where passive detection has nothing to observe.

19.5.2 What a health check should test

A **shallow** check (process up, port open) misses a backend whose database pool is exhausted. A **deep** check that calls every dependency fails the other way: when a *shared* dependency slows, every backend fails at once and the balancer ejects the whole pool, turning degradation into outage. The usual compromise: check the backend's own ability to serve (threads free, caches loaded, not shutting down), report dependency trouble as

metrics, and keep the panic threshold as a backstop. Kubernetes separates **liveness** (restart me) from **readiness** (send me traffic) probes (§42.7).

Probe load is real at scale: 1,000 sidecar proxies each checking 100 backends every 5 s generate $1,000 \times 100/5 = 20,000$ probes per second. Meshes therefore lean on passive detection and on health status pushed by the control plane.

Failure scenarios

Table 19.4 — Health-check failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Whole pool ejected	Deep checks fail on a shared dependency	Healthy-host count drops to 0	Panic threshold / fail open	Shallow readiness checks; dependency signals as metrics
Flapping	Thresholds of 1; probe timeout near p99 latency	Backend toggles every few seconds	Raise rise/fall; longer timeout	Hysteresis; ejection time growing with repeats
Healthy but broken	Probe path skips the failing code path	Errors rise while health is green	Passive ejection	Probe a representative path; outlier detection
Ejection cascade	Overload makes backends fail; ejecting them overloads the rest	Ejections rise with load	Cap ejected fraction (Envoy 10%)	Load shedding (§22.9) instead of ejection
Thundering return	Recovered backend receives a full share while caches are cold	Latency spike after recovery	Slow start	Ramp weights over 30–60 s (HAProxy `slowstart`, Envoy slow start)

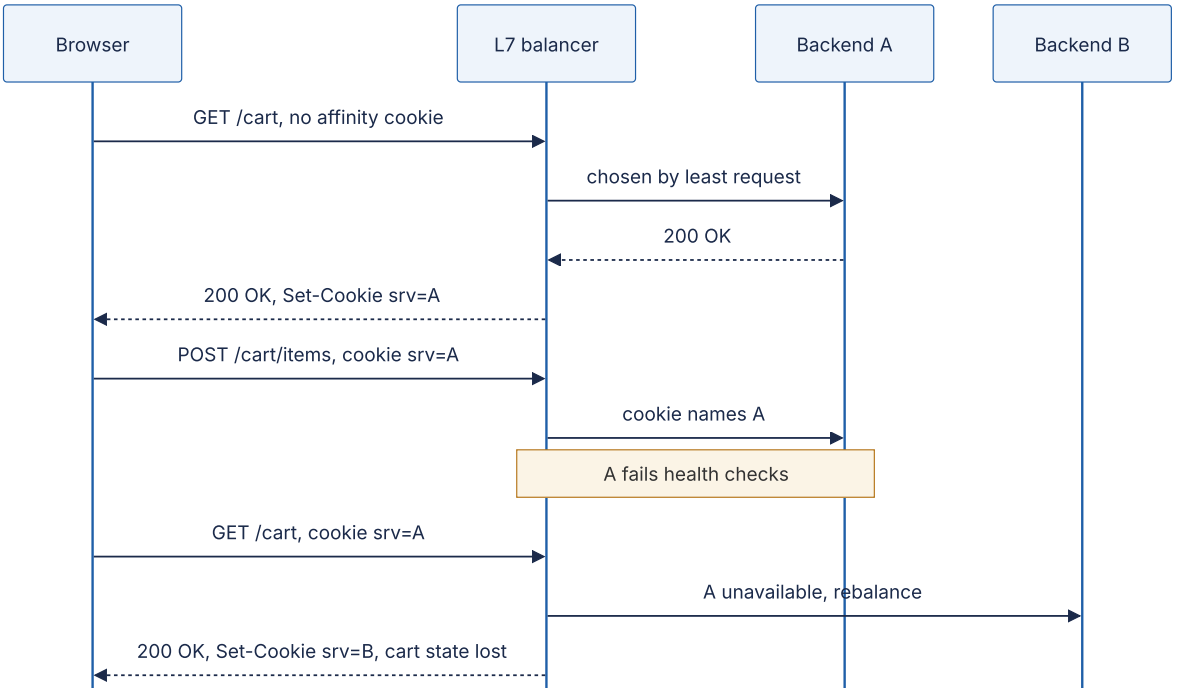
19.6 Session affinity

DEFINITION

Definition — Session affinity (sticky sessions). A balancer policy that sends all requests of one client session to the same backend, identified by a cookie, the client's IP address or a request key.

Affinity exists because some backends keep per-user state in memory: a shopping cart, a WebSocket subscription buffer (§9.6), a local cache of the user's data. It is the balancing equivalent of always seeing the same doctor: convenient, until she is on holiday.

Figure 19.6 — Balancer-inserted affinity cookie.



Reading the diagram. The first request has no cookie, so the balancer chooses normally and sets a cookie naming the backend (in practice an opaque or encrypted value). Later requests carry it and go to A. When A fails, the balancer must break affinity and pick B, and state held only in A's memory, the storage boundary here, is lost. All calls are synchronous. Scaling cost: heavy sessions stay pinned, so load skews.

Table 19.5 — Session affinity methods.

Method	How it works	Advantages	Disadvantages	Choose when
Balancer cookie	Balancer sets a cookie naming the backend	Precise, survives client IP changes	HTTP only; L7 needed	Web apps with in-memory sessions
Application cookie	Balancer hashes an app's session cookie	Uses existing session ID	Same as above	Frameworks with session IDs
Source-IP hash	Hash client IP (L4 works)	No cookies, any protocol	Carrier-grade NAT puts many users on one IP; mobile clients change IP	Non-HTTP protocols, coarse affinity
Consistent hash on key	Hash user ID or header (§19.4.6–19.4.8)	Minimal remapping on resize; works without the client's help	Hot keys; needs a key	Caches, sharded in-memory state

RECOMMENDATION

Prefer statelessness to stickiness. Keep session state in a shared store (Redis, a database) or in a signed token (§8.13), and make every backend able to serve every request (§18.5). Then affinity becomes an *optimization* for cache locality, not a *correctness* requirement, and deploys, autoscaling and failures stop logging users out.

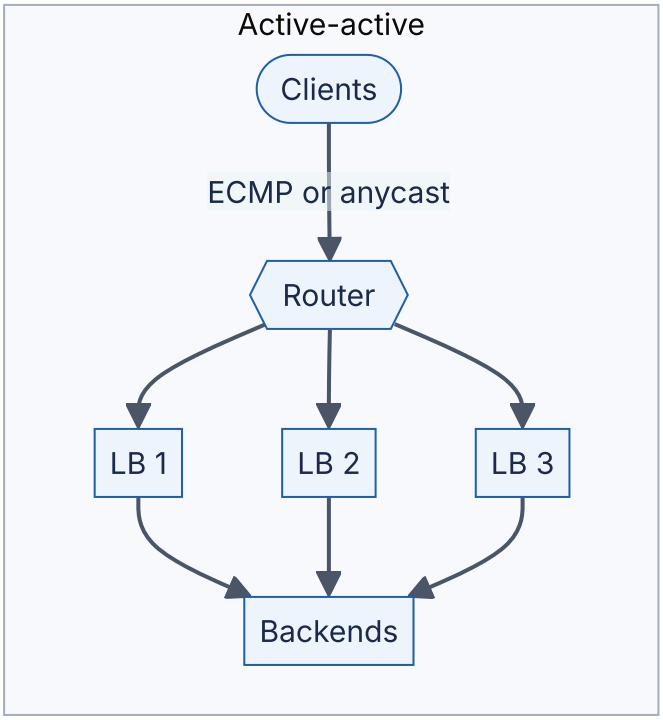
19.7 Active–passive and active–active balancer pairs

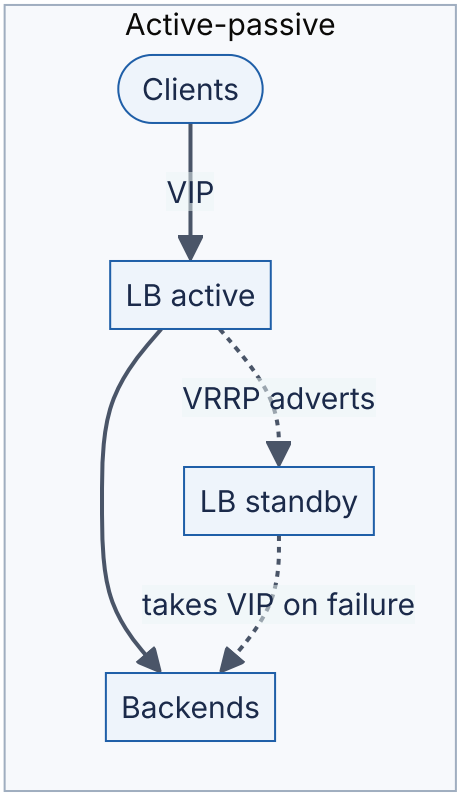
A balancer is a single point of failure until it has a partner.

DEFINITION

Definition — Active-passive and active-active. In an **active-passive** pair, one balancer carries all traffic while a standby monitors it and takes over the VIP on failure. In **active-active**, all balancers carry traffic at once (spread by DNS, ECMP or anycast), and survivors absorb a failed member’s share.

Figure 19.7 — Active-passive versus active-active balancer tiers.





Reading the diagram. Left: the active balancer carries all VIP traffic; the standby receives only heartbeat advertisements (dotted, asynchronous) and claims the VIP when they stop. Right: a router spreads flows across three active balancers and rehashes a failed member’s flows to the others. Neither tier stores data beyond connection tables. Failure points: failover time and split brain on the left; flows moving between balancers

on the right (§19.8.3). Scaling: active–passive grows only vertically; active–active by adding members.

FORMULA

Safe utilization for active-active with k tolerated failures

$$U_{\max} = \frac{N - k}{N}$$

Symbol	Meaning	Units
$U_{\max}$	Highest normal utilization per balancer that still fits all traffic after k failures	dimensionless
N	Balancers in the active–active group	count
k	Simultaneous failures to tolerate	count

WORKED EXAMPLE

Worked example — how many balancers? Peak traffic needs 30 Gbit/s; each balancer handles 10 Gbit/s; tolerate one failure ($k = 1$).

1. $N = 4$: $U_{\max} = 3/4 = 75\%$; normal load per balancer $30/4 = 7.5$ Gbit/s $= 75\%$. Exactly at the limit.
2. $N = 5$: $U_{\max} = 80\%$; normal load 6 Gbit/s $= 60\%$, leaving margin.
3. An active–passive pair would need two 30 Gbit/s balancers, with $U_{\max} = 50\%$ of the installed hardware.

Interpretation. Active–passive wastes half of the hardware but is simple; active–active wastes k/N, which shrinks as N grows. *Engineering implication.* Use active–passive for small sites and appliances, active–active behind ECMP or anycast once traffic exceeds one balancer. Either way, **test** failover: a standby that has never taken traffic is a hope, not a plan.

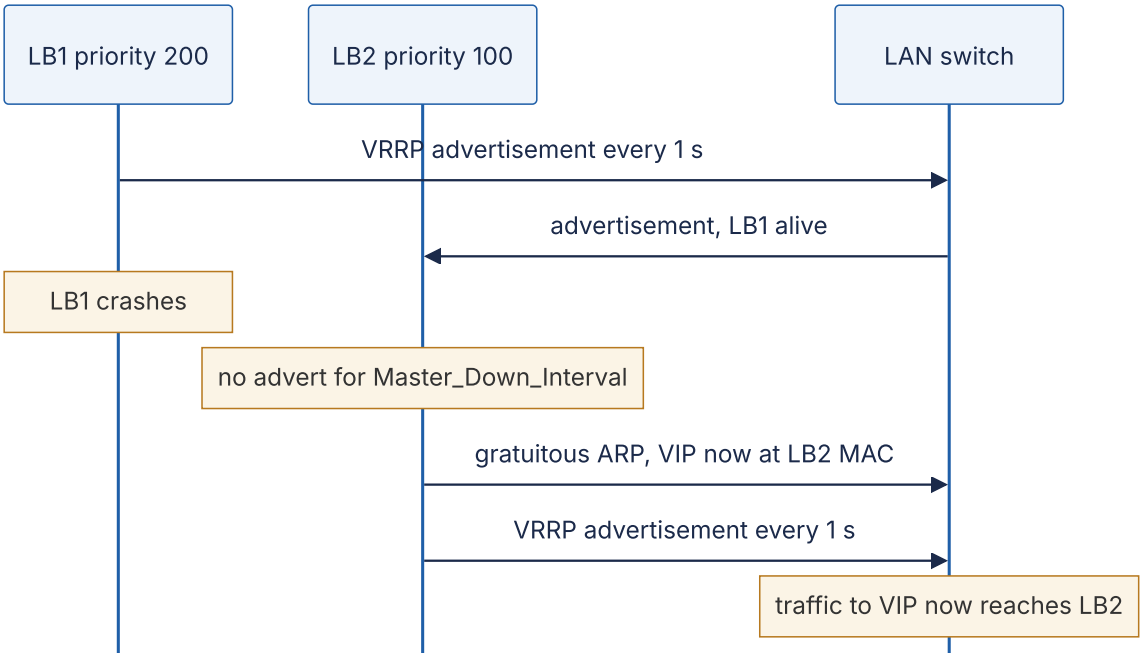
19.8 Balancer failure and redundancy

19.8.1 VRRP and keepalived

The **Virtual Router Redundancy Protocol (VRRP)** lets several machines on one LAN share a virtual IP: the highest-priority machine is the active owner (the RFC's "Master" state) and multicasts advertisements every `Advertisement_Interval`; backups take over when advertisements stop and announce the VIP's new location with gratuitous ARP [RFC

5798]. **keepalived** implements VRRP on Linux and is the usual way to make an HAProxy or NGINX pair highly available.

Figure 19.8 — VRRP failover between two balancers.



Reading the diagram. LB1 owns the VIP and advertises periodically (asynchronous multicast). When LB1 dies, LB2 waits out the master-down interval, then sends a gratuitous ARP so the switch and neighbors map the VIP to its MAC address, and begins advertising itself. Connections in flight through LB1 are lost unless connection state was synchronized (keepalived can pair with `conntrackd`). Failure points: if advertisements are blocked while both machines are alive (a firewall rule, a partitioned link), both claim the VIP, which is **split brain** (§26.12). Many clouds do not support multicast or gratuitous ARP; there, use the provider's managed balancer or a floating-IP API.

FORMULA

VRRP failover time [RFC 5798, §6.1]

$$T_{\text{skew}} = \frac{(256 - P)\,A}{256}, \qquad T_{\text{down}} = 3A + T_{\text{skew}}$$

Symbol	Meaning	Units
A	Advertisement interval (VRRPv3 allows centisecond values)	seconds
P	Backup router's priority, 1–254	dimensionless
T_{skew}	Extra wait so higher-priority backups take over first	seconds
T_{down}	Master-down interval: silence before a backup takes over	seconds

WORKED EXAMPLE

Worked example — default versus tuned timers.

1. $A = 1$ s, $P = 100$: $T_{\text{skew}} = 156/256 = 0.61$ s; $T_{\text{down}} = 3 + 0.61 = 3.61$ s.
2. $A = 0.1$ s, $P = 100$: $T_{\text{skew}} = 0.061$ s; $T_{\text{down}} = 0.361$ s.
3. At 20,000 new connections/s, a 3.61 s gap affects about 72,000 connection attempts, most of which clients retry.

Interpretation. Failover takes seconds with defaults and a few hundred milliseconds when tuned. *Engineering implication.* Shorter intervals detect faster but raise the risk of false failovers under CPU or network jitter; 100 ms is common on dedicated links, 1 s across busier ones.

19.8.2 Anycast

At Internet scale, the same VIP is announced by BGP from many sites (§7.5.3). Routers send each client to a nearby site, and a site that fails withdraws its route. Anycast makes the *first* hop redundant across sites and absorbs DDoS traffic, but it relies on BGP convergence (seconds to minutes) and can move long-lived TCP flows to a site without their state. Section 7.5.3 describes the 2021 Facebook outage in which every site withdrew at once.

19.8.3 ECMP and consistent hashing

Inside a site, the router in front of the balancers uses **equal-cost multipath (ECMP)**: it has several next hops for the VIP (one per balancer, each announcing the VIP by BGP)

and picks one per packet by hashing header fields, so all packets of a flow take the same path [RFC 2992]. When a balancer fails, the router removes one next hop and **rehashes**.

FORMULA

Flows remapped when one of N next hops is removed

$$f_{\text{mod}} \approx 1 - \frac{1}{N}, \qquad \tfrac{1}{4} \lesssim f_{\text{threshold}} \leq \tfrac{1}{2}, \qquad f_{\text{min}} = \frac{1}{N}$$

Symbol	Meaning	Units
f_{mod}	Fraction of flows that change next hop with `hash mod N`	dimensionless
$f_{\text{threshold}}$	Same, for the hash-threshold method analyzed in RFC 2992 (depends on which region is removed)	dimensionless
f_{min}	Minimum: only the failed hop's flows move (resilient or consistent hashing)	dimensionless
N	Next hops (balancers) before the failure	count

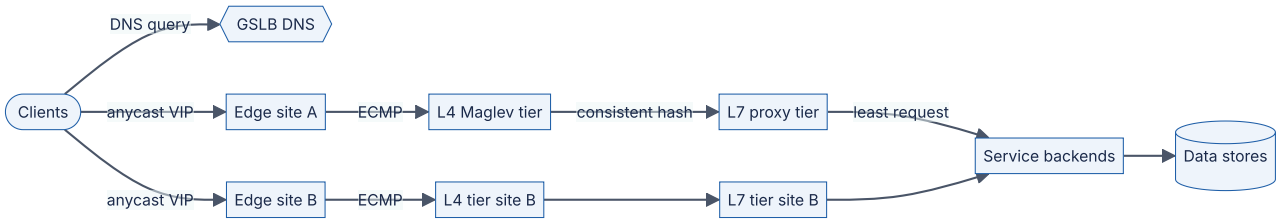
WORKED EXAMPLE

Worked example — eight balancers, one fails.

1. Modulo hashing: $1 - 1/8 = 87.5\%$ of flows land on a different balancer.
2. Hash-threshold: between 28.6% (a middle region removed) and 50% (an end region removed), computed for $N = 8$.
3. Resilient hashing: only the failed balancer's 12.5%.

Interpretation. With 1 million flows, 875,000 land on a balancer with no connection entry for them. *Engineering implication.* Balancers behind ECMP must choose backends with a **consistent** function of the 5-tuple (Maglev hashing, §19.4.8) so that a flow that changes balancer still reaches the same backend, and switches should use resilient ECMP hashing where available.

Figure 19.9 — A layered, redundant front end.



Reading the diagram. DNS (§19.9) picks a region or returns an anycast address; anycast picks the nearest edge site; ECMP spreads flows across the L4 tier, which consistently hashes them to L7 proxies; the proxies balance requests across backends with a load-aware algorithm. All arrows are synchronous request paths, and the data stores are the storage boundary. Each layer covers a failure the next cannot: anycast covers site loss, ECMP balancer loss, consistent hashing rehashing, health checks backend loss. Each tier scales horizontally. Google describes this shape for its frontend: DNS, Maglev, then Google Front End proxies [Beyer et al. 2016, ch. 19].

19.8.4 Connection draining

Removing a backend or balancer on purpose (deploy, scale-in) should break nothing. **Connection draining** (AWS: *deregistration delay*, default 300 s as of 2026; Google SRE: **lame duck** state) works in four steps:

1. Mark the backend *draining*: no new connections or requests, but in-flight ones continue.
2. For HTTP/1.1, send `Connection: close` on responses; for HTTP/2 and gRPC, send `GOAWAY` so clients open new connections elsewhere.
3. Wait until in-flight requests reach zero or a drain timeout expires (set it above the p99.9 request duration).
4. Close remaining long-lived connections (WebSockets, streams), preferably with a reconnect hint and jitter, so clients do not reconnect in one wave (§9.6).

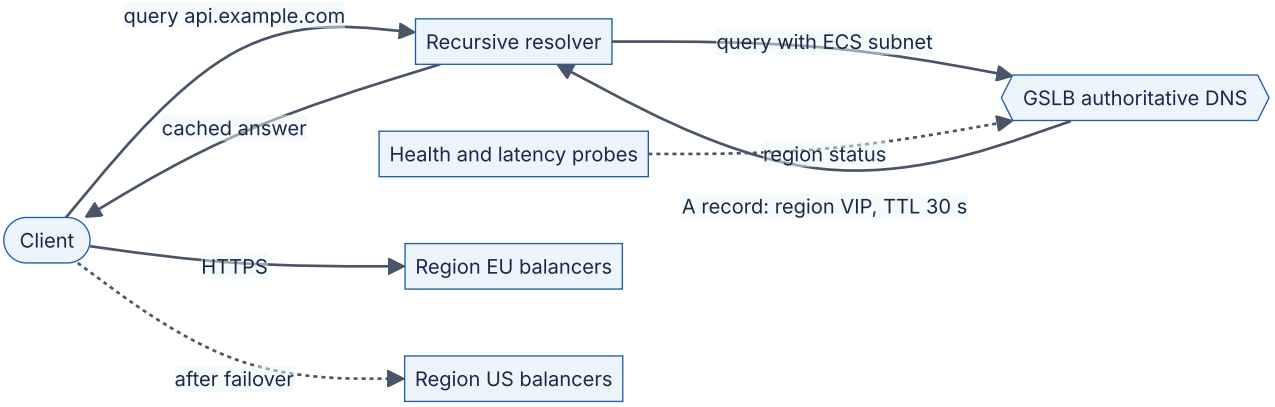
Table 19.6 — Balancer-tier failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Bad configuration everywhere	Global push of a broken rule	Error spike across all sites at once	Roll back	Staged rollout; config validation; canary balancers
Split brain	VRRP adverts lost while both nodes live	Duplicate-IP alerts; ARP flapping	Fence one node	Dedicated heartbeat links; unicast VRRP; managed VIPs
Mass connection resets	ECMP rehash after a balancer change	Reset spike on scale events	Clients reconnect	Consistent hashing; resilient ECMP; graceful BGP withdraw

19.9 DNS and global server load balancing

Global server load balancing (GSLB) chooses a *region or site* before any connection exists, usually by answering DNS queries differently per client. Section 7.6.5 covered DNS load balancing and its limits; Chapter 44 covers global traffic management in depth. Here is the essential shape.

Figure 19.10 — DNS-based global server load balancing.



Reading the diagram. The client's resolver asks the GSLB's authoritative server, which chooses a region from the resolver's location (or the client subnet, if the resolver sends EDNS Client Subnet), from latency measurements, configured weights, and region health fed asynchronously by probes. The answer is cached for its TTL by the resolver, then used by the client to connect synchronously to that region's balancers. Failure point: when a region fails, clients keep using cached answers until the TTL expires, and some clients and resolvers keep them longer. Scaling: DNS answers are cheap; the regional balancer stack (Figure 19.9) does the heavy lifting.

Policies include **geo-DNS** (nearest region), **latency-based** routing (lowest measured latency from the resolver's network, as in AWS Route 53), **weighted** answers and **failover**. The limits are those of §7.6.5: caching makes control coarse and failover TTL-bound, the resolver is not the client, and DNS sees no server load. Anycast (§19.8.2) is the main alternative and fails over at BGP speed; many providers combine both.

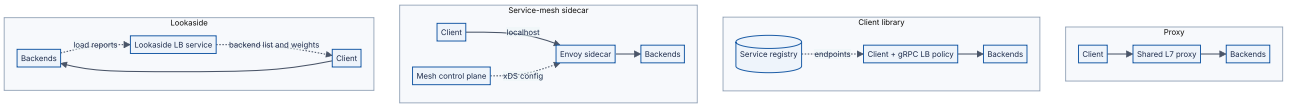
19.10 Client-side load balancing

Every proxy is an extra network hop, an extra machine to run, and an extra failure point. Inside a datacenter, the client can balance for itself.

DEFINITION

Definition — Client-side load balancing. The calling process obtains the list of backend endpoints from service discovery (§34.7) and chooses a backend for each request itself, with no proxy in the path. A **lookaside** balancer is an external service that tells clients *which* backends to use (and with what weights) while the traffic still flows directly from client to backend.

Figure 19.11 — Four places to put the balancing decision.



Reading the diagram. Solid arrows are synchronous requests; dotted arrows are asynchronous control traffic. The **proxy** adds a shared hop. The **library** (gRPC's `round_robin`, `least_request`, `weighted_round_robin`, `ring_hash` policies) balances per call inside the client, using endpoints from a registry, the storage boundary. The **sidecar** moves that logic into a local proxy usable from any language, configured by a control plane over Envoy's xDS APIs (§34.10). **Lookaside** centralizes the decision but keeps traffic direct: backends report load to a service that hands clients weighted backend lists [gRPC Docs: Load balancing]. Failure points: a stale registry, and a control-plane outage, during which sidecars must keep their last configuration. Scaling: no proxy tier; the cost moves into every client.

Client-side balancing gives per-call balancing for gRPC, saves a hop (often 0.1–1 ms in a datacenter) and removes a tier. The costs: every client needs the logic (or a sidecar), and connections multiply. With 1,000 clients and 1,000 backends, a full mesh is 10^6 connections. Google's answer is **subsetting**: each client connects to a deterministic subset of backends, chosen so every backend gets about the same number of clients; the SRE book discusses subsets of 20 to 100 [Beyer et al. 2016, ch. 20]. With subsets of 20, connections fall to 20,000, and P2C works well inside a subset because it needs no global view.

INDUSTRY EXAMPLE

Kubernetes Services. A Kubernetes `ClusterIP` Service is a form of client-side L4 balancing: `kube-proxy` on every node programs iptables, IPVS or nftables rules so that connections to the Service IP are spread over pod endpoints on the *client's* node, with no central balancer. Because it balances connections, long-lived gRPC connections still need L7 or library balancing (§42.9). *Evidence: Primary* — [Kubernetes Docs: Virtual IPs and Service Proxies]

19.11 Choosing a load balancer: products compared

Table 19.7 — Load balancer products (as of 2026; check current documentation).

Product	Layer	Algorithms (selection)	Health checking	Notable traits	Choose when
NGINX (open source)	L7 HTTP; L4 `stream`	Smooth WRR, `least_conn`, `ip_hash`, `hash ... consistent`, `random two least_conn`	Passive (`max_fails`); active in NGINX Plus	Also a web server and cache; huge install base	Web front ends, simple reverse proxying
HAProxy	L4 and L7	`roundrobin`, `leastconn`, `source`, `uri`, `hdr`, `random(<draws>)`, consistent hash with `hash-balance-factor`	Active (rise/fall, agent checks) and passive (`observe`)	Very detailed statistics, stick tables, mature	High-performance self-managed balancing
Envoy	L4 and L7 (HTTP/1, HTTP/2, HTTP/3, gRPC)	Round robin, least request (P2C), ring hash, Maglev, random	Active, outlier detection, panic threshold	Dynamic xDS configuration; service-mesh data plane	Microservices, gRPC, meshes
AWS Application Load Balancer	L7 managed	Round robin, least outstanding requests, weighted random	Active per target group	Managed TLS, path/host routing, WAF integration	HTTP services on AWS
AWS Network Load Balancer	L4 managed (TCP, UDP, TLS)	Flow hash	Active per target group	Static IP per zone, client IP preserved, very high scale	Non-HTTP, extreme volume, static IPs
Google Maglev	L4 software, in-house	Maglev hashing + connection tracking	Backend health drives table	ECMP + BGP, GRE to backends, DSR; underlies Google Cloud's network load balancing	Not a product you run; the reference design for software L4

Also worth knowing: IPVS (in the Linux kernel, used by keepalived and `kube-proxy`) and eBPF/XDP balancers such as Katran.

19.12 Summary and revision notes

SUMMARY

- **L4 versus L7.** L4 balances flows on headers (line rate, any protocol, DSR: $B = Rs_{\text{req}}$); L7 terminates TLS and balances requests (routing, retries, per-call gRPC). Large sites stack ECMP → L4 → L7.
- **Algorithms approximate one shared queue.** RR and smooth WRR ignore load; unweighted RR drove a slow server to 187% at 80% pool load. Least connections equalizes $L_i = \lambda_i W_i$, so rate $\propto 1/W_i$, but herds on stale data and rewards fast failures. EWMA latency adapts at the speed of traffic.
- **Power of two choices.** Max load falls from $\approx \ln n / \ln \ln n$ to $\ln \ln n / \ln 2 + O(1)$; queue tails from λ^i to $\lambda^{2^i - 1}$. Simulated p99 queue: 6 live, 8 stale, versus 27 for least connections on a stale view.
- **Hashing.** Consistent hashing (§14.8) gives locality; bounded loads cap backends at $\lceil (1+\varepsilon)m/n \rceil$; Maglev gives $O(1)$ lookup and balance within one entry, with ~0.66% collateral disruption at 100 backends.
- **Health.** Active detection $\approx F \cdot I + T_o$ (8 s with HAProxy defaults); passive in milliseconds. Use hysteresis, ejection caps, panic thresholds and shallow readiness checks.
- **Affinity** trades balance and resilience for locality; externalize state.
- **Redundancy.** Active–passive wastes 50%, active–active k/N. VRRP fails over in $3A + (256 - P)A/256$ (3.61 s by default). ECMP rehash can move $1 - 1/N$ of flows, so L4 tiers hash consistently. Drain before removal.
- **Global and client-side.** DNS GSLB picks regions within TTL limits; anycast fails over at BGP speed. Library, sidecar and lookaside balancing remove a hop; subsetting bounds connections.

19.13 Knowledge checkpoint

1. Why can an L4 balancer not route `/api/search` and `/api/cart` to different pools when TLS is passed through?
2. A service returns 40 KB responses to 1 KB requests at 50,000 requests/s. What bandwidth crosses the balancer with a full proxy and with DSR?
3. List the smooth WRR sequence for weights $a{:}\,3, b{:}\,1$.
4. Two backends have mean latencies of 20 ms and 80 ms. Under least connections, what fraction of traffic goes to the faster one?
5. Why does least connections herd when many balancers share periodic load reports?
6. For $\lambda = 0.8$, what fraction of servers have at least 4 requests with one and with two random choices?
7. With 9,000 sessions, 30 servers and $\varepsilon = 0.5$, what is the bounded-load capacity?

8. Why must the Maglev table size be prime?
9. A pool uses $I = 5$ s, $F = 3$, timeout 1 s, and receives 200 requests/s per backend. How many requests reach a dead backend before removal?
10. Why can deep health checks cause a full outage?
11. Six active–active balancers must survive two failures. What is the highest safe utilization?
12. Why do balancers behind ECMP need consistent hashing to backends?

Answers

1. The path is inside the encrypted stream; without terminating TLS the balancer sees only IPs, ports and the SNI hostname.
2. Full proxy: $50,000 \times 41,000 = 2.05$ GB/s $= 16.4$ Gbit/s. DSR: $50,000 \times 1,000 = 50$ MB/s $= 0.4$ Gbit/s.
3. Current weights start at 0. Picks: *a* (3,1 → −1,1), *a* (2,2 → tie, *a* first → −2,2), *b* (1,3 → 1,−1), *a* (4,0 → 0,0). Sequence `a a b a`.
4. $\lambda \propto 1/W$: $(1/20)/(1/20 + 1/80) = 0.05/0.0625 = 80\%$.
5. All balancers see the same “least loaded” backend until the next report and all send it traffic, overloading it; the next report then moves the herd elsewhere.
6. One choice: $0.8^4 = 0.41$. Two choices: $0.8^{15} = 0.035$.
7. $\lceil 1.5 \times 9,000/30 \rceil = \lceil 450 \rceil = 450$.
8. So that every skip value in $1..M-1$ is coprime with M, making each preference list a full permutation of positions.
9. $T_{\text{detect}} \approx 3 \times 5 + 1 = 16$ s; $200 \times 16 = 3,200$ requests.
10. When a shared dependency degrades, every backend fails its check together and the balancer ejects all of them.
11. $(6-2)/6 = 66.7\%$.
12. A router rehash moves flows to other balancers that have no connection state; only a deterministic, consistent mapping sends those flows to the same backend.

19.14 Interview questions

Basic

Q1. What is the difference between an L4 and an L7 load balancer, and when would you use each? Answer. L4 balances TCP/UDP flows on headers, so it is fast, protocol-agnostic and can use DSR, but every request on a connection goes to one backend. L7 terminates TLS, parses HTTP, and balances and routes each request, at higher CPU cost. Use L4 for non-HTTP traffic and as the high-volume first tier; L7 for HTTP and gRPC services, path routing and retries. Large systems use both.

Q2. Your backends are a mix of 8-core and 32-core machines. Which algorithm do you use? Answer. Not plain round robin, which gives equal shares and overloads small machines. Weighted round robin with weights 1:4 works if capacity is stable; least request with power of two choices adapts automatically to actual speed and is safer when performance drifts.

Intermediate

Q3. Explain power of two choices and why it beats "always pick the least loaded server" in large systems. Answer. Sample two random backends and pick the less loaded. The maximum load drops from about $\ln n / \ln \ln n$ to $\ln \ln n / \ln 2$, and queue tails fall doubly exponentially. "Least loaded" needs a global, fresh view; with many balancers and stale reports they all pick the same backend (herding). P2C's randomness scatters choices, needs no coordination and tolerates staleness: in our simulation its p99 queue was 8 versus 27 for least connections with 2-second-old data.

Q4. Design health checking for 300 backends behind a fleet of balancers. Answer. Active readiness checks (2–5 s interval, fall 3, rise 2) that test the backend's own ability to serve; passive outlier detection (eject after 5 consecutive 5xx, ejection time growing with repeats, at most 10% ejected); a panic threshold that fails open; slow start on recovery; retries of idempotent requests elsewhere. At mesh scale, prefer passive signals to limit probe volume.

Advanced

Q5. Design the front-end load-balancing stack for a global service at 5 Tbit/s. Answer. GSLB DNS or anycast to pick a site; within the site, ECMP across a software L4 tier (Maglev-style hashing plus connection tracking, DSR or encapsulation) sized for $N - k$ survivors; an L7 proxy tier that terminates TLS and routes by path with least request/P2C; client-side or mesh balancing inside. Discuss consistent hashing across ECMP changes, connection draining, staged configuration rollouts, DDoS absorption, and failure domains per site.

Q6. A cache tier uses consistent hashing on object ID and one server is at 100% CPU during a viral event. What do you do? Answer. The hot key is pinned to one point on the ring. Switch to consistent hashing with bounded loads ($\varepsilon \approx 0.25$) so overflow spills to the next servers, or replicate hot keys to several servers and choose among them with P2C; add a small in-process cache in front for the hottest objects. Accept slightly lower hit ratio for a capped load.

Q7. Your gRPC service sits behind an AWS NLB and one pod receives most of the traffic. Why, and how do you fix it? Answer. NLB balances TCP connections, and gRPC multiplexes all calls from a client over one long-lived HTTP/2 connection, so a few clients

pin to a few pods. Fixes: an L7 balancer that balances per call (ALB with gRPC, Envoy), client-side balancing with a gRPC policy over headless-service endpoints, or a mesh sidecar; as a stopgap, a maximum connection age forcing periodic reconnects.

19.15 Practical exercises

1. Add a `WeightedLeastConnections` policy to the §19.4.5 simulation and compare it with P2C at 85% load, with live and stale views.
2. Extend the simulation to model 5 independent balancers, each counting only its own in-flight requests. Which policy wins now?
3. Change the §19.4.8 program to measure disruption when a backend is *added*, and plot collateral movement against M/N.
4. Configure HAProxy with three backends and `hash-balance-factor 125`; drive skewed traffic with a load generator and record per-server request counts.
5. Set up two VMs with keepalived and measure failover time for advertisement intervals of 1 s and 0.1 s.

19.16 Design challenges

1. **Video edge cache.** 200 cache servers per site serve 2 million objects with Zipf popularity. Choose the routing scheme from the L7 tier to the caches, set ε, estimate hit ratio loss versus plain consistent hashing, and describe behavior during a cache server failure.
2. **Internal RPC platform.** 3,000 services, 40,000 pods, mostly gRPC. Choose between proxy, sidecar, library and lookaside balancing; size subsets; define health checking and outlier detection; explain what happens when the control plane is unavailable for 10 minutes.

19.18 Open verification items

- Maglev paper: confirm GRE encapsulation wording, the $M > 100N$ guidance and the table sizes used in its evaluation (65,537 is used here as a typical prime); full author list.
- AWS defaults (ALB health-check interval 30 s, thresholds 5/2, deregistration delay 300 s) and Envoy outlier-detection defaults (5 consecutive 5xx, 30 s base, 10% max): confirm against current documentation (as of 2026).
- HAProxy: default `<draws>` for `balance random`; `hash-balance-factor` semantics.
- Vimeo post (Rodland 2016): exact title, date and reported results; Google Cloud Pub/Sub use per Google Research blog (2017).
- Katran blog post: authors and date.
- Google SRE book subset sizes (20–100): confirm wording in ch. 20.

Chapter 20 — Caching

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Almost every large system you will design reads far more than it writes, and reads the same few things again and again. A product page, a user's profile, a feed's first screen: each is computed from durable storage that takes milliseconds to answer and can serve only so many queries per second. A **cache** keeps a copy of recent answers in faster memory, closer to whoever asks, so that most requests never reach the slow store. Done well, a cache cuts average latency by an order of magnitude and database load by two. Done badly, it serves stale data, melts the database when it empties, and hides bugs that appear only under load.

You already met caches inside a CPU (§5.4) and inside a database (§13.4). This chapter is about the caches you add yourself: in the browser, at the edge, in your application and in dedicated cache servers such as Redis and Memcached. It explains why a cache holding 1% of your data can absorb more than half the traffic, how to read and write through a cache without corrupting it, how to choose an eviction policy, and how to survive the three classic failure modes of production caches: stampedes, penetration and avalanches.

20.1 Learning objectives

After this chapter you should be able to:

- Compute effective latency and backend load from a hit ratio, and explain why the miss ratio, not the hit ratio, is the number to watch.
- Explain with the Zipf distribution why small caches capture most requests, and estimate the hit ratio of a cache of a given size.
- Place caches in the right layers (client, CDN, gateway, in-process, remote, database) and choose between in-process and remote caches.
- Describe how Redis and Memcached work internally: event loop, data structures, persistence, replication, Redis Cluster hash slots, the slab allocator and segmented LRU.
- Draw the sequence of cache-aside, read-through, write-through, write-back and write-around, and identify the consistency races in each.
- Choose TTLs, add jitter, and choose among LRU, LFU, ARC and W-TinyLFU using measured hit ratios.

- Design invalidation with TTLs, explicit deletes, change data capture and versioned keys.
- Prevent cache stampedes with locks, leases, probabilistic early expiration (XFetch) and stale-while-revalidate, and size XFetch's parameter.
- Defend against cache penetration, avalanches and hot keys.

20.2 Prerequisites

- Latency numbers and percentiles — §5.9.4, §4.8 (every argument here compares memory, network and disk latencies, and tails matter).
- CPU caches and average memory access time — §5.4.5 (the same formula governs application caches).
- Buffer pools and eviction (LRU, clock, LRU-K) — §13.4 (database-side caching and scan resistance).
- Read replicas and replication lag — §14.3–§14.4 (caches and replicas are both stale copies).
- Consistent hashing — §14.8 (how keys are spread over cache nodes).
- Bloom filters and Count-Min sketches — §17.4, §17.6 (used against penetration, for hot-key detection and in TinyLFU).

20.3 Cache fundamentals and hit ratio

20.3.1 What a cache is

> DEFINITION
>
> **Definition — Cache.** A store that holds copies of data whose authoritative version lives elsewhere (the **backing store** or **source of truth**), placed so that reading the copy is faster or cheaper than reading the original. A lookup that finds the data is a **hit**; one that does not is a **miss**. The **cache hit ratio** h is hits divided by lookups; the **miss ratio** is $1 - h$.

First-principles explanation

A reference librarian keeps a shelf of the 200 books people ask for most behind the desk. Most questions are answered from that shelf in seconds; the rare request for an obscure title means a trip to the stacks, after which the book may replace something on the shelf that nobody has asked for lately. Three questions decide how well this works: how often the shelf has the book (hit ratio), how much faster the shelf is than the stacks (the latency gap), and what happens when a book on the shelf is out of date because a new edition came out (staleness).

Why does this exist?

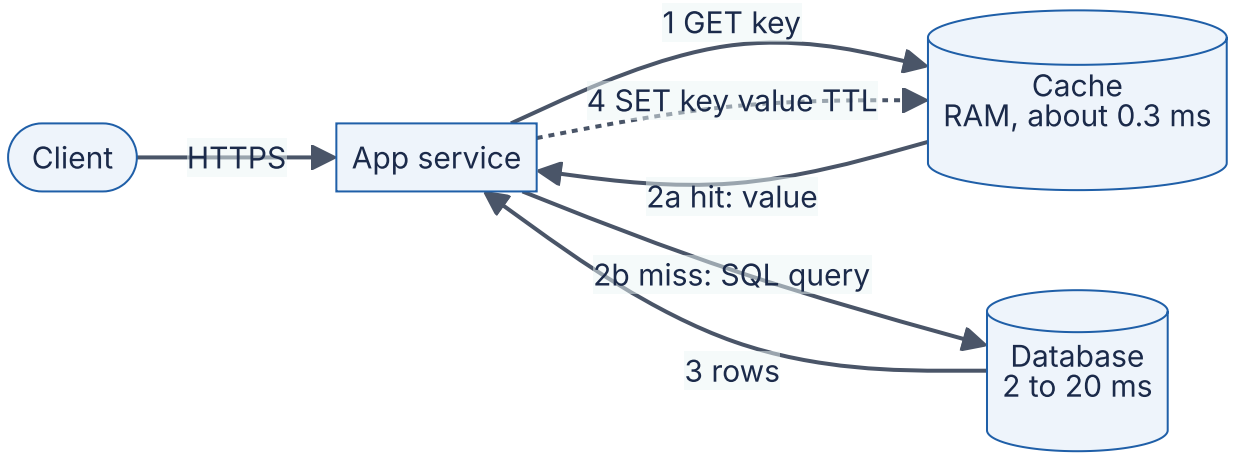
Two engineering problems motivate every cache. **Latency**: a key–value read from memory on another machine in the same datacenter costs about 0.2–0.5 ms, while a database query that touches disk or does real work costs 2–50 ms; a page that makes 20 such reads cannot meet a 200 ms budget without caching. **Capacity**: a database primary may sustain 10,000–50,000 simple queries per second, and every extra read replica adds cost and replication lag (§14.3). A cache node serving 100,000+ reads per second from RAM is cheaper per read by one to two orders of magnitude. Caches buy both, at the price of **staleness**, **memory cost** and **another component that can fail**.

How it works internally

Every cache, from an L1 CPU cache to a CDN, implements the same five decisions:

1. **Lookup**: map a **cache key** (for example `user:42:profile:v3`) to a stored entry, usually through a hash table.
2. **Fill**: on a miss, fetch from the backing store and decide whether to store the result (**admission**).
3. **Expiry**: decide how long an entry is trusted (**time to live**, TTL, §20.8).
4. **Eviction**: when memory is full, decide which entry to discard (§20.9).
5. **Invalidation**: when the source changes, remove or update the copy (§20.10).

Figure 20.1 — The hit and miss paths of a cache in front of a database.



Reading the diagram. The service first asks the cache over TCP; on a hit (2a) it answers immediately, on a miss (2b) it queries the database and fills the cache (4) so the next reader hits. Steps 1–3 are synchronous; the fill (dotted) need not delay the response. Storage boundaries: the disposable cache in RAM and the durable database. Failure points: a cache outage sends every request down path 2b (§20.13); a fill racing a write can store stale data (§20.7.2). Scaling: partition keys over cache nodes (§20.14); the database sees only misses.

20.3.2 Hit ratio, effective latency and backend load

Mathematical foundations

You met this formula for CPU caches as average memory access time (§5.4.5). For an application cache, every request pays for the lookup, and a miss adds the backend read.

FORMULA

Effective latency and backend load of a look-aside cache

$$T_{\text{eff}} = t_c + (1 - h)\, t_b \qquad R_{\text{db}} = (1 - h)\, R_{\text{read}} + R_{\text{write}}$$

Symbol	Meaning	Units
T_{eff}	Mean latency of a read through the cache	ms
t_c	Cache lookup latency (paid on hits and misses)	ms
t_b	Backend read latency, including the fill	ms
h	Cache hit ratio	dimensionless (0–1)
R_{read}	Read requests reaching the cache	requests/s
R_{write}	Writes, which go to the database regardless	requests/s
R_{db}	Requests reaching the database	requests/s

WORKED EXAMPLE

Worked example — What one percentage point of hit ratio is worth. A profile service receives $R_{\text{read}} = 50,000$ reads/s and $R_{\text{write}} = 500$ writes/s. A Redis lookup costs $t_c = 0.3$ ms; a database read costs $t_b = 8$ ms.

1. At $h = 0.90$: $T_{\text{eff}} = 0.3 + 0.10 \times 8 = 1.1$ ms; $R_{\text{db}} = 0.10 \times 50,000 + 500 = 5,500$ queries/s.
2. At $h = 0.98$: $T_{\text{eff}} = 0.3 + 0.02 \times 8 = 0.46$ ms; $R_{\text{db}} = 1,000 + 500 = 1,500$ queries/s.
3. At $h = 0.99$: $T_{\text{eff}} = 0.3 + 0.01 \times 8 = 0.38$ ms; $R_{\text{db}} = 500 + 500 = 1,000$ queries/s.
4. Going from 99% to 98% raises *read* traffic at the database from 500 to 1,000 queries/s: a one-point drop in hit ratio **doubles** the database's read load.
5. Tail: with a 2% miss ratio, more than 1% of requests are misses, so the p99 latency is a miss (about 8.3 ms) even though the mean is 0.46 ms.

Interpretation. Gains at high hit ratios look small as percentages but are large as ratios of miss ratios. **Engineering implication.** Monitor and alert on the miss ratio and on absolute database queries per second, size the database for the miss traffic you would see after a cache restart (§20.13), and remember that the mean hides the tail: p99 latency is set by misses whenever the miss ratio exceeds 1%.

COMMON MISTAKE

"Our cache hit ratio is 95%, so the cache is working." 95% of 1,000 RPS leaves 50 misses/s; 95% of 1,000,000 RPS leaves 50,000, enough to overwhelm most databases. And a page with 20 lookups and one miss is a "95% hit ratio" but a 100% slow page.

20.3.3 Popularity skew: why small caches work

First-principles explanation

If every key were equally popular, a cache holding 1% of the keys would serve 1% of requests, and caching would rarely be worth it. Real access patterns are highly skewed: a few celebrities, products and videos receive most of the traffic, and a long tail of items is requested rarely. Skew is what makes caching pay.

DEFINITION

Definition — Zipf (Zipf-like) distribution. A popularity law in which the item of popularity rank i is requested with probability proportional to $1/i^s$, where $s > 0$ is the **skew exponent**. Breslau et al. found that requests to web proxies follow a Zipf-like law with an exponent below 1 and that, as a consequence, hit ratio grows roughly logarithmically with cache size [Breslau et al. 1999].

Mathematical foundations

FORMULA

Zipf request probability and the hit ratio of an ideal top-C cache

$$p_i = \frac{1/i^s}{H_{N,s}}, \qquad H_{n,s} = \sum_{j=1}^{n} \frac{1}{j^s}, \qquad h_{\text{ideal}}(C) = \frac{H_{C,s}}{H_{N,s}} \overset{s=1}{\approx} \frac{\ln C + \gamma}{\ln N + \gamma}$$

Symbol	Meaning	Units
N	Number of distinct keys	keys
C	Cache capacity	entries
i	Popularity rank (1 = most popular)	dimensionless
s	Zipf skew exponent	dimensionless
p_i	Probability that a request is for rank i	dimensionless
$H_{n,s}$	Generalized harmonic number	dimensionless
$h_{\text{ideal}}(C)$	Hit ratio of a cache that always holds the top C keys	dimensionless
γ	Euler–Mascheroni constant, ≈ 0.5772	dimensionless

WORKED EXAMPLE

Worked example — One percent of the catalog, two thirds of the traffic. $N = 10^6$ keys with $s = 1$; the cache holds $C = 10^4$ entries (1%).

1. $\ln C + \gamma = \ln 10^4 + 0.5772 = 9.210 + 0.577 = 9.787$.
2. $\ln N + \gamma = \ln 10^6 + 0.5772 = 13.816 + 0.577 = 14.393$.
3. $h_{\text{ideal}} = 9.787/14.393 = 0.680$: 1% of the keys can serve 68% of requests (the exact sum, computed by the program below, is also 68.0%).
4. Doubling the cache to 2×10^4: $(\ln(2 \times 10^4) + 0.577)/14.393 = (9.903 + 0.577)/14.393 = 0.728$. Twice the memory buys only 4.8 more points.

Interpretation. Under Zipf, each *doubling* of cache size adds a roughly constant number of points ($\ln 2/14.393 \approx 4.8$ here), so the first gigabytes of cache are worth far more than the last. **Engineering implication.** Size a cache by plotting hit ratio against size from a real trace and stop where the next doubling no longer pays for itself in database capacity; for lower skew ($s < 1$) the curve is flatter and you need a larger fraction of the data.

Code example

The program computes the ideal hit ratio and then simulates a real LRU cache on a sampled Zipf trace, for three skews and three cache sizes.

```
        """Why small caches work: the ideal hit ratio of a cache that holds the C most
        popular of N keys under Zipf popularity, versus a simulated LRU cache."""
        import itertools
        import random
        from collections import OrderedDict

        def zipf_weights(n, s):
            """Unnormalized Zipf weights 1/i^s for ranks 1..n."""
            return [1.0 / i ** s for i in range(1, n + 1)]

        def ideal_hit_ratio(weights, c):
            """Fraction of requests for the top-c keys: H(c, s) / H(n, s)."""
            return sum(weights[:c]) / sum(weights)

        def zipf_trace(weights, length, seed=1):
            """Sample `length` requests; key i has probability weights[i] / sum."""
            cum = list(itertools.accumulate(weights))
            return random.Random(seed).choices(range(len(weights)), cum_weights=cum,
k=length)

        def lru_hit_ratio(trace, capacity, warmup):
            cache, hits = OrderedDict(), 0
            for t, key in enumerate(trace):
                if key in cache:
                    cache.move_to_end(key)
                    hits += t >= warmup
                else:
                    cache[key] = None
                    if len(cache) > capacity:
                        cache.popitem(last=False)          # evict least recently used
            return hits / (len(trace) - warmup)

        if __name__ == "__main__":
            N, LENGTH, WARMUP = 100_000, 1_000_000, 200_000
            sizes = [100, 1_000, 10_000]                    # 0.1%, 1%, 10% of the keys
            print(f"N = {N:,} keys, {LENGTH:,} requests; hit ratio by cache size")
            print("   s   policy        " + "".join(f"{c / N:>9.1%}" for c in sizes))
            for s in (0.7, 0.9, 1.0):
                w = zipf_weights(N, s)
                trace = zipf_trace(w, LENGTH)
                ideal = [ideal_hit_ratio(w, c) for c in sizes]
                lru = [lru_hit_ratio(trace, c, WARMUP) for c in sizes]
                print(f"{s:>4}   ideal top-C    " + "".join(f"{h:>9.1%}" for h in ideal))
                print(f"{s:>4}   LRU (sim)      " + "".join(f"{h:>9.1%}" for h in lru))
            w = zipf_weights(1_000_000, 1.0)
            print(f"worked example: N = 1e6, s = 1, C = 1e4 -> ideal "
                  f"{ideal_hit_ratio(w, 10_000):.1%}")
```

Output (Python 3.13, about 4 s):

```
N = 100,000 keys, 1,000,000 requests; hit ratio by cache size
   s   policy             0.1%     1.0%    10.0%
 0.7   ideal top-C       10.2%    23.1%    48.8%
 0.7   LRU (sim)          2.4%    10.9%    34.7%
 0.9   ideal top-C       29.0%    47.4%    70.7%
 0.9   LRU (sim)         15.6%    34.2%    60.5%
 1.0   ideal top-C       42.9%    61.9%    81.0%
 1.0   LRU (sim)         29.0%    50.6%    73.7%
worked example: N = 1e6, s = 1, C = 1e4 -> ideal 68.0%
```

What to notice:

- Skew dominates: with 1% of keys cached, the ideal hit ratio is 23% at $s = 0.7$ but 62% at $s = 1.0$. Measure your skew before promising a hit ratio.
- Each tenfold increase in size adds a roughly constant number of points, the logarithmic growth Breslau et al. observed.
- LRU falls 8–13 points short of the ideal because it keeps whatever was used last, including one-off keys from the tail. §20.9 measures policies that close most of that gap.
- `warmup` excludes the first 200,000 requests, so the numbers describe a warm cache; a cold cache after a restart does much worse (§20.13).

20.4 CPU cache versus application cache

The principles are the same at every level of the memory hierarchy: locality, a hit/miss formula, eviction and coherence. The engineering is very different, as Table 20.1 shows.

Table 20.1 — CPU caches (Chapter 5) versus application caches (this chapter).

Aspect	CPU cache (L1–L3)	Application cache (Redis, Memcached, in-process)
Unit	64-byte cache line	Whole object or query result, bytes to megabytes
Hit latency	~1–15 ns	~50 ns (in-process) to ~0.3 ms (remote)
Managed by	Hardware, transparently	Your code: keys, TTLs, fills and invalidation are explicit
Placement and eviction	Set-associative, pseudo-LRU (§5.4.4)	Hash table plus LRU, LFU, W-TinyLFU or approximations
Coherence	Hardware protocol (MESI, §5.4.6) keeps copies consistent	None by default: you invalidate, expire or accept staleness
Failure	Never “down”	Can fail, restart empty or be partitioned from clients
What a miss costs	~100 ns DRAM access	2–50 ms database query, and load on a shared database

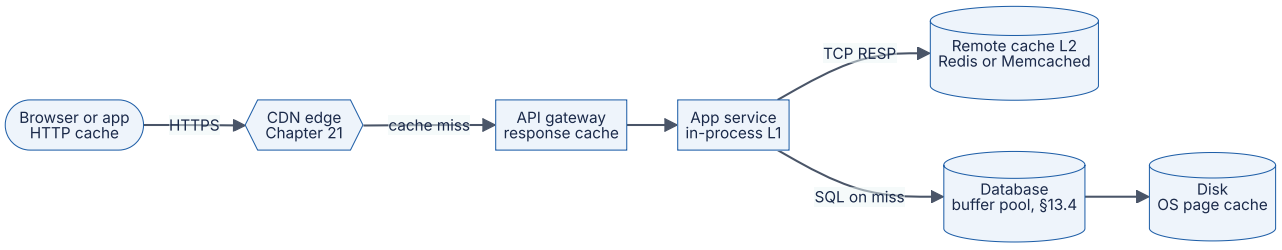
The most important row is coherence. A CPU guarantees that no core reads a stale line after another core’s write commits. An application cache gives you no such guarantee: you must design how copies are invalidated (§20.10), and you must decide how stale is acceptable for each piece of data. The second most important row is failure: a CPU cache never disappears, but a cache cluster can restart empty and expose the database to the full read load.

20.5 Where to cache

20.5.1 The layers

A request passes through several places where a copy can be kept. The closer to the client, the more latency and backend work a hit saves, but the less control you have over invalidation and the more copies there are to keep fresh.

Figure 20.2 — Cache layers from the client to the database.



Reading the diagram. From left to right the copies get more authoritative and more expensive to reach. The browser’s HTTP cache can answer with no network at all; the CDN

edge (an external system, Chapter 21) answers from a nearby point of presence; the gateway caches whole responses; the service's in-process L1 cache answers in microseconds; the remote L2 cache answers in a fraction of a millisecond over the Redis or Memcached protocol; the database's buffer pool and the operating system's page cache avoid disk reads. All arrows are synchronous request paths; each layer forwards only its misses. Storage boundaries: client device, CDN, application memory, cache cluster, database. Failure points: a copy in a layer you do not control (browser, CDN) cannot be deleted instantly; each extra layer adds a place where data can be stale. Scaling: each layer absorbs a share of traffic so the next sees only misses.

Table 20.2 — What each cache layer is good for.

Layer	Typical hit latency	Stores	Invalidation	Best for
Client (browser, mobile)	0 (no network)	HTTP responses, app state	Only by TTL or validation (`ETag`)	Static assets, per-user data that may be slightly old
CDN edge	5–30 ms from the user	Public HTTP responses	TTL, purge API (seconds, §21.6)	Images, video, scripts, public pages
API gateway	Sub-ms after reaching it	Whole API responses	TTL, explicit purge	Expensive public `GET`s
In-process (L1)	50 ns–1 µs	Objects in the heap	TTL; broadcast or none	Very hot, small, read-mostly data
Remote (L2)	0.2–0.5 ms in-datacenter	Serialized objects, counters, sessions	Delete on write, TTL, CDC	Shared hot data across many service instances
Database	Inside the query	Pages, query plans	Automatic, coherent	Everything; you tune its size (§13.4.3)

20.5.2 Client and HTTP caching

HTTP caching is standardized in RFC 9111 [RFC 9111]; §21.6.1 treats it in depth for CDNs. The origin controls client and intermediary caches with headers:

- `Cache-Control: max-age=600` permits reuse for 600 s; `s-maxage` sets the lifetime for shared caches; `private` keeps per-user responses out of shared caches; `no-store` forbids storage.
- **Validators** (`ETag`, `Last-Modified`): a stale copy is revalidated with `If-None-Match`, and `304 Not Modified` saves the body but not the round trip.
- `stale-while-revalidate` serves a stale copy while refreshing in the background; `stale-if-error` serves it when the origin fails [RFC 5861]. §20.11.3 applies the idea to server-side caches.

For static assets, the standard trick is **cache busting**: put a content hash in the file name (`app.3f9a2c.js`) and set a TTL of a year. The URL changes whenever the content changes,

so no invalidation is ever needed.

20.5.3 CDN and gateway

A **CDN** is a geographically distributed set of HTTP caches (Chapter 21). An **API gateway** or reverse proxy (NGINX, Envoy, Varnish) caches whole responses keyed by method, URL and selected headers. At both layers the risk is the **cache key**: if a response varies by a header (language, authorization) missing from the key, one user's response is served to another.

20.5.4 Application caches: in-process versus remote

An **in-process cache** (Caffeine in Java, an LRU dictionary in Python, `ristretto` in Go) lives in the service's own heap. A **remote cache** (Redis, Memcached) is a separate cluster shared by all instances.

Table 20.3 — In-process versus remote application caches.

Aspect	In-process (L1)	Remote (L2)
What it is	A map in the service's memory	A separate in-memory server cluster
How it works	Direct object reference; no serialization	Network round trip; serialize and deserialize
Advantages	~100 ns hits; no network; survives cache-cluster outage	Shared by all instances; one copy to invalidate; large capacity
Disadvantages	One copy per instance (N× memory, N× misses); hard to invalidate; lost on deploy	~0.3 ms per hit; network and serialization CPU; another system to operate
Performance	Millions of lookups/s per core	100,000+ simple ops/s per Redis node, more with I/O threads or Memcached threads
Operational complexity	Low, but GC pressure in managed runtimes	Medium: clustering, failover, memory tuning
Cost	Uses service RAM (multiplied by instance count)	Dedicated nodes
Use cases	Configuration, feature flags, hot keys (§20.15)	Sessions, profiles, rendered fragments, counters
Choose when	Data is small, very hot and tolerates seconds of staleness	Data is shared, larger, or must be invalidated reliably

Production systems often use both: an L1 with a TTL of seconds in front of an L2 with a TTL of minutes. The L1 absorbs hot keys; the L2 provides a single place to invalidate.

20.5.5 Database-side caching

The database already caches pages in its buffer pool (§13.4) and the operating system caches file blocks (§6.6.6). These caches are **coherent**: they never return stale data, because the database owns both the copy and the original. They cannot, however, avoid the cost of parsing, planning and executing a query, or of a network hop to the database. MySQL removed its query cache in version 8.0 because invalidating every cached result on every write to a table scaled poorly under concurrency [MySQL Server Team 2017]. Materialized views (§11.5.5) and read replicas (§14.3) are the database's own answers to repeated expensive reads.

RECOMMENDATION

Cache as close to the client as freshness allows. Static, versioned assets: browser and CDN, one-year TTL. Public pages: CDN with short TTL plus purge. Per-user API data: remote cache with delete-on-write. Very hot small objects: add an in-process L1 with a TTL of a few seconds. Never add a layer without stating how it is invalidated and what happens when it is empty.

20.6 Redis and Memcached internals

Redis and Memcached are the two dominant remote caches. Memcached is a deliberately minimal, multithreaded cache of opaque byte strings; Redis is a single-threaded data-structure server that also persists and replicates. §20.16 compares them.

20.6.1 Redis: a single-threaded event loop

DEFINITION

Definition — Event loop. A single thread that waits on many sockets at once with an operating-system readiness API (`epoll` on Linux, `kqueue` on BSD and macOS, §6.13.2–§6.13.4) and handles each ready socket in turn, without blocking on any one of them.

First-principles explanation

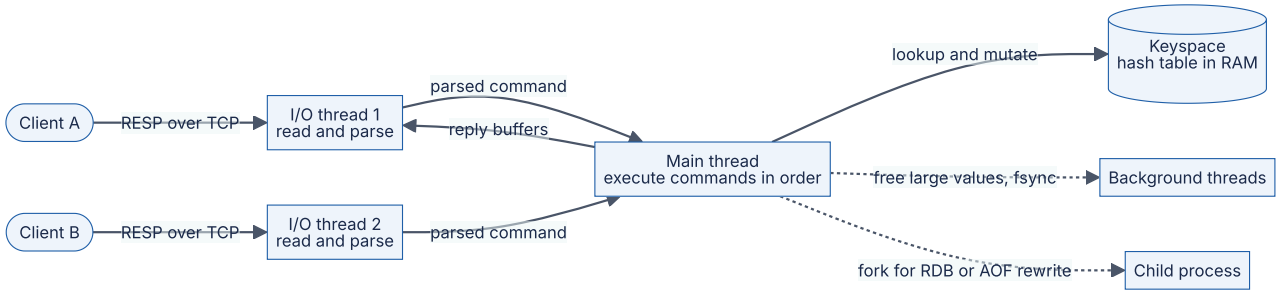
Picture one very fast chef who never waits: while one pot heats, he chops for the next order, and because only he touches the kitchen, nobody locks the knife drawer. Redis executes every command on one main thread, to completion, so every command (including a Lua script) is **atomic** without locks.

How it works internally

1. The main thread calls `epoll_wait` to learn which client sockets are readable.
2. For each, it reads bytes, parses commands in the **RESP** protocol and looks up the key in the **keyspace**, a hash table that grows by **incremental rehashing** (two tables; each operation moves a few buckets, so no single command pays for a full resize).
3. It executes the command against the in-memory data structure and appends the reply to the client's output buffer.
4. Before sleeping again it writes pending replies and runs timers: **active expiry**, which samples keys with TTLs and deletes expired ones, background rehashing and replication bookkeeping.

Background threads free large values (`UNLINK`) and `fsync` the append-only file. **I/O threads** (Redis 6.0 onward, `io-threads`) parse requests and write replies in parallel while execution stays single-threaded [Redis Docs: Redis configuration]. Valkey 8.0 reworked them to run concurrently with the main thread and reports about 1.2 million requests/s on one AWS r7g instance (as of 2024) [Valkey Blog 2024].

Figure 20.3 — Redis's event loop with I/O threads.



Reading the diagram. Clients send RESP commands over TCP. Optional I/O threads parse and write in parallel; the single main thread executes every command against the in-RAM keyspace. Side work runs asynchronously (dotted): background threads free memory and `fsync`, a forked child writes snapshots. Storage boundary: RAM for data, disk only for persistence files. Failure points: one slow command (`KEYS *`, a huge `DEL`, a long script) blocks *all* clients for tens of milliseconds, so use `SCAN`, `UNLINK` and `SLOWLOG`; forking a large process pauses the main thread. Scaling: execution uses one core, so scale out with Redis Cluster (§20.6.4).

20.6.2 Data structures and encodings

Redis values are typed. **Strings** (binary-safe, up to 512 MB) hold serialized objects and counters (`INCR`); **hashes** hold objects field by field; **lists** are queues; **sets** and **sorted sets** support membership and ranking (`ZADD`, `ZRANGE`), the latter as a skip list plus hash table (§17.7); **streams** are append-only logs; and HyperLogLog, bitmaps and geospatial

indexes are built on strings and sorted sets (§17.5, §17.9) [Redis Docs: Data types]. Small collections use a compact contiguous **listpack** encoding and are converted to hash tables or skip lists when they exceed thresholds such as `hash-max-listpack-entries` (128 by default), trading CPU for memory.

20.6.3 Persistence: RDB and AOF

A cold restart of a large cache is expensive (§20.13), and Redis also holds data that must survive restarts.

Table 20.4 — Redis persistence options.

Option	How it works	Data lost on crash	Cost
None	Pure in-memory	Everything	None
RDB snapshot	`fork()`; the child writes a compact binary snapshot while copy-on-write (§6.6.5) preserves the parent's view	Writes since the last snapshot (minutes)	Fork pause; up to 2× memory if many pages change during the dump
AOF, `appendfsync everysec`	Every write command appended to a log; `fsync` once per second; the log is periodically rewritten	About 1 s of writes	Disk bandwidth; rewrite cost
AOF, `appendfsync always`	`fsync` before acknowledging	Nothing acknowledged	Throughput limited by `fsync` latency
RDB + AOF (RDB preamble)	Rewritten AOF starts with an RDB image, then appends	About 1 s	Fast restart, small log

[Redis Docs: Persistence]. For a pure cache, many teams disable AOF and keep RDB only for faster warm restarts.

20.6.4 Replication and Redis Cluster

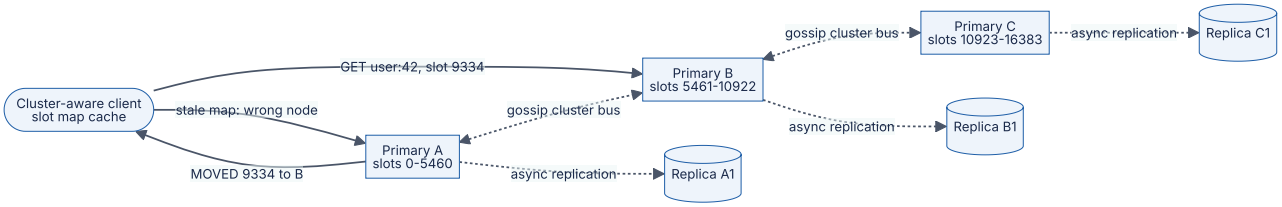
Replication is asynchronous: a primary streams its writes to replicas; a briefly disconnected replica resumes from a **replication backlog** (`PSYNC` with replication ID and offset), otherwise it receives a full snapshot. A failover can lose the last acknowledged writes; `WAIT` reduces but does not eliminate this [Redis Docs: Replication]. **Redis Sentinel** handles failover for unpartitioned deployments.

DEFINITION

Definition — Hash slot (Redis Cluster). One of 16,384 buckets into which Redis Cluster divides the keyspace: `slot = CRC16(key) mod 16384`. Each primary owns a set of slots. If a key contains `{...}`, only the substring inside the braces (a **hash tag**) is hashed, so related keys can be forced into one slot [Redis Docs: Cluster specification].

A node asked for a slot it does not own replies `MOVED <slot> <host:port>`; a slot under migration returns `ASK` for keys already moved. Nodes gossip over a **cluster bus** (client port + 10,000), and a majority of primaries authorizes a replica to take over a failed primary's slots. Multi-key commands work only within one slot.

Figure 20.4 — Redis Cluster: hash slots, redirects and replicas.



Reading the diagram. The client computes the slot and sends the command directly to the owning primary (slot 9334 on B). With a stale map it reaches the wrong node, which answers `MOVED`; the client updates its map and retries. Primaries replicate asynchronously (dotted) and gossip on the cluster bus. Storage boundaries: each primary holds only its slots. Failure points: failover loses unreplicated writes; the minority side of a network partition stops accepting writes. Scaling: add primaries and move slots, a fixed-partition scheme (§14.9.2) rather than a hash ring (§20.14).

20.6.5 Memcached: threads, slabs and segmented LRU

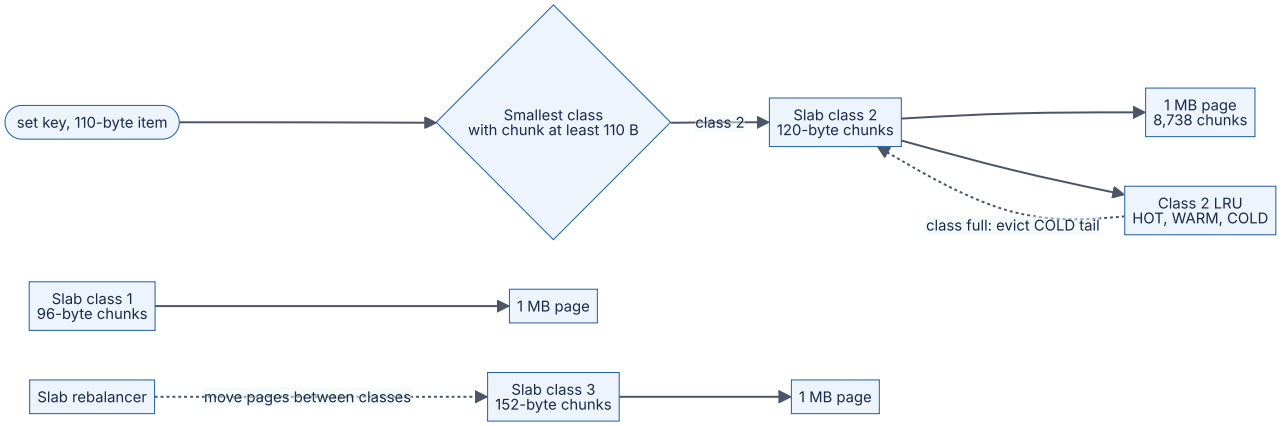
Memcached stores opaque values (1 MB maximum by default) with `get`, `set`, `delete`, `incr`, compare-and-set (`cas`) and a **meta protocol** whose flags can serve stale items while electing one client to refresh them [Memcached Docs: Meta commands]. It has no built-in persistence or replication; clients spread keys by consistent hashing (§20.14).

Threads. A listener thread hands connections to `-t` worker threads (4 by default), each with its own `libevent` loop, sharing one hash table under striped locks, so one process uses many cores [Memcached Docs: Overview].

The slab allocator. `malloc` and `free` on millions of variable-size objects fragment the heap. Memcached instead carves memory into 1 MB **pages**, assigns each to a **slab class** and cuts it into equal **chunks** whose sizes grow by the factor `-f` (1.25 by default): 96,

120, 152, 192, 240, 304 bytes and so on. An item (key, value and a header of about 50 bytes) takes the smallest chunk that fits.

Figure 20.5 — Memcached's slab allocator and per-class LRUs.



Reading the diagram. A 110-byte item goes to class 2; a 1 MB page holds $\lfloor 1,048,576/120 \rfloor = 8,738$ such chunks. Each class has its own LRU, so a full class evicts its coldest item even if other classes have free chunks. Background maintenance is dotted. Storage boundary: RAM (optional flash extension, extstore). Failure point: **slab calcification**, pages stuck in classes the current size mix no longer needs, which the slab rebalancer fixes by moving pages. Scaling: add memory or servers.

FORMULA

Slab internal fragmentation

$$c_{k+1} \approx f \cdot c_k, \qquad \text{waste}(x) = c_k - x \text{ for } c_{k-1} < x \le c_k, \qquad \frac{\text{waste}}{c_k} < 1 - \frac{1}{f}, \qquad \mathbb{E}[\frac{\text{waste}}{c_k}] \approx \frac{1}{2}(1 - \frac{1}{f})$$

Symbol	Meaning	Units
c_k	Chunk size of slab class k (rounded to 8 bytes)	bytes
f	Growth factor between classes (`-f`)	dimensionless
x	Item size, including header	bytes
waste	Unused bytes in the chunk	bytes

WORKED EXAMPLE

Worked example — Memory for 20 million session objects. Each item is a 40-byte key, a 300-byte value and a 50-byte header: $x = 390$ bytes.

1. Classes near 390 bytes: 304, then $304 \times 1.25 = 380$ (chunk 384), then $384 \times 1.25 = 480$. The item exceeds 384, so it uses a 480-byte chunk.
2. Waste per item: $480 - 390 = 90$ bytes, 18.8% of the chunk, close to the worst case $1 - 1/1.25 = 20\%$.
3. Memory: $20 \times 10^6 \times 480 = 9.6 \times 10^9$ bytes = 9.6 GB, versus 7.8 GB of item bytes. With mixed sizes, expected waste is about $\frac{1}{2}(1 - 0.8) = 10\%$.

Interpretation. Slab allocation trades 10–20% of memory for no external fragmentation and constant-time allocation. **Engineering implication.** If one item size dominates, check `stats slabs` and consider a smaller growth factor (for example `-f 1.08`) so a class lands just above your common size; budget memory by chunk size, not value size.

Segmented LRU. Since version 1.5.0, each class's LRU is split into **HOT**, **WARM** and **COLD** segments (plus **TEMP** for very short TTLs). New items enter HOT; items reaching a segment's tail move to COLD unless accessed, in which case they go to WARM; evictions take COLD's tail. A background **LRU maintainer** moves items, so a hit only sets a flag instead of relinking a locked list [Memcached Blog: Modern LRU]: InnoDB's scan-resistant midpoint idea (§13.4.2) applied to a cache.

INDUSTRY EXAMPLE

Netflix EVCache. Netflix built EVCache, a client library and tooling around Memcached, to cache data for its streaming services; writes are replicated to copies in several availability zones and regions by the client so a zone failure does not empty the cache, and it was open-sourced [Netflix: EVCache]. The design shows the Memcached philosophy: keep the server simple and put replication and routing in the client or a proxy. *Evidence: Primary* — [Netflix: EVCache]

20.7 Caching patterns: cache-aside, read-through, write-through, write-back, write-around

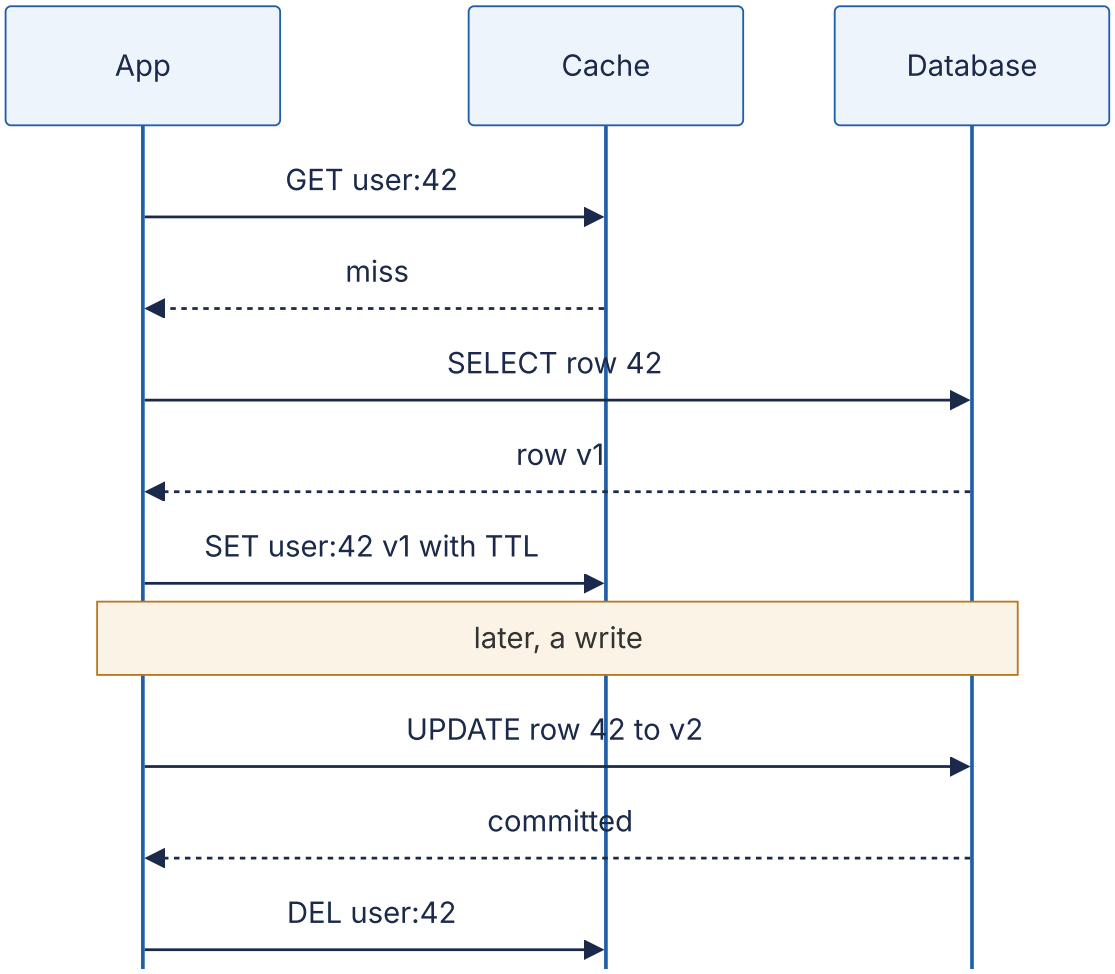
A caching pattern answers two questions: *who* fills the cache on a read miss (your code or the cache), and *what happens to the cache* on a write. Each answer moves the consistency risk somewhere else.

20.7.1 Cache-aside (look-aside)

DEFINITION

Definition — Cache-aside. The application reads the cache first; on a miss it reads the database and populates the cache itself. On a write it updates the database and then **deletes** (invalidates) the cache entry. The cache never talks to the database. Also called **look-aside** or **demand-filled** caching.

Figure 20.6 — Cache-aside read and write paths.



Reading the diagram. All calls are synchronous and made by the application. On a miss it reads the database and sets the value with a TTL; on a write it commits first, then deletes the key. Storage boundaries: cache and database, with no transaction spanning both. Failure points: a failed delete (the TTL bounds staleness) and a concurrent read re-inserting old data (§20.7.2). Scaling: memory follows the read working set.

Cache-aside is the default for remote caches because it is simple, keeps the cache optional (if the cache is down, reads go to the database) and caches only data that is actu-

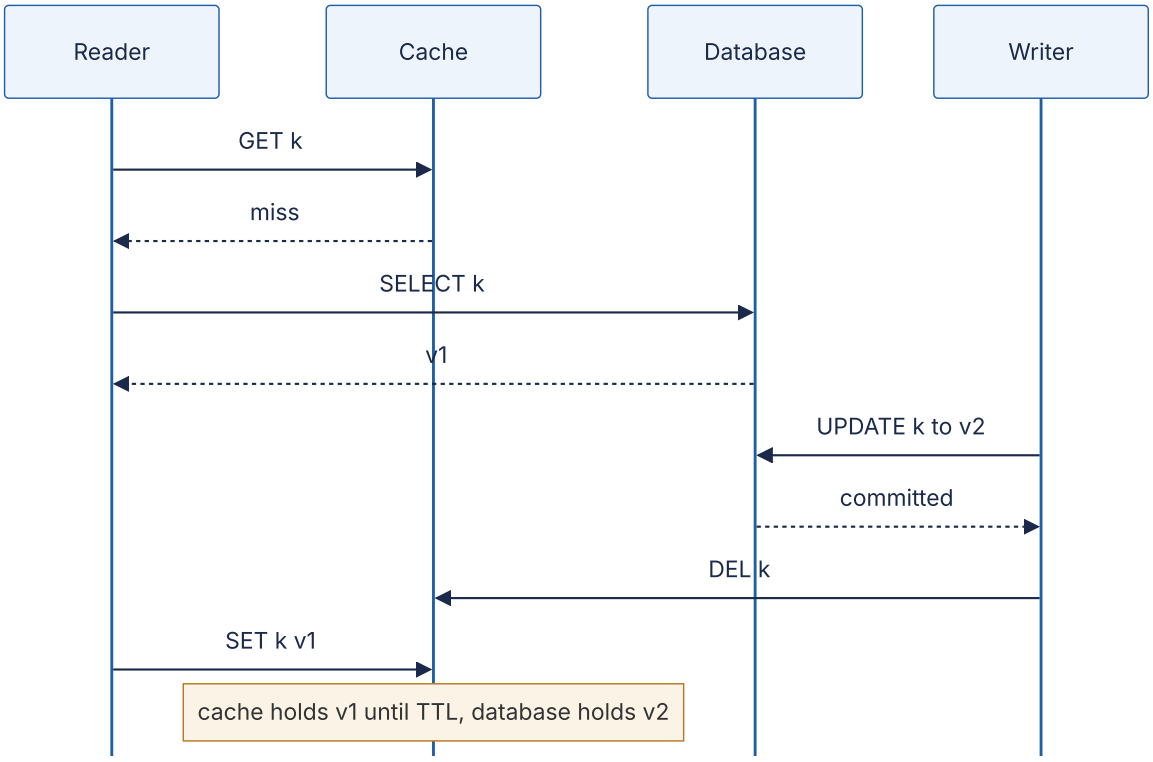
ally read. Facebook's Memcache deployment is the canonical large-scale example [Nishtala et al. 2013].

Why delete instead of update? If writers *set* the new value, two concurrent writers can commit to the database in one order and set the cache in the other, leaving the older value cached indefinitely. A delete is idempotent: whichever order deletes arrive in, the result is "absent", and the next read loads the committed value. Nishtala et al. chose deletes for exactly this reason [Nishtala et al. 2013].

20.7.2 Consistency races in cache-aside

Deleting after the write narrows the window for stale data but does not close it.

Figure 20.7 — The stale-set race in cache-aside.



Reading the diagram. Time flows downward. The reader misses and reads v_1 but is delayed (a GC pause, a slow network) before setting it. Meanwhile the writer commits v_2 and deletes the key, which is already absent. The reader's late `SET` then installs v_1, and every subsequent reader sees stale data until the TTL expires. All steps are synchronous; the hazard is the gap between the reader's database read and its cache write. The race is rare, but at millions of reads per second rare events happen every day.

The opposite ordering is worse. If the writer deletes the cache *before* updating the database, any reader arriving between the delete and the commit refills the cache with the old value, a window as long as the write transaction.

Mitigations, from simplest to strongest:

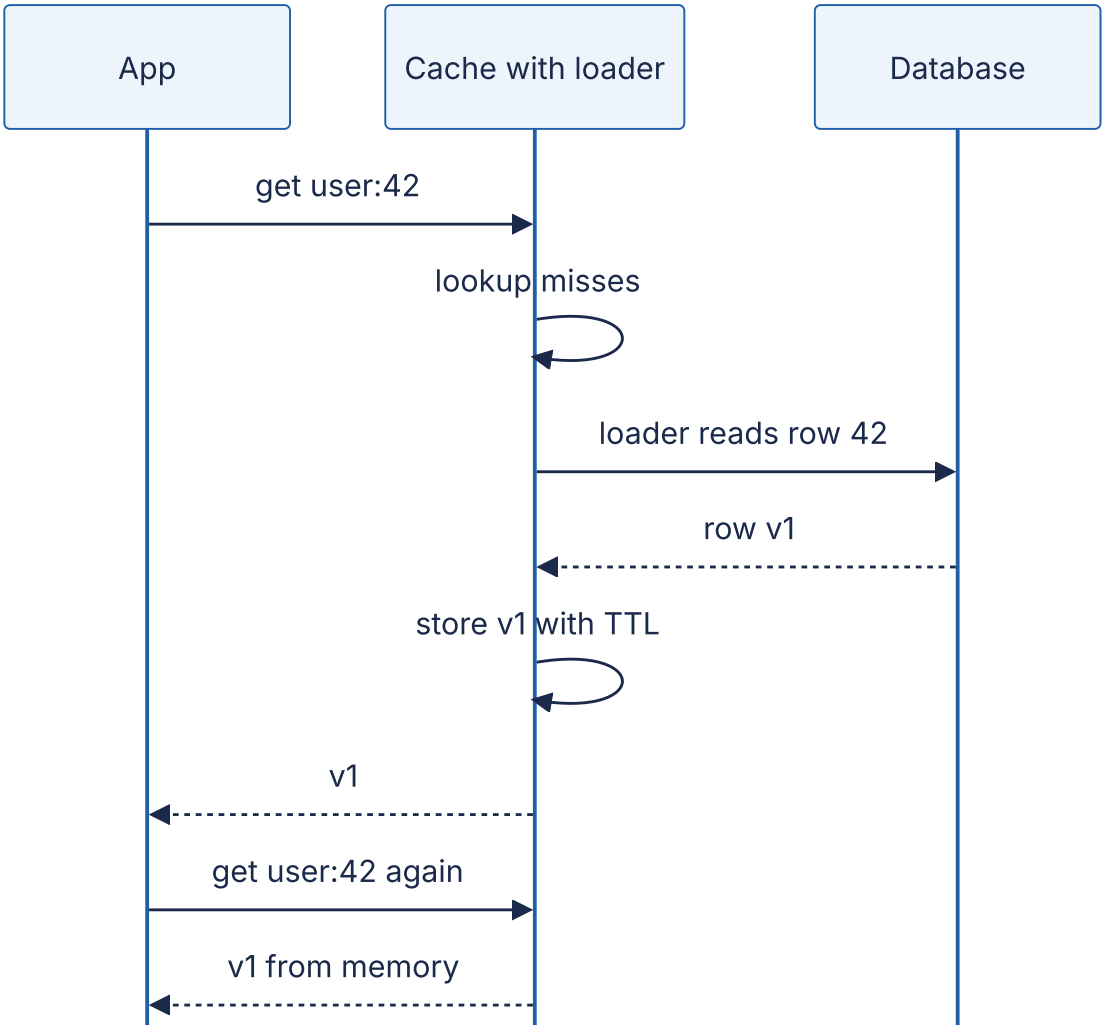
1. **Short TTLs** bound how long a stale entry can survive. Always set one.
2. **Delayed double delete**: delete, commit, then delete again after a delay longer than a typical read–fill (for example 500 ms). It shrinks the window but is a heuristic.
3. **Leases**: on a miss the cache hands the reader a token; a delete invalidates outstanding tokens, and a `SET` with an invalid token is rejected. In Figure 20.7 the writer's `DEL` would void the reader's lease, so the stale `SET` fails [Nishtala et al. 2013]. Memcached's `cas` and meta-protocol tokens provide similar building blocks.
4. **Versioned sets**: store a version (a database row version or commit LSN) with the value and set only if the cached version is older, using compare-and-set or a server-side script.
5. **Invalidation from the database's change stream** (§20.10.2): deletes are issued after commit by a process that tails the log, so no application crash can skip them.

20.7.3 Read-through

DEFINITION

Definition — Read-through. The application asks only the cache; on a miss the *cache* loads the value from the database through a configured loader, stores it and returns it.

Figure 20.8 — Read-through.



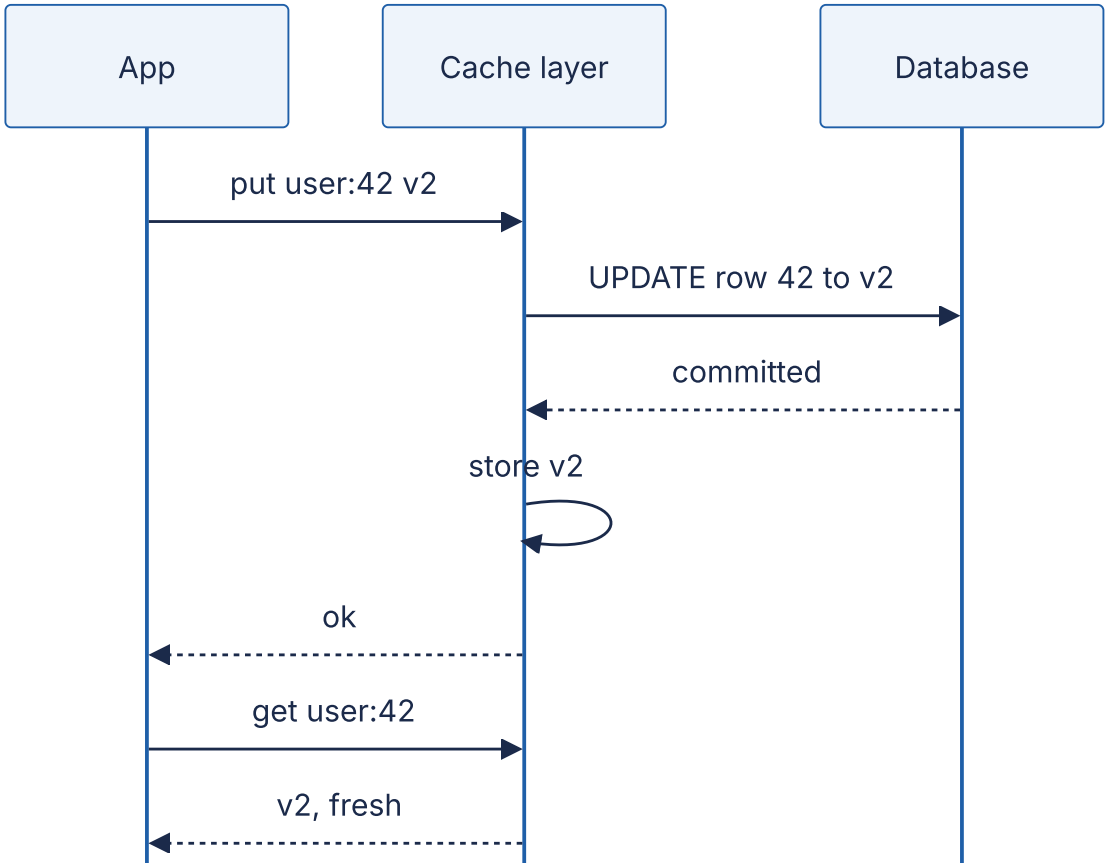
Reading the diagram. The application sees one synchronous interface; the cache loads. Because the loader sits inside the cache, concurrent misses for a key can be **coalesced** into one database read (§20.11). Storage boundaries are as in cache-aside, but a cache outage also blocks reads unless the client falls back. Caffeine's `LoadingCache` is an in-process example; remote read-through usually comes from a proxy or loader plug-in.

20.7.4 Write-through

DEFINITION

Definition — Write-through. Every write goes to the cache, which synchronously writes it to the database before acknowledging; the cache is updated and the database is updated as one client-visible operation.

Figure 20.9 — Write-through.

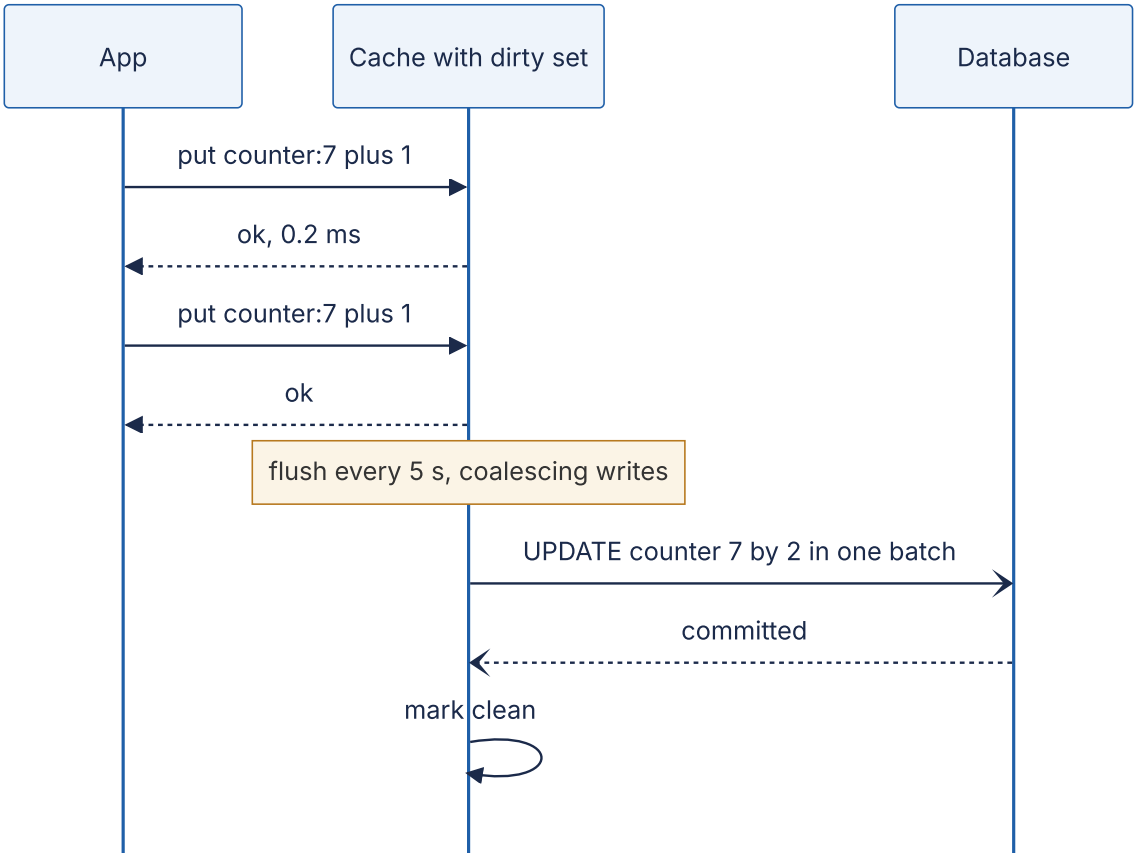


Reading the diagram. The write is acknowledged only after both the database commit and the cache update, so a subsequent read through the same cache sees the new value. Write latency is the sum of both, and every written key is cached, even if never read. Failure points: a crash between the database commit and the cache store leaves the cache without the value (harmless) or, if ordered the other way, with a value the database never committed (harmful), so the database must be written first. Writes that bypass the cache layer (an admin script, another service) still make it stale.

20.7.5 Write-back (write-behind)

> DEFINITION
>
> **Definition — Write-back.** Writes update only the cache and are acknowledged immediately; the cache marks entries **dirty** and flushes them to the database asynchronously, in batches or after a delay.

Figure 20.10 — Write-back.



Reading the diagram. Writes are acknowledged from memory; the flush to the database is asynchronous (open arrowheads) and coalesces many writes to the same key into one. This is how CPU caches (§5.4) and database buffer pools (§13.4) handle writes. The storage boundary that matters is the dirty set: until flushed, acknowledged data exists only in cache memory. Failure point: a cache node crash loses every unflushed write unless the cache itself is replicated or logged. Scaling: write-back absorbs write bursts that the database could not take directly.

FORMULA

Data at risk under write-back

$$W_{\text{risk}} \approx r_w \times T_{\text{flush}}, \qquad \text{write reduction} = \frac{r_w}{r_{\text{flush}}}$$

Symbol	Meaning	Units
W_{risk}	Acknowledged writes that a crash can lose	writes
r_w	Write rate into the cache	writes/s
T_{flush}	Maximum time a dirty entry waits before flushing	s
r_{flush}	Database writes per second after coalescing	writes/s

WORKED EXAMPLE

Worked example — View counters. A video service counts 200,000 views/s spread over 50,000 videos active in any 5-second window, flushing every $T_{\text{flush}} = 5$ s.

1. Writes at risk: $200,000 \times 5 = 10^6$ view increments lost if a node crashes just before a flush.
2. Database load after coalescing: at most 50,000 rows updated per 5 s, so $r_{\text{flush}} = 10,000$ writes/s.
3. Write reduction: $200,000/10,000 = 20\times$.

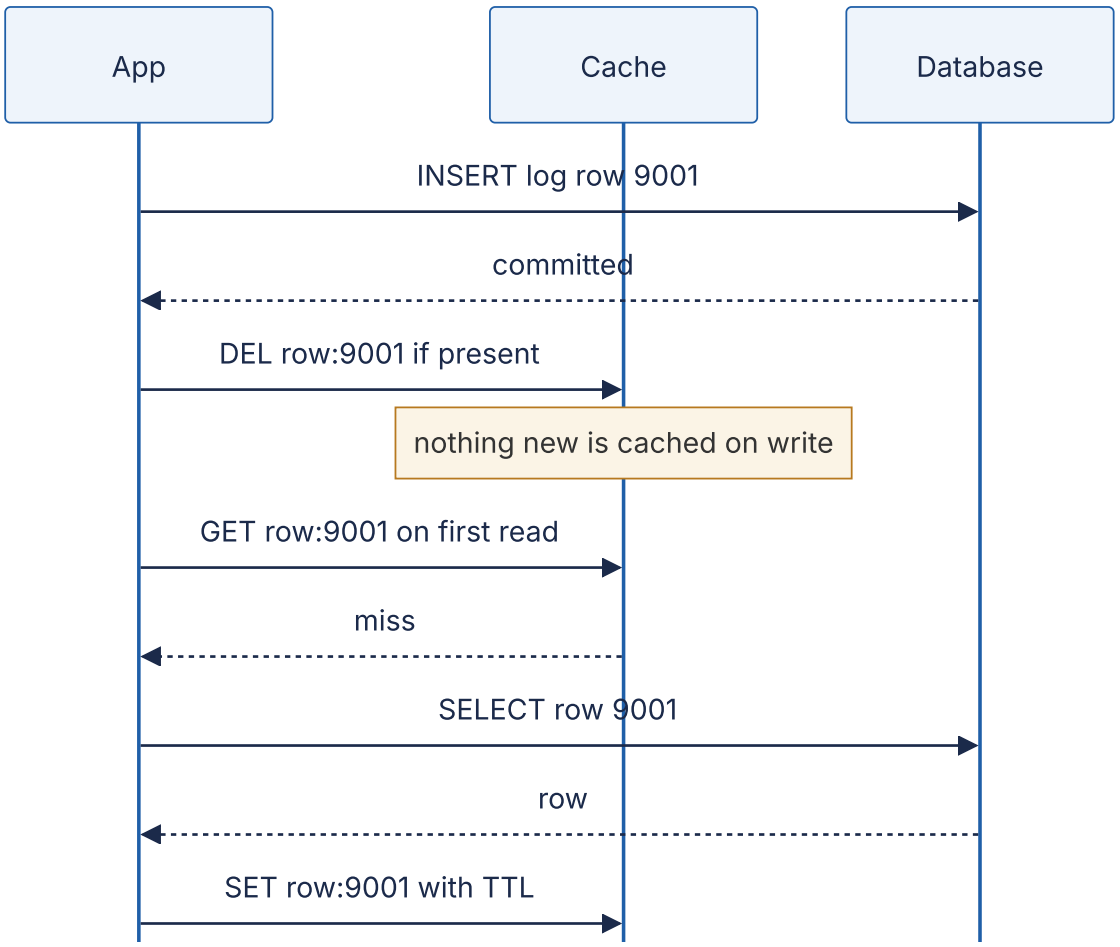
Interpretation. For view counts, losing a few seconds of increments is acceptable, and a 20× write reduction is decisive. **Engineering implication.** Use write-back only for data whose loss you can tolerate or reconstruct (counters, metrics, presence); for orders and payments, the database must commit first.

20.7.6 Write-around

DEFINITION

Definition — Write-around. Writes go directly to the database and bypass the cache; the cache is populated only by reads (usually cache-aside), and the written key is invalidated or left to expire.

Figure 20.11 — Write-around.



Reading the diagram. Writes touch only the database (and delete a stale key); only a later read caches the row, so write-once data such as logs and audit rows never evicts hot entries. The cost: the first read after a write misses. Cache-aside with delete-on-write *is* write-around; the name matters in contrast with write-through.

20.7.7 Choosing a pattern

Table 20.5 — Caching patterns compared.

Pattern	Read miss filled by	Write path	Consistency risk	Write latency	Choose when
Cache-aside	Application	DB, then delete key	Stale-set race; missed deletes	DB only	Default for remote caches
Read-through	Cache loader	(combine with a write pattern)	As cache-aside	—	In-process caches; coalescing misses
Write-through	Cache loader	Cache writes DB synchronously	Writes bypassing the layer	DB + cache	Read-after-write freshness via one layer
Write-back	Cache loader	Cache only; async flush	Loss of unflushed writes	Cache only	Counters, bursts, tolerable loss
Write-around	Application	DB only	First read misses	DB only	Write-heavy, rarely re-read data

COMMON MISTAKE

"Write-through means the cache and database are always consistent." Only for writers that go through that cache layer, and only if the database is written first. Concurrent writers, a second cache tier, or a batch job writing the database directly all reintroduce staleness. No pattern gives you linearizability across two stores without a protocol (Chapter 25); pick the pattern whose failure mode you can tolerate.

20.8 Time to live (TTL)

DEFINITION

Definition — Time to live (TTL). The maximum time an entry may be served after it was stored. After the TTL the entry is treated as absent (or, with stale-while-revalidate, as stale). Redis removes expired keys lazily when they are accessed and actively by periodically sampling keys that have a TTL [Redis Docs: EXPIRE].

A TTL is your **staleness budget** and your safety net: even if every invalidation mechanism fails, no entry is wrong for longer than its TTL. Choose it per data type from the question "how wrong may a user see this, and for how long?": seconds for prices and inventory, minutes for profiles, hours for rendered public pages, a year for content-addressed assets. Shorter TTLs cost more misses: an entry read λ times per second with TTL T misses about once per T seconds, a miss ratio near $1/(\lambda T)$ for hot keys.

The danger is synchronized expiry. If a deploy, a batch job or a cache restart writes a million keys in one minute with the same TTL, they all expire in the same minute an hour

later, and the database receives a million refills at once. **Jitter** spreads them out.

FORMULA

TTL with uniform jitter

$$T_i = T_{\text{base}} + U_i, \quad U_i \sim \text{Uniform}(0, J), \qquad \text{peak refills/s} \approx \frac{K}{\max(J, t_{\text{write}})}$$

Symbol	Meaning	Units
T_i	TTL given to key i	s
T_{base}	Base TTL	s
J	Jitter range	s
K	Keys written together	keys
t_{write}	Time span over which the keys were originally written	s

WORKED EXAMPLE

Worked example — Choosing a jitter range. A nightly job writes $K = 1,200,000$ product keys in 60 s with $T_{\text{base}} = 3,600$ s. The database can absorb 2,000 extra refill queries/s.

1. Without jitter: $1,200,000/60 = 20,000$ refills/s for a minute, an hour later. Ten times the safe level.
2. Required spread: $J \geq 1,200,000/2,000 = 600$ s.
3. Use $T_i = 3,600 + \text{Uniform}(0, 600)$ s. Peak refill rate: $1,200,000/600 = 2,000$ queries/s.
4. The cost: the longest-lived entries are now 4,200 s old, so the staleness bound grows from 60 to 70 minutes.

Interpretation. Jitter converts a spike into a plateau whose height you choose. **Engineering implication.** Add jitter of 10–20% to every TTL by default; for the very hottest keys combine it with the stampede defenses of §20.11, because jitter spreads *different* keys but cannot help one key that everyone reads.

20.9 Eviction: LRU, LFU, ARC and TinyLFU

When memory is full, the cache must choose a **victim**. The ideal is Belady's MIN: evict the entry whose next use is furthest in the future [Belady 1966]. It needs knowledge of the future, so real policies predict the future from the past using **recency** (used lately?),

frequency (used often?) or both. §13.4.2 covered LRU, clock and LRU-K inside databases; here we focus on policies used by application caches.

20.9.1 LRU and LFU

LRU (least recently used) keeps entries in a list ordered by last access, moving an entry to the head on each hit and evicting from the tail; a hash map plus a doubly linked list gives $O(1)$ operations. It adapts instantly to change but is polluted by **scans** and one-hit wonders: a burst of keys read once pushes out keys that are read every second.

LFU (least frequently used) evicts the entry with the smallest access count. It protects consistently popular keys from scans but has two flaws: it must store counts, and old counts never fade, so yesterday's hits keep today's useless entries in the cache (**cache pollution by history**). Practical LFUs age counts by halving or decay.

20.9.2 ARC

ARC (Adaptive Replacement Cache) keeps two LRU lists of cached entries, T_1 for keys seen once recently and T_2 for keys seen at least twice, plus two **ghost lists** B_1 and B_2 that remember only the *keys* recently evicted from each [Megiddo & Modha 2003]. A hit in ghost list B_1 means "T_1 was too small" and shifts the target size p toward recency; a hit in B_2 shifts it toward frequency. ARC therefore tunes itself between LRU and LFU with no parameters, resists scans, and costs $O(1)$ per access with metadata for $2C$ keys. OpenZFS's ARC is a modified version of it [OpenZFS Docs]. IBM held a patent on ARC, which kept it out of some open-source projects.

20.9.3 TinyLFU and W-TinyLFU

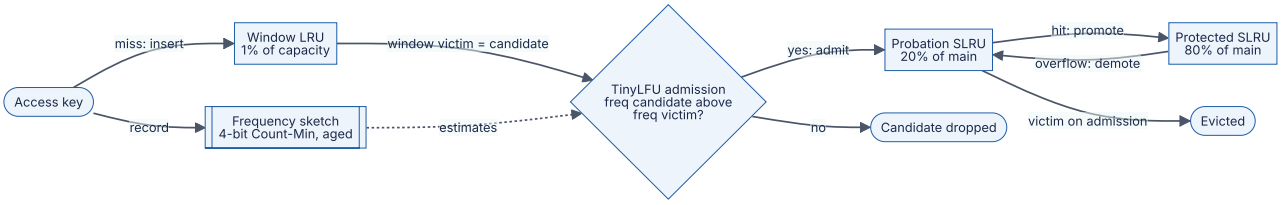
DEFINITION

Definition — TinyLFU. An **admission policy**: when the cache is full and a new candidate arrives, admit it only if its estimated access frequency exceeds that of the victim the eviction policy would remove. Frequencies are estimated by a small approximate sketch (a Count-Min sketch with 4-bit counters, §17.6) over a sample of recent requests, and **aged** by halving every counter after a fixed number of requests [Einziger, Friedman & Manes 2017].

Admission solves LRU's problem from the other side: instead of choosing a better victim, it refuses to let a one-hit wonder in at all. Pure TinyLFU, however, rejects new keys that are about to become popular, because they have no history yet. **W-TinyLFU** adds a small **window** LRU (1% of capacity by default) that admits everything; entries leaving the window compete through TinyLFU for a place in the **main** area, a segmented LRU with a probation and a protected segment. A **doorkeeper** Bloom filter can absorb first occur-

rences so they do not take sketch counters. Caffeine, the standard Java cache library, uses W-TinyLFU and adapts the window size with a hill-climbing algorithm [Caffeine Wiki: Efficiency].

Figure 20.12 — W-TinyLFU: window, admission filter and segmented main cache.



Reading the diagram. Every access updates the frequency sketch. A missed key first enters the small window LRU, which gives new keys a chance to prove themselves. When the window overflows, its LRU entry becomes a candidate and is compared with the probation segment's LRU victim; the one with the higher estimated frequency stays. Hits in probation promote entries to the protected segment, whose overflow is demoted back to probation. All of this is in-process memory and synchronous; the sketch is shared state read by the admission decision (dotted). Failure points: a stale sketch (fixed by periodic halving) and hash-flooding attacks on admission (Caffeine adds a little randomness). Scaling: sketch memory is about 8 bytes per cache entry.

20.9.4 Redis's approximated LRU and LFU

Redis does not keep a global LRU list, which would cost two pointers per key and a list update on every read. Each object header instead stores a 24-bit clock of its last access. When memory exceeds `maxmemory`, Redis **samples** `maxmemory-samples` keys (5 by default), adds the best candidates to a small pool of 16, and evicts the one idle longest; 10 samples come very close to true LRU [Redis Docs: Key eviction]. In LFU mode the same 24 bits hold a 16-bit decay timestamp and an 8-bit **logarithmic counter** (a Morris counter), incremented with probability that falls as the counter grows (`lfu-log-factor`, default 10) and decremented as time passes (`lfu-decay-time`, default 1 minute); new keys start at 5 so they are not evicted immediately. The policy is chosen with `maxmemory-policy`: `noeviction` (the default, which rejects writes when full), `allkeys-lru`, `allkeys-lfu`, `allkeys-random`, and `volatile-*` variants that consider only keys with a TTL, plus `volatile-ttl`.

> WARNING / TRADE-OFF
>
> **A Redis used as a cache must not run with `noeviction`.** With the default policy a full Redis rejects writes with an out-of-memory error, so cache fills fail and every request becomes a miss. Set `maxmemory` below physical RAM (leave room for fork copy-on-write and fragmentation) and choose `allkeys-lru` or `allkeys-lfu`.

20.9.5 Measuring policies on a Zipf trace

The program implements LRU, LFU (with least-recently-used tie-breaking), ARC from the paper’s pseudocode, and a simplified W-TinyLFU (no doorkeeper or hill climbing), and runs them on three traces of 400,000 requests over 50,000 keys: stationary Zipf ($s = 0.9$); the same Zipf interrupted every 8,000 requests by a scan of 2,000 never-repeated keys; and Zipf whose popularity ranks are reshuffled four times.

```
        """Hit ratios of LRU, LFU, ARC and a simplified W-TinyLFU on three synthetic
traces."""
        import itertools
        import random
        from collections import OrderedDict, defaultdict

        class LRU:
            def __init__(self, capacity):
                self.c, self.d = capacity, OrderedDict()
            def access(self, key):                      # returns True on a hit
                if key in self.d:
                    self.d.move_to_end(key)
                    return True
                self.d[key] = None
                if len(self.d) > self.c:
                    self.d.popitem(last=False)
                return False

        class LFU:
            """O(1) in-cache LFU: evict the lowest count, least recent among ties."""
            def __init__(self, capacity):
                self.c, self.freq = capacity, {}
                self.buckets, self.min_f = defaultdict(OrderedDict), 0
            def access(self, key):
                if key in self.freq:
                    f = self.freq[key]
                    del self.buckets[f][key]
                    if not self.buckets[f] and self.min_f == f:
                        self.min_f = f + 1
                    self.freq[key] = f + 1

cies]
                    print(f"  {tname:<17}" + "".join(f"{h:>11.1%}" for h in row))
```

Output (about 13 s):

```
cache = 500 entries (1% of 50,000 keys)
  trace                    LRU        LFU        ARC  W-TinyLFU
  stationary Zipf        32.3%      42.5%      43.0%      43.5%
  Zipf + scans           25.2%      33.8%      34.3%      34.6%
  shifting Zipf          32.1%      14.8%      42.1%      41.9%
cache = 2,500 entries (5% of 50,000 keys)
  trace                    LRU        LFU        ARC  W-TinyLFU
  stationary Zipf        50.1%      58.3%      58.3%      59.4%
  Zipf + scans           36.4%      46.2%      46.9%      47.1%
  shifting Zipf          49.7%      33.3%      55.7%      54.2%
```

What to notice:

- On the stationary trace the ideal top-C hit ratios are 45.8% (1%) and 62.0% (5%). W-TinyLFU gets within 2.5 points of ideal; LRU is 12–13 points behind.
- Scans hurt LRU most (−7 to −14 points); in this trace 20% of requests are unrepeatable scan keys, so 80% of the ideal, about 36.6% at 1%, is the ceiling, and ARC

and W-TinyLFU reach about 34%.

- In-cache LFU collapses on the shifting trace (14.8%) because entries that were hot in an earlier phase keep their high counts. Aging in W-TinyLFU and adaptation in ARC avoid this.
- The sketch's hash matters. An earlier version of this program that indexed rows with Python's tuple `hash((row, key))` produced correlated rows and lost 2–7 points; a multiplicative hash per row fixed it (§17.3).
- These are synthetic traces; Caffeine's comparisons on real traces mostly show W-TinyLFU at or near the top [Caffeine Wiki: Efficiency], but replay your own trace before switching.

Table 20.6 — Eviction and admission policies.

Policy	Signal	Scan resistant	Adapts to change	Metadata	Used in
LRU	Recency	No	Instantly	List pointers per entry	Defaults in many libraries
Sampled LRU	Approximate recency	No	Instantly	24-bit clock per key	Redis `allkeys-lru`
LFU with decay	Frequency	Yes	Slowly	Counter per entry	Redis `allkeys-lfu`
Segmented LRU	Recency with probation	Partly	Quickly	Segment flag	Memcached (HOT/WARM/COLD), InnoDB midpoint
ARC	Recency and frequency, self-tuning	Yes	Yes	Ghost keys for $2C$ entries	OpenZFS (modified)
W-TinyLFU	Frequency-based admission plus recency	Yes	Yes (aging, adaptive window)	~8 bytes per entry sketch	Caffeine

20.10 Cache invalidation

Invalidation keeps copies from outliving the truth. There are four mechanisms, and serious systems combine them.

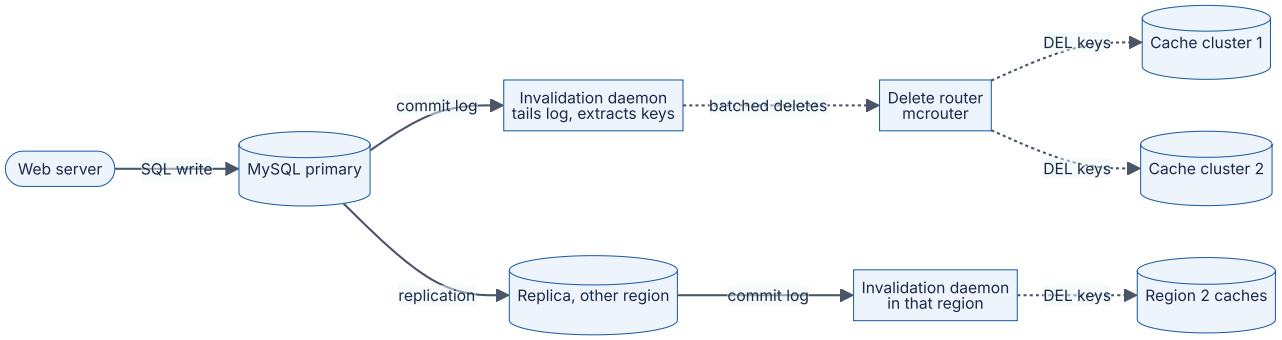
20.10.1 TTL and explicit deletes

TTL-only invalidation is simple and self-healing but guarantees staleness up to the TTL. **Explicit deletes** from the code path that writes (cache-aside, §20.7.1) make data fresh within milliseconds, but every write path must remember to delete every affected key: the profile, the list it appears in, the rendered page fragment. A missed path is a staleness bug that the TTL eventually hides, which is why you always keep a TTL as a backstop.

20.10.2 Event-driven invalidation from the change stream

Instead of trusting every writer, derive deletes from the database's own log. A **change data capture** (CDC) process tails the commit log (MySQL binlog, PostgreSQL logical decoding, §32.6), maps each changed row to cache keys and issues deletes. Because the log contains only committed changes, in commit order, nothing is invalidated too early and no application crash can skip an invalidation.

Figure 20.13 — CDC-driven invalidation across regions (after Facebook's mcsqueal).



Reading the diagram. The web server writes only to the database (synchronous). A daemon on the database host reads the commit log, extracts keys, batches them and sends deletes asynchronously (dotted) through a router to every cache cluster. In another region the replica's own log drives deletes, so local caches are invalidated only after the replica has the new data. Storage boundaries: database, log, cache clusters. Failure points: daemon lag, lost batches (replay from the log position) and deletes overtaking replication (hence per-region daemons). Scaling: batching reduces packet rates.

INDUSTRY EXAMPLE

Facebook: mcsqueal and leases. Facebook's Memcache deployment served billions of requests per second as a demand-filled look-aside cache in front of MySQL. Invalidation daemons called **mcsqueal** run on each database, extract deletes from committed transactions and broadcast them, batched, through **mcrouter** to all front-end clusters; in remote regions the replica's daemons do the same. **Leases** (64-bit tokens issued on a miss and voided by a delete) prevent stale sets, and, because a server returns a token only once every 10 seconds per key, they also throttle thundering herds; the paper reports a peak database query rate falling from 17K/s to 1.3K/s in one instance. A small **gutter** pool (about 1% of servers) takes over for failed cache servers with short TTLs, so a failure does not dump its load onto the databases [Nishtala et al. 2013]. *Evidence: Primary* — [Nishtala et al. 2013]

20.10.3 Versioned keys

Instead of deleting, change the key. Store a version number per entity (or per namespace) and include it in every cache key: `product:42:v17`. A write increments the version in the database (or in a small, strongly consistent version store); readers fetch the current version, then the versioned key. Old entries become unreachable and age out by TTL or eviction. Versioned keys make invalidation of whole groups cheap (bump `catalog_version` to invalidate every catalog page) and never suffer the stale-set race, because a stale value is written under an old key nobody reads. The cost is an extra lookup for the version and wasted memory until old versions are evicted. Content-hashed asset URLs (§20.5.2) are the same idea.

COMMON MISTAKE

"There are only two hard things in computer science: cache invalidation and naming things." The quip, usually attributed to Phil Karlton, is often used to excuse not designing invalidation. The hard part is enumerating which keys depend on which rows. Write the dependency down: for each cached object, list the tables and columns it is derived from and the mechanism (TTL, delete, CDC, version) that invalidates it.

20.11 Cache stampede

DEFINITION

Definition — Cache stampede (thundering herd, dog-piling). When a popular entry expires or is evicted, many concurrent requests miss at once and all recompute or reload it, multiplying load on the backend exactly when it is busiest.

If a key is read λ times per second and recomputing it takes δ seconds, about $\lambda\delta$ requests miss before the first refill lands. For $\lambda = 2,000$ requests/s and a 500 ms query, that is 1,000 identical queries.

20.11.1 Locks, leases and single-flight

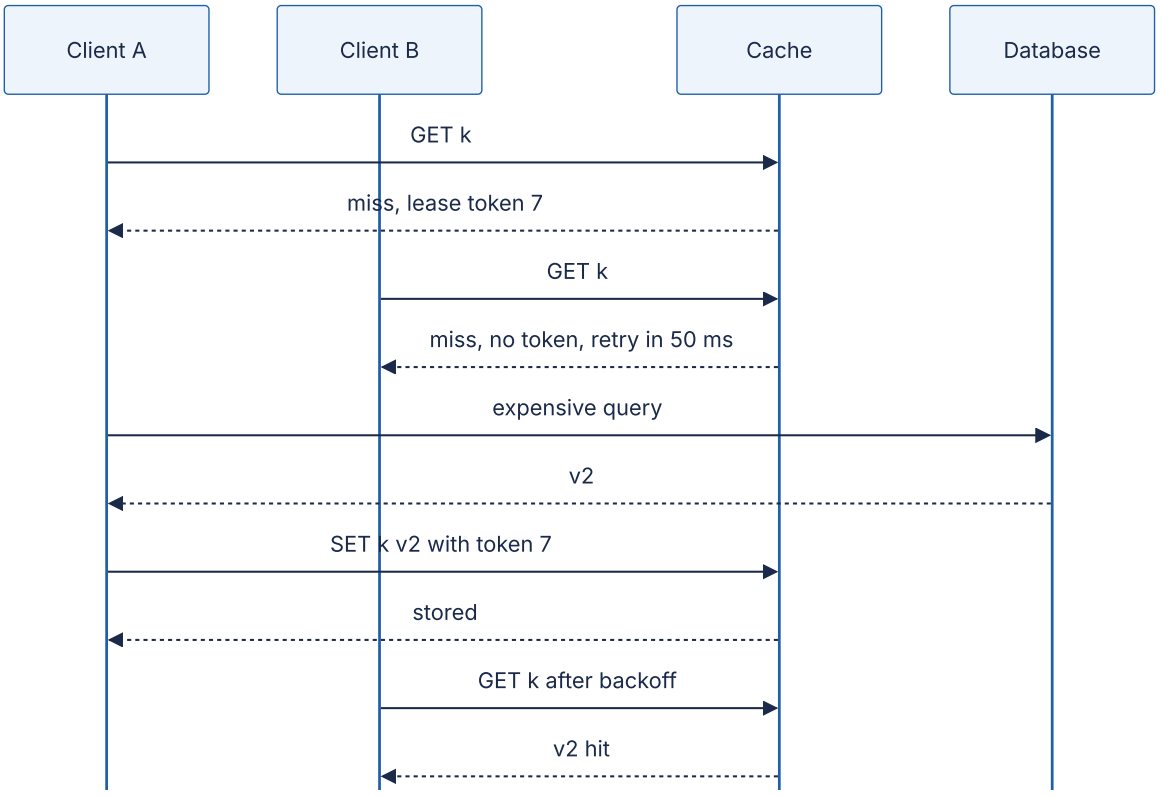
Let one request recompute and make the others wait or use a stale copy.

- **Single-flight (request coalescing)** inside a process: concurrent misses for a key share one in-flight load (Go's `singleflight`, Caffeine's `LoadingCache`). Across A app instances this still allows A loads.
- **Distributed lock**: the first misser sets `SET lock:k token NX PX 3000`; others wait briefly and retry the cache, or serve stale data. The lock needs a timeout in case the

holder dies (§26.10).

- **Leases** in Memcache (§20.10.2): the cache itself hands out one token per key per interval and tells other clients to retry shortly.

Figure 20.14 — Stampede protection with a lease: one recompute, others wait or serve stale.



Reading the diagram. Only the first misser gets a lease token; later missers are told to retry (or get a stale value), so only A queries the database. The `SET` needs a valid token, which also blocks the stale-set race of Figure 20.7. All calls are synchronous. Failure points: if A dies, its token expires and another client gets one; waiting adds latency. Scaling: one database query per refresh regardless of λ.

20.11.2 Probabilistic early expiration (XFetch)

Locks add coordination. **XFetch** avoids it: each reader independently decides, with a probability that rises as expiry approaches, to recompute *before* the entry expires, while everyone else keeps getting hits [Vattani, Chierichetti & Lowenstein 2015].

FORMULA

XFetch early-recomputation rule and its consequences (Poisson arrivals)

$$\text{recompute if } \; t - \delta\beta \, \ln(u) \geq t_{\text{exp}}, \quad u \sim \text{Uniform}(0, 1] \qquad \Rightarrow \qquad P(\text{early} \mid r) = e^{-r/(\delta\beta)}$$

$$\mathbb{E}[\text{lead}] \approx \delta\beta(\ln(\lambda\delta\beta) + \gamma), \qquad \mathbb{E}[\text{recomputes per refresh}] \approx e^{1/\beta}$$

Symbol	Meaning	Units
t	Current time	s
t_{exp}	Entry's expiry time	s
$r = t_{\text{exp}} - t$	Time remaining before expiry	s
δ	Measured recompute time, stored with the value	s
β	Aggressiveness; 1 is the recommended default	dimensionless
u	Uniform random number per request	dimensionless
λ	Request rate for the key	requests/s
γ	Euler–Mascheroni constant, ≈ 0.5772	dimensionless

Since $-\ln u$ is exponentially distributed, triggers form a Poisson process of intensity $\lambda e^{-r/(\delta\beta)}$; the remaining time at the first trigger is Gumbel-distributed, which gives the expected lead, and requests during the δ-second recompute add $e^{1/\beta} - 1$ extra triggers on average, independent of λ (§20.19, Q7).

WORKED EXAMPLE

Worked example — A hot key with a 2-second recompute. $\lambda = 100$ requests/s, $\delta = 2$ s, $\beta = 1$, TTL 60 s.

1. Per-request trigger probability with 10 s left: $e^{-10/2} = e^{-5} = 0.0067$; with 2 s left: $e^{-1} = 0.37$.
2. Expected lead: $\lambda\delta\beta = 200$; $\ln 200 = 5.298$; $2 \times (5.298 + 0.577) = 11.75$ s before expiry.
3. Recomputes per refresh: $e^{1} \approx 2.72$, against $\lambda\delta = 200$ with no protection.
4. Extra cost: the entry is refreshed every $60 - 11.75 + 2 \approx 50$ s instead of 62 s, about 23% more refreshes.
5. With $\beta = 2$: lead $4 \times (\ln 400 + 0.577) = 4 \times 6.569 = 26.3$ s and $e^{0.5} = 1.65$ recomputes; with $\beta = 0.5$: lead 5.2 s and $e^{2} = 7.4$ recomputes.

Interpretation. β trades earlier refreshes for fewer duplicate recomputations; the lead grows only logarithmically with traffic, so XFetch scales to any λ. **Engineering implication.** Store δ with each value, start with $\beta = 1$, and if duplicate recomputes are expensive combine XFetch with a non-blocking lock so only the first trigger recomputes; no request ever waits.

The simulation below checks these numbers.

```
        """One hot key under Poisson traffic: recomputations and misses per refresh for
        no protection, a recompute lock, and XFetch [Vattani et al. 2015]."""
        import math

Output:

```
rate 100 req/s, TTL 60 s, recompute time 2 s, 3 hours
policy         beta  recomputes/refresh  miss ratio  mean lead (s)  theory lead
none            1.0              202.77     3.1517%          -0.01            -
lock            1.0                1.00     3.2451%          -0.01            -
xfetch          0.5                6.71     0.0000%           5.30         5.18
xfetch          1.0                2.50     0.0000%          12.05        11.75
xfetch          2.0                1.66     0.0000%          26.58        26.27
xfetch+lock     1.0                1.00     0.0000%          11.83        11.75
```

What to notice:

- Without protection each refresh costs about 200 recomputations ($\lambda\delta$) and 3.2% of requests miss ($\delta/(\text{TTL}+\delta) = 2/62$).
- A lock fixes the duplicate work but not the misses: requests during the recompute still wait.
- XFetch removes misses entirely, and its leads match the formula within half a second. Duplicate recomputes (6.71, 2.50, 1.66) sit within sampling error of $e^{1/\beta}$ (7.39, 2.72, 1.65); averaged over 40 simulated hours they are 7.50, 2.71 and 1.63.
- XFetch plus a non-blocking lock gives exactly one recompute and no misses.

20.11.3 Stale-while-revalidate

Keep entries past their **soft TTL**: after it, serve the stale value immediately and trigger one background refresh; delete only at a later **hard TTL**. This is HTTP's `stale-while-revalidate` (§20.5.2) applied to an application cache, and it gives the same result as XFetch plus a lock when traffic is steady. It also enables **stale-if-error**: if the database is down, keep serving the last good value. The price is explicit staleness, so use it only where showing a value a few seconds old is acceptable.

20.12 Cache penetration

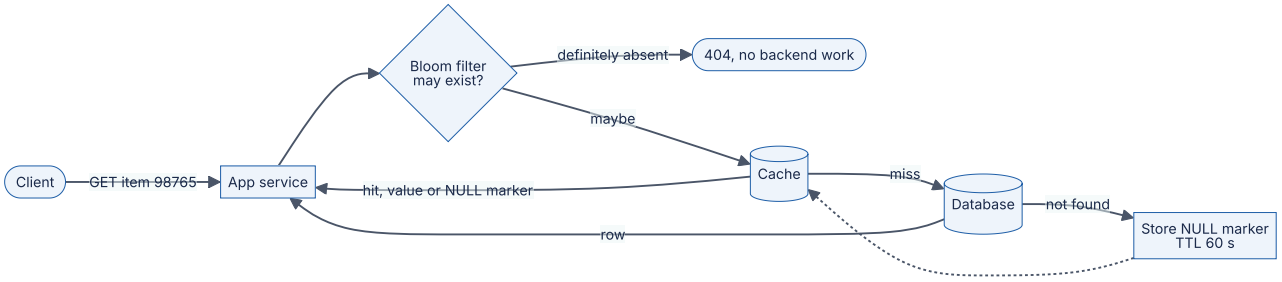
DEFINITION

Definition — Cache penetration. Requests for keys that do not exist in the database. Because there is nothing to cache, every such request misses and reaches the database. A bug or an attacker iterating random IDs can push the database's full read load through the cache.

Two defenses work together:

1. **Negative caching**: cache the “not found” result under the key with a short TTL (for example 30–60 s), so repeated lookups of the same missing key hit. It fails against random keys, each requested once, and wastes memory on them.
2. **A Bloom filter of existing keys** in front of the cache: if the filter says “definitely absent”, return 404 without touching cache or database. False positives (1% at about 9.6 bits per key, §17.4.3) only let a small fraction through. The filter must be updated on insert and rebuilt periodically to remove deleted keys, or use a cuckoo filter that supports deletion (§17.4.7).

Figure 20.15 — Defenses against cache penetration.



Reading the diagram. The in-memory Bloom filter rejects most nonexistent IDs before any network call. Survivors go to the cache, which returns a value or a cached “not found” marker; only true misses reach the database, and a not-found result is stored with a short TTL (dotted). All checks are synchronous. Storage boundaries: filter, cache, database. Failure points: a filter that lags behind inserts returns false 404s, so add keys before they become visible, and delete negative markers on creation. Scaling: at 1% false positives, 100,000 random IDs/s let about 1,000 through.

Rate limiting per client (§22.3) and validating ID formats before lookup complete the defense.

20.13 Cache avalanche

DEFINITION

Definition — Cache avalanche. A large fraction of cache entries becomes unavailable at once, because many keys expire together or because cache nodes fail or restart, so the database suddenly receives the full read load.

At $h = 0.99$ the database sees 1% of reads; with the cache gone it sees 100%, a 100× jump, and the resulting timeouts and retries add more load (§22.12).

Defenses:

- **TTL jitter** (§20.8) so mass-written keys do not expire together.
- **Replicated, highly available cache** (Redis replicas with automatic failover; a gutter pool, §20.10.2), so one node failure does not empty its share of keys.
- **Warming**: before a new or restarted cache takes traffic, load the hottest keys from a key list, a snapshot (RDB) or a warm peer; Facebook warms a new cluster by letting it read from a warm cluster's caches instead of the database [Nishtala et al. 2013].
- **Tiered fallback**: an in-process L1 (§20.5.4) and stale-if-error serving keep answering hot keys during an L2 outage.
- **Protect the database**: admission control, load shedding and circuit breakers (§22.9, §22.13) so it degrades by rejecting a fraction of requests rather than collapsing.

Table 20.7 — The three classic cache failure modes.

What goes wrong	Why	Detection	Recovery	Prevention
Stampede	One hot key expires; $\lambda\delta$ concurrent recomputes	Spikes of identical queries; per-key miss bursts	Shed load; serve stale	Leases or single-flight, XFetch, stale-while-revalidate
Penetration	Requests for nonexistent keys bypass the cache	High miss ratio with many "not found" results	Block abusive clients	Negative caching, Bloom filter, rate limits, ID validation
Avalanche	Many keys expire together, or cache nodes fail	Hit ratio collapses; database queries/s jump	Throttle, warm caches, fail over	Jitter, replication, warming, L1 and stale-if-error, load shedding

20.14 Distributed caching and consistent hashing

A single cache node is limited by its RAM (tens to hundreds of GB) and, for Redis, by one execution core. A distributed cache partitions keys over N nodes. With `hash(key) mod N`, adding a node remaps about $N/(N+1)$ of keys, which for a cache means that fraction of entries effectively vanishes: a self-inflicted avalanche. **Consistent hashing** with virtual nodes moves only about $1/(N+1)$ of keys and spreads the moved load evenly; §14.8 derives it, and §3.3.2 works through a cache example. Three routing designs exist:

- **Client-side routing**: the client library holds the ring (most Memcached clients, Ketama hashing).
- **Proxy routing**: a proxy such as mcrouter or Twemproxy routes, replicates and fails over on behalf of thin clients.
- **Server-assisted routing**: Redis Cluster's fixed 16,384 slots with `MOVED` redirects (§20.6.4), which moves whole slots on resharding rather than ring arcs.

When a node fails, its keys move to their successors cold. Replication (Redis replicas, EVCache copies) or a gutter pool avoid that miss spike.

20.15 Hot keys

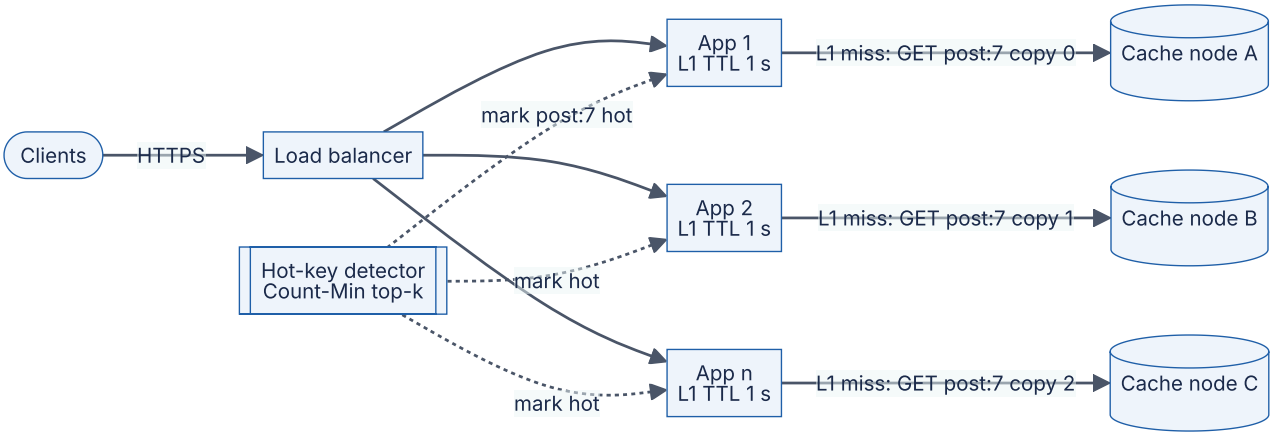
DEFINITION

Definition — Hot key. A single key whose request rate exceeds what the node holding it can serve, so partitioning cannot help: all requests for one key go to one node.

A celebrity's post, a flash-sale product or a global configuration key can draw hundreds of thousands of requests per second. **Detect** hot keys by sampling requests into a Count-Min sketch or top-*k* structure per cache client or proxy (§17.6), or with server tools such as `redis-cli --hotkeys` (which needs an LFU eviction policy). Then **mitigate**:

1. **Local L1 caches** with a short TTL in each app instance, so each instance asks the remote cache at most once per TTL. Redis 6's **client-side caching** sends invalidation messages to clients that track the keys they cached [Redis Docs: Client-side caching].
2. **Key replication**: store copies under `k#0` … `k#r-1` on different nodes, read a random copy and write or delete all copies.
3. **Request coalescing** at the proxy so concurrent identical gets become one.

Figure 20.16 — Hot-key mitigation with L1 caches and replicated keys.



Reading the diagram. Each of *n* app instances keeps hot keys in its L1 for one second, so it sends at most one request per second per hot key to the remote tier, choosing one of three replicated copies at random. A detector fed by sampled requests marks keys hot asynchronously (dotted). Storage boundaries: process memory and three cache nodes. Failure points: L1 staleness up to its TTL; writes and deletes must reach every copy. Scaling: remote load grows with instance count, so lengthen the L1 TTL or add copies.

FORMULA

Remote load from a hot key with L1 caches and replication

$$R_{\text{remote}} \le \min\left(\lambda_k, \frac{A}{T_{L1}}\right), \qquad R_{\text{per node}} = \frac{R_{\text{remote}}}{r}$$

Symbol	Meaning	Units
λ_k	Request rate for the hot key	requests/s
A	Number of app instances with an L1 cache	instances
T_{L1}	L1 TTL	s
r	Number of replicated copies of the key	copies
R_{remote}, $R_{\text{per node}}$	Requests to the remote tier, and to each node holding a copy	requests/s

WORKED EXAMPLE

Worked example — A viral post. $\lambda_k = 600,000$ requests/s; one cache node can serve about 100,000 requests/s (illustrative).

1. Without mitigation: 600,000 requests/s to one node, six times its capacity.
2. Replication alone with $r = 8$: $600,000/8 = 75,000$ per node, under capacity but with little headroom.
3. L1 caches on $A = 300$ instances with $T_{L1} = 1$ s: $R_{\text{remote}} \le 300/1 = 300$ requests/s.

Interpretation. A one-second L1 cuts remote load by a factor of 2,000 at the cost of up to one second of staleness. **Engineering implication.** Use L1 caching for read-hot keys whenever a second of staleness is acceptable; reserve key replication for keys that must stay fresher or for write-hot counters (which need sharded counters instead, §14.10).

20.16 Redis versus Memcached

Table 20.8 — Redis (and Valkey) versus Memcached.

Aspect	Redis / Valkey	Memcached
What it is	In-memory data-structure server	In-memory cache of opaque blobs
How it works	Single-threaded command execution; optional I/O threads	Multithreaded workers sharing one hash table; slab allocator
Advantages	Rich types (hashes, sorted sets, streams), atomic scripts, persistence, replication, Cluster, pub/sub	Simple; scales vertically across cores; predictable memory; very mature
Disadvantages	One core executes commands; fork for persistence; more to tune	Strings only; no persistence or replication (client or proxy must provide them)
Performance	~100,000+ ops/s per core; more with I/O threads or pipelining	Millions of ops/s per server with many threads
Operational complexity	Medium–high (Sentinel or Cluster, persistence, memory policy)	Low (stateless nodes, client-side hashing)
Cost	Higher memory overhead per small key; replicas double RAM	Low overhead; slab waste 10–20%
Use cases	Sessions, leaderboards, rate limiters, queues, caches needing structure	Large look-aside caches of serialized objects
Choose when	You need data structures, atomic operations or durability	You need a fast, simple, horizontally scaled cache

Licensing (as of 2026). Redis was BSD-licensed until March 2024, when Redis 7.4 moved to a dual RSALv2/SSPLv1 license, which is not an open-source license under the OSI definition. The Linux Foundation then launched **Valkey**, a BSD-licensed fork of Redis 7.2.4 supported by several cloud providers. Redis 8.0 (2025) added the OSI-approved AGPLv3 as a third licensing option [Redis Blog 2024; Redis Blog 2025; Linux Foundation 2024]. Managed services such as AWS ElastiCache offer Valkey, Redis OSS and Memcached engines. For system design the engines are protocol-compatible for the features in this chapter; check the license and feature set of the specific version you deploy.

20.17 Summary and revision notes

SUMMARY

- A cache trades staleness, memory and a new failure mode for latency and backend capacity. $T_{\text{eff}} = t_c + (1-h)t_b$; database reads $= (1-h)R$. Watch the miss rate: 99% → 98% doubles database reads, and p99 is a miss once the miss ratio exceeds 1%.
- Zipf skew makes small caches effective: the ideal top-C hit ratio is $H_{C,s}/H_{N,s}$, about 68% for 1% of a million keys at $s = 1$, and grows by a roughly constant amount per doubling.
- Cache at every layer that freshness allows: browser and CDN for versioned and public content, in-process L1 for tiny hot data, remote L2 as the shared, invalidatable tier; the database's buffer pool is the only coherent one.
- Redis: one thread executes commands (atomic, but one slow command blocks all), optional I/O threads, RDB/AOF persistence, asynchronous replication, 16,384 hash slots with `MOVED` / `ASK`. Memcached: multithreaded, slab allocator (10–20% waste), segmented HOT/WARM/COLD LRU, no persistence or replication.
- Cache-aside with delete-after-commit is the default; it still has a stale-set race, closed by leases, versioned sets or CDC deletes, and bounded by TTLs. Write-through adds write latency; write-back risks $r_w T_{\text{flush}}$ writes; write-around avoids polluting the cache.
- Every entry needs a TTL; add jitter so peak refills are K/J.
- LRU is scan-sensitive, in-cache LFU cannot forget; ARC and W-TinyLFU combine recency and frequency and come within a few points of ideal. Redis samples keys to approximate LRU and LFU; never run a cache with `noeviction`.
- Invalidate with TTL + explicit deletes, CDC from the commit log (mcsqueal), or versioned keys.
- Stampede: leases/single-flight, XFetch ($t - \delta\beta \ln u \geq t_{\text{exp}}$; lead $\approx \delta\beta(\ln \lambda\delta\beta + \gamma)$; $e^{1/\beta}$ recomputes), stale-while-revalidate. Penetration: negative caching and Bloom filters. Avalanche: jitter, replication, warming, L1 and stale-if-error, load shedding.
- Distribute keys by consistent hashing or slots; hot keys need L1 caches ($\leq A/T_{L1}$ remote requests/s) or replicated copies.

20.18 Knowledge checkpoint

1. A cache lookup costs 0.4 ms and a database read 12 ms. What is the mean read latency at $h = 0.95$?
2. Why can a 1-point drop in hit ratio double database load?

3. Using the $s = 1$ approximation, what is the ideal hit ratio for $C = 10^5$ of $N = 10^7$ keys?
4. Why are Redis commands atomic without locks, and what is the operational cost of that design?
5. How does Redis Cluster map a key to a node, and how do you make two keys land in the same slot?
6. An item with header is 200 bytes. Which Memcached chunk (growth factor 1.25) holds it, and what fraction is wasted?
7. Describe the stale-set race in cache-aside and one mechanism that prevents it.
8. Why delete the cache entry after a write instead of setting the new value?
9. A write-back cache receives 50,000 writes/s and flushes every 2 s. How many acknowledged writes can a crash lose?
10. 600,000 keys were written in 30 s with the same TTL. The database tolerates 1,500 refills/s. What jitter range do you need?
11. Why does in-cache LFU do badly when popularity shifts, and how does W-TinyLFU avoid it?
12. What do ARC's ghost lists record, and what does a ghost hit change?
13. For XFetch with $\lambda = 400$ requests/s, $\delta = 0.5$ s, $\beta = 1$, what is the expected lead before expiry?
14. 200 app instances use a 2 s L1 TTL for a hot key. What is the maximum remote request rate for it?

Answers

1. $0.4 + 0.05 \times 12 = 1.0$ ms.
2. Database reads are proportional to the miss ratio; going from 99% to 98% doubles the miss ratio from 1% to 2%.
3. $(\ln 10^5 + 0.577)/(\ln 10^7 + 0.577) = (11.513 + 0.577)/(16.118 + 0.577) = 12.090/16.695 \approx 0.724$.
4. One thread executes all commands sequentially. Any slow command (`KEYS` , large `DEL` , long scripts) blocks every client, and a process uses only one core for execution.
5. `CRC16(key) mod 16384` gives the slot; each primary owns a set of slots. Put the same hash tag in both keys, for example `{user:42}:profile` and `{user:42}:cart` .
6. Classes: 152, 192, 240. 200 > 192, so the 240-byte chunk; waste $40/240 = 16.7\%$.
7. A reader reads v_1 from the database, a writer commits v_2 and deletes the key, and the reader then sets v_1, which stays until TTL. Leases (the delete voids the reader's token), versioned compare-and-set, or CDC-issued deletes after commit prevent or repair it.
8. Concurrent writers can set values in a different order from their database commits, leaving an old value cached; deletes are idempotent and order-insensitive.
9. $50,000 \times 2 = 100,000$ writes.
10. $J \geq 600,000/1,500 = 400$ s.
11. Counts of formerly hot entries stay high, so they are never evicted. W-TinyLFU halves sketch counters periodically (aging) and admits new keys through a recency

window.
12. The keys (not values) recently evicted from T_1 and T_2. A hit in B_1 increases the target size of T_1 (more recency); a hit in B_2 decreases it (more frequency).
13. $\lambda\delta\beta = 200$; $0.5 \times (\ln 200 + 0.577) = 0.5 \times 5.875 = 2.94$ s.
14. $200/2 = 100$ requests/s.

20.19 Interview questions

Basic

Q1. When would you add a cache, and what do you need to state when you do? Answer. When reads repeat, the store is too slow or near capacity, and the data tolerates bounded staleness. State the hit ratio and resulting database load, the pattern, TTL and invalidation, the outage behavior and the memory size.

Q2. Explain cache-aside versus write-through. Answer. Cache-aside: the application reads the cache, fills it from the database on a miss and deletes the key after writing the database; the cache is optional and holds only read data. Write-through: writes go through the cache layer, which writes the database synchronously and updates itself, so reads through that layer are fresh, at the cost of higher write latency and caching data that may never be read.

Q3. Redis or Memcached? Answer. Memcached for a simple, multithreaded, large look-aside cache of serialized objects. Redis (or Valkey) when you need data structures, atomic operations, persistence or replication: sessions, leaderboards, rate limiters. Mention the Redis licensing change and Valkey as of 2026.

Intermediate

Q4. Users sometimes see their old profile picture for an hour after changing it. Diagnose. Answer. The one-hour duration points to a TTL acting as backstop for a stale-set race, a missed delete on some write path, delete-before-write ordering, or a CDN or browser layer. Fix: delete after commit, leases or versioned keys, CDC-driven invalidation, and a versioned image URL.

Q5. Your database melts down every day at 09:00. Why might the cache be involved? Answer. A cache avalanche: a job warms or rewrites many keys at the same time each day with identical TTLs, or a daily cache restart empties it. Add TTL jitter, warm caches gradually, keep replicas, add stale-if-error serving, and protect the database with load shedding.

Q6. How do you protect a hot key that expires? Answer. Make sure only one request recomputes it: single-flight in process plus a lease or lock across processes, or XFetch to

refresh before expiry with $\beta \approx 1$, or stale-while-revalidate. For read volume beyond one node, add L1 caches and key replication.

Advanced

Q7. Derive why XFetch's duplicate recomputations do not grow with traffic. Answer. Each request triggers with probability $e^{-r/(\delta\beta)}$; Poisson arrivals give trigger intensity $\lambda e^{-r/(\delta\beta)}$. Let $G = \lambda\delta\beta e^{-R/(\delta\beta)}$ at the first trigger time R; since $P(\text{no trigger before } r) = \exp(-\lambda\delta\beta e^{-r/(\delta\beta)})$, G is exponential with mean 1. Triggers in the following δ seconds have expected count $G(e^{1/\beta} - 1)$, so the mean total is $e^{1/\beta}$ for any λ, while the lead $\delta\beta(\ln \lambda\delta\beta + \gamma)$ grows only logarithmically.

Q8. Design invalidation for a multi-region cache in front of a MySQL primary with cross-region replicas. Answer. Writers delete local keys after commit; a CDC daemon per database (primary and each replica) tails the commit log and issues batched deletes to that region's caches, so a region's caches are invalidated only after its replica has applied the change, preventing refills from lagging replicas. Keep TTLs as a backstop, use leases against stale sets, and for read-your-writes after a user's own update, route that user's reads to the primary or mark the key so misses read the primary (Facebook's remote markers) [Nishtala et al. 2013].

Q9. A team proposes replacing LRU with LFU in a 200 GB cache. How do you decide? Answer. Replay a production trace through LRU, LFU with aging, ARC and W-TinyLFU at several sizes and compare hit ratios and database queries per second (§20.9.5); scans hurt LRU, popularity shifts hurt pure LFU. In Redis this is `allkeys-lfu` versus `allkeys-lru`.

20.20 Practical exercises

1. **Measure skew.** Extend the §20.3.3 program to read a log of keys (one per line), fit the Zipf exponent by linear regression of log frequency on log rank, and plot measured LRU hit ratio against cache size.
2. **Add a doorkeeper.** Add a Bloom-filter doorkeeper (§17.4) to the W-TinyLFU class in §20.9.5 and report the hit-ratio change on the three traces.
3. **Reproduce the race.** With Redis and PostgreSQL in Docker, write a reader that sleeps 200 ms between its database read and its cache `SET`, and a writer that updates and deletes. Count stale entries over 10,000 iterations; then add a version check with a Lua script and count again.
4. **Stampede test.** Put a 1 s sleep behind a cached endpoint, expire the key under 500 concurrent clients, and measure database calls with no protection, with a `SET NX PX` lock, and with XFetch.

5. **Redis eviction.** Fill a Redis instance with `maxmemory 100mb` under `allkeys-lru` with `maxmemory-samples` 1, 5 and 10, replay a Zipf trace and compare hit ratios with exact LRU from §20.9.5.

20.21 Design challenges

1. **Product catalog for a flash sale.** 5 million products, 400,000 reads/s at peak with one product drawing 30% of traffic during the sale, prices that must be correct within 2 s. Design the cache layers, TTLs, invalidation and hot-key handling, and compute database load at the expected hit ratio.
2. **Session store.** 20 million active sessions of 1 KB, 100,000 reads/s, sessions must survive a single node failure. Compare Redis with replicas against Memcached with client-side replication, including memory with slab overhead.
3. **Social feed cache.** Feeds are lists of post IDs per user, rebuilt from a fan-out service. Design the keys, eviction policy, invalidation on post deletion, and the warm-up plan for a new region.

Chapter 21 — Content Delivery Networks

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3 h

At 10 million daily users, PhotoShare serves about 28 Gbit/s of images at peak (§1.9). Chapter 1 drew the box that makes this affordable, a **CDN**, as a hexagon labeled "external". This chapter opens the hexagon. A CDN is a geographically distributed cache built from the ideas of Chapters 7 and 20: anycast and DNS steer each user to a nearby site, TLS terminates close to the user, and a hierarchy of caches keeps most requests away from your servers. You will learn how shielding turns hundreds of misses into one, how cache keys and headers decide what is shared, how to purge in a fraction of a second, how video adapts to the network, and how Netflix built a CDN inside other people's networks.

21.1 Learning objectives

After this chapter you should be able to:

- Draw a CDN (points of presence, mid-tier, origin) and trace a cache hit and a cache miss end to end.
- Compare DNS-based request routing with anycast and choose between them.
- Compute request and byte offload ratios, compose hit ratios across cache tiers, and estimate origin bandwidth and monthly egress cost.
- Explain why origin shielding reduces origin load and quantify the reduction with a Poisson model and a simulation.
- Design cache keys and `Cache-Control` policies (`max-age`, `s-maxage`, `stale-while-revalidate`, `stale-if-error`, `ETag`) under RFC 9111, and choose between URL purge, tag-based purge and versioned URLs.
- Explain dynamic site acceleration and edge-side includes, and estimate when they help.
- Size video delivery for an adaptive bitrate ladder and compare throughput-based and buffer-based bitrate adaptation.
- Describe edge compute runtimes, Netflix Open Connect and the CDN's role in security.

21.2 Prerequisites

- Anycast, BGP, DNS resolution and TTLs — §7.5–§7.6 (both request-routing methods build on them).
- TCP handshake, slow start, TLS 1.3, HTTP/2 and HTTP/3 — §7.7, §7.9, §7.10 (the latency a CDN removes is round trips).
- HTTP methods, status codes, `ETag` and conditional requests — §8.6.3–§8.6.4; cookies — §8.10.1.
- Cache hit ratio, TTL, eviction and stampedes — §20.3, §20.8, §20.9, §20.11 (a CDN is a cache; this chapter does not repeat the general theory).
- Consistent hashing — §14.8 (used inside each CDN site).
- Units: **MB/GB/TB/PB** are powers of ten; bit rates use **Mb/s** and **Gb/s** (10^6 and 10^9 bits per second). One byte is eight bits.

21.3 CDN architecture

21.3.1 What a CDN is and why it exists

> DEFINITION
>
> **Definition — Content delivery network (CDN).** A distributed system of caching reverse proxies (§7.12) deployed in many network locations, which serves content on behalf of an **origin** (the authoritative server for the content) from the location nearest each user, fetching from the origin only on a cache miss.

First-principles explanation

A bestselling author lives in one city. If every reader had to travel there to buy a book, the queue would stretch for kilometers and most readers would give up. Instead, the publisher prints copies and ships them to bookshops in every town. Readers walk to a local shop; only when a shop runs out does it order from the warehouse. A CDN is that network of bookshops: the **origin** is the author's house, the **edge** servers are the bookshops, and a **cache miss** is a shop reordering from the warehouse.

Why does this exist?

A CDN solves four problems at once:

1. **Latency.** Light in fiber covers about 200 km per millisecond, so a Sydney user talking to a server in Virginia pays roughly 200 ms per round trip, and a fresh HTTPS fetch needs several round trips (§7.15; [Grigorik 2013]). An edge 10 ms away cuts each round trip twentyfold.

2. **Origin load.** A hit is served without touching the origin, so the origin is sized for misses, not for total traffic.
3. **Egress cost and backbone capacity.** Bytes served from inside or near the user's network do not cross expensive long-haul links or the origin's metered egress.
4. **Surges and attacks.** Hundreds of sites with terabits of aggregate capacity absorb flash crowds and DDoS floods that would saturate any single data center (§10.11).

Mathematical foundations

FORMULA

Time to fetch an object over a new connection

$$T_{\text{fetch}} \approx (n_{\text{hs}} + \lceil \log_2 (\frac{S}{W_0} + 1) \rceil) \times \text{RTT} + t_{\text{server}}$$

Symbol	Meaning	Units
n_{hs}	Handshake round trips before the request (TCP + TLS 1.3 = 2; QUIC = 1; reused connection = 0)	round trips
S	Response size	bytes
W_0	Initial congestion window (typically 10 segments × 1,460 B ≈ 14.6 KB)	bytes
$\lceil \log_2 (S/W_0 + 1) \rceil$	Slow-start rounds to deliver S, the first of which carries the request (§7.7.7)	round trips
RTT	Round-trip time between client and server	s
t_{server}	Server processing time	s

WORKED EXAMPLE

Worked example — A 100 KB photo from Virginia versus a Sydney edge.

1. Slow-start rounds: $S/W_0 = 100,000/14,600 = 6.85$; $\log_2(7.85) = 2.97$, so 3 rounds (14.6 + 29.2 + 58.4 = 102.2 KB ≥ 100 KB).
2. Round trips: $n_{hs} = 2$ (TCP + TLS 1.3), so $2 + 3 = 5$.
3. From the origin (RTT 200 ms): $5 \times 200 = 1,000$ ms, plus server time.
4. From a Sydney edge (RTT 10 ms), on a cache hit: $5 \times 10 = 50$ ms.

Interpretation. The same bytes arrive 20 times sooner, and no amount of origin bandwidth could close that gap: the cost is round trips, not throughput. **Engineering implication.** For small and medium objects, moving the server closer beats every other optimization; on a cache miss the edge still saves the handshakes, as §21.7.2 shows.

21.3.2 Points of presence

DEFINITION

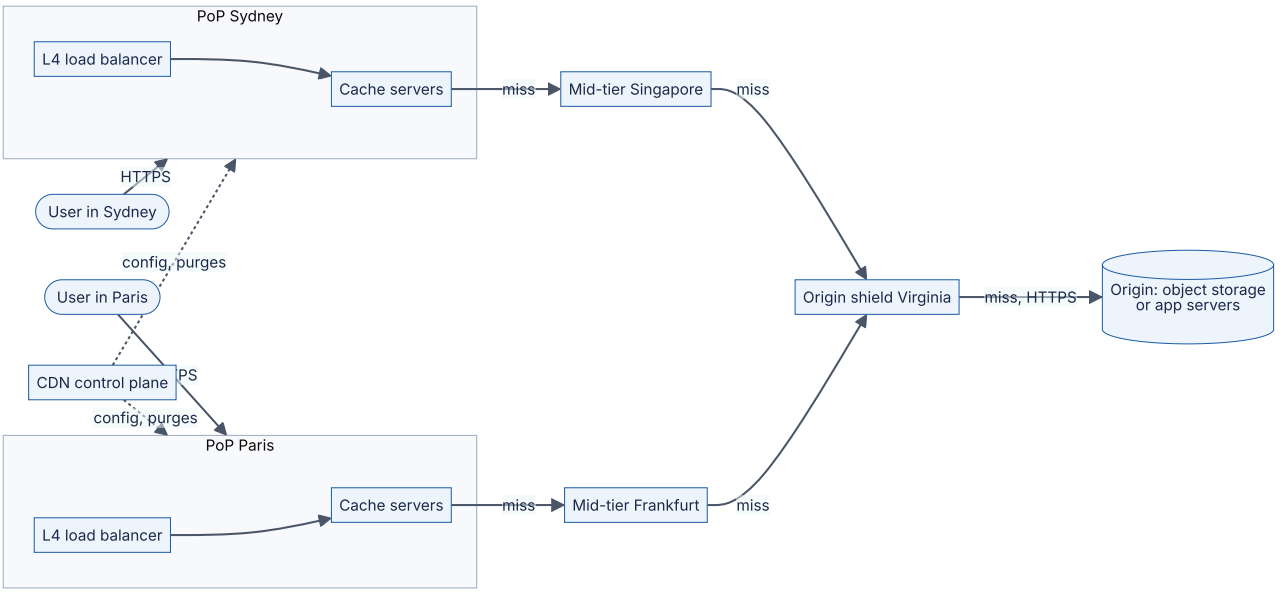
Definition — Point of presence (PoP). A CDN site in one metropolitan area or interconnection facility, containing load balancers, caching proxy servers with RAM and SSD storage, and connections to local networks. Large CDNs operate hundreds of PoPs; some also place servers inside Internet service provider (ISP) networks.

Inside a PoP, a request passes through three layers:

1. **Layer 4 load balancing.** Routers spread packets across servers with equal-cost multipath (ECMP) and a stateless L4 load balancer (§19.3, §19.8).
2. **TLS termination and HTTP processing.** A proxy (for example Varnish, NGINX, Apache Traffic Server, or a CDN's own software) decrypts the request, applies rules, and computes the cache key (§21.6.2).
3. **Cache lookup across the PoP.** Rather than store each popular object on all 100 servers, the PoP hashes the cache key to an "owner" server with consistent hashing (§14.8), so each object is stored roughly once per PoP. Consistent hashing was invented for exactly this problem [Karger et al. 1997].

The cache itself is a two-level store: hot objects in RAM and the long tail on SSD, with eviction policies of the kind described in §20.9.

Figure 21.1 — A CDN: users, PoPs, mid-tier and origin.



Reading the diagram. Users (stadiums) connect over HTTPS to the nearest PoP, where an L4 load balancer spreads connections across cache servers. A miss moves one hop inward at a time: to a regional mid-tier cache, then to an origin shield near the origin, and finally to the origin (object storage or application servers). Solid arrows are synchronous request/response paths; the dotted arrows from the control plane are asynchronous pushes of configuration and purge commands. Storage boundaries: every PoP, mid-tier and shield holds a cache (RAM and SSD); only the origin holds the authoritative copy. Failure points: a PoP outage (users are rerouted, §21.3.3), a shield outage (misses must bypass it), and the origin itself. Scaling: add servers inside a PoP, add PoPs for coverage, and add tiers to protect the origin (§21.5).

21.3.3 Request routing: DNS versus anycast

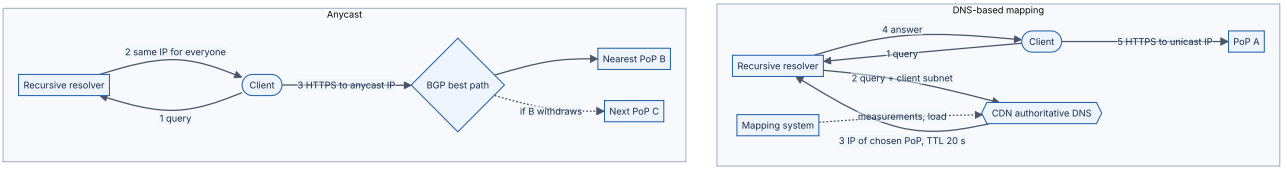
Before a user can hit a cache, something must decide *which* PoP serves them. Two mechanisms dominate, both introduced in Chapter 7.

DNS-based routing. The site's hostname is a CNAME to a CDN-controlled name (`img.photoshare.example` → `photoshare.cdn-provider.example`). The CDN's authoritative DNS answers each query with a PoP chosen by a **mapping system** from network measurements, PoP health and load, and the resolver's location. Akamai describes this design, with short TTLs so users can be re-steered quickly [Nygren et al. 2010]. The weakness from §7.6.5 applies: the DNS server sees the *resolver's* address, not the user's. The **EDNS Client Subnet** extension lets a resolver pass a truncated client prefix, such as a /24, to the authoritative server [RFC 7871]; Akamai reported substantial latency improvements for users of public resolvers after adopting it ("end-user mapping") [Chen et al. 2015].

Anycast routing. Every PoP announces the same IP prefix over BGP (§7.5.3), and routing delivers each packet to the "closest" site by BGP policy; DNS returns the same address

everywhere. Cloudflare describes serving its services from every data center over anycast [Cloudflare Docs: Network]. A PoP that withdraws its announcement disappears from routing within seconds to minutes. The weaknesses: BGP's "closest" is not always lowest latency, and load is hard to steer without changing announcements that affect many networks. A measurement study of Microsoft's anycast CDN found that anycast picked a good PoP for most clients but a noticeably worse one for a meaningful minority [Calder et al. 2015].

Figure 21.2 — Request routing with DNS mapping versus anycast.



Reading the diagram. In the DNS mode (top), steps 1–4 are synchronous DNS exchanges over UDP; the mapping system feeds the authoritative servers asynchronously (dotted). The choice is cached for the answer's TTL, so a PoP failure is corrected only as TTLs expire. In the anycast mode (bottom), BGP chooses per packet; when PoP B withdraws its route (dotted), packets flow to PoP C and in-flight TCP connections reset. No storage is involved; failure points are the resolver, the mapping system and routing instability. Scaling: add PoPs (and, for DNS, measurements).

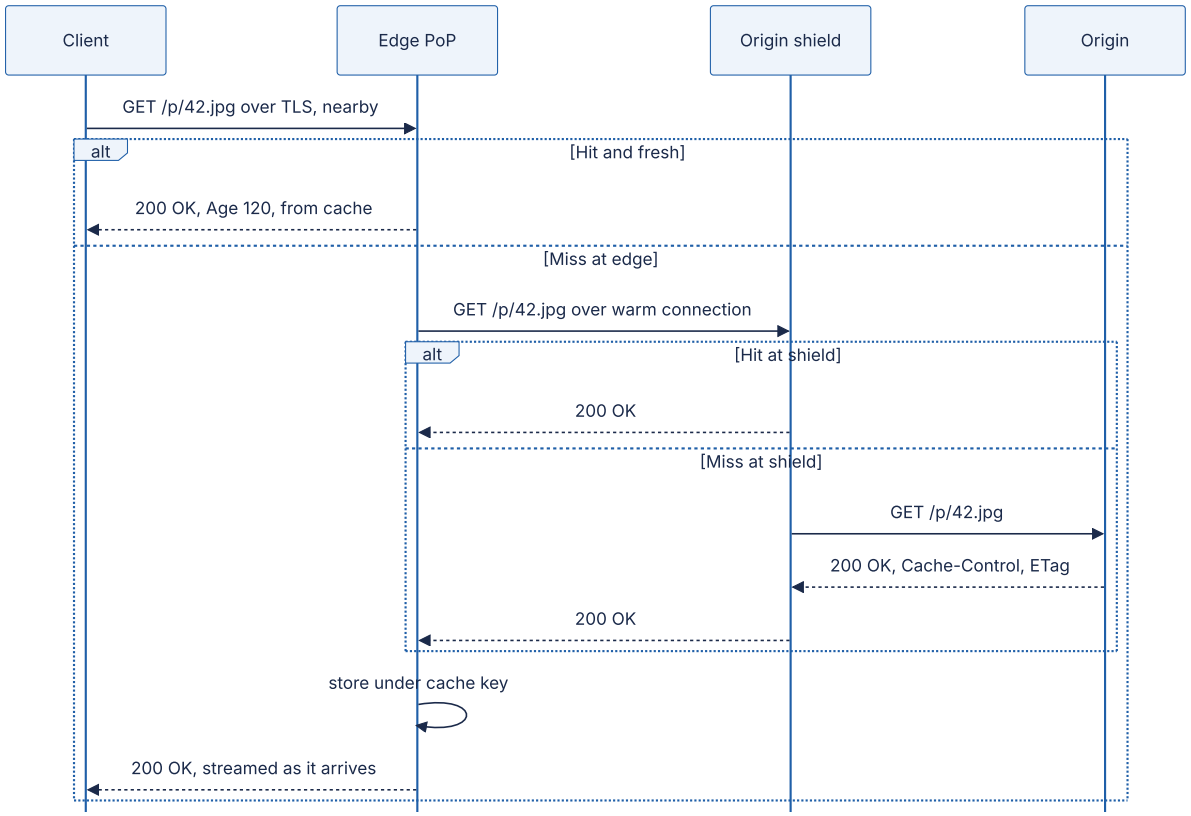
Table 21.1 — DNS-based routing versus anycast.

	DNS-based mapping	Anycast
Who chooses the PoP	CDN's mapping system, per DNS answer	BGP, per packet
Granularity	Per resolver (per client subnet with ECS)	Per network path
Load control	Fine: change answers per network	Coarse: change announcements
Failover speed	Bounded by DNS TTL and client caching	Seconds to minutes (BGP convergence)
DDoS absorption	Attack aimed at one PoP's IPs	Attack spread across all PoPs automatically
Risks	Resolver far from user; stale answers	Suboptimal paths; connection resets on route change
Choose when	You need precise steering, many small or ISP-embedded sites	You want simplicity, resilience and DDoS dispersion

Real CDNs combine the two, for example anycast for DNS servers and DNS steering for some customers. Global traffic management across your own regions uses the same tools (§19.9, Chapter 44).

21.3.4 Anatomy of a cache hit and a cache miss

Figure 21.3 — A cache hit and a cache miss at an edge PoP.



Reading the diagram. Time runs downward. TLS ends at the nearby edge. On a fresh hit the edge answers at once, adding an `Age` header (seconds spent in cache). On a miss it forwards over a long-lived connection to the shield; only a shield miss reaches the origin. All exchanges are synchronous, and responses are **streamed**: the edge forwards bytes while still receiving them. Storage boundaries: edge and shield caches, and the origin. Failure points: a slow or down shield or origin (the edge may serve stale, §21.6.1). Scaling: more tiers or bigger caches raise the hit ratio.

Three details matter in production:

- **Request collapsing.** If 500 users request the same uncached object within 50 ms, a naive edge sends 500 origin requests. CDNs **collapse** concurrent misses for one cache key into one upstream fetch, the stampede defense of §20.11 applied at the edge.
- **Negative caching.** Error responses such as `404` can be cached briefly, so a burst of requests for a missing object does not become a burst at the origin.
- **Range requests.** For large files the edge caches fixed-size chunks (say 1–2 MB), so a seek into a video need not fetch the first gigabyte.

Table 21.2 — CDN architecture failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
PoP outage	Power, fiber or software failure	Synthetic probes per PoP; traffic drop	Withdraw anycast route or remove from DNS answers	Capacity headroom in neighboring PoPs
Users mapped far away	Resolver location, BGP policy	Real-user latency by network	Adjust mapping or announcements	ECS; per-network latency monitoring
Origin overwhelmed after a purge	Every PoP misses at once	Origin RPS spike; edge 5xx	Serve stale; rate-limit fetches	Shielding, request collapsing, soft purge
Bad configuration pushed globally	One change reaches all PoPs	Error-rate jump everywhere	Roll back config	Staged rollout to canary PoPs

21.4 Edge, mid-tier and origin

21.4.1 Three tiers

DEFINITION

Definition — Cache tiers. The **edge** tier is the set of PoPs that accept user connections. A **mid-tier** (also *parent, regional* or *upper-tier* cache) is a smaller set of larger caches that edges consult on a miss. An **origin shield** is a mid-tier designated as the single path to a given origin. The **origin** is the customer's own infrastructure that holds the authoritative content.

First-principles explanation

Return to the bookshops. A town shop stocks the 2,000 titles its customers buy most; for an obscure title it phones the regional warehouse, which stocks 200,000, and only the warehouse contacts the publisher. Each tier holds more items, serves larger areas, and sees only what the tier below could not answer.

Why does this exist?

Edges must be numerous and close to users, so each one is small relative to the catalog and sees only a slice of the audience. For long-tail content (most images, most video titles, most software versions) each edge misses often. A mid-tier aggregates the misses of many edges, so an object requested once in each of 50 cities becomes popular *at the mid-tier* and is fetched from the origin once.

Table 21.3 — Roles of the cache tiers.

	Edge PoP	Mid-tier / shield	Origin
Location	Near users, often in ISPs or exchange points	Few, well-connected regions; shield near the origin	Your region(s) or cloud
Count	Tens to thousands	A handful to tens	One to a few
Cache size per site	Small relative to catalog	Large	Holds everything (authoritative)
Sees	All user requests	Edge misses	Shield misses
Main job	Latency, TLS termination, absorbing traffic	Aggregating misses, protecting origin	Correctness and freshness

The origin can be **object storage** (static assets, images, video files; §15.4), an **application tier** behind a load balancer (HTML, APIs), or a **media packager** (live video). Whatever it is, the origin should accept traffic only from the CDN: allow-list the CDN's address ranges or require a shared secret header or mutual TLS on origin pulls (§21.11), otherwise attackers bypass the cache and hit the origin directly.

INDUSTRY EXAMPLE

Akamai, Amazon CloudFront and Cloudflare tiering. Akamai's 2010 description of its platform includes **tiered distribution**: edge clusters fetch from a smaller set of well-provisioned "parent" clusters rather than from the origin, which Akamai reports substantially reduces origin load, especially for less popular content [Nygren et al. 2010]. CloudFront documents **regional edge caches** between its edge locations and the origin, and an optional **Origin Shield** layer through which all requests for an origin pass [AWS Docs: CloudFront Origin Shield]. Cloudflare documents **Tiered Cache**, in which lower-tier data centers fetch from upper-tier data centers instead of the origin [Cloudflare Docs: Tiered Cache]. *Evidence: Primary* — [Nygren et al. 2010]; [AWS Docs: CloudFront Origin Shield]; [Cloudflare Docs: Tiered Cache]

21.5 Cache hierarchy and origin shielding

21.5.1 Offload ratio

DEFINITION

Definition — Offload ratio. The fraction of traffic a CDN serves without contacting the origin. **Request offload** counts requests; **byte offload** counts bytes. Both are a cache hit ratio (§20.3) measured at the boundary between the CDN and the origin.

FORMULA

Request and byte offload

$$O_R = 1 - \frac{N_{\text{origin}}}{N_{\text{total}}} \qquad O_B = 1 - \frac{V_{\text{origin}}}{V_{\text{total}}}$$

Symbol	Meaning	Units
O_R, O_B	Request offload, byte offload	dimensionless (0–1)
N_{origin}	Requests the CDN sent to the origin	requests
N_{total}	Requests users sent to the CDN	requests
V_{origin}	Bytes the origin sent to the CDN	bytes
V_{total}	Bytes the CDN sent to users	bytes

WORKED EXAMPLE

Worked example — Two offloads for the same day. A CDN receives $N_{\text{total}} = 10^9$ requests carrying $V_{\text{total}} = 500$ TB, and sends $N_{\text{origin}} = 4 \times 10^7$ requests to the origin, which return $V_{\text{origin}} = 40$ TB.

1. $O_R = 1 - 4 \times 10^7 / 10^9 = 1 - 0.04 = 0.96$.
2. $O_B = 1 - 40/500 = 1 - 0.08 = 0.92$.

Interpretation. Misses are disproportionately large objects (long-tail videos, rarely downloaded installers), so byte offload is lower than request offload here; with other mixes it can be higher. **Engineering implication.** Origin CPU and request rate follow O_R; origin egress cost and bandwidth follow O_B. Track both, and do not quote one when the decision depends on the other.

21.5.2 Composing tiers

A request reaches the origin only if it misses at *every* tier, so the miss ratios multiply.

FORMULA

Origin fraction and origin bandwidth across tiers

$$f_{\text{origin}} = \prod_{i=1}^{k} (1 - h_i) \qquad B_{\text{origin}} = B_{\text{users}} \times (1 - O_B)$$

Symbol	Meaning	Units
h_i	Hit ratio of tier i, measured on the requests that *reach* that tier	dimensionless
k	Number of cache tiers (browser, edge, mid-tier, ...)	count
f_{origin}	Fraction of all requests that reach the origin, $1 - O_R$	dimensionless
B_{users}	Bandwidth delivered to users	Gb/s
B_{origin}	Bandwidth the origin must serve	Gb/s

WORKED EXAMPLE

Worked example — Facebook's photo-serving stack. A study of Facebook photo traffic found that browser caches served 65.5% of requests, edge caches 20.0%, the origin cache (a shield-like tier in Facebook's data centers) 4.6%, and the Haystack storage backend the remaining 9.9% [Huang et al. 2013].

1. Browser: $h_1 = 0.655$; 34.5% of requests continue.
2. Edge: $h_2 = 20.0/34.5 = 0.580$; 14.5% continue.
3. Origin cache: $h_3 = 4.6/14.5 = 0.317$.
4. Check: $(1 - 0.655)(1 - 0.580)(1 - 0.317) = 0.345 \times 0.420 \times 0.683 = 0.099$, the 9.9% that reached storage.

Now apply the bandwidth form to PhotoShare's 28 Gb/s peak: at $O_B = 0.90$, $B_{\text{origin}} = 28 \times 0.10 = 2.8$ Gb/s; at $O_B = 0.98$, only 0.56 Gb/s.

Interpretation. No single tier is spectacular (the edge hit ratio is 58%, the origin cache's 32%), yet together they keep 90% of requests away from storage. A tier with a modest hit ratio still pays off when the tier behind it is expensive. **Engineering implication.** Measure each tier's hit ratio on *its own* input, and remember that raising offload from 90% to 98% cuts origin load fivefold.

21.5.3 Origin shielding

DEFINITION

Definition — Origin shielding. Routing every cache miss for an origin through one designated cache tier (the **shield**), so that the origin sees at most one request per object per freshness period, regardless of how many edge PoPs missed.

Why does this exist?

Without a shield, each PoP is an independent client of your origin. An object that is cold everywhere is fetched once *per PoP*, and when a TTL expires, every PoP that holds it revalidates separately. With 300 PoPs, a purge of a popular object turns into up to 300 near-simultaneous origin requests, the CDN-scale version of a cache stampede (§20.11).

FORMULA

Origin fetches per object per TTL window, without and with a shield

$$F_{\text{no shield}} \approx N(1 - e^{-\lambda T/N}) \qquad F_{\text{shield}} \approx 1$$

Symbol	Meaning	Units
N	Number of edge PoPs, with requests spread evenly among them	count
λ	Global request rate for the object	requests/s
T	Freshness lifetime (TTL) of the object	s
$1 - e^{-\lambda T/N}$	Probability that a given PoP sees at least one request in T (Poisson arrivals)	dimensionless
F	Expected origin fetches for the object per window T	fetches

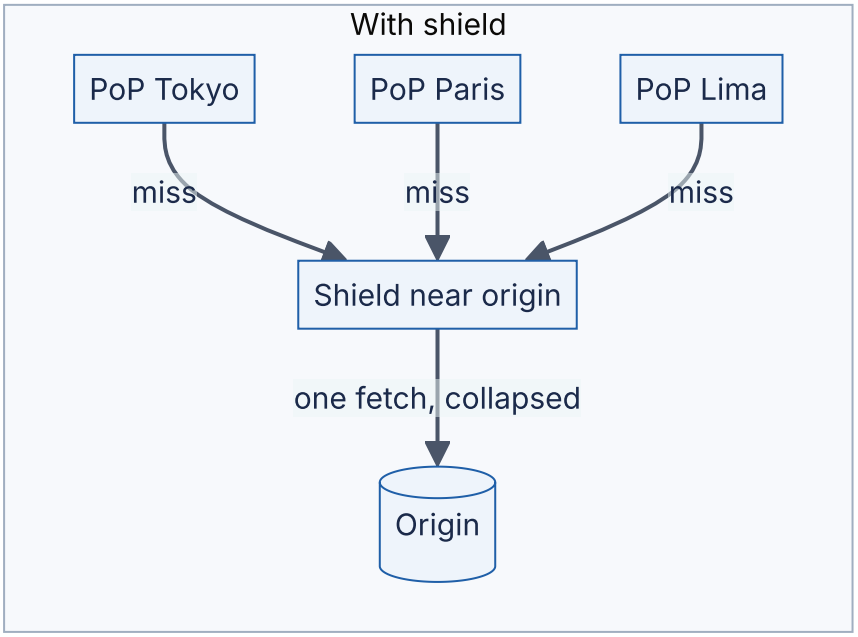
WORKED EXAMPLE

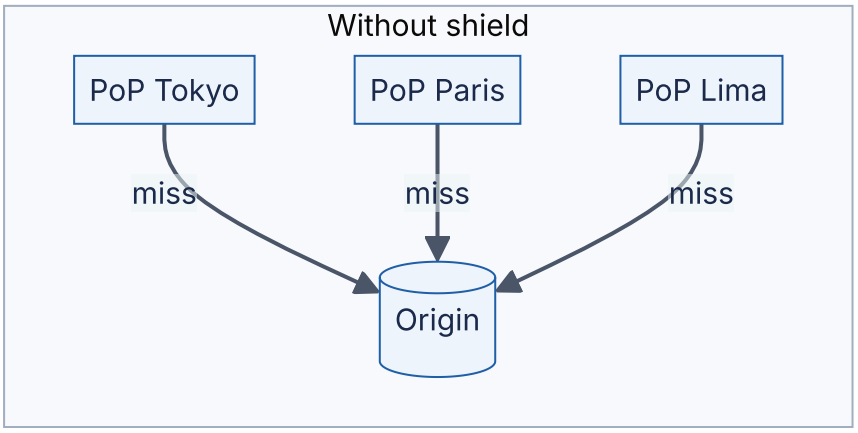
Worked example — A long-tail photo and a popular photo across 100 PoPs, TTL 1 hour.

1. Long-tail photo, $\lambda = 0.01$ req/s: $\lambda T = 36$ requests per hour; $\lambda T/N = 0.36$; $e^{-0.36} = 0.698$.
2. $F_{\text{no shield}} = 100 \times (1 - 0.698) = 30.2$ origin fetches per hour, out of 36 requests: the edges' hit ratio for this object is $1 - 30.2/36 = 16\%$.
3. Popular photo, $\lambda = 1$ req/s: $\lambda T/N = 36$, so $e^{-36} \approx 0$ and $F_{\text{no shield}} \approx 100$ fetches per hour out of 3,600 requests (97.2% edge hit ratio).
4. With a shield that retains both objects, $F_{\text{shield}} = 1$ per hour in each case.

Interpretation. The shield cuts origin fetches 30-fold for the long-tail photo and 100-fold for the popular one. **Engineering implication.** Shielding matters most when there are many PoPs, a long tail of content, short TTLs, or frequent purges; it matters little for a tiny catalog of very hot objects.

Figure 21.4 — Origin traffic without and with a shield.





Reading the diagram. On the left, three PoPs (rectangles) each send their miss for the same object straight to the origin (cylinder), so the origin serves it three times, or 300 times with 300 PoPs. On the right, every miss goes to a shield located close to the origin; the shield collapses concurrent requests and fetches once. All arrows are synchronous HTTPS. Storage boundaries: every PoP and the shield are caches; the origin is authoritative. Failure points: the shield is a concentration point, so it is itself a cluster of servers, and edges must be able to bypass it (or use a backup shield) if it fails. Scaling: shield capacity scales by consistent hashing objects across shield servers; a second shield region adds redundancy.

21.5.4 Origin egress and cost

FORMULA

Monthly delivery cost

$$C = V \times p_{\text{cdn}} + V \times (1 - O_B) \times p_{\text{origin}}$$

Symbol	Meaning	Units
V	Bytes delivered to users per month	GB
p_{cdn}	CDN delivery price	$/GB
p_{origin}	Origin egress price (cloud Internet egress)	$/GB
O_B	Byte offload	dimensionless
C	Monthly delivery cost (excluding request fees and commitments)	$

WORKED EXAMPLE

Worked example — PhotoShare's image bill, with and without a shield. Prices are **illustrative, as of 2026**: cloud Internet egress list prices at petabyte-scale tiers are on the order of $0.05/GB, and large customers negotiate CDN delivery far below list prices; assume $p_{\text{cdn}} = \$0.01$/GB and $p_{\text{origin}} = \$0.05$/GB.

1. Volume: 9.3 Gb/s average (§1.9) $= 1.16$ GB/s; $\times\ 2,592,000$ s per 30-day month $= 3.01 \times 10^6$ GB, about 3 PB.
2. CDN delivery: $3.0 \times 10^6 \times 0.01 = \$30,000$.
3. Origin egress without shield ($O_B = 0.90$): 3.0×10^5 GB $\times\ 0.05 = \$15,000$.
4. Origin egress with shield ($O_B = 0.98$): 6.0×10^4 GB $\times\ 0.05 = \$3,000$.
5. Without any CDN, the origin would serve everything: $3.0 \times 10^6 \times 0.05 = \$150,000$, and would need about 28 Gb/s of peak serving capacity.

Interpretation. The shield saves $12,000 per month ($144,000 per year) on egress and cuts peak origin bandwidth from 2.8 to 0.56 Gb/s. **Engineering implication.** Check whether your cloud waives origin-to-CDN egress for its own CDN (several do), include shield request fees, and remember that offload also shrinks the origin fleet, which is often the larger saving.

21.5.5 Simulating shielding

The model above assumes caches never evict. The program below drops that assumption: 20 edge PoPs, each a byte-capacity LRU cache holding 3% of a 50,000-object catalog, receive one million Zipf-distributed requests (exponent 1.0, the skew typical of web content), with and without a shield.

```
        # Two-tier CDN simulation: how much traffic reaches the origin with and
        # without an origin shield. Edge PoPs and the shield are byte-capacity LRU
caches;
        # object popularity follows a Zipf distribution.
        import random
        from collections import OrderedDict

        class LRUCache:
            """Least-recently-used cache whose capacity is measured in bytes."""

            def __init__(self, capacity_bytes):
                self.capacity = capacity_bytes
                self.used = 0
                self.items = OrderedDict()          # key -> size, oldest first

            def get(self, key):
                if key in self.items:
                    self.items.move_to_end(key)     # mark as most recently used
                    return True
                return False

            def put(self, key, size):
                if size > self.capacity:
                    return                          # too big to cache at all
                if key in self.items:
                    self.used -= self.items.pop(key)
                while self.used + size > self.capacity:
                    _, old_size = self.items.popitem(last=False)   # evict LRU
                    self.used -= old_size
                self.items[key] = size
                self.used += size

        def make_workload(n_objects, n_requests, n_pops, alpha, seed):
            """Return object sizes and a trace of (pop, object) requests."""
            rng = random.Random(seed)
            sizes = [rng.choice([20_000, 50_000, 200_000, 1_000_000]) for _ in
range(n_objects)]
            cum, total = [], 0.0
            for rank in range(1, n_objects + 1):    # Zipf: weight of rank k is
1/k^alpha
                total += 1.0 / rank ** alpha
                cum.append(total)
            objs = rng.choices(range(n_objects), cum_weights=cum, k=n_requests)
            pops = [rng.randrange(n_pops) for _ in range(n_requests)]
            return sizes, list(zip(pops, objs))

        def simulate(sizes, trace, n_pops, edge_bytes, shield_bytes=None):
            """Replay the trace. shield_bytes=None means edges go straight to origin."""
            edges = [LRUCache(edge_bytes) for _ in range(n_pops)]
            shield = LRUCache(shield_bytes) if shield_bytes else None
            s = dict(requests=0, edge_hits=0, shield_hits=0, origin_fetches=0,
                     bytes_served=0, origin_bytes=0)
            for pop, obj in trace:
```

```
                size = sizes[obj]
                s["requests"] += 1
                s["bytes_served"] += size
                if edges[pop].get(obj):
                    s["edge_hits"] += 1
                    continue
                if shield is not None and shield.get(obj):
                    s["shield_hits"] += 1
                else:                                  # fetch from origin
                    s["origin_fetches"] += 1
                    s["origin_bytes"] += size
                    if shield is not None:
                        shield.put(obj, size)
                edges[pop].put(obj, size)
            s["request_offload"] = 1 - s["origin_fetches"] / s["requests"]
            s["byte_offload"] = 1 - s["origin_bytes"] / s["bytes_served"]
            return s

        if __name__ == "__main__":
            N_OBJ, N_REQ, N_POPS = 50_000, 1_000_000, 20
            sizes, trace = make_workload(N_OBJ, N_REQ, N_POPS, alpha=1.0, seed=21)
            catalog = sum(sizes)
            edge = int(0.03 * catalog)                 # each PoP holds 3% of the catalog
            print(f"catalog {catalog / 1e9:.1f} GB, {N_POPS} PoPs x {edge / 1e9:.2f} GB
each")
            for label, shield in [("no shield", None),
                                  ("shield 10% of catalog", int(0.10 * catalog)),
                                  ("shield 30% of catalog", int(0.30 * catalog))]:
                r = simulate(sizes, trace, N_POPS, edge, shield)
                print(f"{label:<22} edge hit {r['edge_hits'] / r['requests']:6.1%}  "
                      f"origin fetches {r['origin_fetches']:>7,}  "
                      f"request offload {r['request_offload']:6.1%}  "
                      f"byte offload {r['byte_offload']:6.1%}  "
                      f"origin egress {r['origin_bytes'] / 1e9:5.1f} GB")
```

Output (Python 3.13, about 3 s):

```
catalog 15.8 GB, 20 PoPs x 0.47 GB each
no shield              edge hit  58.3%  origin fetches 417,280  request offload  58.3%
byte offload  62.4%  origin egress 132.4 GB
shield 10% of catalog  edge hit  58.3%  origin fetches 278,623  request offload  72.1%
byte offload  74.9%  origin egress  88.2 GB
shield 30% of catalog  edge hit  58.3%  origin fetches 156,952  request offload  84.3%
byte offload  85.9%  origin egress  49.5 GB
```

What to notice:

- The edge hit ratio is identical in all three runs: the shield does not change what edges see, only where their misses go.
- A shield holding 30% of the catalog absorbs $1 - 156,952/417,280 = 62\%$ of edge misses and cuts origin egress from 132.4 GB to 49.5 GB. It aggregates 20 PoPs' long tails, so objects that are rare at each PoP are popular at the shield.

- `put` is byte-based, so one 1 MB object evicts fifty 20 KB ones; size-aware policies (§20.9) can do better.
- Tests in `code/ch21/test_listing_01.py` check LRU eviction, that shield hits plus origin fetches equal edge misses, that a shield never increases origin fetches, and that with unlimited caches the origin sees one fetch per object with a shield but one per (PoP, object) pair without.

Advantages, disadvantages and failure scenarios

A shield adds a hop (cheap if it sits near the origin) and concentrates traffic, so it must be redundant. Place it closest to the origin, not to users, with one shield per origin region.

> COMMON MISTAKE
>
> **"Our CDN hit ratio is 95%, so the origin is safe."** A dashboard hit ratio usually counts edge hits only, often by request. The origin cares about requests and bytes that cross the CDN–origin boundary, including revalidations and purge-driven refetches. Measure offload at the origin's own access logs.

21.6 Cache keys, HTTP caching headers and invalidation

21.6.1 Freshness and validation under RFC 9111

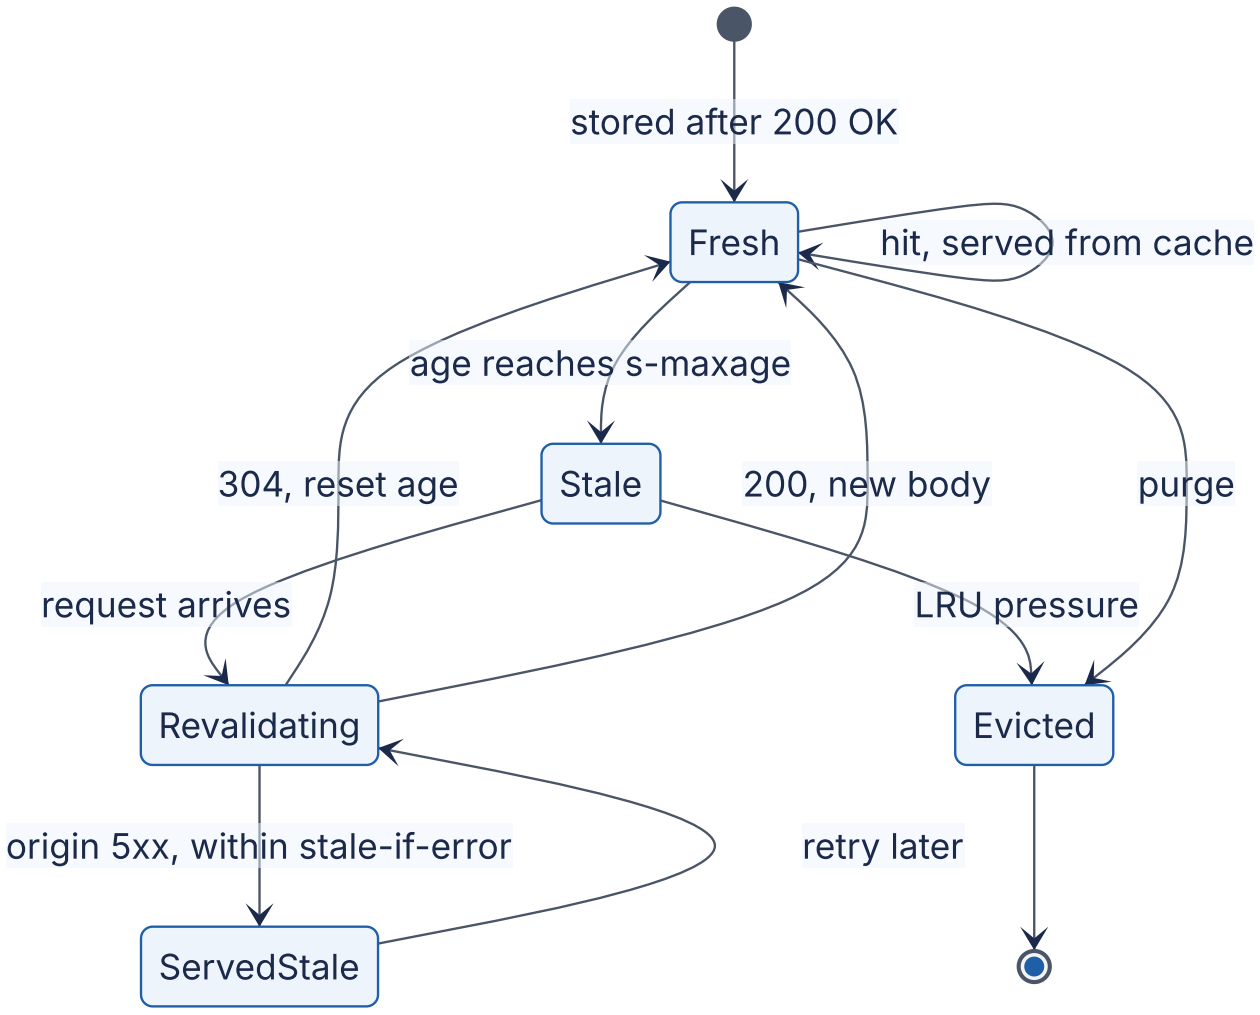
A CDN is a **shared cache** in the vocabulary of RFC 9111, which defines HTTP caching: it stores responses and reuses them for many users. The origin controls that reuse with response headers.

> DEFINITION
>
> **Definition — Freshness and validation.** A stored response is **fresh** while its age is below its **freshness lifetime** and may then be served without contacting the origin; once **stale**, it must normally be **revalidated**, by sending a conditional request (`If-None-Match` with the stored `ETag` , or `If-Modified-Since`), to which the origin answers `304 Not Modified` (keep using the copy) or `200 OK` with a new body [RFC 9111; RFC 9110].

Table 21.4 — Caching directives a CDN designer uses.

Header or directive	Meaning	Typical use
`max-age=N`	Fresh for N seconds in any cache	Browser and CDN lifetime
`s-maxage=N`	Overrides `max-age` in shared caches only	CDN longer than browsers
`no-cache`	May store, but must revalidate before every use	HTML that must be current
`no-store`	Must not store at all	Sensitive responses
`private`	Only the user's own browser may store it	Personalized pages
`immutable`	Will never change during freshness; skip reload revalidation [RFC 8246]	Versioned assets
`stale-while-revalidate=N`	Serve stale for up to N s while refreshing in background [RFC 5861]	Hide origin latency
`stale-if-error=N`	Serve stale for up to N s if the origin errors [RFC 5861]	Survive origin outages
`ETag` / `If-None-Match`	Validator and conditional request; `304` if unchanged	Cheap revalidation
`Age`	Seconds the response has spent in caches	Lets browsers subtract CDN time
`CDN-Cache-Control`	Same directives, aimed only at CDNs [RFC 9213]	Separate CDN and browser policy

Figure 21.5 — Life of a cached response at the edge.



Reading the diagram. States describe one stored response at one edge. A **Fresh** response is served directly until its age reaches the shared-cache lifetime. A request for a **Stale** response triggers revalidation, synchronously by default or in the background within the `stale-while-revalidate` window (the user gets the stale copy at once). A `304` or new `200` makes it fresh; an origin error within the `stale-if-error` window means stale content is served instead of an error. Purges and eviction remove it. The storage boundary is the edge cache; the failure point is the origin during revalidation; every PoP runs this machine independently, which is why shields matter (§21.5.3).

FORMULA

Freshness test in a shared cache

$$\text{fresh} \iff a < L, \qquad L = \begin{cases} \texttt{s-maxage} & \text{if present} \\ \texttt{max-age} & \text{otherwise} \end{cases}$$

Symbol	Meaning	Units
a	Current age of the stored response, including time spent in upstream caches (`Age`)	s
L	Freshness lifetime for a shared cache (RFC 9111 §4.2.1; `Expires` or heuristics apply if neither directive is present)	s

WORKED EXAMPLE

Worked example — One header, three behaviors. The origin sends `Cache-Control: max-age=60, s-maxage=600, stale-while-revalidate=30, stale-if-error=86400` with `ETag: "v7"` .

1. **Edge:** fresh for 600 s. Between ages 600 and 630 s it serves the stale copy and revalidates in the background. A `304` costs a few hundred bytes instead of resending, say, a 2 MB body.
2. **Browser:** uses `max-age=60` , but the edge forwards `Age` . A copy fetched from the edge at age 50 s is fresh in the browser for only $60 - 50 = 10$ s.
3. **Origin outage:** for up to 86,400 s after a copy goes stale, the edge may serve it instead of a `5xx` .

Interpretation. The CDN holds content ten times longer than browsers, because the CDN can be purged and browsers cannot. **Engineering implication.** Give browsers short lifetimes for anything that might need recall, give the CDN long lifetimes plus a purge path, and always add `stale-if-error` : it turns many origin outages into non-events.

21.6.2 Cache keys

DEFINITION

Definition — Cache key. The value a cache uses to decide whether two requests may receive the same stored response. By default it is the method plus the full URL (scheme, host, path and query string), extended by any request headers listed in the response's `Vary` header.

Two requests that should get the same bytes but differ in their key produce two cache entries and two origin fetches: the hit ratio **fragments**. Two requests that should get *different* bytes but share a key leak one user's response to another. Cache-key design steers between these.

- **Normalize.** Lowercase the host, sort query parameters, drop parameters that do not change the response (tracking tags such as `utm_source`, session IDs). An allow-list of meaningful parameters is safer than a deny-list.
- **Tame `Vary`.** `Vary: Accept-Encoding` is necessary for compressed text, but browsers send dozens of distinct `Accept-Encoding` strings; normalize them to a few values (`br`, `gzip`, `identity`). `Vary: User-Agent` creates thousands of variants and effectively disables caching; derive a small device class at the edge instead.
- **Strip cookies.** Cookies are usually ignored or excluded from the key for static assets; a response that depends on a cookie must be `private` or keyed on a small derived value (for example a language), never on the raw cookie.

```
        # Cache-key normalization: map many equivalent requests to one cache key.
        from urllib.parse import parse_qsl, urlencode, urlsplit

        KEEP_PARAMS = {"v", "lang"}   # allow-list: only params that change the bytes

        def cache_key(url, accept_encoding=""):
            parts = urlsplit(url)
            host = parts.hostname.lower()             # hostnames are case-insensitive
            path = parts.path or "/"                  # paths are case-sensitive: keep
            params = sorted((k.lower(), v) for k, v in parse_qsl(parts.query)
                            if k.lower() in KEEP_PARAMS)
            # Collapse Accept-Encoding to the few variants the edge actually stores.
            enc = accept_encoding.lower()
            enc = "br" if "br" in enc else "gzip" if "gzip" in enc else "identity"
            query = urlencode(params)
            return f"{host}{path}" + (f"?{query}" if query else "") + f"|{enc}"

        if __name__ == "__main__":
            requests = [
                ("https://CDN.example.com/js/app.js?v=7&lang=en", "gzip, deflate, br"),
                ("https://cdn.example.com/js/app.js?lang=en&v=7&utm_source=mail",
"br;q=1.0, gzip;q=0.8"),
                ("https://cdn.example.com/js/app.js?LANG=en&v=7&sessionid=abc123",
"br"),
                ("https://cdn.example.com/js/app.js?v=7&lang=en", "gzip, deflate"),
                ("https://cdn.example.com/js/app.js?v=7&lang=en", ""),
            ]
            keys = [cache_key(u, ae) for u, ae in requests]
            for k in keys:
                print(k)
            print("distinct keys:", len(set(keys)), "of", len(keys), "requests")
```

Output:

```
cdn.example.com/js/app.js?lang=en&v=7|br
cdn.example.com/js/app.js?lang=en&v=7|br
cdn.example.com/js/app.js?lang=en&v=7|br
cdn.example.com/js/app.js?lang=en&v=7|gzip
cdn.example.com/js/app.js?lang=en&v=7|identity
distinct keys: 3 of 5 requests
```

What to notice: five raw requests collapse to three keys, one per encoding the edge must store; parameter order, host case, tracking tags and session IDs no longer fragment the cache; the path keeps its case because URL paths are case-sensitive.

WARNING / TRADE-OFF

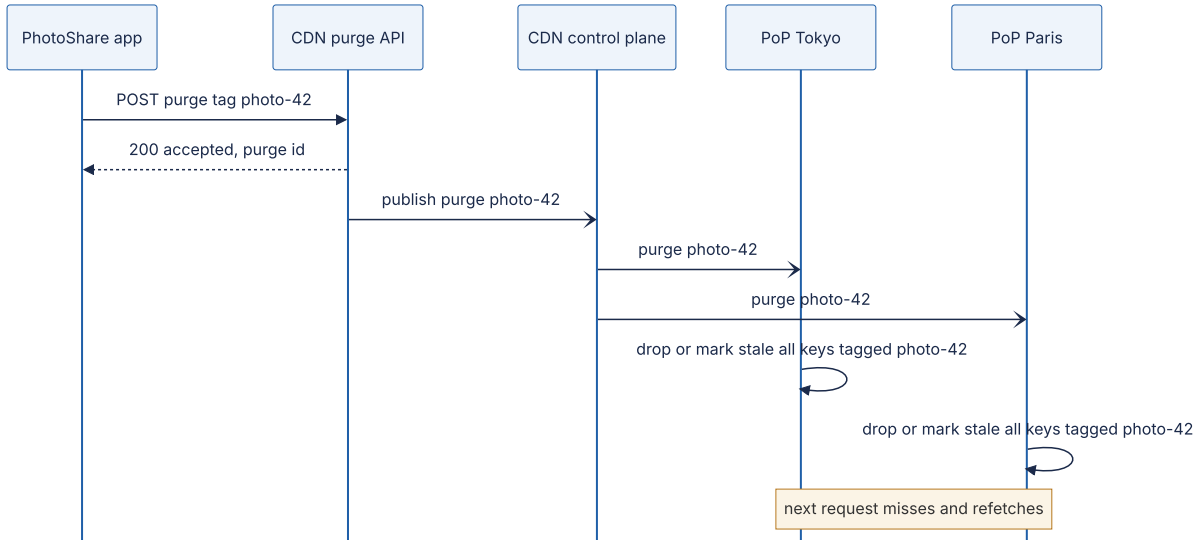
Unkeyed inputs are a security boundary. In **web cache poisoning**, an attacker sends a request whose *unkeyed* header (for example `X-Forwarded-Host`) changes the response, so the poisoned response is stored under a normal key and served to everyone [Kettle 2018]. In **web cache deception**, an attacker lures a victim to `/account/profile.css`; a lenient origin returns the private profile page, and a CDN that caches by extension stores it publicly [Gil 2017]. Defenses: key on every input that affects the response, cache by explicit `Cache-Control` rather than by file extension, and mark personalized responses `private`.

21.6.3 Invalidation and purge

Expiry is passive. When content must change *now* (a corrected price, a deleted photo, a legal takedown), you need active invalidation (§20.10). CDNs offer three tools.

1. **Purge by URL.** An API call removes one cache key from every PoP. Simple, but you must know every URL and variant affected.
2. **Purge by surrogate key (tag).** The origin labels responses with tags, for example `Surrogate-Key: user-881 photo-42` on Fastly or `Cache-Tag` on Cloudflare; one API call then invalidates every response carrying a tag, across all variants and pages [Fastly Docs: Purging; Cloudflare Docs: Purge by tag]. A **soft purge** marks matching objects stale instead of deleting them, so `stale-while-revalidate` and `stale-if-error` still protect the origin.
3. **Versioned URLs.** Put a content hash or version in the URL (`app.3f9a1c.js`), cache it for a year with `immutable`, and "invalidate" by publishing new HTML that references a new URL. Nothing is purged; the old object simply stops being requested.

Figure 21.6 — Tag-based purge propagation.



Reading the diagram. The application calls the purge API synchronously; propagation to PoPs is asynchronous (open arrowheads), fanned out by the control plane. Each PoP keeps an index from tag to cache keys and applies the purge locally. Storage boundaries are the per-PoP caches. Failure points: a PoP partitioned from the control plane keeps serving old content until it reconnects or the TTL expires, so purge is fast in practice but not linearizable; mass refetching can stampede the origin unless a shield or soft purge is used. Scaling: purge is a broadcast whose cost grows with PoP count, not traffic.

INDUSTRY EXAMPLE

Fastly Instant Purge. Fastly built its CDN around fast invalidation of surrogate keys, broadcast to all PoPs. A Fastly developer advocate has written that a surrogate-key purge starts taking effect within a few milliseconds and completes at every PoP worldwide in around 150 ms, while “purge all” uses a different, slower mechanism [Betts, Fastly Blog]. Fast purge lets customers cache content once considered dynamic, such as news articles and API responses, with long TTLs and purge on change. *Evidence: Primary* — [Betts, Fastly Blog]; [Fastly Docs: Purging]

Table 21.5 — Invalidation methods compared.

	URL purge	Tag purge	Versioned URL
How it works	Delete one key everywhere	Delete all keys with a tag	New URL; old one ages out
Advantages	Simple, universal	One call covers many pages	No purge needed; perfect browser caching
Disadvantages	Must enumerate variants	Tagging discipline; vendor-specific	Needs a reference that changes (HTML, manifest)
Origin impact	Refetch of that key	Refetch of every tagged key	None until new URL is requested
Choose when	Rare, specific fixes	Content shown on many pages (a photo in feeds)	Static assets (JS, CSS, images by hash)

RECOMMENDATION

A default policy. Version every static asset and cache it for a year with `immutable`. Serve HTML and API responses with a short browser lifetime, a longer `s-maxage`, `stale-while-revalidate` and `stale-if-error`, and tag them by the entities they display so a write can purge exactly what changed. For PhotoShare, a deleted photo is purged by tag `photo-42`, removing it from every feed page that embedded it.

21.7 Static versus dynamic content

21.7.1 What can be cached

Table 21.6 — Content classes and CDN treatment.

Class	Examples	Cacheable?	CDN treatment
Static, versioned	JS, CSS, fonts, images by hash	Yes, for a year	`immutable`, versioned URLs
Static, mutable	Photos, product images, video segments	Yes, hours to days	Long `s-maxage` plus tag purge
Shared dynamic	Home page, article, public API list	Yes, seconds to minutes	**Micro-caching** (1–10 s), `stale-while-revalidate`, request collapsing
Personalized	Feed, cart, account page	Mostly no	Cache fragments (ESI), or accelerate only
Writes	`POST` upload, checkout	No	Dynamic acceleration, WAF, rate limits

Micro-caching is underrated: a shared page requested 2,000 times per second and cached for just 1 s sends at most one request per second per cache to the origin, a 99.95% offload at a cost of one second of staleness.

21.7.2 Dynamic site acceleration

DEFINITION

Definition — Dynamic site acceleration (DSA). Routing uncacheable requests through the CDN anyway, so that TCP and TLS terminate near the user and the edge forwards each request to the origin over pre-established, tuned, long-lived connections, sometimes along an overlay path chosen from measurements.

The insight is that most of a dynamic request’s latency is handshakes and slow start on a long path, not origin processing. Akamai’s platform paper describes this suite: persistent connections between edge and origin, transport tuning, and overlay routing that picks a faster path through Akamai’s own servers than BGP’s default [Nygren et al. 2010].

FORMULA

Time to first byte, direct versus through an edge

$$T_{\text{direct}} = (n_{\text{hs}} + 1)\,\text{RTT}_{uo} + t_{\text{app}} \qquad T_{\text{edge}} = (n_{\text{hs}} + 1)\,\text{RTT}_{ue} + \text{RTT}_{eo} + t_{\text{app}}$$

Symbol	Meaning	Units
n_{hs}	Client handshake round trips (2 for TCP + TLS 1.3, 0 if reused)	round trips
RTT_{uo}	Round trip, user to origin	ms
RTT_{ue}	Round trip, user to edge	ms
RTT_{eo}	Round trip, edge to origin over a warm, already-open connection	ms
t_{app}	Origin processing time	ms

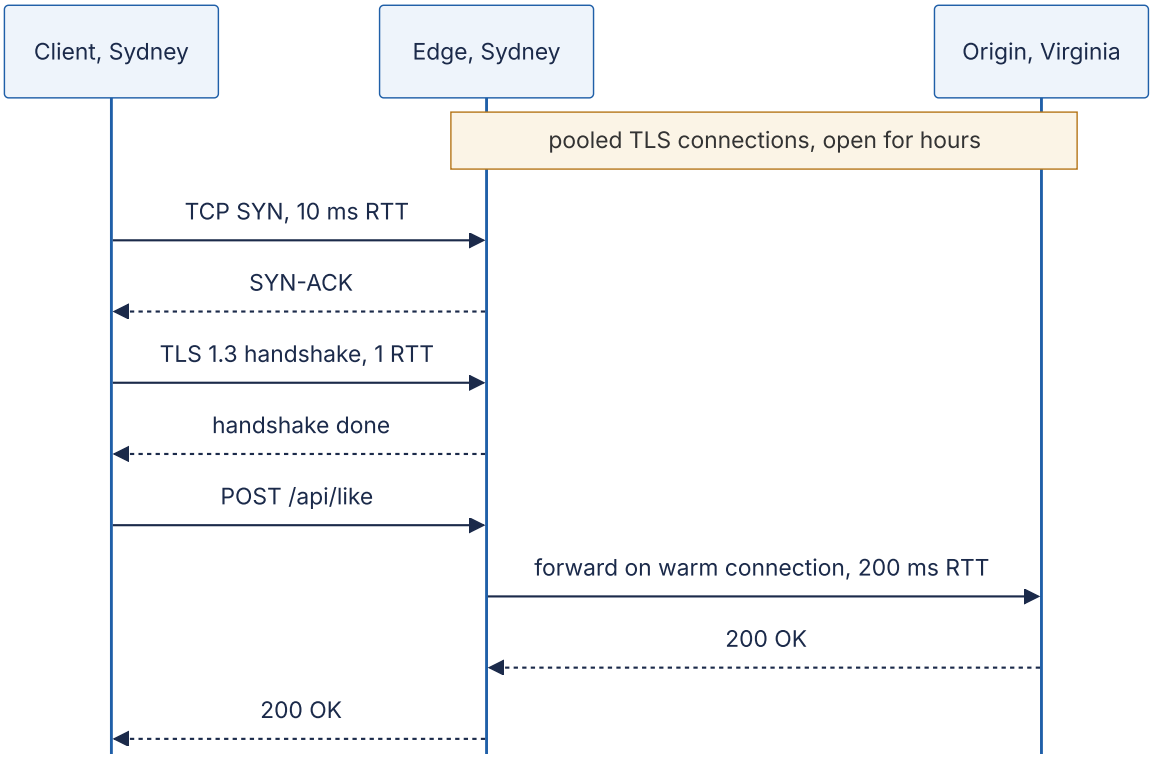
WORKED EXAMPLE

Worked example — A Sydney user calling a Virginia API. $\text{RTT}_{uo} = \text{RTT}_{eo} = 200$ ms, $\text{RTT}_{ue} = 10$ ms, $t_{\text{app}} = 50$ ms.

1. New connection, direct: $(2 + 1) \times 200 + 50 = 650$ ms.
2. New connection, via edge: $(2 + 1) \times 10 + 200 + 50 = 280$ ms, saving 370 ms (57%).
3. Reused connection ($n_{\text{hs}} = 0$), direct: $200 + 50 = 250$ ms; via edge: $10 + 200 + 50 = 260$ ms.

Interpretation. The edge wins on new connections and loses about one user-edge RTT when the client already holds a warm connection. **Engineering implication.** DSA helps most for users far from the origin making few requests per connection (mobile apps, first page loads). Large responses also gain because the edge–origin connection's congestion window is already open, so slow start is not repeated.

Figure 21.7 — Dynamic site acceleration.



Reading the diagram. Time runs downward. The client's handshakes are short because the edge is 10 ms away; the edge already holds encrypted, warmed-up connections to the origin (the note), so the request crosses the ocean exactly once each way. Every exchange is synchronous; nothing is cached, so the storage boundary is the origin alone. Failure points: the edge–origin pool (stale connections must be health-checked) and the origin itself. Scaling: the pool multiplexes many users' requests over few connections (HTTP/2), reducing the origin's connection count, a benefit of its own (§7.16).

21.7.3 Edge-side includes

A personalized page is often 95% shared content plus a small personal fragment. **Edge-side includes (ESI)**, a markup language specified in 2001 by Akamai and others, lets the origin return a cacheable page template containing include tags; the edge fetches each fragment separately, with its own cache policy, and assembles the page [Tsimelzon et al. 2001]:

```
<html><body>
  <esi:include src="/fragments/header?user=$(HTTP_COOKIE{uid})"/>  <!-- private, un-
cached -->
  <esi:include src="/fragments/trending" />                        <!-- cached 60 s -->
</body></html>
```

ESI is supported by several CDNs and by Varnish in subsets; today the same composition is often written as edge compute code (§21.9) or done in the browser.

21.8 Video delivery

Video dominates Internet traffic by volume, and it is a CDN's ideal workload: large, immutable, highly shared files. Two ideas make it work: cut the video into small HTTP objects so ordinary caches can serve it, and let the player choose quality continuously.

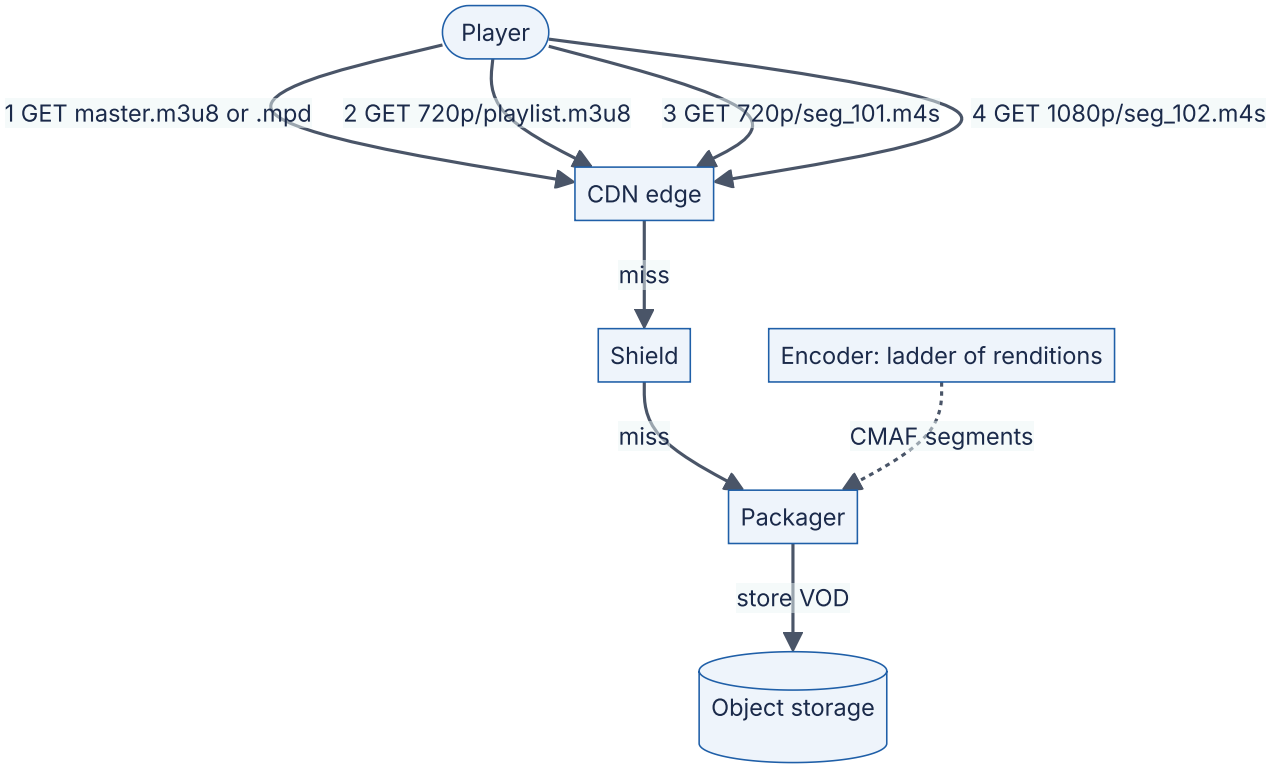
21.8.1 Segments, manifests and the bitrate ladder

> DEFINITION
>
> **Definition — HTTP adaptive streaming.** Video is encoded at several quality levels (a **bitrate ladder**), each cut into **segments** of a few seconds stored as ordinary files. A **manifest** lists the levels and segment URLs. The player downloads the manifest, then fetches segments one by one over HTTP, choosing a level for each segment.

Two formats dominate. **HLS** (HTTP Live Streaming), created by Apple and published as RFC 8216, uses text playlists (`.m3u8`): a multivariant (master) playlist listing renditions and a media playlist per rendition listing segments [RFC 8216]. **MPEG-DASH**, the international standard ISO/IEC 23009-1, uses an XML **Media Presentation Description** (MPD) [ISO/IEC 23009-1]. Historically HLS used MPEG-2 transport-stream segments and DASH used fragmented MP4, so a service supporting both stored everything twice. **CMAF** (Common Media Application Format, ISO/IEC 23000-19) defines one fragmented-MP4 segment format that both manifests can reference, halving storage and doubling cache efficiency.

```
#EXTM3U
#EXT-X-STREAM-INF:BANDWIDTH=3300000,RESOLUTION=1280x720,CODECS="avc1.64001f,mp4a.40.2"
720p/playlist.m3u8
#EXT-X-STREAM-INF:BANDWIDTH=6600000,RESOLUTION=1920x1080,CODECS="avc1.640028,mp4a.40.2"
1080p/playlist.m3u8
```

Figure 21.8 — HLS and DASH structure on a CDN.



Reading the diagram. The player first fetches the master manifest, then a media playlist, then segments; step 4 switches to 1080p for the next segment, which is just a different URL. All player requests are synchronous HTTP GETs to the edge; misses go through the shield to the packager or to object storage. The encoder produces renditions asynchronously (dotted) as CMAF segments. Storage boundaries: edge and shield caches, and object storage for video on demand (VOD). Failure points: for live video, the packager and encoder (a missing segment stalls every viewer); for VOD, cold long-tail titles. Scaling: segments are immutable and cacheable for a long time; live media playlists change every segment and get TTLs of about half a segment duration.

21.8.2 Bandwidth arithmetic

FORMULA

Edge egress and storage for a bitrate ladder

$$B_{\text{edge}} = V \times \sum_r s_r b_r \qquad B_{\text{origin,live}} \approx M \times \sum_r b_r \qquad S_{\text{title}} = \frac{D}{8} \sum_r b_r$$

Symbol	Meaning	Units
V	Concurrent viewers	viewers
b_r	Bitrate of rendition r	Mb/s
s_r	Share of viewers on rendition r ($\sum s_r = 1$)	dimensionless
M	Number of shields (or PoPs, if un-shielded) fetching each live rendition	count
D	Title duration	s
S_{title}	Stored size of one encoding of the full ladder	Mb ÷ 8 = MB

WORKED EXAMPLE

Worked example — A live match for two million viewers. Ladder: 0.4, 0.8, 1.5, 3.0, 4.5, 6.0 Mb/s (sum 16.2 Mb/s). Viewer shares: 5% at 0.8, 15% at 1.5, 30% at 3.0, 30% at 4.5, 20% at 6.0.

1. Mean bitrate: $0.04 + 0.225 + 0.9 + 1.35 + 1.2 = 3.715$ Mb/s.
2. Edge egress: $2 \times 10^6 \times 3.715 = 7.43 \times 10^6$ Mb/s $= 7.43$ Tb/s.
3. Origin egress with 10 shields: $10 \times 16.2 = 162$ Mb/s. Without shields, 200 PoPs each pull every rendition: $200 \times 16.2 = 3,240$ Mb/s.
4. Byte offload with shields: $1 - 162/(7.43 \times 10^6) = 99.998\%$.
5. Storage for a 2-hour VOD title: $7,200 \times 16.2/8 = 14,580$ MB ≈ 14.6 GB per codec.

Interpretation. The origin's job is trivial; the hard part is 7.4 Tb/s of edge capacity in the right places, which is why large live events are often spread across several CDNs. **Engineering implication.** Plan live events from the edge inward (capacity per metro and per ISP), and shield so the packager is never exposed to PoP count.

21.8.3 Adaptive bitrate algorithms

The player's **adaptive bitrate (ABR)** algorithm chooses the rendition for each segment. Too high and the buffer drains and video **rebuffers** (freezes); too low and quality suffers

needlessly; too jumpy and viewers notice switches.

- **Throughput-based.** Estimate bandwidth from recent segment downloads, typically a harmonic mean, which discounts outliers that would inflate an arithmetic mean, and choose the highest rendition below a safety fraction of it [Jiang et al. 2012].
- **Buffer-based (BBA).** Ignore the estimate in steady state and choose the rate from the buffer level: the minimum rate below a **reservoir**, the maximum above reservoir plus **cushion**, and linearly in between [Huang et al. 2014].
- **Hybrids and learning.** Model-predictive control combines both signals [Yin et al. 2015]; BOLA derives a buffer-based rule from utility maximization and is used in the open-source dash.js player [Spiteri et al. 2016]; Pensieve learns a policy with reinforcement learning [Mao et al. 2017].

FORMULA

Throughput rule and buffer-based rate map

$$\hat{C} = \frac{n}{\sum_{i=1}^{n} 1/c_i}, \quad R_{\text{tput}} = \max\{b_r \le \beta \hat{C}\} \qquad R_{\text{BBA}}(x) = \begin{cases} b_{\min} & x \le x_r \\ b_{\min} + \frac{x - x_r}{x_c}(b_{\max} - b_{\min}) & x_r < x < x_r + x_c \\ b_{\max} & x \ge x_r + x_c \end{cases}$$

Symbol	Meaning	Units
c_i	Measured throughput of the i-th most recent segment download	Mb/s
n	Number of recent segments averaged	count
$\hat{C}$	Harmonic-mean throughput estimate	Mb/s
β	Safety factor (e.g. 0.8)	dimensionless
x	Current buffer level	s
x_r, x_c	Reservoir and cushion	s
$b_{\min}$, $b_{\max}$	Lowest and highest ladder rates; the BBA result is rounded down to a ladder rung	Mb/s

WORKED EXAMPLE

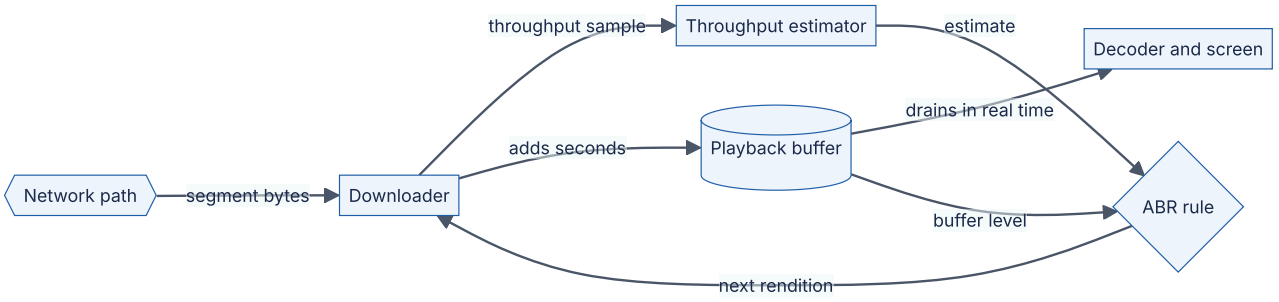
Worked example — Both rules on the ladder above. Throughput rule: the last five segments downloaded at 8, 7, 6, 2 and 8 Mb/s.

1. Harmonic mean: $5/(0.125 + 0.143 + 0.167 + 0.5 + 0.125) = 5/1.060 = 4.72$ Mb/s; $\times 0.8 = 3.78$ → choose 3.0 Mb/s.
2. The arithmetic mean would be 6.2 Mb/s; $\times 0.8 = 4.96$ → 4.5 Mb/s, betting on a link that just delivered 2 Mb/s.

BBA with $x_r = 10$ s, $x_c = 30$ s: at a 25 s buffer, $0.4 + (15/30)(5.6) = 3.2$ → 3.0 Mb/s; at 8 s → 0.4 Mb/s; at 45 s → 6.0 Mb/s.

Interpretation. The throughput rule reacts to the network, the buffer rule to the consequence that matters, a draining buffer. **Engineering implication.** Throughput estimates are essential at startup, when the buffer is empty and says nothing; in steady state the buffer is the more reliable signal.

Figure 21.9 — The ABR control loop.



Reading the diagram. The downloader fetches one segment at a time across the network (hexagon, outside the player's control), adding its duration to the buffer (cylinder), which the decoder drains at one second per second. The ABR rule reads the throughput estimate, the buffer level or both, and picks the next rendition, closing a feedback loop. Fetches are synchronous; the buffer decouples download from playback. The failure point is an empty buffer (a rebuffer). Each client runs its own loop; CDN load is the sum of their choices.

```
        # Throughput-based versus buffer-based (BBA-style) bitrate selection on the
        # same synthetic bandwidth trace. Rates in Mb/s, times in seconds.
        LADDER = [0.4, 0.8, 1.5, 3.0, 4.5, 6.0]   # bitrate ladder, Mb/s
        SEG = 4.0                                  # segment duration, s
        B_MAX = 60.0                               # player buffer limit, s
        DT = 0.05                                  # simulation step, s

        def bandwidth(t):
            """6 Mb/s, except a 60 s collapse to 0.6 Mb/s starting at t = 30 s."""
            return 0.6 if 30 <= t < 90 else 6.0

        def throughput_rule(history, buffer):
            if not history:
                return LADDER[0]
            recent = history[-5:]
            estimate = len(recent) / sum(1 / x for x in recent)   # harmonic mean
            fits = [r for r in LADDER if r <= 0.8 * estimate]     # 20% safety margin
            return fits[-1] if fits else LADDER[0]

        def buffer_rule(history, buffer, reservoir=10.0, cushion=30.0):
            if buffer <= reservoir:
                return LADDER[0]
            if buffer >= reservoir + cushion:
                return LADDER[-1]
            target = LADDER[0] + (buffer - reservoir) / cushion * (LADDER[-1] -
LADDER[0])
            return max(r for r in LADDER if r <= target)

        def play(rule, duration=200.0):
            t = buffer = stall = 0.0
            history, chosen, started = [], [], False
            while t < duration:
                rate = rule(history, buffer)
                bits, start = rate * SEG, t
                while bits > 0:                    # download one segment
                    bits -= bandwidth(t) * DT
                    t += DT
                    if started:
                        if buffer > 0:
                            buffer = max(0.0, buffer - DT)
                        else:
                            stall += DT            # empty buffer: the video freezes
                history.append(rate * SEG / (t - start))
                buffer += SEG
                started = True
                chosen.append(rate)
                if buffer > B_MAX - SEG:           # buffer full: idle until room
                    t += buffer - (B_MAX - SEG)
                    buffer = B_MAX - SEG
            switches = sum(a != b for a, b in zip(chosen, chosen[1:]))
            return sum(chosen) / len(chosen), stall, switches
```

```
        if __name__ == "__main__":
            for name, rule in [("throughput-based", throughput_rule), ("buffer-based",
buffer_rule)]:
                avg, stall, switches = play(rule)
                print(f"{name:<17} mean bitrate {avg:4.2f} Mb/s  stalled {stall:4.1f} s
"
                      f"switches {switches}")
```

Output:

```
throughput-based  mean bitrate 3.48 Mb/s  stalled 17.3 s  switches 9
buffer-based      mean bitrate 3.64 Mb/s  stalled  0.0 s  switches 15
```

What to notice:

- Just before the collapse at $t = 30$ s, both rules request a 4.5 Mb/s segment (18 Mb), which takes about 29 s at 0.6 Mb/s. The throughput rule ramped up at once and holds only 15 s of buffer, so the video freezes; the buffer rule started conservatively, built 38.5 s of buffer, and rides it out.
- Afterwards the throughput rule's history still contains fast samples, so it overestimates and stalls again. The buffer rule oscillates between 0.4 and 0.8 Mb/s near its reservoir, hence more switches; real players add hysteresis.
- This is one synthetic trace, an illustration rather than a benchmark.

INDUSTRY EXAMPLE

Netflix and buffer-based adaptation. Netflix and Stanford researchers ran buffer-based algorithms in a randomized experiment on Netflix's production service. They reported that BBA reduced the rebuffer rate by roughly 10–20% compared with the then-default ABR algorithm while delivering a similar average video rate, and that throughput estimates remained useful during startup, when the buffer is still filling [Huang et al. 2014]. *Evidence: Primary* — [Huang et al. 2014]

21.8.4 Live latency

For live video, the player starts several segments behind the newest one so that it has a buffer; RFC 8216 says a client should not start playback less than three target durations from the end of the playlist [RFC 8216].

FORMULA

Glass-to-glass latency of segmented live video

$$L \approx t_{enc} + k \times D_{seg} + t_{poll}$$

Symbol	Meaning	Units
t_{enc}	Capture, encode and package delay	s
k	Segments (or parts) held back by the player	count
D_{seg}	Segment (or part) duration	s
t_{poll}	Delay before the player learns a new segment exists, plus download	s
L	Delay from camera to screen	s

WORKED EXAMPLE

Worked example — Classic HLS versus low-latency parts. Classic: $t_{enc} = 2$ s, $k = 3$, $D_{seg} = 6$ s, $t_{poll} \approx 3$ s, so $L \approx 2 + 18 + 3 = 23$ s. With 1 s parts and blocking playlist reloads: $L \approx 1 + 3 \times 1 + 0.5 = 4.5$ s.

Interpretation. Segment duration dominates. **Engineering implication.** Cutting latency means smaller units and push-like signaling, which multiplies requests per viewer and makes request collapsing at the CDN essential.

Low-Latency HLS (introduced by Apple in 2019) adds **partial segments** published while the full segment is still being encoded, **blocking playlist reloads** (the edge holds a playlist request until the next part exists, removing polling delay) and **preload hints** [Apple Docs: Low-Latency HLS]. **Low-latency DASH** achieves similar results by delivering CMAF chunks of a segment with HTTP chunked transfer as they are encoded. Both demand CDNs that can hold requests open and stream objects that are still being written.

21.9 Edge computing on CDNs

Since every request already passes through a programmable proxy 10 ms from the user, you can run your own code there: validating tokens, A/B-test assignment, redirects, image-format choice, custom cache keys, page assembly. The problem is isolation: thousands of customers' code must share each server safely and start far faster than a container or virtual machine can.

Table 21.7 — Edge compute runtimes (brief; as of 2026).

Platform	Isolation model	Where it runs	Notable limits and traits
Cloudflare Workers	V8 **isolates**: many customers' scripts in one process, each in its own JavaScript heap	Every Cloudflare data center	JavaScript and WebAssembly; isolates start in milliseconds, avoiding container cold starts [Bloom 2018]
CloudFront Functions	Lightweight JavaScript runtime	CloudFront edge locations	Viewer request and response only; sub-millisecond execution budget; no network calls [AWS 2021]
Lambda@Edge	AWS Lambda functions	Regional edge caches	Node.js and Python; network access; up to 5 s on viewer triggers and 30 s on origin triggers [AWS 2021]
Fastly Compute	WebAssembly module instantiated per request	Fastly PoPs	Any language compiling to Wasm (Rust, Go, JavaScript); sandbox per request [Fastly Docs: Compute]

The design rule is to keep edge code stateless and cheap, and to treat edge storage (key-value stores, durable objects) as a separate consistency question. Runtimes, cold starts, Firecracker microVMs and edge data patterns are covered in depth in Chapter 48.

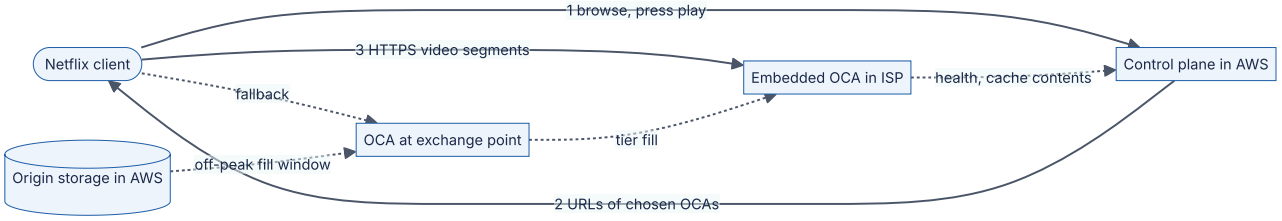
21.10 Netflix Open Connect

Netflix is the extreme case of video delivery: at peak it is one of the largest sources of Internet traffic, and its content is long-form, licensed, and therefore known in advance. Since 2012 it has delivered video through its own CDN, **Open Connect**.

INDUSTRY EXAMPLE

Netflix Open Connect. Netflix designs its own cache servers, **Open Connect Appliances (OCAs)**, and deploys them in two ways: **embedded** inside ISP networks, where Netflix provides the hardware to qualifying ISPs at no charge and the ISP provides space, power and connectivity, and at **Internet exchange points**, where Netflix peers with ISPs directly. The split of responsibilities is clean: services running in AWS handle everything before playback (browsing, authorization, choosing which OCAs a client should use) and return URLs pointing at OCAs; the OCAs then serve the video bytes. Rather than fill caches on demand, Netflix predicts what each OCA's population will watch and **proactively fills** OCAs during an off-peak **fill window** agreed with each ISP, so that peak-hour traffic is served almost entirely from caches that are already full. Fill is tiered: an OCA copies from a peer in the same location first, then from an upstream OCA, and only then from origin storage in AWS [Netflix TechBlog 2016]. *Evidence: Primary* — [Netflix Open Connect Overview]; [Netflix TechBlog 2016]

Figure 21.10 — Open Connect: control plane in the cloud, bytes from the ISP.



Reading the diagram. Steps 1–2 are synchronous API calls to Netflix's control plane in AWS, which knows which OCAs hold each file and how healthy and loaded they are. Step 3 streams segments from an embedded OCA inside the user's ISP; an OCA at an exchange point is the fallback. Dotted edges are asynchronous: content is pushed from origin storage to exchange-point OCAs and then to embedded OCAs during off-peak fill windows, and OCAs report health and contents to the control plane. Storage boundaries: origin storage in AWS and each OCA's disks and flash. Failure points: an OCA failure (the client is directed to another), a missed fill (the title is served from a farther OCA), and the control plane (playback cannot start, but running streams continue). Scaling: add OCAs in ISPs, which also removes traffic from the ISP's transit links.

21.10.1 Why it works, and when it would not

Proactive fill turns caching into **replica placement**: with a known catalog and good popularity predictions, peak-hour hit ratios approach those of a perfect cache, and fill uses idle off-peak capacity. Embedding removes transit costs for both parties, which is why ISPs accept the boxes. It depends on a curated catalog, predictable demand and enor-

mous volume; a site with viral user-generated content or modest volume is better served by a commercial CDN with tiered caching.

> COMMON MISTAKE
>
> **"Netflix streams from AWS."** Netflix runs its control plane in AWS, but the video bytes come from Open Connect appliances, mostly inside or next to the viewer's ISP. Conflating the two leads to wildly wrong egress estimates in interviews (§54.5 develops the full design).

21.11 CDN security

A CDN sits in front of everything, so it becomes the natural place for several security controls (Chapter 10 holds the foundations).

- **DDoS absorption.** Anycast spreads volumetric floods across every PoP, and the aggregate capacity of a large CDN exceeds any single attack's bandwidth; stateless edge proxies absorb SYN floods (Figure 10.9, §10.11).
- **WAF, bot management and rate limiting.** Application-layer rules, challenges and per-client limits (§22.3) run at the edge, before traffic reaches the origin.
- **TLS certificate management.** To terminate TLS, the CDN needs a certificate and private key for your domain. CDNs automate issuance and renewal with ACME [RFC 8555] and select certificates per hostname with SNI. If policy forbids handing over the private key, designs such as Cloudflare's **Keyless SSL** keep the key on the customer's server and perform only the private-key operation there [Sullivan 2014]. Certificate expiry at the edge is a classic outage (§10.5).
- **Origin protection.** Accept origin traffic only from the CDN, using address allowlists plus authenticated origin pulls (mutual TLS) or a secret header; otherwise attackers bypass every control above.
- **Private content.** For PhotoShare's private photos, the API issues a short-lived **signed URL** or token (an HMAC over path and expiry, §10.4.6), and the edge verifies it before serving from cache. The signature is excluded from the cache key, so one cached copy serves all authorized viewers while unauthorized requests are rejected at the edge.

21.12 Summary and revision notes

SUMMARY

- A **CDN** is a hierarchy of caching reverse proxies: **edge PoPs** near users, **mid-tier/shield** caches, and the authoritative **origin**. It cuts latency (round trips, not bandwidth), origin load, egress cost and DDoS exposure.
- **Request routing**: DNS mapping steers precisely but per resolver and bounded by TTLs (ECS helps); **anycast** steers by BGP, fails over automatically and disperses attacks, but with coarse load control. Real CDNs combine them.
- **Offload**: O_R (requests) and O_B (bytes) differ; miss ratios multiply across tiers, $f_{\text{origin}} = \prod (1 - h_i)$; $B_{\text{origin}} = B_{\text{users}}(1 - O_B)$. Going from 90% to 98% offload cuts origin load fivefold.
- **Shielding** funnels all misses through one tier: per object and TTL the origin sees about 1 fetch instead of $N(1 - e^{-\lambda T/N})$. It matters most with many PoPs, long tails, short TTLs and frequent purges.
- **RFC 9111 headers**: `s-maxage` for the CDN, short `max-age` for browsers, `stale-while-revalidate` and `stale-if-error` for resilience, `ETag` with `304` for cheap revalidation, `private` / `no-store` for personal data.
- **Cache keys**: normalize (host case, sorted allow-listed parameters, collapsed `Accept-Encoding`), avoid `Vary: User-Agent` and raw cookies; unkeyed inputs enable cache poisoning.
- **Invalidation**: URL purge, **tag (surrogate-key) purge** in about 150 ms on fast CDNs, soft purge, and **versioned URLs** with `immutable` for static assets.
- **Dynamic content**: micro-caching, ESI fragments, and **dynamic site acceleration** (TLS near the user, warm connections to origin).
- **Video**: HLS (RFC 8216) and DASH (ISO/IEC 23009-1) cut renditions into segments listed in manifests; CMAF unifies segments. ABR is throughput-based (harmonic mean × safety factor), buffer-based (reservoir and cushion) or hybrid; live latency ≈ encode + held-back segments × duration, reduced by LL-HLS parts.
- **Netflix Open Connect** embeds appliances in ISPs and fills them proactively off-peak; the control plane lives in AWS. Edge compute (isolates, Wasm, Lambda@Edge) runs small stateless logic at PoPs (Chapter 48).

21.13 Knowledge checkpoint

1. Why does a CDN reduce the time to fetch a 100 KB object even when the origin has plenty of bandwidth?
2. Give one advantage and one disadvantage of anycast relative to DNS-based routing.
3. A CDN’s request offload is 97% but its byte offload is 85%. What does that suggest?

4. Edge hit ratio is 80% and shield hit ratio (on edge misses) is 60%. What fraction of requests reaches the origin?
5. Why does a shield help a long-tail object more than its edge hit ratio suggests?
6. With `Cache-Control: max-age=300` and `Age: 280` from the CDN, how long is the browser's copy fresh?
7. What does `stale-if-error=3600` allow?
8. Why is `Vary: User-Agent` harmful at a CDN?
9. Compare tag purge with versioned URLs.
10. When does dynamic site acceleration *not* reduce latency?
11. Why did HLS and DASH originally require storing video twice, and what fixed it?
12. Compute the harmonic mean of 4 and 1 Mb/s and explain why ABR uses it.
13. Why can Netflix fill caches before demand arrives, and why can most sites not?
14. How should a CDN serve private photos without caching one copy per user?

Answers

1. Fetch time is dominated by handshake and slow-start round trips; the edge shortens each round trip (for example from 200 ms to 10 ms).
2. Advantage: automatic failover and DDoS dispersion with one IP. Disadvantage: BGP may choose a non-lowest-latency PoP, and load is hard to steer.
3. Misses are disproportionately large objects (long-tail video or downloads); origin egress is driven by those.
4. $0.2 \times 0.4 = 0.08$, i.e. 8%.
5. The object is rare at each PoP but common across all of them; the shield aggregates those misses into one fetch per TTL.
6. $300 - 280 = 20$ s.
7. Serving the stale response for up to an hour after it becomes stale if the origin returns errors or is unreachable.
8. It creates a separate cache entry for every distinct User-Agent string (thousands), destroying the hit ratio.
9. Tag purge actively removes everything labeled with an entity, across pages, but needs tagging and a purge API; versioned URLs need no purge and cache forever, but need a referring document that changes.
10. When the client already has a warm connection to the origin, or the user is near the origin: the edge then adds about one user–edge RTT.
11. HLS used MPEG-2 transport stream and DASH fragmented MP4; CMAF defines one fragmented-MP4 format both manifests can reference.
12. $2/(1/4 + 1/1) = 1.6$ Mb/s. It is dominated by slow samples, so a single fast outlier does not lead the player to choose a rate the link cannot sustain.
13. Its catalog is curated and demand is predictable from viewing history; user-generated, viral content is not predictable.
14. Verify a short-lived signed URL or token at the edge and exclude the signature from the cache key, so one cached copy serves all authorized viewers.

21.14 Interview questions

Basic

Q1. What is a CDN and when would you add one? Answer. A distributed set of caching reverse proxies near users that serves content for an origin. Add one when users are far from your servers, when static or shareable content dominates bandwidth, when origin egress or load is expensive, or when you need DDoS protection. Quantify the gain: round trips saved per request and origin bandwidth $B_{\text{users}}(1 - O_B)$.

Q2. How does a user get routed to a nearby PoP? Answer. Either the CDN's DNS answers with a PoP chosen by a mapping system (using resolver location, ECS, load and health), or all PoPs announce the same anycast prefix and BGP delivers packets to the nearest. DNS gives finer control but is bounded by TTLs; anycast fails over automatically and spreads attacks.

Intermediate

Q3. Your origin falls over every time marketing purges the home page. Why, and what do you change? Answer. Every PoP misses simultaneously and fetches independently, a CDN-wide stampede. Enable origin shielding and request collapsing, use soft purge so stale content is served while revalidating, add `stale-while-revalidate`, purge by tag rather than everything, and cache the page briefly (micro-caching) instead of marking it uncacheable.

Q4. Design the caching policy for PhotoShare. Answer. Images: URL carries photo ID and rendition, `s-maxage` of days, tagged by photo ID for deletion, private photos via edge-verified signed URLs. JS and CSS: hashed filenames, `max-age=31536000, immutable`. Feed API: `private`, or micro-cache public parts. Normalize keys, add `stale-if-error`, shield near the origin, and measure offload at the origin.

Q5. How does a video player decide which quality to download? Answer. Throughput-based rules pick the highest ladder rung below a safety fraction of a harmonic-mean bandwidth estimate; buffer-based rules map buffer level to rate (minimum below a reservoir, maximum above reservoir plus cushion). Production players use hybrids: throughput at startup, buffer in steady state, with hysteresis to limit switching.

Advanced

Q6. Estimate CDN and origin capacity for a 5-million-viewer live event. Answer. With a mean bitrate of about 3.7 Mb/s, edge egress is $5 \times 10^6 \times 3.7 \approx 18.5$ Tb/s, so plan capacity per metro and per ISP and probably use several CDNs. Origin egress is only shields × the ladder sum (for example $20 \times 16.2 = 324$ Mb/s). Use 2–4 s segments or LL-HLS parts,

short TTLs on live playlists, long TTLs on segments, request collapsing, redundant encoders and packagers, and a lower maximum rung as a load-shedding lever.

Q7. Would you build your own CDN? Answer. Only at very large, predictable volume where transit costs dominate and you can run hardware and ISP partnerships, as Netflix does. Otherwise commercial CDNs (possibly several, steered by DNS) give reach, DDoS capacity and features at lower total cost; a middle path is a commercial CDN plus your own shield.

21.15 Practical exercises

1. Run the shielding simulation with Zipf exponents 0.7, 1.0 and 1.2 and with 5, 20 and 100 PoPs. Plot origin fetches with and without a 30% shield, and explain which parameter makes shielding most valuable.
2. Configure NGINX or Varnish as a caching reverse proxy in front of a small origin. Verify `s-maxage`, `stale-while-revalidate` and `stale-if-error` with `curl -I` while stopping the origin, and confirm request collapsing with 100 concurrent requests.
3. Extend the ABR program with a hybrid rule (throughput during the first 20 s, buffer afterwards, switch only if the new rate differs for two consecutive decisions). Compare stalls and switches on three bandwidth traces.

21.16 Design challenges

1. **Global news site.** 50 million page views per day, breaking-news articles that must update within 5 seconds of an edit, personalized headers, and an origin in one region. Choose cache keys, TTLs, tagging and purge strategy, ESI or edge compute for personalization, and shielding; estimate offload and origin request rate.
2. **Live sports streaming.** 3 million concurrent viewers across three continents with a 5-second latency target. Choose segment and part durations, ladder, CDN strategy (single or multi-CDN), shield placement and failure handling for an encoder outage; estimate edge and origin bandwidth.

21.18 Open verification items

- Fastly purge timing (~150 ms) and the publication date of [Betts, Fastly Blog]; fastly.com was unreachable from the authoring environment.
- Netflix Open Connect claims (no-charge embedded OCAs, AWS control plane, fill-window and tiered-fill order, 2012 launch): openconnect.netflix.com was unreachable; confirm against the Overview PDF and the 2016 “Netflix and Fill” post (exact date and authors).
- Huang et al. 2014: confirm the “10–20% rebuffer reduction” wording.
- Illustrative 2026 prices in §21.5.4 ($0.05/GB origin egress tier, $0.01/GB negotiated CDN rate).
- CloudFront Functions and Lambda@Edge limits (sub-millisecond; 5 s/30 s) as of 2026.
- LL-HLS details (part hold-back of about three parts; 2019 introduction).
- Exact title and authors of the ESI 1.0 W3C Note.

Chapter 22 — API and Traffic Management

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 3 h

Every service eventually receives more requests than it can handle: from success (a launch), abuse (a scraper) or, very often, itself (a slow database makes callers time out, they retry, and the retries triple the load). As utilization approaches 100%, queueing delay grows without bound (§4.10.3); this chapter is the toolbox for staying on the safe side of that curve. It covers **rate limiting** (deciding how much each client may send), **load shedding** and **backpressure** (what a server does when total demand exceeds capacity), the client-side disciplines of **timeouts, deadlines, retries, circuit breakers and bulkheads**, and finally **idempotency keys**, which make retries safe for operations that must never happen twice, such as charging a card.

The running example is PhotoShare (Chapter 1), which now offers a public API and sells a "PhotoShare Pro" subscription through an external payment provider: the API needs quotas, the upload service needs overload protection, and the purchase must never charge twice. The traffic figures in this chapter describe PhotoShare several years after the v3 stage of §1.9, with rates 15–30× higher than Chapter 1's; each worked example states its own capacity and load, so treat them as independent scenarios rather than one consistent fleet.

22.1 Learning objectives

After this chapter you should be able to:

- Choose where to enforce a rate limit (client, edge, gateway, service) and what to key it on, and signal limits correctly with HTTP 429, `Retry-After` and the draft `RateLimit` header fields.
- Implement and parameterize the token bucket, leaky bucket (including GCRA), fixed window, sliding log and sliding window counter algorithms, and compare their accuracy, memory and burst behavior with numbers.
- Design a distributed rate limiter (centralized Redis with Lua, local counting with synchronization, quota distribution) and quantify its latency/accuracy trade-off.
- Explain load shedding, priority-based shedding, CoDel-style queue control and adaptive LIFO, and compute when an overloaded server's goodput collapses.
- Size bounded queues and connection pools with Little's Law, and explain backpressure from TCP to reactive streams.

- Propagate deadlines across a call chain and allocate a timeout budget.
- Configure retries with exponential backoff, full/equal/decorrelated jitter and retry budgets, and calculate retry amplification in a deep call graph.
- Implement a circuit breaker and bulkheads, and choose their thresholds.
- Design an idempotency-key layer: key scope, request fingerprinting, storage schema, concurrency control, leases and retention.

22.2 Prerequisites

- Queueing, utilization and the M/M/1 latency curve — §4.10 (why overload makes latency explode).
- Little's Law, $L = \lambda W$ — §4.11 (sizing queues, pools and in-flight limits).
- TCP flow control and the receive window — §7.7.6 (the original backpressure mechanism).
- HTTP methods, safety and idempotency; status codes 429 and 503 — §8.6.3–§8.6.4 (this chapter builds the full idempotency design on them).
- gRPC status codes and deadlines — §8.8 (deadline propagation in RPC frameworks).
- Redis basics (in-memory key-value store) — §12.4 (the usual home for shared rate-limit counters; internals in §20.6).
- Units: time in milliseconds (ms) and seconds (s); request rates in requests per second (RPS); storage in decimal units (1 KB = 10^3 bytes, 1 GB = 10^9 bytes).

22.3 Rate limiting

22.3.1 What rate limiting is and why it exists

> DEFINITION
>
> **Definition — Rate limiting.** Enforcing an upper bound on how many requests (or how much work) a given **client identity** may submit to a resource over time. Requests beyond the bound are rejected (or, less often, delayed). The bound is usually stated as a **rate** (for example 100 requests per minute) plus a **burst** allowance.

First-principles explanation

A popular museum caps entries per half hour and per booking, so that one tour bus of 200 people cannot crowd out everyone else. A rate limiter does the same for an API: it caps how many requests each client may make per unit of time, so no single client can consume the shared capacity.

Why does this exist?

Rate limits solve five distinct problems: **abuse** (credential stuffing, scraping, application-layer DoS, §10.11; 5 login attempts per minute turns a million-password attack into a multi-year project), **fairness** between tenants, **protecting downstream capacity**, **cost control** for expensive calls (paid APIs, GPU inference), and **product tiers** ("Free: 60 requests/minute; Pro: 5,000").

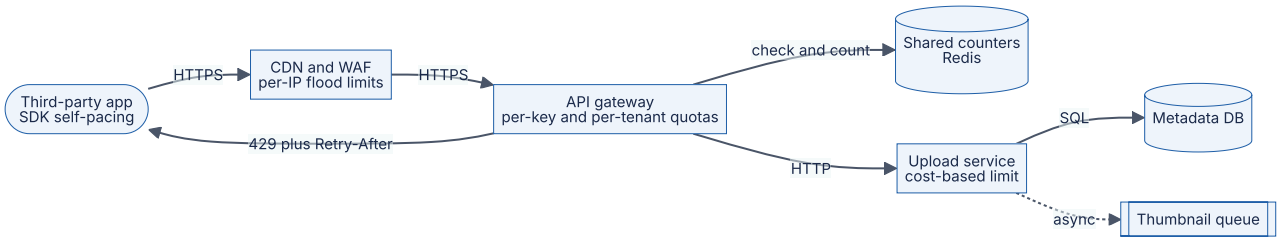
Rate limits answer "is this client within its contract?"; load shedding (§22.9) answers "can I afford this request right now?". Keep the two separate.

22.3.2 Where to enforce limits

Mature systems enforce limits in layers:

1. **Client side.** SDKs pace themselves and honor `Retry-After`; useful, but never trusted for protection.
2. **Edge (CDN or WAF).** Coarse per-IP limits stop floods before they reach your network (§10.11).
3. **API gateway.** After authentication it can limit per API key, user, tenant and route; the usual home of contractual quotas.
4. **Service.** Only the service knows a request's true cost (rows scanned, bytes uploaded, tokens generated), so it can limit on cost rather than count.

Figure 22.1 — Layered rate limiting for the PhotoShare API.



Reading the diagram. A third-party app sends HTTPS requests through three enforcement layers: the *CDN/WAF* (cheap per-IP limits), the *API gateway* (per-key and per-tenant quotas checked against *shared counters* in Redis, a storage boundary shared by all gateway nodes, §22.8) and the *upload service* (a cost-based limit in bytes per minute). Solid arrows are synchronous; the thumbnail queue is asynchronous. Whichever layer rejects returns 429 with `Retry-After`. Failure point: the counter store is on every request's hot path, so its outage policy (§22.8.5) must be decided in advance. Scaling: edge and gateway scale horizontally; counters are partitioned by key.

22.3.3 Choosing the key

The **rate-limit key** is the identity whose usage is counted.

Table 22.1 — Rate-limit keys.

Key	Strengths	Weaknesses	Typical use
Client IP address	Available before authentication	Many users share one IP behind carrier-grade NAT (§7.13); attackers rotate IPs	Edge flood control, login, sign-up
User or account ID	Fair per person	Needs authentication; attackers create accounts	Per-user actions
API key or OAuth client ID	Maps to a contract and a bill	A leaked key consumes the owner's quota	Public developer APIs
Tenant	Isolates customers	One heavy user exhausts the tenant	Noisy-neighbor control
Route plus one of the above	Tighter limits on expensive endpoints	More counters	`POST /uploads`
Cost units	Reflects true resource use	Cost must be estimated up front	GraphQL cost (§8.7), LLM tokens

Production systems apply **hierarchical limits**: a request must pass every applicable bucket (per-IP *and* per-key *and* per-tenant *and* a route ceiling).

22.3.4 Telling the client: 429, Retry-After and RateLimit headers

- **429 Too Many Requests** [Nottingham and Fielding 2012] blames the client; **503 Service Unavailable** blames the server and is right for load shedding (§22.9).
- `Retry-After` (RFC 9110 §10.2.3) gives seconds or a date after which to retry; compute it from the limiter's state.
- **RateLimit header fields** are being standardized in the IETF Internet-Draft *RateLimit header fields for HTTP* [Polli et al., draft], as of 2026 still a **draft, not an RFC**. Early drafts used `RateLimit-Limit`, `-Remaining` and `-Reset`; recent drafts use `RateLimit-Policy` (quota `q`, window `w`) and `RateLimit` (remaining `r`, seconds to reset `t`). Many APIs still use their own `X-RateLimit-*` headers.

```
HTTP/1.1 429 Too Many Requests
Content-Type: application/problem+json
Retry-After: 18
RateLimit-Policy: "default";q=100;w=60
RateLimit: "default";r=0;t=18

{"type": "https://api.photoshare.example/errors/rate-limited",
 "title": "Rate limit exceeded", "status": 429,
 "detail": "API key pk_live_42 is limited to 100 requests per 60 s."}
```

What to notice:

- The body uses RFC 9457 problem details; `Retry-After: 18` and `t=18` agree, so older clients still behave.
- Send the `RateLimit` fields on *successful* responses too, so clients slow down before being rejected.

INDUSTRY EXAMPLE

GitHub REST API. GitHub returns `x-ratelimit-limit`, `x-ratelimit-remaining`, `x-ratelimit-used`, `x-ratelimit-reset` (a Unix timestamp) and `x-ratelimit-resource`, answers excess requests with 403 or 429, and may send `retry-after` for secondary limits [GitHub Docs: REST rate limits]. De-facto conventions predate the IETF draft, so client libraries must handle several dialects. *Evidence: Primary* — [GitHub Docs: REST rate limits]

Table 22.2 — Rate-limiting failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Thousands of mobile users blocked at once	Per-IP limit applied to a carrier NAT address	429 spike concentrated on few IPs with many user agents	Raise or bypass the IP limit for authenticated traffic	Key on user or API key after authentication; IP limits only pre-auth
Clients hammer after 429	No `Retry-After`; SDK retries immediately	429 rate rises in lockstep with request rate	Return `Retry-After`; block abusive keys	SDK backoff with jitter (§22.12)
Legitimate burst rejected	Burst allowance smaller than the client's natural burst (app start-up sync)	429s at app launch time, low average usage	Increase bucket capacity	Size burst from observed per-session peaks (§22.4)

COMMON MISTAKE

Mistake — "Rate limiting protects my service from overload." 10,000 customers each within 100 RPS can still send 1,000,000 RPS in total. Capacity protection needs load shedding and backpressure (§22.9–§22.10).

22.4 Token bucket

22.4.1 The algorithm

> DEFINITION
>
> **Definition — Token bucket.** A rate limiter that keeps a counter of **tokens**, refilled continuously at **rate** *r* up to a maximum **capacity** (burst size) *b*. Each request consumes one token (or a cost *c*); a request that finds too few tokens is rejected. The long-run admitted rate is at most *r*, and up to *b* requests may be admitted at once.

First-principles explanation

A jar is topped up with one sweet every six seconds but holds only 20. After an hour away you can eat 20 in a row (a **burst**), then only as fast as sweets arrive. The jar size limits the burst; the top-up speed limits the average.

Why does this exist?

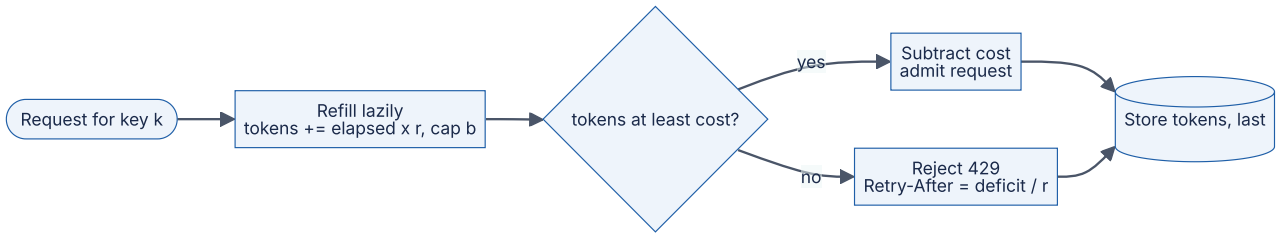
Real clients are bursty: an app opening fetches a profile, a feed and ten thumbnails in one second, then goes quiet. The token bucket separates average rate from burst size, exactly how capacity is planned; it came from network traffic policing and underlies most gateways' "rate and burst" settings.

How it works internally

No timer is needed. Store `tokens` and `last` (time of last update) per key and refill lazily:

1. `elapsed = now − last`; `tokens = min(b, tokens + elapsed × r)`; `last = now`.
2. If `tokens ≥ cost`: subtract the cost and admit.
3. Otherwise reject, and report `Retry-After = (cost − tokens) / r`.

Figure 22.2 — Token bucket admission decision.



Reading the diagram. A request triggers a lazy refill capped at *b*; the decision compares tokens with the request's cost; admitted requests subtract it, rejected ones compute when the deficit refills. Both paths write the two-number state back to storage (local memory, or a shared store in §22.8). Everything is synchronous and constant-time. Failure

point: the read-modify-write must be atomic when threads or nodes share a key (§22.8.2). Scaling: two numbers per key, so millions of keys are cheap.

Mathematical foundations

FORMULA

Token bucket state and admission bound

$$\text{tokens}(t) = \min\left(b,\ \text{tokens}(t_0) + r\,(t - t_0)\right) \qquad A(T) \le b + rT$$

Symbol	Meaning	Units
r	Refill rate (sustained allowed rate)	tokens/s (= requests/s at unit cost)
b	Bucket capacity (maximum burst)	tokens
t_0, t	Time of last update, current time	s
$A(T)$	Maximum requests admitted in any interval of length T	requests

WORKED EXAMPLE

Worked example — PhotoShare free tier: $r = 10$ RPS, $b = 20$.

1. A client idle for a while has a full bucket of 20. It fires 50 requests at $t = 0$: the first 20 are admitted, 30 are rejected. Deficit for the next request is 1 token, so `Retry-After` $= 1/10 = 0.1$ s.
2. The client waits 1 s: the bucket refills $1 \times 10 = 10$ tokens, so 10 more requests succeed.
3. Maximum admitted in any 60 s interval: $A(60) = 20 + 10 \times 60 = 620$ requests, an average of 10.3 RPS. The burst adds only 3% over a minute.
4. Time to refill from empty to full: $b/r = 20/10 = 2$ s.
5. Sustained 15 RPS for 10 s against a full bucket (150 requests over a 9.93 s span): the bound is $20 + 10 \times 9.93 = 119.3$, so at most 119 are admitted; the code below admits exactly 119.

Interpretation. r governs the minute-scale average; b only the first seconds.
Engineering implication. Set r from capacity planning and b from the largest legitimate client burst; if the downstream cannot absorb b requests at once from many clients, the burst, not the rate, will hurt you.

Code example

```
        import random
        import time

        class FakeClock:
            """A controllable clock so tests are deterministic (time in seconds)."""
            def __init__(self, t=0.0):
                self.t = t
            def __call__(self):
                return self.t
            def advance(self, dt):
                self.t += dt

        class TokenBucket:
            """Refill at `rate` tokens/s up to `capacity`; each request spends `cost`
tokens."""
            def __init__(self, rate, capacity, clock=time.monotonic):
                self.rate, self.capacity, self.clock = float(rate), float(capacity),
clock
                self.tokens = float(capacity)          # start full: a new client may
burst at once
                self.last = clock()

            def _refill(self):
                now = self.clock()
                elapsed = max(0.0, now - self.last)    # ignore a clock that steps back-
wards
                self.tokens = min(self.capacity, self.tokens + elapsed * self.rate)
                self.last = now

            def try_acquire(self, cost=1.0):
                self._refill()
                if self.tokens >= cost:
                    self.tokens -= cost
                    return True
                return False

            def retry_after(self, cost=1.0):
                """Seconds until `cost` tokens are available: the value for a Retry-
After header."""
                self._refill()
                return max(0.0, (cost - self.tokens) / self.rate)

        if __name__ == "__main__":
            clock = FakeClock()
            tb = TokenBucket(rate=10, capacity=20, clock=clock)

            # 1. A burst of 50 requests at t = 0
            admitted = sum(tb.try_acquire() for _ in range(50))
            print(f"t=0.0 s burst of 50: admitted {admitted}, retry after
{tb.retry_after():.2f} s")
            assert admitted == 20
```

```
            # 2. One second later the bucket has refilled 10 tokens
            clock.advance(1.0)
            admitted = sum(tb.try_acquire() for _ in range(50))
            print(f"t=1.0 s burst of 50: admitted {admitted}")
            assert admitted == 10

            # 3. Sustained 15 RPS for 10 s against a fresh (full) bucket
            clock, n_ok = FakeClock(), 0
            tb = TokenBucket(rate=10, capacity=20, clock=clock)
            for k in range(150):
                clock.t = k / 15
                n_ok += tb.try_acquire()
            bound = 20 + 10 * (149 / 15)               # b + r*T over the 9.93 s span
            print(f"15 RPS for 10 s: admitted {n_ok} of 150 (bound b + rT =
{bound:.1f})")
            assert n_ok <= bound
```

Output:

```
t=0.0 s burst of 50: admitted 20, retry after 0.10 s
t=1.0 s burst of 50: admitted 10
15 RPS for 10 s: admitted 119 of 150 (bound b + rT = 119.3)
```

What to notice:

- The injected clock makes tests exact. In production use a **monotonic** clock, never wall-clock time, which can jump backwards (§24.9).
- `retry_after` falls out of the state, so the 429 can say exactly when to return; a non-unit `cost` makes it a cost-based limiter.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Stripe's API rate limiters.** Stripe described four limiters: a per-user **request rate limiter** (a token bucket in Redis, shared by all API servers), a **concurrent requests limiter**, a **fleet usage load shedder** reserving capacity for critical requests, and a **worker utilization load shedder** that sheds lower-priority traffic first. It recommends dark-launching new limiters, logging what would be rejected before enforcing [Tarjan 2017]. *Evidence: Primary* — [Tarjan 2017]

INDUSTRY EXAMPLE

Amazon API Gateway. AWS documents token-bucket throttling with a configurable *rate* and *burst* per account, stage, method or usage-plan client; excess requests receive 429 [AWS Docs: API Gateway throttling]. *Evidence: Primary* — [AWS Docs: API Gateway throttling]

Common misconceptions

COMMON MISTAKE

Mistake — "$r = 10$ RPS means no client ever exceeds 10 RPS." At $b = 20$, 20 requests can arrive in one millisecond. By Little's Law, in-flight requests $= \lambda W$ (§4.11), so a rate limit bounds concurrency only while latency stays bounded; add a **concurrency limit** too.

22.5 Leaky bucket

22.5.1 Two different algorithms with one name

DEFINITION

Definition — Leaky bucket. (a) **As a queue:** requests enter a FIFO buffer of capacity Q that is drained at a constant rate r; arrivals that find the buffer full are dropped. Output is perfectly smooth. (b) **As a meter:** a counter (the "water level") increases by one per admitted request and leaks at rate r; a request that would overflow capacity is rejected immediately. The meter form makes the same admit/reject decisions as a token bucket with the same rate and capacity.

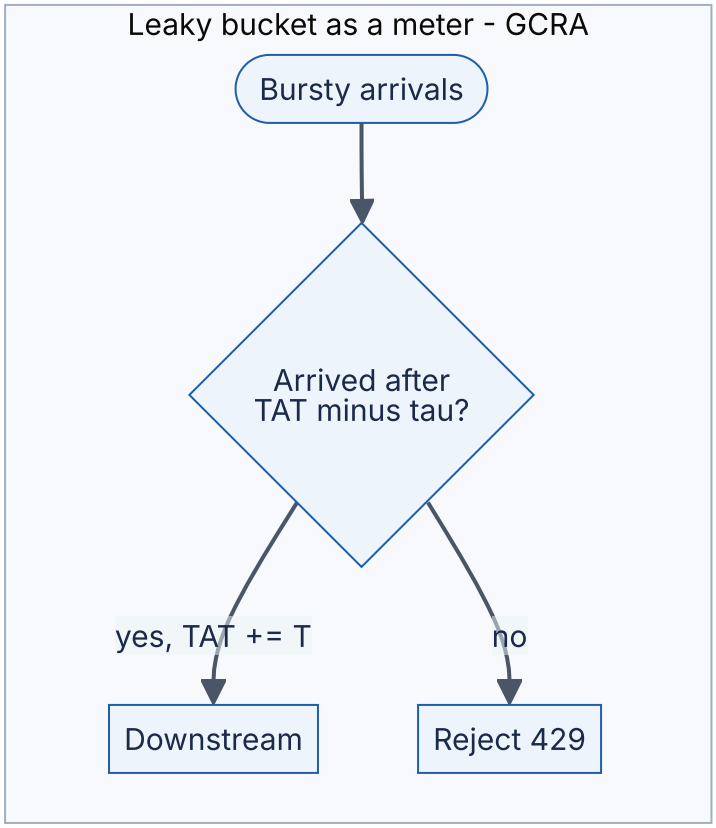
First-principles explanation

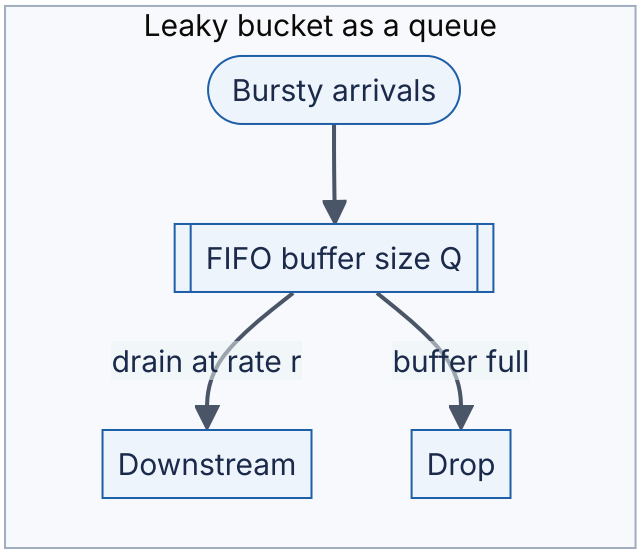
Water poured unevenly into a bucket with a hole leaks out at a steady drip; pour too fast and it overflows. In the **queue** form the water is the requests themselves: they wait and leave smoothly, but *delayed*. In the **meter** form the water is only a measurement: each request is admitted or rejected at once.

Why does this exist?

It comes from telecommunications, where switches policed and shaped fixed-size cells. For APIs, the queue form suits a downstream that needs smooth arrivals (a partner API allowing exactly 5 calls/s); the meter form needs only *one* number per key.

Figure 22.3 — Leaky bucket as a queue versus as a meter.





Reading the diagram. Left: arrivals are buffered in a FIFO (an in-memory storage boundary of size Q) and released asynchronously at rate r, adding up to Q/r latency; a full buffer drops arrivals. Right: nothing is buffered; each arrival is checked synchronously against one stored timestamp (TAT, below) and admitted or rejected. The queue *shapes*, the meter *polices*. Failure points: queued requests are lost on a crash and may time out while waiting. Scaling: the meter's single number per key shards trivially.

22.5.2 GCRA: the leaky bucket as a single timestamp

The **Generic Cell Rate Algorithm (GCRA)** is the meter form defined for ATM (Asynchronous Transfer Mode) networks in ITU-T Recommendation I.371 and the ATM Forum Traffic Management specification [ITU-T I.371; ATM Forum TM 4.0]. Of its two equivalent formulations, the "virtual scheduling" form is the one adapted for APIs: instead of counting tokens, it remembers when the next request is *due* at exactly the allowed rate.

FORMULA

GCRA (virtual scheduling form)

$$T = \frac{1}{r}, \qquad \tau = (b-1)\,T, \qquad \text{admit at time } t \;\Leftrightarrow\; t \geq \text{TAT} - \tau, \qquad \text{then TAT} \leftarrow \max(\text{TAT}, t) + T$$

Symbol	Meaning	Units
r	Sustained allowed rate	requests/s
T	Emission interval: ideal spacing between requests	s
b	Burst size (requests that may arrive back to back)	requests
τ	Tolerance: how early a request may be relative to its ideal schedule	s
TAT	Theoretical arrival time of the next request (the only stored state)	s (timestamp)
t	Arrival time of the current request	s (timestamp)

WORKED EXAMPLE

Worked example — GCRA with $r = 10$ RPS, $b = 20$.

1. $T = 1/10 = 100$ ms; $\tau = 19 \times 100 = 1,900$ ms.
2. An idle client sends 50 requests at $t = 0$. TAT starts at 0 (or is reset to t because $\max(\text{TAT}, t)$ ignores a stale past TAT).
3. Request 1: $0 \geq 0 - 1.9$ ✓; TAT $= 0.1$ s. Request 20: TAT before it is 1.9; $0 \geq 1.9 - 1.9 = 0$ ✓; TAT becomes 2.0.
4. Request 21: $0 \geq 2.0 - 1.9 = 0.1$? No → reject. `Retry-After` $=$ TAT $- \tau - t = 0.1$ s.

Interpretation. Identical to the token bucket of §22.4. **Engineering implication.** One timestamp per key and no refill arithmetic make GCRA attractive in shared stores such as Redis.

```
        import random

        class GCRA:
            """Generic Cell Rate Algorithm, virtual-scheduling form. State per key: one
integer (TAT).
            Times are integer nanoseconds so that repeated additions do not drift."""
            def __init__(self, rate, burst):
                self.T = round(1e9 / rate)          # emission interval (ns): ideal gap
between requests
                self.tau = (burst - 1) * self.T     # tolerance (ns): how far ahead of
schedule we accept
                self.tat = None                     # theoretical arrival time of the
next request

            def try_acquire(self, now_s):
                now = round(now_s * 1e9)
                tat = now if self.tat is None else max(self.tat, now)
                if tat - now > self.tau:            # arrived earlier than TAT - tau:
non-conforming
                    return False
                self.tat = tat + self.T             # conforming: push the schedule one
interval out
                return True

            def retry_after(self, now_s):
                """Seconds until the next request would conform."""
                return max(0.0, (self.tat - self.tau) / 1e9 - now_s)

        def token_bucket_decisions(rate, capacity, times):
            """Reference token bucket (starts full) for comparison."""
            tokens, last, out = float(capacity), times[0], []
            for t in times:
                tokens = min(capacity, tokens + (t - last) * rate)
                last = t
                ok = tokens >= 1.0
                tokens -= 1.0 if ok else 0.0
                out.append(ok)
            return out

        if __name__ == "__main__":
            g = GCRA(rate=10, burst=20)
            burst = [g.try_acquire(0.0) for _ in range(50)]
            print(f"burst of 50 at t=0: admitted {sum(burst)}, retry after
{g.retry_after(0.0):.2f} s")

            # Equivalence check on 100,000 random arrivals (Poisson, average 14 RPS)
            rng = random.Random(7)
            times, t = [], 0.0
            for _ in range(100_000):
                t += rng.expovariate(14.0)
                times.append(t)
            g = GCRA(rate=10, burst=20)
            gcra = [g.try_acquire(x) for x in times]
```

```
    tb = token_bucket_decisions(10, 20, times)
    mismatches = sum(a != b for a, b in zip(gcra, tb))
    print(f"admitted: GCRA {sum(gcra)}, token bucket {sum(tb)}; "
          f"decisions that differ: {mismatches}")
    assert sum(burst) == 20 and mismatches == 0
```

Output:

```
burst of 50 at t=0: admitted 20, retry after 0.10 s
admitted: GCRA 71137, token bucket 71137; decisions that differ: 0
```

What to notice:

- Identical decisions on 100,000 arrivals: GCRA with $\tau = (b-1)/r$ *is* a token bucket of capacity b.
- Integer nanoseconds matter: a floating-point version admitted only 19, because repeated addition of 0.1 slightly exceeded 1.9.
- `max(self.tat, now)` stops an idle client banking more than the burst.

Alternatives and trade-offs

Use the **queue form** only when the downstream needs smooth arrivals and callers can wait, keeping Q/r below their timeout (§22.10); use the **meter form** for API admission.

> COMMON MISTAKE
>
> **Mistake — Treating "leaky bucket" and "token bucket" as rivals.** The meter form and the token bucket are the same policy. The real distinction is *shaping* (queue and delay) versus *policing* (admit or reject); ask which one is meant.

22.6 Fixed window

22.6.1 Counting per calendar window

> DEFINITION
>
> **Definition — Fixed window counter.** A limiter that divides time into aligned windows of length W (for example each clock minute), keeps one counter per key per window, and admits a request if the current window's counter is below the limit L. The counter resets at each window boundary.

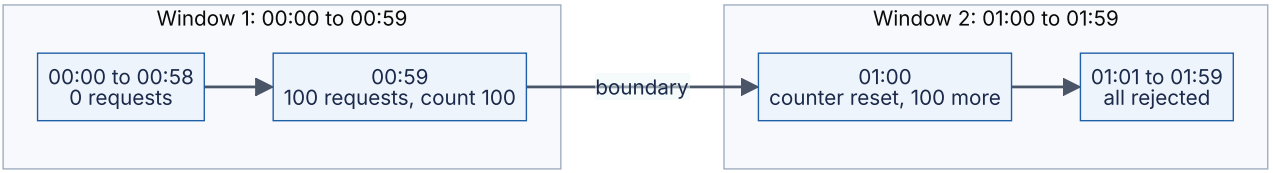
How it works internally

1. Window index $= \lfloor t/W \rfloor$; counter key = `key:window_index`.

2. Increment the counter atomically (in Redis: `INCR` plus `EXPIRE` set to W).
3. Admit if the new value is at most L.

It is simple (one integer, one atomic increment, automatic cleanup), but suffers the **boundary burst**: a full quota at the end of one window and another at the start of the next.

Figure 22.4 — The fixed-window boundary burst.



Reading the diagram. Two one-minute windows, limit 100 each. The client sends 100 requests in the last second of window 1 (counter reaches 100); the counter, a per-window storage record, is discarded at the boundary, so 100 more in the first second of window 2 are also admitted. The failure point is the downstream service, which receives 200 requests in two seconds; clients whose cron jobs fire on the minute produce such synchronized bursts.

FORMULA

Worst-case burst of a fixed window

$$A_{\max}(W) = 2L \qquad \text{peak short-term rate} \approx \frac{2L}{\delta}$$

Symbol	Meaning	Units
L	Limit per window	requests
W	Window length	s
$A_{\max}(W)$	Most requests admitted in some interval of length W that straddles a boundary	requests
δ	Duration of the straddling burst (can be arbitrarily small)	s

WORKED EXAMPLE

Worked example — 100 requests per minute.

1. Intended average rate: $100/60 = 1.67$ RPS.
2. Client sends 100 requests during 00:59.00–00:59.99 and 100 during 01:00.00–01:00.99. All 200 are admitted (the code in §22.7 confirms it).
3. In the 2 s interval the client achieved $200/2 = 100$ RPS, which is $100/1.67 = 60$ times the intended average, and any 60 s interval containing both bursts held $2L = 200$ requests.

Interpretation. The limit holds per calendar window, not per sliding minute. **Engineering implication.** Use fixed windows only for coarse daily or monthly quotas; protect backends with a token bucket or sliding window.

22.7 Sliding window log and sliding window counter

22.7.1 Sliding window log

DEFINITION

Definition — Sliding window log. A limiter that stores the timestamp of every admitted request per key and admits a new request only if fewer than L timestamps fall in the interval $(t - W, t]$.

The log is exact (in Redis, a sorted set per key) but costs up to L timestamps per key: 1 million keys at 1,000 requests per hour need $10^6 \times 1,000 \times 8$ bytes $= 8$ GB raw, more with sorted-set overhead. Use it when L is small (5 login attempts per 15 minutes) or exactness is contractual.

22.7.2 Sliding window counter

DEFINITION

Definition — Sliding window counter. A limiter that keeps fixed-window counters for the current and previous windows and estimates the count over the last W seconds by weighting the previous window's count by the fraction of it that still overlaps the sliding interval.

First-principles explanation

You made 84 calls last hour and 36 so far this hour; it is quarter past. If last hour's calls were spread evenly, three-quarters (63) fall inside the sliding hour, so the estimate is $63 + 36 = 99$. The counter assumes exactly this uniformity.

FORMULA

Sliding window counter estimate

$$\hat{N}(t) = C_{\text{prev}} \cdot \frac{W - e}{W} + C_{\text{curr}}, \qquad \text{admit if } \hat{N}(t) + 1 \le L$$

Symbol	Meaning	Units
$\hat{N}(t)$	Estimated requests in the sliding interval $(t - W, t]$	requests
C_{prev}	Count in the previous fixed window	requests
C_{curr}	Count so far in the current fixed window	requests
e	Time elapsed since the current window started	s
W	Window length	s
L	Limit per sliding window	requests

WORKED EXAMPLE

Worked example — $L = 100$ per minute, 15 s into the current minute.

1. $C_{\text{prev}} = 84$, $C_{\text{curr}} = 36$, $e = 15$ s, $W = 60$ s.
2. Overlap weight: $(60 - 15)/60 = 0.75$; weighted previous count: $84 \times 0.75 = 63$.
3. $\hat{N} = 63 + 36 = 99$. Admit test: $99 + 1 = 100 \le 100$ → admit; C_{curr} becomes 37.
4. Next request at the same instant: $\hat{N} = 63 + 37 = 100$; $100 + 1 > 100$ → reject.
5. When does the next request fit? The previous window's contribution falls by $84/60 = 1.4$ requests per second, so after $1/1.4 \approx 0.71$ s the estimate drops to 99. `Retry-After` rounds up to 1 s.
6. Memory: two counters plus a window start, about 16 bytes per key, versus up to 8,000 bytes for a log at $L = 1,000$; for 1 million keys, 16 MB versus 8 GB.

Interpretation. Two integers per key give a smooth sliding limit. **Engineering implication.** It is the usual choice for large-scale per-minute or per-hour limits; its error depends on how uneven traffic is within a window, measured below.

Code example

```
        import math
        import random
        from collections import deque

        class FixedWindow:
            def __init__(self, limit, window):
                self.limit, self.window = limit, window
                self.start, self.count = None, 0

            def try_acquire(self, now):
                start = math.floor(now / self.window) * self.window
                if start != self.start:                      # a new window: reset the
counter
                    self.start, self.count = start, 0
                if self.count < self.limit:
                    self.count += 1
                    return True
                return False

        class SlidingLog:
            def __init__(self, limit, window):
                self.limit, self.window, self.log = limit, window, deque()

            def try_acquire(self, now):
                while self.log and self.log[0] <= now - self.window:
                    self.log.popleft()                       # forget requests older
than one window
                if len(self.log) < self.limit:
                    self.log.append(now)
                    return True
                return False

        class SlidingWindowCounter:
            """Two counters per key; estimate = prev * (overlap fraction) + curr."""
            def __init__(self, limit, window):
                self.limit, self.window = limit, window
                self.start, self.curr, self.prev = 0.0, 0, 0

            def estimate(self, now):
                start = math.floor(now / self.window) * self.window
                if start != self.start:                      # roll forward
                    gap = round((start - self.start) / self.window)
                    self.prev = self.curr if gap == 1 else 0  # an idle gap > 1 window
empties both
                    self.curr, self.start = 0, start
                overlap = 1.0 - (now - start) / self.window  # share of previous window
still inside
                return self.prev * overlap + self.curr

            def try_acquire(self, now):
                if self.estimate(now) + 1 <= self.limit:     # never let the estimate
```

```
exceed the limit
                    self.curr += 1
                    return True
                return False

        def boundary_burst(limiter):
            """100 requests in the last second of a minute, 100 in the first second of
the next."""
            times = [59 + i / 100 for i in range(100)] + [60 + i / 100 for i in
range(100)]
            return sum(limiter.try_acquire(t) for t in times)

        if __name__ == "__main__":
            L, W = 100, 60.0
            print("Boundary burst (limit 100 per 60 s, 200 requests within 2 s):")
            for name, cls in [("fixed window", FixedWindow), ("sliding log",

                              ("sliding counter", SlidingWindowCounter)]:
                print(f"  {name:16s} admitted {boundary_burst(cls(L, W))}")

            # Worked example of section 22.7: prev = 84, curr = 36, 15 s into the window
            swc = SlidingWindowCounter(L, W)
            swc.start, swc.prev, swc.curr = 60.0, 84, 36
            print(f"\nestimate at t=75 s: {swc.estimate(75.0):.1f}; "
                  f"next two requests: {swc.try_acquire(75.0)},
{swc.try_acquire(75.0)}")

            # Accuracy against the exact sliding log: 4 hours of random traffic
            def worst_window(ts):                           # most admitted requests in
any 60 s span
                best, j = 0, 0
                for i, x in enumerate(ts):
                    while ts[j] <= x - W:
                        j += 1
                    best = max(best, i - j + 1)
                return best

            print("\npattern  RPS  offered  | log: admitted worst60 | counter: admitted
worst60 "
                  "| fixed: admitted worst60")
            for pattern in ("steady", "on/off"):            # on/off: 40 s on, 20 s
silent
                for rate in (1.5, 3.0):
                    rng, times, t = random.Random(42), [], 0.0
                    while t < 4 * 3600:
                        t += rng.expovariate(rate)
                        if pattern == "steady" or int(t // 20) % 3 != 2:
                            times.append(t)
                    row = []
                    for cls in (SlidingLog, SlidingWindowCounter, FixedWindow):
                        lim = cls(L, W)
                        ok = [x for x in times if lim.try_acquire(x)]
                        row.append(f"{len(ok):>6} {worst_window(ok):>4}")
                    print(f"{pattern:7s} {rate:4.1f} {len(times):>8}  |  " + "      |
".join(row))
```

```
            assert boundary_burst(FixedWindow(L, W)) == 200
            assert boundary_burst(SlidingLog(L, W)) == 100
```

Output:

```
Boundary burst (limit 100 per 60 s, 200 requests within 2 s):
  fixed window     admitted 200
  sliding log      admitted 100
  sliding counter  admitted 101

estimate at t=75 s: 99.0; next two requests: True, False

pattern  RPS  offered  | log: admitted worst60 | counter: admitted worst60 | fixed: ad-
mitted worst60
steady   1.5    21574  |   21034  100      |   21166  113      |   21383  115
steady   3.0    43246  |   23726  100      |   23683  105      |   24001  137
on/off   1.5    14342  |   14342   86      |   14339   85      |   14342   86
on/off   3.0    28717  |   23110  100      |   17845  100      |   23929  137
```

What to notice:

- **Boundary burst:** fixed admits 200, log 100, counter 101 (one slips in 0.6 s after the boundary).
- **Steady traffic:** the counter admits within 1% of the log; its worst real 60 s window is 105–113 (5–13% over) versus 137 for the fixed window.
- **Periodic traffic** (40 s on, 20 s off, in step with the window) breaks the uniformity assumption: at 3 RPS the counter admits 23% fewer than the log (17,845 versus 23,110).

INDUSTRY EXAMPLE

Cloudflare's rate limiting. Cloudflare described rate limiting for millions of domains with this two-counter approximation, chosen for its tiny per-key memory; its analysis of 400 million requests from 270,000 sources found 0.003% wrongly allowed or limited [Desgats 2017]. *Evidence: Primary* — [Desgats 2017]

22.7.3 Comparing the algorithms

Table 22.3 — Rate-limiting algorithms compared.

	Token bucket	Leaky bucket (queue)	GCRA (meter)	Fixed window	Sliding log	Sliding counter
What it is	Tokens refill at r up to b	FIFO drained at r	One time-stamp (TAT)	Counter per aligned window	Timestamp per request	Two window counters, weighted
State per key	2 numbers	Queue of up to Q requests	1 number	1 counter	Up to L timestamps	2 counters
Burst behavior	Up to b at once	Absorbs bursts by delaying	Up to b at once	Up to $2L$ across a boundary	Exactly L per window	About L; small overshoot
Accuracy	Exact for its definition	Exact; adds latency	Exact (= to-ken bucket)	Poor at boundaries	Exact	Approximate (uniformity assumption)
Rejects or delays?	Rejects	Delays, drops when full	Rejects	Rejects	Rejects	Rejects
Operational complexity	Low	Medium (queue, timeouts)	Low	Lowest	Medium (memory)	Low
Choose when	API rate plus burst	Downstream needs smooth flow	Minimal shared state	Coarse daily or monthly quotas	Small exact limits	Large-scale per-minute limits

22.8 Distributed rate limiting

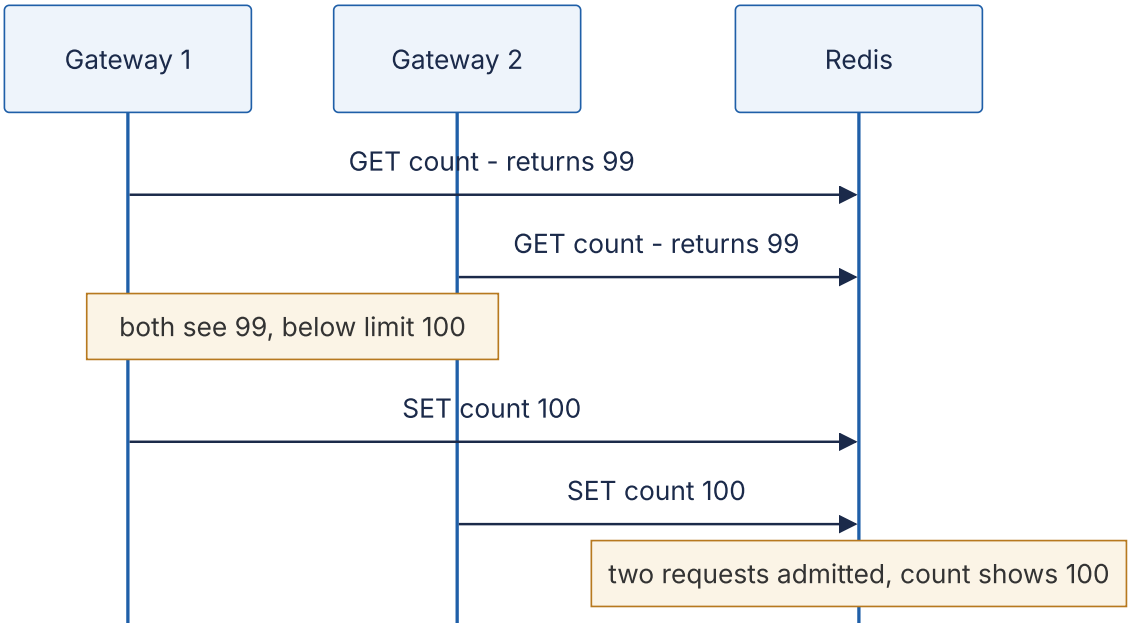
22.8.1 The problem

N gateway nodes must enforce *one* limit per key, but each sees only part of the traffic, rarely split evenly (long-lived connections concentrate a client on few nodes, §19.6), and every coordination step either adds latency or lets counts go stale.

22.8.2 Centralized counters: Redis with Lua

The simplest correct design keeps state in a shared store, usually Redis, partitioned by key. The naive implementation races.

Figure 22.5 — The read-modify-write race in a shared counter.



Reading the diagram. Two gateways issue synchronous `GET`s for the same key, both see 99, both admit and both write 100: the limit is exceeded and the stored count is wrong. The failure point is the gap between read and write, which more nodes and hotter keys widen. The fix moves the decision into the store so read, decide and write are one atomic step.

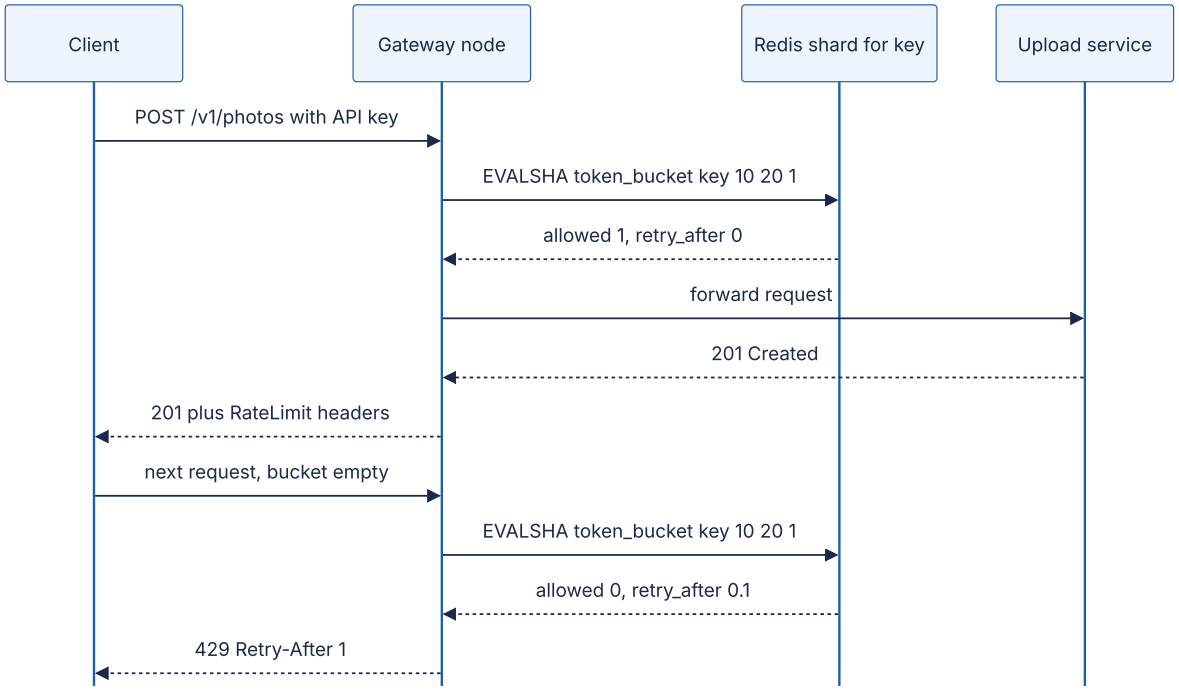
Redis executes a Lua script atomically: no other command runs on that shard while the script executes [Redis Docs: Lua scripting]. The token bucket of §22.4 becomes:

```
        -- Token bucket in Redis. KEYS[1] = bucket key; ARGV = rate (tokens/s), capac-
ity, cost
        local rate     = tonumber(ARGV[1])
        local capacity = tonumber(ARGV[2])
        local cost     = tonumber(ARGV[3])
        local t        = redis.call('TIME')                -- Redis server clock, not
the caller's
        local now      = tonumber(t[1]) + tonumber(t[2]) / 1000000
        local state    = redis.call('HMGET', KEYS[1], 'tokens', 'ts')
        local tokens   = tonumber(state[1]) or capacity     -- unknown key: start with a
full bucket
        local ts       = tonumber(state[2]) or now
        tokens = math.min(capacity, tokens + math.max(0, now - ts) * rate)
        local allowed, retry_after = 0, 0
        if tokens >= cost then
          tokens, allowed = tokens - cost, 1
        else
          retry_after = (cost - tokens) / rate
        end
        redis.call('HSET', KEYS[1], 'tokens', tokens, 'ts', now)
        redis.call('PEXPIRE', KEYS[1], math.ceil(capacity / rate * 1000) + 1000)  --
idle keys vanish
        return {allowed, tostring(retry_after)}            -- Lua numbers would be trun-
cated to integers
```

What to notice:

- Tested on Redis 7.0: 50 pipelined `EVALSHA` calls on a fresh key (`10 20 1`) returned 20 admits and 30 rejections.
- `TIME` uses the server's clock, so skewed gateway clocks (§24.9) cannot corrupt buckets; Redis 5+ replicates script *effects*, which makes this safe.
- Idle keys expire. In Redis Cluster all keys a script touches must share a shard (use a hash tag such as `{tenant42}`).

Figure 22.6 — Centralized rate limiting with an atomic script.



Reading the diagram. The gateway makes one synchronous round trip to the Redis shard owning the key (§14.8); the script runs atomically and returns a decision and retry hint. Admitted requests go to the upload service; rejected ones get 429 without touching it. The Redis shard is the storage boundary; failover may reset some buckets (usually acceptable). Failure points: Redis latency on every request, a failed shard blocking its keys, and hot keys. Scaling: add shards; pre-aggregate hot keys locally (§22.8.3).

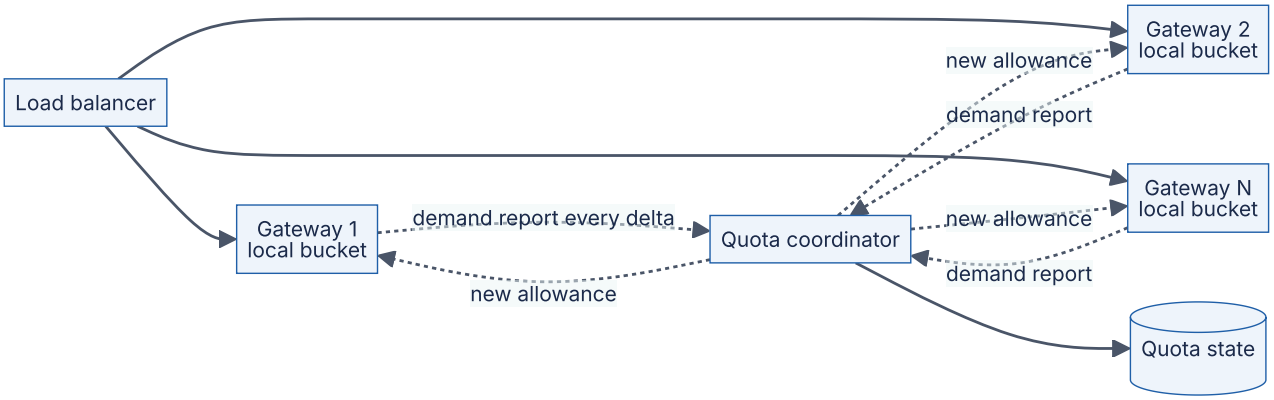
22.8.3 Local counting with synchronization, and quota distribution

Two families avoid a remote call on every request.

1. **Local counting with periodic synchronization.** Nodes count locally and exchange counts every Δ seconds, deciding in between on a stale global view.
2. **Quota distribution (leases).** A coordinator divides the limit into per-node allowances in proportion to recent demand, re-divided periodically; nodes enforce them with local buckets. Gateways offer related building blocks: Envoy, for example,

supports an external global rate-limit service and a local token-bucket filter [Envoy Docs: rate limiting].

Figure 22.7 — Local enforcement with synchronization or quota leases.



Reading the diagram. Each gateway decides synchronously against a local bucket, so the request path has no remote call. Asynchronously (dotted), nodes report demand to a coordinator, which persists state and pushes back allowances summing to the global limit (in the sync variant, nodes exchange counts instead). Failure points: an unreachable coordinator leaves nodes on their last allowance; allowances lag demand by one period. Scaling: coordination grows with N per period, not with request rate.

Mathematical foundations

FORMULA

Overshoot of local counting with synchronization interval Δ

$$E_{\max} \approx \lambda \cdot \Delta \qquad M_{\text{sync}} = \frac{N(N-1)}{\Delta} \text{ (all-to-all)} \quad \text{or} \quad \frac{2N}{\Delta} \text{ (via a store or coordinator)}$$

Symbol	Meaning	Units
$E_{\max}$	Worst-case requests admitted beyond the limit per window	requests
λ	Offered rate for the key across all nodes	requests/s
Δ	Synchronization interval	s
N	Number of gateway nodes	nodes
M_{sync}	Coordination messages per second (each message can carry all keys)	messages/s

WORKED EXAMPLE

Worked example — 10 gateways, limit 1,000 requests/s for one tenant, offered 3,000 RPS.

1. $\Delta = 100$ ms: $E_{\max} \approx 3,000 \times 0.1 = 300$ excess requests per second, up to 30% over. Messages: $10 \times 9/0.1 = 900$/s all-to-all.
2. $\Delta = 10$ ms: $E_{\max} \approx 30$ (3%); messages $= 9,000$/s.
3. Centralized Redis: zero overshoot, but one round trip per request: 3,000 Redis calls/s for this tenant alone, and roughly 0.2–1 ms added to each request inside a datacenter (§7.15).
4. Simulation (below): with $\Delta = 100$ ms the measured overshoot averages 147/s (bound 300); with $\Delta = 10$ ms, 9.5/s (bound 30).

Interpretation. Accuracy, latency and coordination traffic form a triangle; pick two.
Engineering implication. Centralize contractual limits on costly operations; use local-plus-sync or quotas on hot paths where a few percent of overshoot is harmless.

Code example: a Redis-free simulation

```
        """Simulate one tenant's global limit of 1,000 requests per 1-second window, en-
forced by
        10 gateway nodes that receive skewed traffic. No Redis needed: the 'central
store' is a dict."""
        import random

        LIMIT, NODES, SECONDS = 1000, 10, 20
        WEIGHTS = [0.5] + [0.5 / 9] * 9                # node 0 gets half the tenant's
traffic

        def arrivals(offered_rps, seed=1):
            rng, events = random.Random(seed), []
            for node, w in enumerate(WEIGHTS):
                t = 0.0
                while True:
                    t += rng.expovariate(offered_rps * w)
                    if t >= SECONDS:
                        break
                    events.append((t, node))
            return sorted(events)

counting does not
```

Output:

```
Offered 1500 RPS, global limit 1000/s, 10 nodes, node 0 gets 50%
static split (L/N each)    mean   840.1/s  max   895  coordination msgs/s         0
centralized counter        mean  1000.0/s  max  1000  coordination msgs/s      1495
local + sync every 100 ms  mean  1041.2/s  max  1079  coordination msgs/s       896
local + sync every 10 ms   mean  1005.5/s  max  1010  coordination msgs/s      8996
demand-weighted quotas     mean   995.4/s  max   997  coordination msgs/s        19

Offered 3000 RPS, global limit 1000/s, 10 nodes, node 0 gets 50%
static split (L/N each)    mean  1000.0/s  max  1000  coordination msgs/s         0
centralized counter        mean  1000.0/s  max  1000  coordination msgs/s      2979
local + sync every 100 ms  mean  1147.4/s  max  1170  coordination msgs/s       896
local + sync every 10 ms   mean  1009.5/s  max  1020  coordination msgs/s      8996
demand-weighted quotas     mean   994.5/s  max   996  coordination msgs/s        19
```

What to notice:

- **Static split under-admits under skew:** at 1,500 RPS the tenant gets only 840/s because node 0 sees 750 RPS but may admit 100.
- **Synchronization overshoots** in proportion to Δ, within $\lambda\Delta$.
- **Quotas** are accurate with 19 messages/s only because demand is stationary.

22.8.4 Comparison

Table 22.4 — Distributed rate-limiting strategies.

Strategy	Added latency	Accuracy	Coordination cost	Failure behavior	Choose when
Static split L/N	None	Under-admits with skewed traffic	None	Independent	Even traffic, rough limits
Centralized (Redis + Lua)	One round trip per request	Exact	One call per request	Store outage blocks the decision	Contractual or costly limits
Local + periodic sync	None	Overshoot up to $\lambda\Delta$	$O(N^2/\Delta)$ or $O(N/\Delta)$	Stale but working	Very high rates, tolerant limits
Quota distribution (leases)	None	Exact sum; lags demand shifts	$O(N/\Delta)$	Keeps last allowance	Large fleets, stable demand
Hybrid: local bucket batches reservations from a central store	Rare round trips	Bounded by batch size	One call per batch	Degrades to local	Hot keys at very high rates

22.8.5 Failure scenarios

Table 22.5 — Distributed limiter failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
All requests fail when Redis is down	Limiter fails *closed*	Limiter error spike	Fail open with local limits	Per limit: open for quotas, closed for login limits
One shard at 100% CPU	Hot key (one huge tenant)	Per-shard skew	Split key or pre-aggregate locally	Hot-key detection (§17.6, §20.15)
Buckets drift	Gateway clocks skewed	Inconsistent `Retry-After`	Server-side time	Redis `TIME`
Limiter adds p99 latency	Remote call per request	Gateway p99 tracks Redis p99	Short limiter timeout, then fail open	Cache “deny” until `Retry-After`

22.9 Throttling and load shedding

22.9.1 Goodput and overload

DEFINITION

Definition — Load shedding and throttling. Load shedding is a server rejecting some requests early and cheaply (usually with 503) because accepting them would push it past capacity, regardless of whether each client is within its quota. **Throttling** is slowing a client down, by delaying or rejecting its requests; rate limiting is the quota-based form. **Goodput** is the rate of requests completed *usefully*: correctly and before the client gave up.

A kitchen that accepts every order on a busy night serves every dish late; diners leave before food arrives, so it works flat out producing nothing useful. Turning new arrivals away keeps the seated diners served. The AWS Builders' Library describes this failure: once latency exceeds client timeouts, a server can run at maximum throughput while goodput falls toward zero [Yanacek: load shedding].

FORMULA

Time until goodput collapses without shedding

$$q(t) = (\lambda - \mu)\,t, \qquad w(t) = \frac{q(t)}{\mu}, \qquad t_{\text{collapse}} = \frac{\mu\, T_{\text{out}}}{\lambda - \mu} \quad (\lambda > \mu)$$

Symbol	Meaning	Units
λ	Offered request rate	requests/s
μ	Server capacity (maximum completion rate)	requests/s
$q(t)$	Queue length after t seconds of overload (unbounded FIFO)	requests
$w(t)$	Queueing delay seen by a request arriving at t	s
T_{out}	Client timeout	s
t_{collapse}	Time after which every completed request is already too late	s

WORKED EXAMPLE

Worked example — PhotoShare upload service, $\mu = 1,000$ RPS, clients time out after 1 s, a spike brings $\lambda = 1,500$ RPS.

1. The queue grows at $1,500 - 1,000 = 500$ requests per second.
2. $t_{\text{collapse}} = 1,000 \times 1/500 = 2$ s. After two seconds the queue holds 1,000 requests and every new request waits 1 s, the full timeout.
3. From then on the server still completes 1,000 requests/s, but goodput is roughly zero. Worse, clients retry, raising λ further (§22.12).
4. With shedding (a queue bounded at 200 requests, i.e. at most $200/1,000 = 200$ ms of waiting), the server rejects the excess 500 RPS in microseconds and goodput stays at 1,000 RPS.

Interpretation. Unbounded queueing turns a 50% overload into a total outage in two seconds. **Engineering implication.** Bound queues by *time*, and make rejection far cheaper than service.

22.9.2 Priority-based shedding

An upload or checkout matters more than a recommendations prefetch. **Priority-based shedding** tags each request with a **criticality** class at the edge, propagates it, and sheds the lowest class first. Google's SRE book describes four classes: `CRITICAL_PLUS`, `CRITICAL`, `SHEDDABLE_PLUS` and `SHEDDABLE`, propagated automatically with RPCs [Beyer et al. 2016, ch. 21]. Stripe's worker-utilization load shedder similarly sheds test-mode and other lower-priority traffic before critical API methods [Tarjan 2017].

Clients can shed too. In the SRE book's **client-side adaptive throttling**, each client tracks requests sent and accepted over the last two minutes and drops requests locally as rejections grow.

FORMULA

Client-side adaptive throttling (Google SRE)

$$P_{\text{reject}} = \max\left(0, \frac{\text{requests} - K \cdot \text{accepts}}{\text{requests} + 1}\right)$$

Symbol	Meaning	Units
requests	Requests the client attempted in the recent window	count
accepts	Requests the backend accepted (did not reject for overload)	count
K	Multiplier; how many requests per accept the client may still send (typically 2)	dimensionless
P_{reject}	Probability the client rejects a new request locally, without sending it	dimensionless

WORKED EXAMPLE

Worked example — A client in a two-minute window sent 10,000 requests and 4,000 were accepted, $K = 2$.

1. $K \times \text{accepts} = 8,000$.
2. $P_{\text{reject}} = (10,000 - 8,000)/10,001 = 0.20$.
3. The client now drops 20% of new requests locally at zero network cost. If the backend recovers and accepts everything, $\text{requests} < 2 \times \text{accepts}$ and P_{reject} returns to 0.

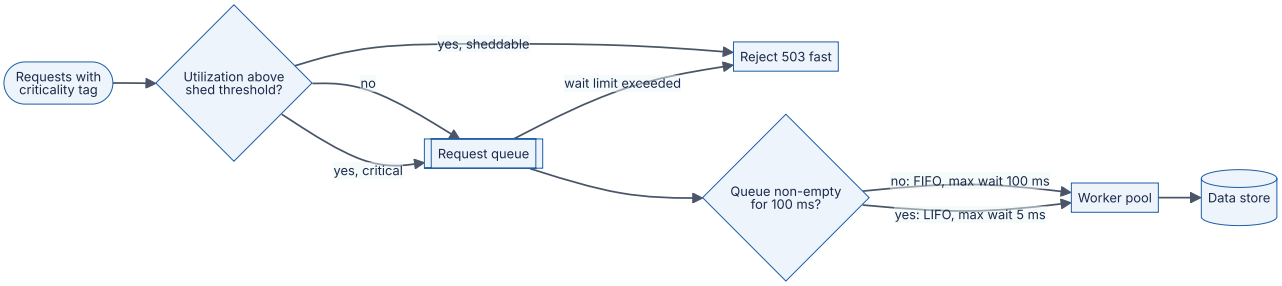
Interpretation. The client sends about K times what the backend accepts, enough to detect recovery. **Engineering implication.** Lower K sheds harder but recovers slower; $K = 2$ is a sensible default.

22.9.3 Controlling queue delay: CoDel and adaptive LIFO

Queue *length* is a poor overload signal; queue *delay* is better. **CoDel** (Controlled Delay), designed by Nichols and Jacobson for network routers, watches the time packets spend in the queue (their *sojourn time*). If the *minimum* sojourn time over an interval (100 ms by default) stays above a target (5 ms), the queue is a standing queue rather than a passing burst, and CoDel starts dropping, with the gap between drops shrinking as $\text{interval}/\sqrt{n}$ for the n-th drop: 100 ms, 70.7 ms, 57.7 ms, 50 ms, until the delay falls below target [Nichols and Jacobson 2012].

Facebook adapted this to RPC queues with **adaptive LIFO** [Maurer 2015]: when the queue has not been empty for *N* ms (100 ms), requests may wait at most *M* ms (5 ms), and the queue switches to **LIFO**, because the newest request's client is the one most likely still waiting.

Figure 22.8 — Overload control at a service: priority shedding and an adaptive queue.



Reading the diagram. Requests carry a criticality tag. Above a utilization threshold, sheddable requests get a fast 503 while critical ones are queued. The queue is FIFO while it drains regularly and LIFO with a 5 ms wait limit once it has stayed non-empty for 100 ms; requests over their limit are rejected. Workers call the data store synchronously. Failure points: tagging everything critical, or a threshold above where latency explodes. Scaling: all controls are per instance.

COMMON MISTAKE

Mistake — "Autoscaling makes load shedding unnecessary." Instances take minutes to start; a queue passes client timeouts in seconds (§22.9.1). You need both.

22.10 Backpressure

DEFINITION

Definition — Backpressure. A flow-control mechanism in which a slower downstream component signals upstream components to reduce their sending rate, by blocking, by advertising available capacity, or by rejecting, so that work in progress stays bounded instead of piling up in unbounded buffers.

When a packing station falls behind, the assembly line stops feeding it rather than heaping goods on the floor (an unbounded queue). Backpressure is that stop signal traveling upstream.

TCP is the canonical example (§7.7.6): when the receiver stops reading, its advertised window drops to zero and the sender's `write()` blocks. Systems break the chain by in-

serting **unbounded** buffers (a list a handler appends to, a task per message), turning backpressure into memory growth and latency.

Three rules give you backpressure at the application level:

1. **Bound every queue,** and size the bound from the latency you can tolerate, not from available memory (formula below).
2. **Decide what happens when it is full:** block the producer (pipelines inside one process), reject (request/response APIs: 503 or 429), or drop the oldest or least important (telemetry, video frames).
3. **Signal demand explicitly across asynchronous boundaries.** The **Reactive Streams** specification standardizes this for asynchronous stream libraries on the JVM: a subscriber calls `request(n)` to say it can accept *n* more items, and a publisher may never send more than has been requested [Reactive Streams 2015]. Java 9's `java.util.concurrent.Flow` adopted the same interfaces, and gRPC and HTTP/2 use per-stream flow-control windows for the same purpose.

Figure 22.9 — Backpressure through a processing pipeline.

Reading the diagram. Items flow left to right through bounded in-memory buffers (100 items) to a sink that writes to a database. Demand flows right to left as asynchronous `request(n)` signals (dotted). If the database slows, the sink requests less, buffers fill, and the producer stops being asked, so at most about 200 items are in flight. Failure point: any component accepting data without demand. Scaling: add parallel sinks; demand rises automatically.

FORMULA

Bounding a queue by time (Little's Law)

$$Q_{\max} = \mu \times D_{\text{queue}}$$

Symbol	Meaning	Units
$Q_{\max}$	Maximum queue length	items
μ	Rate at which the consumer drains the queue	items/s
D_{queue}	Maximum acceptable time an item may wait in the queue	s

WORKED EXAMPLE

Worked example — Sizing the upload service's request queue. Consider a single upload cell (half the fleet of §22.9's example) whose workers complete $\mu = 500$ requests/s; the gateway's timeout leaves at most 200 ms for queueing.

1. $Q_{max} = 500 \times 0.2 = 100$ requests.
2. A request arriving behind 100 others waits $100/500 = 0.2$ s, the full budget; request 101 should be rejected immediately rather than queued to time out.
3. If workers slow to $\mu = 250$/s (a slow database), the same 100-item queue now means 400 ms of waiting. Bound queues by *measured wait time* (as CoDel does) rather than by item count when service time varies.

Interpretation. A queue longer than $\mu\times$ timeout holds only doomed requests. **Engineering implication.** Framework default queue sizes are usually far too large for interactive services.

22.11 Timeouts and deadlines

DEFINITION

Definition — Timeout and deadline. A **timeout** is a relative duration after which a caller stops waiting for one operation (for example 300 ms). A **deadline** is an absolute point in time by which the *whole* request must complete; it is passed along the call chain so that every downstream call knows how much time remains.

Without a timeout, a caller waits forever on a hung dependency, holding a thread and a connection; by Little's Law (§4.11) held resources grow until the caller itself stops. Every network call needs connect and request timeouts.

Choosing a timeout. Set it from the dependency's measured latency distribution, not from intuition. The AWS Builders' Library recommends choosing an acceptable rate of false timeouts (for example 0.1%) and using the corresponding latency percentile (p99.9) of the downstream service, plus padding for network variance [Brooker: timeouts and retries].

Why deadlines must propagate. Suppose each hop independently uses a 1 s timeout. The user's app gives up after 1 s, but a service three hops down started 600 ms late and keeps working for its full second, then the database query beneath it keeps running too. All of that work is wasted. With **deadline propagation**, the edge sets an absolute deadline and each hop passes the *remaining* time downstream; gRPC does this automatically, sending the remaining time in the `grpc-timeout` header and failing calls with `DEADLINE_EXCEEDED` once it passes [gRPC Docs: deadlines]. Over HTTP you carry it in a

header of your own. Each service should check the remaining budget before starting expensive work and refuse work it cannot finish in time [Beyer et al. 2016, ch. 22].

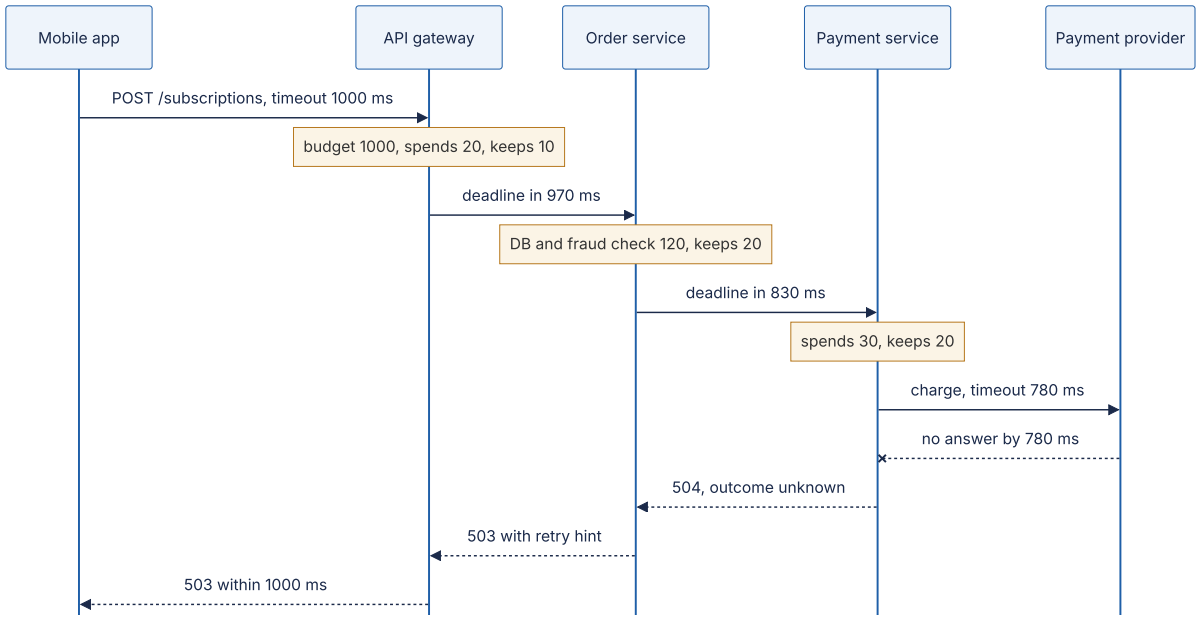
FORMULA

Timeout budget along a call chain

$$B_{i+1} = B_i - e_i - m_i, \qquad \text{start the call only if } B_{i+1} > \hat{s}_{i+1}$$

Symbol	Meaning	Units
B_i	Remaining budget when hop i receives the request	ms
e_i	Time hop i spends before calling hop $i+1$ (local work, earlier calls)	ms
m_i	Margin hop i reserves to build and return its own response	ms
B_{i+1}	Budget passed to hop $i+1$	ms
$\hat{s}_{i+1}$	Typical latency of hop $i+1$ (for example its p50)	ms

Figure 22.10 — Deadline propagation through the PhotoShare Pro purchase path.



Reading the diagram. The app waits at most 1,000 ms. Each hop subtracts elapsed time and a response margin before passing the budget on: 970, 830, then 780 ms for the external provider. All calls are synchronous. When the provider misses its budget, the payment service reports an *unknown outcome*, and every hop still has its margin to answer before the app gives up. The provider's state is the critical storage boundary, which is why re-

tries need an idempotency key (§22.15). Budgets are per request and need no shared state.

WORKED EXAMPLE

Worked example — Budget for the purchase path, client deadline 1,000 ms.

1. Gateway: $B_1 = 1,000$; $e_1 = 20$ (authentication, rate-limit check), $m_1 = 10 \rightarrow B_2 = 970$ ms.
2. Order service: $e_2 = 120$ (database read, fraud check), $m_2 = 20 \rightarrow B_3 = 830$ ms.
3. Payment service: $e_3 = 30$, $m_3 = 20 \rightarrow B_4 = 780$ ms for the provider call. The provider's p50 is 300 ms and p99.9 is 900 ms, so $B_4 > \hat{s}_4$ and the call starts.
4. Contrast with fixed per-hop timeouts of 1 s, 1 s and 2 s: when the provider hangs, the payment service, which started the call at 170 ms, waits until 2,170 ms: 1,170 ms after the app has given up; every thread on the path is held for work nobody receives.

Interpretation. The provider gets 78% of the user's budget, the most that is consistent with the earlier hops. **Engineering implication.** Propagate absolute deadlines (or remaining durations), subtract as you go, and make inner timeouts shorter than outer ones. Note the provider's p99.9 (900 ms) exceeds its budget, so roughly 0.1–1% of purchases will hit the deadline; either raise the client budget or make the purchase asynchronous (accept with 202 and confirm by push).

COMMON MISTAKE

Mistake — "A timeout means the operation failed." It means *you do not know*. The request may never have arrived, may have failed, or may have succeeded with the response lost. For reads this ambiguity is harmless; for writes it is the central problem that idempotency keys solve (§22.15).

22.12 Retries with exponential backoff and jitter

22.12.1 When to retry

Retries turn transient failures (lost packets, restarts, elections) into successes, but each is *extra load on a system that just failed*. Retry only when all hold:

1. The error is **retryable**: timeouts, connection resets, 429, 502, 503, 504, gRPC `UNAVAILABLE`. Never retry 400, 401, 403, 404 or 422; they will fail again.
2. The operation is **idempotent** or carries an idempotency key (§22.15).
3. **Time remains** in the deadline (§22.11).

4. The **retry budget** is not exhausted (§22.12.4).

22.12.2 Exponential backoff and jitter

Exponential backoff doubles the wait after each failure, up to a cap. Clients that failed together still retry in synchronized waves; **jitter** randomizes the wait to spread them. Brooker's analysis for the AWS Architecture Blog compared three variants [Brooker 2015]:

FORMULA

Backoff with jitter (attempt $k = 1, 2, \ldots$)

$$s_k = \min(\text{cap}, \text{base} \cdot 2^k)$$

full: $U(0, s_k)$ equal: $\frac{s_k}{2} + U(0, \frac{s_k}{2})$ decorrelated: $\min(\text{cap}, U(\text{base}, 3 w_{k-1}))$

Symbol	Meaning	Units
k	Retry number	count
base	Initial backoff unit	ms
cap	Maximum wait	ms
s_k	Exponential backoff ceiling for retry k	ms
$U(a, b)$	A uniformly random value between a and b	ms
w_{k-1}	The previous wait for decorrelated jitter ($w_0 = \text{base}$)	ms

WORKED EXAMPLE

Worked example — base 100 ms, cap 20 s.

1. Ceilings s_k for $k = 1…8$: 200, 400, 800, 1,600, 3,200, 6,400, 12,800, 20,000 (capped) ms.
2. Full jitter at $k = 3$: a wait anywhere in 0–800 ms, mean 400 ms. Equal jitter: 400–800 ms, mean 600 ms.
3. Cumulative worst-case wait before the 5th retry with full jitter: $200 + 400 + 800 + 1,600 + 3,200 = 6,200$ ms, so five retries do not fit a 1 s user deadline; they fit a background job.

Interpretation. Exponential growth reaches the cap quickly; jitter decides how evenly clients are spread within each ceiling. **Engineering implication.** For interactive requests, one or two retries with small bases are all the deadline allows; long backoff sequences belong to asynchronous work.

Code example: measuring contention

The simulation has N clients each needing one successful write to a contended resource with optimistic concurrency: a write conflicts and fails if another started less than 1 ms earlier. All clients begin within the same millisecond, as after a brief outage.

```
        """N clients each need one successful write to a contended resource (optimistic
        concurrency: if another write started less than WORK ms earlier, this one con-
flicts).
        Compare backoff strategies by total calls (work) and time until every client
succeeds."""
        import heapq
        import random

        BASE, CAP, WORK = 5.0, 2000.0, 1.0              # milliseconds

        def no_jitter(attempt, prev, rng):
            return min(CAP, BASE * 2 ** attempt)

        def full_jitter(attempt, prev, rng):
            return rng.uniform(0, min(CAP, BASE * 2 ** attempt))

        def equal_jitter(attempt, prev, rng):
            v = min(CAP, BASE * 2 ** attempt)
            return v / 2 + rng.uniform(0, v / 2)

        def decorrelated_jitter(attempt, prev, rng):
            return min(CAP, rng.uniform(BASE, prev * 3))

        def simulate(strategy, clients, seed, max_attempts=200):
            rng = random.Random(seed)
            # every client makes its first call within the same 1 ms (a synchronized
wave)
            queue = [(rng.uniform(0, 1.0), c, 0, BASE) for c in range(clients)]
            heapq.heapify(queue)
            busy_until, calls, finish = -1.0, 0, 0.0
            while queue:
                t, c, attempt, prev = heapq.heappop(queue)
                calls += 1
                if t >= busy_until:                     # no conflicting write in
flight: success
                    busy_until, finish = t + WORK, t
                elif attempt + 1 < max_attempts:        # conflict: back off and try
again
                    sleep = strategy(attempt + 1, prev, rng)
                    heapq.heappush(queue, (t + WORK + sleep, c, attempt + 1, sleep))
            return calls, finish

        if __name__ == "__main__":
            strategies = [("exponential, no jitter", no_jitter), ("full jitter",
full_jitter),
                          ("equal jitter", equal_jitter), ("decorrelated jitter",
decorrelated_jitter)]
            seeds = range(20)
            for n in (25, 100):
                print(f"{n} clients (mean of {len(seeds)} runs)     calls   calls/client
time to finish")
                results = {}
                for name, fn in strategies:
```

```
                    runs = [simulate(fn, n, s) for s in seeds]
                    calls = sum(r[0] for r in runs) / len(runs)
                    finish = sum(r[1] for r in runs) / len(runs)
                    results[name] = calls
                    print(f"  {name:24s} {calls:8.0f}   {calls / n:10.1f}
{finish:10.0f} ms")
                print()
                assert results["full jitter"] < results["exponential, no jitter"] / 3
```

Output:

```
25 clients (mean of 20 runs)     calls   calls/client   time to finish
  exponential, no jitter        325         13.0        34575 ms
  full jitter                    76          3.1           93 ms
  equal jitter                   83          3.3          139 ms
  decorrelated jitter            73          2.9          108 ms

100 clients (mean of 20 runs)     calls   calls/client   time to finish
  exponential, no jitter       5050         50.5       184650 ms
  full jitter                   459          4.6          498 ms
  equal jitter                  475          4.8          636 ms
  decorrelated jitter           450          4.5          406 ms
```

What to notice:

- **Without jitter, contention is quadratic.** The clients stay synchronized forever, so each wave lets exactly one through: $100 + 99 + \ldots + 1 = 5,050$ calls, and the last client finishes after three minutes because waits hit the 2 s cap.
- **Any jitter cuts work by 11×** (5,050 → about 460 calls) and completion time by over 300×. Full and decorrelated jitter are slightly better than equal jitter, matching Brooker's qualitative result; the exact numbers depend on the model.

22.12.3 Retry storms and amplification

Figure 22.11 — Retry amplification in a four-layer call graph.

Reading the diagram. Each layer, reasonably in isolation, makes up to three attempts. When the database fails every call, attempts multiply synchronously down the chain: 3, 9, 27, then 81 calls at the database, aimed precisely at the failing component: a **retry storm**. The fix is structural: retry at one layer, cap retries with budgets, and stop when a circuit breaker opens (§22.13).

FORMULA

Retry amplification

$$A = \prod_{i=1}^{d} a_i = a^d \text{ (identical layers)}, \qquad \mathbb{E}[\text{attempts per layer}] = \sum_{j=0}^{a-1} p^j = \frac{1-p^a}{1-p}$$

Symbol	Meaning	Units
A	Worst-case calls reaching the bottom layer per user request	calls
a_i	Maximum attempts (1 + retries) at layer i	attempts
d	Number of layers that retry	layers
p	Probability that one attempt fails ($p < 1$)	dimensionless

WORKED EXAMPLE

Worked example — 10,000 user RPS through four retrying layers.

1. Database hard down ($p = 1$): $A = 3^4 = 81$; the database receives $10,000 \times 81 = 810,000$ RPS of doomed calls.
2. Database partly overloaded, $p = 0.5$: expected attempts per layer $= (1 - 0.5^3)/(1 - 0.5) = 1.75$; if failures compound through layers, the multiplier approaches $1.75^4 \approx 9.4$, a 9× load increase on a system already failing half its calls.
3. Retry only at the SDK: $A = 3$, so 30,000 RPS at worst.
4. Retry budget of 10% at every layer: each layer adds at most 10%, so $A \le 1.1^4 = 1.46$, about 14,600 RPS.

Interpretation. Per-layer retries look harmless locally but compound exponentially with depth. **Engineering implication.** Retry at one layer, or bound retries by a budget that is a fraction of normal traffic; never let every layer retry independently.

22.12.4 Retry budgets

A **retry budget** caps retries as a fraction of successful or total requests, rather than per request. Google's SRE book describes a per-request limit (at most three attempts) combined with a per-client budget (retries no more than 10% of requests) [Beyer et al. 2016, ch. 21]. A simple implementation is a token bucket for retries: each success deposits 0.1 token, each retry spends 1, and when the bucket is empty the error is returned to the caller without a retry. When the dependency is healthy, occasional retries always find tokens; when it fails broadly, retries are limited to 10% extra load. The AWS SDKs implement a comparable client-side retry quota, and Envoy offers a retry budget expressed as

a percentage of active requests [AWS SDK Docs: retry behavior; Envoy Docs: retry budgets].

INDUSTRY EXAMPLE

AWS guidance on retries. The Builders' Library article on timeouts and retries recommends capped exponential backoff with jitter, retrying at a single point in the stack, local retry limits implemented with a token bucket so that retries stop when most calls fail, and treating timeouts as signals to be measured; it also warns that retries are "selfish": they spend server resources to raise one client's chance of success [Brooker: timeouts and retries]. *Evidence: Primary* — [Brooker: timeouts and retries]

Table 22.6 — Retry failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Outage worsens as clients retry	Every layer retries; no budget	Request rate rises while success rate falls	Disable retries via configuration; open breakers; shed	One retrying layer, budgets, jitter
Synchronized retry waves every few seconds	Backoff without jitter; reconnect after a shared failure	Periodic spikes at backoff intervals	Add jitter, server-side shedding	Full or decorrelated jitter (§9.9 reconnect storms)
Duplicate side effects	Retried non-idempotent `POST` after a timeout	Duplicate rows seconds apart	Reconcile and refund	Idempotency keys (§22.15)
Retries outlive the user	Retry delays ignore the deadline	Work completing after client timeout	Check remaining budget before retrying	Deadline propagation (§22.11)

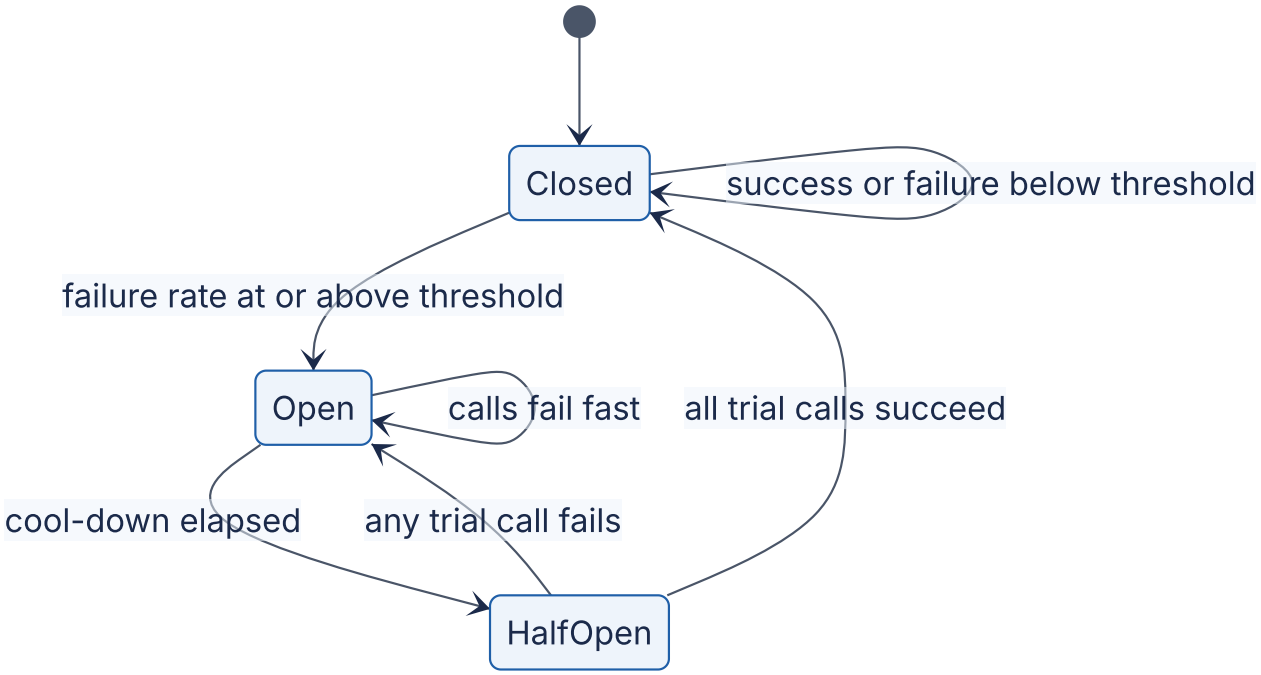
22.13 Circuit breakers

DEFINITION

Definition — Circuit breaker. A client-side proxy for calls to a dependency that tracks recent failures and, when they cross a threshold, **opens**: it fails calls immediately without contacting the dependency for a cool-down period, then lets a few trial calls through (**half-open**) and **closes** again only if they succeed.

An electrical circuit breaker cuts power when current is dangerous, so a fault in one appliance does not burn down the house; you reset it once the fault is fixed. The software version, popularized by Nygard's *Release It!* [Nygard 2018] and Fowler's description [Fowler 2014], protects two parties: the *caller*, which stops tying up threads waiting on a dead dependency, and the *dependency*, which gets breathing room to recover instead of a retry storm.

Figure 22.12 — Circuit breaker state machine.



Reading the diagram. In **Closed**, calls pass through and outcomes are recorded in a sliding window (the last *n* calls, or the last *t* seconds). When the window's failure rate reaches the threshold (and a minimum number of calls has been seen), the breaker moves to **Open**, where every call fails immediately with a local error, costing microseconds and no network traffic. After the cool-down, the next caller moves it to **HalfOpen**, where a small fixed number of trial calls reach the dependency; one failure reopens it, success of all trials closes it. Transitions are local to each client instance (no shared storage), so different instances may briefly disagree. Failure points: thresholds set too low trip on normal noise; too high trip only after the damage is done. Fallbacks (cached data, a default, a degraded page) decide what the user sees while open.

Choosing thresholds.

- **Window and minimum volume.** Count-based (last 20–100 calls) or time-based (last 10 s). Require a minimum number of calls so that 2 failures out of 3 at 3 a.m. do not trip it. Netflix's Hystrix library, for example, documented defaults of a 10 s rolling window, a minimum of 20 requests and a 50% error threshold, with a 5 s sleep window [Netflix Hystrix wiki]; Hystrix has been in maintenance mode since 2018, and Resilience4j is a common successor on the JVM.
- **What counts as failure.** Timeouts, connection errors and 5xx, but not 4xx: a client's bad request says nothing about the dependency's health. Slow calls above a latency threshold can also count.
- **Cool-down.** Long enough for typical recovery (seconds to a minute), ideally with jitter so that many instances do not probe in unison.

22.13.1 Implementation and simulation

```
        import time
        from collections import deque

        class CircuitOpenError(Exception):
            """Raised instead of calling the dependency while the breaker is open."""

        class CircuitBreaker:
            def __init__(self, failure_rate=0.5, window=20, open_for=5.0, probes=3,
                         clock=time.monotonic):
                self.failure_rate, self.window = failure_rate, window
                self.open_for, self.probes, self.clock = open_for, probes, clock

            def _record(self, ok):
                now = self.clock()
                if self.state == "half_open":
                    if not ok:                               # dependency still sick:
reopen
                        self.opened_at = now
                        self._move("open")
                    else:
                        self.probe_successes += 1
                        if self.probe_successes >= self.probes:
                            self.results.clear()
                            self._move("closed")
                    return
                self.results.append(ok)
                failures = self.results.count(False)
                if len(self.results) == self.window and failures / self.window >=
self.failure_rate:
```

```
                    self.opened_at = now
                    self._move("open")

            def call(self, fn, *args, **kwargs):
                if not self._allow():
                    raise CircuitOpenError("circuit open")
                try:
                    result = fn(*args, **kwargs)
                except Exception:
                    self._record(False)
                    raise
                self._record(True)
                return result

        if __name__ == "__main__":
            from itertools import count

            class Clock:
                t = 0.0
                def __call__(self):
                    return self.t

            clock = Clock()
            breaker = CircuitBreaker(clock=clock)
            reached = short_circuited = failed = 0

            def dependency():
                global reached
                reached += 1
                if 10.0 <= clock.t < 28.0:                  # outage from t = 10 s to t
= 28 s
                    raise ConnectionError("upstream down")
                return "ok"

            for i in count():                               # 20 requests per second
for 60 s
                clock.t = i * 0.05
                if clock.t >= 60.0:
                    break
                try:
                    breaker.call(dependency)
                except CircuitOpenError:
                    short_circuited += 1
                except ConnectionError:
                    failed += 1

            print(f"requests 1200, reached dependency {reached}, failed {failed}, "
                  f"short-circuited {short_circuited}")
            print("transitions:", breaker.transitions)
            assert breaker.state == "closed" and short_circuited > 350 and failed < 20
```

Output:

```
requests 1200, reached dependency 804, failed 13, short-circuited 396
transitions: [(10.5, 'open'), (15.5, 'half_open'), (15.5, 'open'), (20.5, 'half_open'),
(20.5, 'open'), (25.5, 'half_open'), (25.5, 'open'), (30.5, 'half_open'), (30.6,
'closed')]
```

What to notice:

- The breaker trips 0.5 s into the 18 s outage (10 failures out of the last 20 calls) and probes every 5 s; only 13 calls fail against the dead dependency instead of 360.
- It closes at 30.6 s, 2.6 s after recovery: the cool-down trades recovery speed against probing load.
- Little's Law shows the saving: if each failed call had hung for a 2 s timeout, 360 calls over 18 s would have held $(360/18) \times 2 = 40$ threads continuously; with the breaker, almost none.

COMMON MISTAKE

Mistake — Using a breaker instead of a timeout. A breaker learns only from completed calls. If calls hang with no timeout, nothing is ever recorded as failed and the breaker never opens. Timeouts come first; breakers build on them.

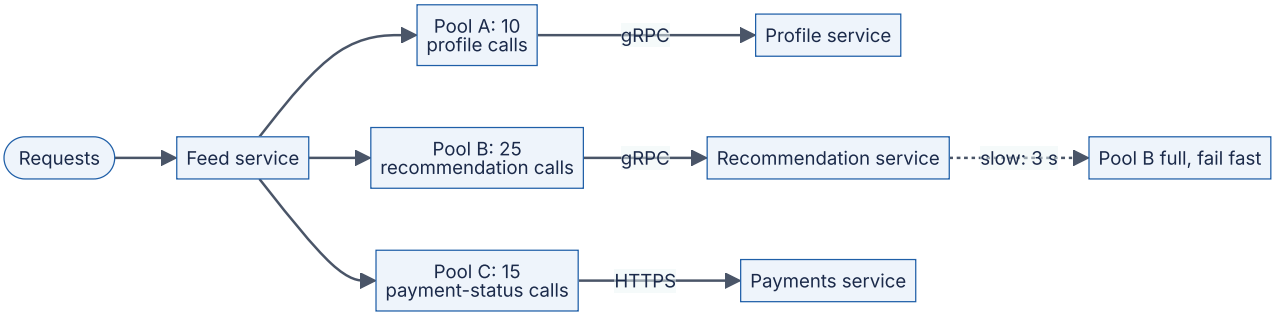
22.14 Bulkheads

DEFINITION

Definition — Bulkhead. Partitioning a service's limited resources (threads, connections, memory, instances) into isolated pools, one per dependency, tenant or workload class, so that exhaustion of one pool cannot starve the others.

A ship's hull is divided into watertight compartments (bulkheads): a breach floods one compartment, not the whole ship [Nygard 2018]. In a service, the classic failure is a shared thread pool: one slow dependency holds every thread, and requests that never touch that dependency also stall. Bulkheads give each dependency its own pool (or a semaphore limiting concurrent calls to it) sized from Little's Law, so that when a pool is full, calls to that dependency are rejected immediately while the rest of the service carries on. The same idea applies at larger scale: separate connection pools per database, separate instance groups for internal and public traffic, and cell-based architectures that confine a failure to one cell of customers (§33.12).

Figure 22.13 — Bulkheads isolating dependencies in the feed service.



Reading the diagram. The feed service makes synchronous calls to three dependencies, each through its own bounded pool of concurrent slots. When the recommendation service slows to 3 s, its 25 slots fill and further calls fail fast (the feed is rendered without recommendations, a graceful degradation), while profile and payment-status calls keep their own slots and continue normally. There is no shared storage between pools. Failure points: pools sized too small reject healthy traffic; too large a sum exhausts the host. Scaling: pools are per instance, so fleet capacity for a dependency is pool size × instances.

WORKED EXAMPLE

Worked example — Sizing the pools with Little's Law ($L = \lambda W$) and 1.5–2× headroom.

1. Profile: 300 RPS × 0.020 s = 6 in flight → pool 10.
2. Recommendations: 100 RPS × 0.150 s = 15 → pool 25.
3. Payment status: 20 RPS × 0.400 s = 8 → pool 15.
4. Incident: recommendations slow to 3 s. Demand becomes $100 \times 3 = 300$ concurrent calls. In a single shared 200-thread pool, all 200 threads would block on recommendations within about 2 s and the whole feed would stop. With bulkheads, the 25 slots stay busy and complete only $25/3 \approx 8$ recommendation calls per second, so about 92 of the 100 per second fail fast (the 275 calls of excess concurrency are never admitted), and profile and payment calls use their own 10 and 15 slots normally.

Interpretation. Bulkheads convert a total outage into a partial degradation.
Engineering implication. Give every remote dependency its own concurrency limit, combine it with timeouts and a breaker, and design the fallback the user sees when the bulkhead rejects.

22.15 Idempotency and idempotency keys

22.15.1 Why retries need idempotency

Section 8.6.3 defined an **idempotent** operation: performing it $N > 0$ times has the same effect as performing it once. `GET`, `PUT` and `DELETE` are idempotent by definition; `POST` and most `PATCH` operations are not. Every technique in §22.11–§22.13 ends in the same place: a client that timed out does not know whether its request took effect, and the only safe way to find out is to send it again. For "create a charge", "send a message" or "place an order", a naive retry can do the thing twice. This chapter owns the deep treatment of how to make such operations safe to retry; Chapters 30 and 32 apply the same idea to message consumers (§32.10).

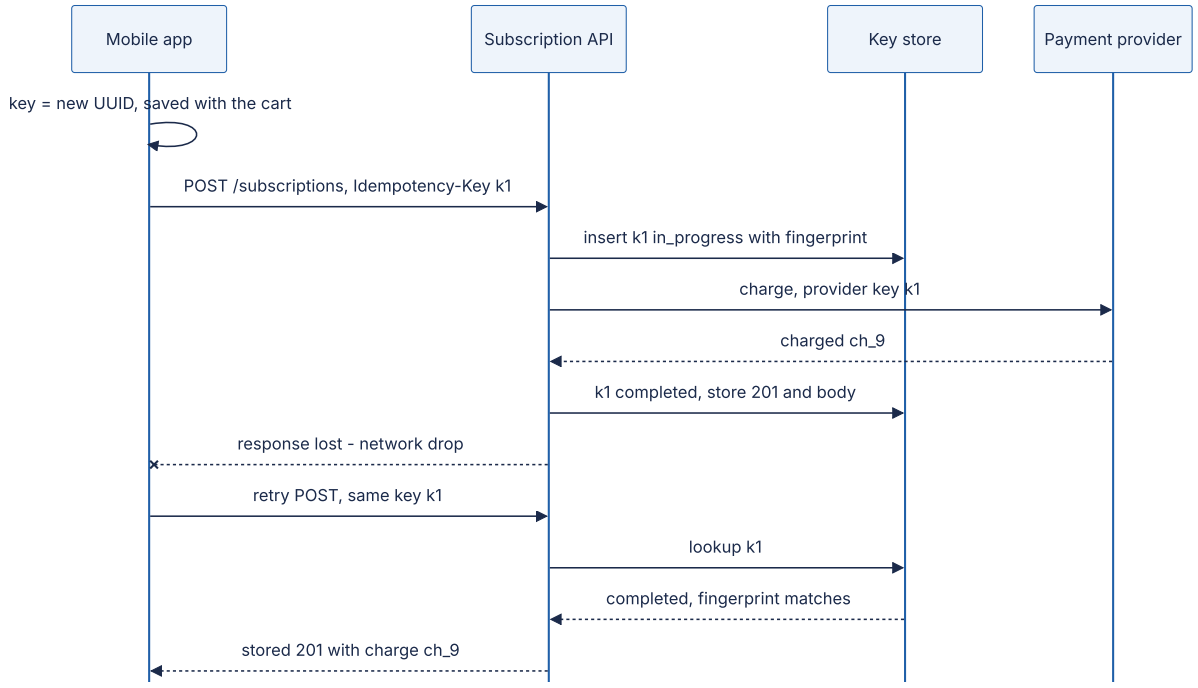
> DEFINITION
>
> **Definition — Idempotency key.** A unique value, generated by the client once per *logical* operation and sent with every attempt of that operation (for example in an `Idempotency-Key` header), that the server uses to recognize retries: the first attempt executes and its result is stored under the key; later attempts with the same key return the stored result instead of executing again.

Think of a cloakroom ticket you write *before* handing over your coat: if unsure the attendant took it, you show the same number again, and the attendant finds ticket 417 already on the rack. The client must choose the key before the first attempt, because it may never see the server's reply.

22.15.2 The protocol

Stripe's API popularized the pattern: clients send an `Idempotency-Key` header (a random V4 UUID is recommended) on `POST` requests, and the server guarantees at-most-once execution per key within a retention window [Leach 2017; Stripe Docs: idempotent requests]. The IETF HTTPAPI working group has an Internet-Draft standardizing the header, *The Idempotency-Key HTTP Header Field* [Jena and Dalal, draft], which, as of its 2025 revision, suggests 409 Conflict when a retry arrives while the original is still being processed and 422 when a key is reused with a different payload; it is a draft, not an RFC.

Figure 22.14 — An idempotent purchase retried after a lost response.



Reading the diagram. The app generates `k1` before the first attempt and persists it with the cart, so even an app restart reuses it. The API records `k1` as in progress in the key store (a table in its own database, the storage boundary), calls the provider with a key derived from `k1`, records the response and replies; the reply is lost. The retry finds a completed record with a matching fingerprint and gets the stored response without a second charge. All calls are synchronous. Failure points: a crash between charge and "completed" write (§22.15.4) and a concurrent retry (the in-progress state). Scaling: partition the key store by account.

22.15.3 Storage, fingerprinting and concurrency

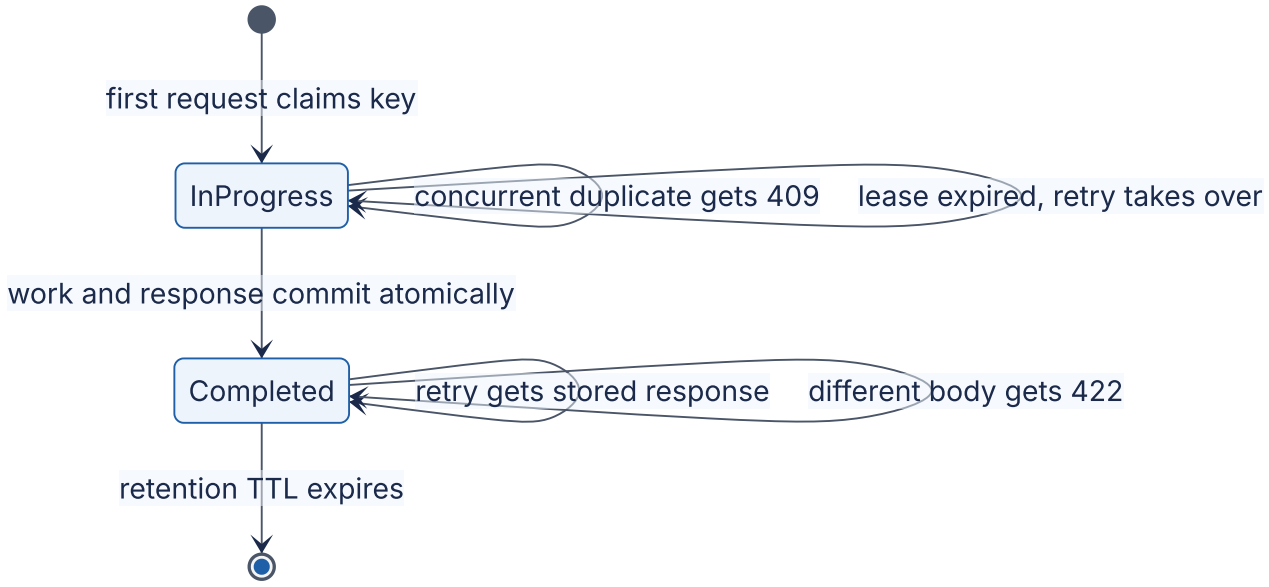
A production idempotency layer must answer five questions.

1. **Scope.** Keys are unique *per client account*, not globally: the primary key is `(account_id, idem_key)`, so one customer cannot collide with, or probe, another's keys.
2. **Fingerprint.** Store a hash of the method, path and canonicalized body. A retry with the same key but a different body is a client bug (or a reused key) and must be rejected (422), not answered with the first request's result.
3. **Concurrency.** Two attempts with the same key can arrive at once (a client that retries before the first attempt times out at the server). Exactly one may execute: insert the key with a uniqueness constraint (`INSERT ... ON CONFLICT DO NOTHING`); the loser receives 409 and retries later.
4. **Crash recovery.** A worker can die after claiming a key. Give the claim a **lease** (`locked_until`); once it expires, a retry may take over. A worker that was merely

slow must not then complete as well, so the final write checks that it still holds its lease, a **fencing token** (§26.13).

5. **Atomicity.** The business write (the charge row) and the "completed" record must commit in the *same* database transaction. Then a crash leaves either both or neither, and a takeover after lease expiry can safely re-execute.

Figure 22.15 — Lifecycle of an idempotency-key record.



Reading the diagram. The first request's insert creates the record **InProgress**, atomically thanks to the uniqueness constraint. Duplicates get 409 while the lease is live; after it expires a retry takes over and the original worker's late completion is fenced off. Work and response commit together into **Completed**; then retries get the stored response and mismatched bodies 422. At TTL expiry the record is deleted and the key would execute again. Storage boundary: one row per key in the business database, which enables the atomic commit.

Code example

```
        import hashlib
        import json
        import sqlite3
        import uuid

        SCHEMA = """
        CREATE TABLE idempotency_keys (
            account_id    TEXT    NOT NULL,
            idem_key      TEXT    NOT NULL,
            fingerprint   TEXT    NOT NULL,          -- hash of method + path + canoni-
cal body
            status        TEXT    NOT NULL,          -- 'in_progress' or 'completed'
            locked_until  REAL,                      -- lease for the worker executing
the request
            response_code INTEGER,
            response_body TEXT,
            created_at    REAL    NOT NULL,
            PRIMARY KEY (account_id, idem_key)       -- keys are scoped to the caller
        );
        CREATE TABLE charges (id TEXT PRIMARY KEY, account_id TEXT, amount INTEGER, cur-
rency TEXT);
        """

        def fingerprint(method, path, body):
            canonical = json.dumps(body, sort_keys=True, separators=(",", ":"))
            return hashlib.sha256(f"{method} {path}\n{canonical}".encode()).hexdigest()

past its lease
            c = api.claim("acct_1", k2, "POST", "/v1/charges", body)
            api.execute("acct_1", k2, c[1], create_charge, body)  # the retry takes over
and finishes
            try:
                api.execute("acct_1", k2, a[1], create_charge, body)  # the stalled
worker wakes up
            except LeaseLost:
                print("5. stalled worker's late write rejected and rolled back")
            print("   retry took over:", c[0], "| charges in DB:", charges())
            assert c[0] == "proceed" and charges() == 2           # one charge per logi-
cal operation

            clock.t += 25 * 3600                                  # beyond the 24 h re-
tention window
            late = api.handle("acct_1", key, "POST", "/v1/charges", body, create_charge)
            print("6. same key after TTL expired:", late[0], "| charges in DB:",
charges())
            assert late[0] == 201 and charges() == 3              # the duplicate is no
longer caught
```

Output (charge IDs are random):

```
1. first call: (201, {'id': 'ch_56b3f43ff904', 'amount': 2000, 'status': 'succeeded'})
2. retry     : (201, {'id': 'ch_56b3f43ff904', 'amount': 2000, 'status': 'succeeded'}) |
charges in DB: 1
3. same key, different body: 422
4. concurrent duplicate while first in progress: 409
5. stalled worker's late write rejected and rolled back
   retry took over: proceed | charges in DB: 2
6. same key after TTL expired: 201 | charges in DB: 3
```

What to notice:

- The uniqueness constraint, not application logic, decides who executes: `INSERT ... ON CONFLICT DO NOTHING` (SQLite 3.24+, PostgreSQL 9.5+) returns a row count of 1 for exactly one claimant.
- Canonical JSON (`sort_keys=True`) makes `{"a":1,"b":2}` and `{"b":2,"a":1}` the same fingerprint; whitespace and key order must not turn a retry into a "different request".
- Case 5 is the subtle one: without the `locked_until=?` fencing condition, the stalled worker's late commit would have created a second charge.
- Case 6 shows the retention trade-off: after the TTL the key is forgotten and a very late retry executes again.

22.15.4 External side effects, retention and alternatives

Side effects outside your database. The atomic commit in case 5 works only when the effect lives in the same database as the key. A call to a payment provider, an email gateway or another service cannot join your transaction. The remedies, in order of preference: pass an idempotency key *downstream* (derived from yours, for example `k1:charge`), so the provider deduplicates; split the request into **atomic phases** with recorded **recovery points**, so a retry resumes after the last completed phase instead of starting over, as described in Leach's PostgreSQL implementation [Leach 2017b]; or, for effects that cannot be made idempotent, record intent first and reconcile later (the transactional outbox, §32.5).

FORMULA

Idempotency-key storage

$$S = \lambda_w \times T_{\text{ttl}} \times s_r$$

Symbol	Meaning	Units
S	Steady-state storage for key records	bytes
λ_w	Rate of keyed (non-idempotent) requests	requests/s
T_{ttl}	Retention window	s
s_r	Average record size (key, fingerprint, stored response)	bytes

WORKED EXAMPLE

Worked example — PhotoShare's write APIs. 2,000 keyed `POST` requests per second at peak (use peak as a conservative average), 24 h retention, records of about 1 KB (a 36-byte key, a 32-byte fingerprint, a stored JSON response of most of the rest).

1. Records retained: $2,000 \times 86,400 = 172.8$ million.
2. Storage: $172.8 \times 10^6 \times 1,000$ bytes $= 172.8$ GB.
3. Storing only the response's status and resource ID (about 200 bytes per record) and re-reading the resource on replay cuts this to 34.6 GB.

Interpretation. Retention is a capacity decision. **Engineering implication.** Make T_{ttl} exceed the longest retry horizon (including offline mobile queues), partition by time so expiry is a cheap partition drop, and document the window.

INDUSTRY EXAMPLE

Stripe idempotency keys. Stripe's documentation (as of 2026) describes keys of up to 255 characters, recommends V4 UUIDs, stores the status code and body of the first request for a key *whether it succeeded or failed* (including 500 errors) and returns them for retries, compares parameters and returns an error if a retry's parameters differ, and allows keys to be removed after they are at least 24 hours old. Leach's 2017 engineering post explains the motivation: networks fail in ambiguous ways, so clients must be able to retry any mutating request safely, with backoff and jitter [Stripe Docs: idempotent requests; Leach 2017]. *Evidence: Primary* — [Stripe Docs: idempotent requests; Leach 2017]

INDUSTRY EXAMPLE

Amazon EC2 client tokens. EC2's `RunInstances` accepts a `ClientToken`; retrying with the same token returns the original result instead of launching more instances, and reusing a token with different parameters fails with an `IdempotentParameterMismatch` error. The AWS Builders' Library article on idempotent APIs explains why the service, not the client, must detect parameter mismatch and why the response to a retry should be semantically equivalent to the original [Yanacek: idempotent APIs]. *Evidence: Primary* — [Yanacek: idempotent APIs]

Alternatives. Not every operation needs a key store. A **client-chosen resource ID** with `PUT /subscriptions/{uuid}` is naturally idempotent. **Conditional requests** (`If-Match` with an ETag, §8.6) make updates safe to retry. A **natural unique constraint** (one active subscription per user) rejects duplicates in the database. Idempotency keys are the general solution when the operation is a `POST` with server-assigned identity and real-world effects.

Table 22.7 — Idempotency failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Customer charged twice	Key generated per *attempt*, not per operation	Two charges, two different keys, same cart	Refund and reconcile	Generate the key once and persist it with the cart
Retry gets the wrong result	No fingerprint; key reused for a new purchase	Responses that do not match request bodies	Return 422 on mismatch	Fingerprint method, path and canonical body
Double execution under concurrency	Check-then-insert race on the key	Duplicate effects milliseconds apart	Reconcile	Uniqueness constraint plus lease and fencing
Charge made, record says in progress	Crash between external call and commit	Stuck in-progress keys past lease	Retry passes the same downstream key; provider deduplicates	Downstream keys, recovery points
Late retry executes again	Retry after the retention TTL	Duplicates spaced by more than the TTL	Reconcile	TTL longer than client retry horizon

COMMON MISTAKE

Mistake — “We return the stored response, so the operation is exactly-once.” Idempotency keys give *at-most-once execution per key within the retention window* on top of *at-least-once delivery* by the client: effectively-once processing. They say nothing about a client that generates a new key per attempt, a key that has expired, or a side effect that escaped your transaction. Exactly-once delivery is not achievable over an unreliable network; effectively-once processing is (§32.9).

22.16 Summary and revision notes

SUMMARY

- **Rate limits are per-client contracts; load shedding protects total capacity.** You need both. Enforce limits in layers (edge per IP, gateway per key/tenant, service per cost) and signal them with 429, `Retry-After`, and the draft `RateLimit-Policy` / `RateLimit` fields.
- **Token bucket:** rate r, burst b, admitted $A(T) \le b + rT$; two numbers per key; `Retry-After` = deficit/r. **GCRA** is the same policy stored as one timestamp. The leaky bucket *as a queue* shapes traffic by delaying it.
- **Fixed window** admits up to $2L$ across a boundary. The **sliding log** is exact but stores L timestamps per key. The **sliding window counter** $\hat{N} = C_{\text{prev}}(W - e)/W + C_{\text{curr}}$ is cheap and close to exact for random traffic, but biased for traffic phase-locked to the window.
- **Distributed limiting:** centralized Redis with an atomic Lua script is exact but costs a round trip; local counting with sync overshoots by up to $\lambda\Delta$; quota distribution is cheap but lags demand shifts. Decide fail-open versus fail-closed per limit.
- **Overload:** without shedding, goodput collapses after $t = \mu T_{\text{out}}/(\lambda - \mu)$. Shed by priority, bound queues by time ($Q_{\max} = \mu D$), and use CoDel-style delay targets and adaptive LIFO.
- **Backpressure** propagates "slow down" upstream: bounded buffers, blocking or rejection, and explicit demand (`request(n)`, TCP windows).
- **Deadlines** propagate absolute time budgets: $B_{i+1} = B_i - e_i - m_i$. A timeout means "unknown outcome", not "failed".
- **Retries:** only retryable errors, idempotent operations, remaining budget. Use capped exponential backoff with full or decorrelated jitter. Amplification is a^d across d retrying layers; retry at one layer and cap with a budget (about 10%).
- **Circuit breakers** fail fast when a dependency's failure rate crosses a threshold, probe in half-open, and need timeouts underneath. **Bulkheads** give each dependency its own Little's-Law-sized pool.
- **Idempotency keys:** client-generated once per logical operation; scoped per account; fingerprinted; claimed with a uniqueness constraint; leased and fenced; committed atomically with the business write; retained longer than the retry horizon ($S = \lambda_w T_{\text{ttl}} s_r$).

22.17 Knowledge checkpoint

1. Why is a rate limit not sufficient protection against overload?

2. A token bucket has $r = 50$ RPS and $b = 200$. What is the most it admits in any 10 s interval, and how long does it take to refill from empty?
3. What is the difference between the leaky bucket as a queue and as a meter?
4. With a fixed window of 1,000 requests per hour, what is the most a client can send in any one-hour interval?
5. Sliding window counter, $L = 60$/min: previous window 40, current 25, 30 s elapsed. Is the next request admitted?
6. Why must a Redis-based limiter use a Lua script (or equivalent atomic operation) rather than `GET` then `SET`?
7. With 20 gateways synchronizing every 50 ms and 4,000 RPS offered for one key, what is the worst-case overshoot per second?
8. A server handles 400 RPS; clients time out after 2 s; 600 RPS arrive. When does goodput collapse without shedding?
9. Why does adaptive LIFO help an overloaded server?
10. What does a timeout tell the caller about a write operation?
11. Five layers each make up to 2 attempts. What is the worst-case amplification at the bottom?
12. Why does a circuit breaker need a minimum call volume?
13. What does the fencing check in an idempotency layer prevent?
14. Name three request properties that should go into an idempotency fingerprint.

Answers

1. It bounds each client individually; the sum of all clients' allowed traffic can still exceed capacity. Global protection needs load shedding and backpressure.
2. $A(10) = 200 + 50 \times 10 = 700$ requests; refill time $b/r = 200/50 = 4$ s.
3. The queue form buffers requests and releases them at a constant rate (delaying them, smoothing output); the meter form admits or rejects immediately and is equivalent to a token bucket.
4. $2L = 2,000$, by spending a full quota at the end of one window and another at the start of the next.
5. $\hat{N} = 40 \times 0.5 + 25 = 45$; $45 + 1 \le 60$, so yes.
6. Between a read and a write, other nodes can read the same value and also admit, exceeding the limit and losing increments. A script runs atomically on the shard.
7. $E_{\max} \approx \lambda\Delta = 4,000 \times 0.05 = 200$ requests.
8. $t = \mu T/(\lambda - \mu) = 400 \times 2/200 = 4$ s.
9. Under a standing queue the oldest requests have probably timed out at the client; serving the newest first spends capacity on requests someone is still waiting for.
10. Nothing definite: the write may not have arrived, may have failed, or may have succeeded with the response lost.
11. $2^5 = 32$.
12. Without it, a handful of failures at low traffic (2 of 3 calls) would exceed a percentage threshold and trip the breaker on noise.

13. A slow worker whose lease expired committing its result after another worker took over, which would execute the operation twice.
14. HTTP method, path (resource), and canonicalized body; optionally the API version and relevant headers.

22.18 Interview questions

Basic

Q1. Design a rate limiter for a public API. Answer. Clarify keys (API key; per-IP before authentication), tiers (rate and burst) and accuracy. Token bucket per key in Redis, updated by an atomic Lua script from the gateway; 429 with `Retry-After` and `RateLimit` headers. Discuss the added round trip, hot keys, fail-open versus fail-closed, and hierarchical tenant and route limits.

Q2. Why add jitter to exponential backoff? Answer. Clients that failed together back off by identical amounts and retry together, so each wave collides again. Randomizing the wait spreads retries over time; in this chapter's simulation, jitter reduced calls from 5,050 to about 460 for 100 contending clients.

Intermediate

Q3. Compare token bucket, fixed window and sliding window counter for a 100-requests-per-minute limit. Answer. Token bucket (r = 1.67/s, b chosen for bursts) is exact, two numbers per key, controls bursts explicitly. Fixed window is one counter but admits up to 200 across a boundary. Sliding counter is two counters and approximates a true sliding minute well for random traffic (5–13% worst-window overshoot in simulation) but is biased for periodic traffic. Choose token bucket for API admission, fixed windows for coarse daily quotas.

Q4. A dependency gets slow and your service's p99 explodes even for endpoints that don't call it. Why and what do you change? Answer. The slow dependency holds threads from a shared pool (Little's Law: in-flight $= \lambda W$ grows with W), starving other endpoints. Add timeouts set from the dependency's p99.9, a bulkhead (dedicated pool or semaphore) sized for normal concurrency, a circuit breaker to fail fast, and a fallback.

Advanced

Q5. Design idempotent payment creation across your API and an external payment provider. Answer. Client generates a UUID key per checkout and persists it; server scopes keys per account, stores fingerprint and status with a uniqueness constraint; concurrent duplicates get 409; mismatched bodies 422. The server passes a de-

rived key to the provider so that a crash between charge and commit is safe to retry; it splits work into atomic phases with recovery points; stores the final response atomically with local state; leases claims and fences completions; retains keys longer than the client's retry horizon; and reconciles stuck in-progress keys with the provider.

Q6. A five-service call chain melts down during a database brownout. Explain the dynamics and a fix. Answer. Each layer retries three times, so load at the database multiplies up to $3^5 = 243\times$; queues grow beyond client timeouts so goodput collapses; fixed per-hop timeouts keep inner calls running after the user has given up. Fix: retry at one layer with jittered backoff and a 10% budget, propagate deadlines, shed sheddable traffic by priority with bounded queues, add circuit breakers at each dependency, and use adaptive client throttling.

22.19 Practical exercises

1. Extend the `TokenBucket` class with per-request cost and a `RateLimit` header generator; test with a fake clock that a 5-token upload request is rejected when 3 tokens remain and that `Retry-After` is correct.
2. Run the Lua script from §22.8.2 against a local Redis, then write a version *without* atomicity (separate `HMGET` and `HSET` from 20 concurrent threads) and measure how many requests exceed the limit.
3. Modify the distributed limiter simulation so that node 0's share of traffic jumps from 10% to 60% at $t = 10$ s. Measure how long each strategy under- or over-admits.
4. Add a retry budget (10% token bucket) to the backoff simulation and measure total calls when the resource fails every call for 5 s.
5. Port the idempotency layer to PostgreSQL and test concurrent claims from two processes with `INSERT ... ON CONFLICT DO NOTHING`.

22.20 Design challenges

1. **Multi-tier quota service.** A SaaS platform with 50,000 tenants, 200 gateway nodes in three regions and 1 million RPS must enforce per-tenant per-minute quotas and per-user burst limits with less than 1 ms added p99 latency. Choose algorithms, storage and synchronization; quantify overshoot and coordination traffic; define behavior during a region partition.
2. **Overload-proof checkout.** Design PhotoShare Pro's purchase path to survive a 5× traffic spike and a 10-minute payment-provider brownout without double charges: deadlines, retries, breakers, bulkheads, shedding priorities and the idempotency layer, with a failure-mode table.

22.22 Open verification items

- ITU-T I.371 edition year and the exact ATM Forum TM 4.0 document number for the GCRA definition (cited without a specific edition).
- Current revision and field syntax of the IETF RateLimit header draft (search results indicated draft-10, September 2025, and draft-11, May 2026; ietf.org was unreachable from the build environment).
- Idempotency-Key draft: status after revision -07 (October 2025) and whether its 409/422 recommendations changed.
- Cloudflare post (Desgats 2017): exact URL and the "0.003% of 400 million requests" figure.
- Stripe documentation details (255-character keys, 24-hour pruning, stored 500 responses) as of 2026.
- Hystrix default values and AWS SDK retry-quota behavior; ACM Queue URLs for Nichols and Jacobson 2012 and Maurer 2015.

Chapter 23 — Performance Engineering

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

A checkout page that was fast last month now takes two seconds for one user in fifty. The dashboards show 40% CPU. Someone suggests doubling the instance count; someone else blames the database; a third engineer wants to rewrite the JSON serializer. All three are guessing. Performance engineering replaces the guessing with method: a checklist that finds the saturated resource, a profiler that finds the hot code, a load test that measures what users actually experience, and a model that predicts how many machines next year's traffic will need.

Chapter 4 gave you the mathematics (percentiles, queueing, Little's Law, the Universal Scalability Law) and Chapter 2 the bottleneck and the utilization law. This chapter turns them into a practice: where to look first, how to measure without fooling yourself, why the slowest 1% of requests dominates large systems, and how to cut that tail. Four runnable Python programs reproduce the key effects.

23.1 Learning objectives

After this chapter you should be able to:

- Apply USE to resources and RED or the four golden signals to services, following a workflow from symptom to cause.
- Choose sampling or instrumenting profilers, read flame graphs, use off-CPU analysis, and profile Python with `cProfile` and `tracemalloc`.
- Distinguish open and closed workload models, demonstrate coordinated omission and correct for it, and record latency with HDR histograms.
- Quantify fan-out tail amplification and list the main sources of latency variability (garbage collection, queueing, background work, noisy neighbors, CPU throttling).
- Design hedged and tied requests, compute their latency benefit and extra load, and explain when hedging becomes dangerous.
- Size batches and pipelines with a latency–throughput model and decide when compression pays for its CPU cost.
- Explain generational GC, stop-the-world pauses, collector trade-offs (G1, ZGC, Shenandoah, Go) and JIT warm-up.
- Fit the Universal Scalability Law to benchmark data, predict the throughput peak and convert the model into a fleet size.

23.2 Prerequisites

- Percentiles, histograms and fan-out amplification — §4.8 (tail latency is the central quantity of this chapter).
- Queueing theory, Little's Law and the M/M/1 latency curve — §4.10, §4.11 (load testing and hedging both change utilization).
- Amdahl's Law and the Universal Scalability Law — §4.12, §4.13 (§23.10 fits the USL to data).
- The resource model, utilization law and USE method overview — §2.6 (§23.3 extends them into a full workflow).
- CPU caches, CPU-bound versus I/O-bound workloads — §5.4, §5.8 (what a CPU profile can and cannot show).
- Threads, scheduling and context switches — §6.3–§6.5 (on-CPU versus off-CPU time).
- TCP behavior, including Nagle's algorithm — §7.7.8 (the original batching trade-off).

23.3 Performance methodology

23.3.1 What performance engineering is

DEFINITION

Definition — Performance engineering. The practice of measuring, explaining and improving the **latency**, **throughput** and **resource efficiency** of a system against explicit targets, using repeatable methods rather than intuition. Its outputs are diagnoses (why is it slow?), changes (make it faster or cheaper) and predictions (how much capacity will we need?).

First-principles explanation

A doctor facing a fever does not start with antibiotics. She takes vital signs in a fixed order, forms a hypothesis, orders a targeted test, treats, and follows up. In performance work the vital signs are a few metrics per resource and per service, the tests are profilers and tracers, and the follow-up is a measurement confirming the fix.

Brendan Gregg names the **anti-methods** that replace this discipline [Gregg 2020]: the *streetlight* anti-method (look only where your favorite tool shines), *random change* (tweak settings until the problem goes away) and *blame-someone-else* ("it's the network"). The methods below are evidence-driven and take minutes.

23.3.2 The USE method

DEFINITION

Definition — USE method. For every **resource**, check **U**tilization (the fraction of time the resource was busy, or the fraction of its capacity in use), **S**aturation (the amount of extra work queued because the resource could not service it) and **E**rrors (the count of error events) [Gregg USE]. A resource is any physical or software component with finite capacity: CPUs, memory, disks, network interfaces, controllers and interconnects, but also locks, thread pools, connection pools and file descriptors.

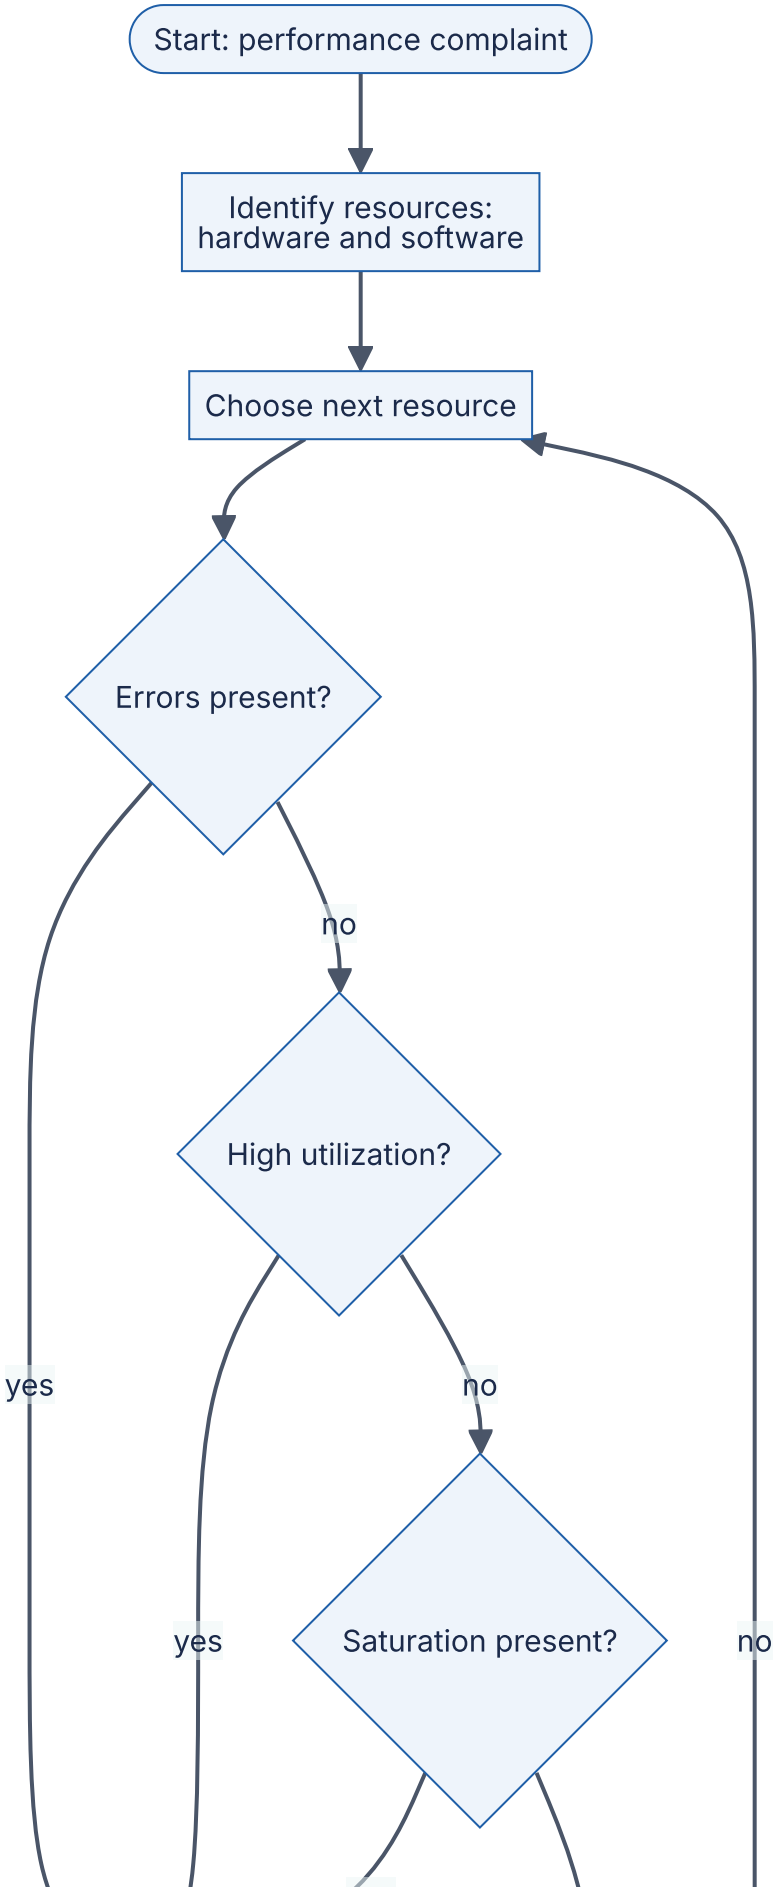
Why does this exist?

Dashboards built from whatever metrics were easy to collect are both overwhelming and incomplete. USE inverts the process: start from the finite list of resources and ask three questions of each, so no saturated resource is missed because nobody graphed it. Chapter 2 introduced USE as a bottleneck finder (§2.6); here it becomes a complete procedure.

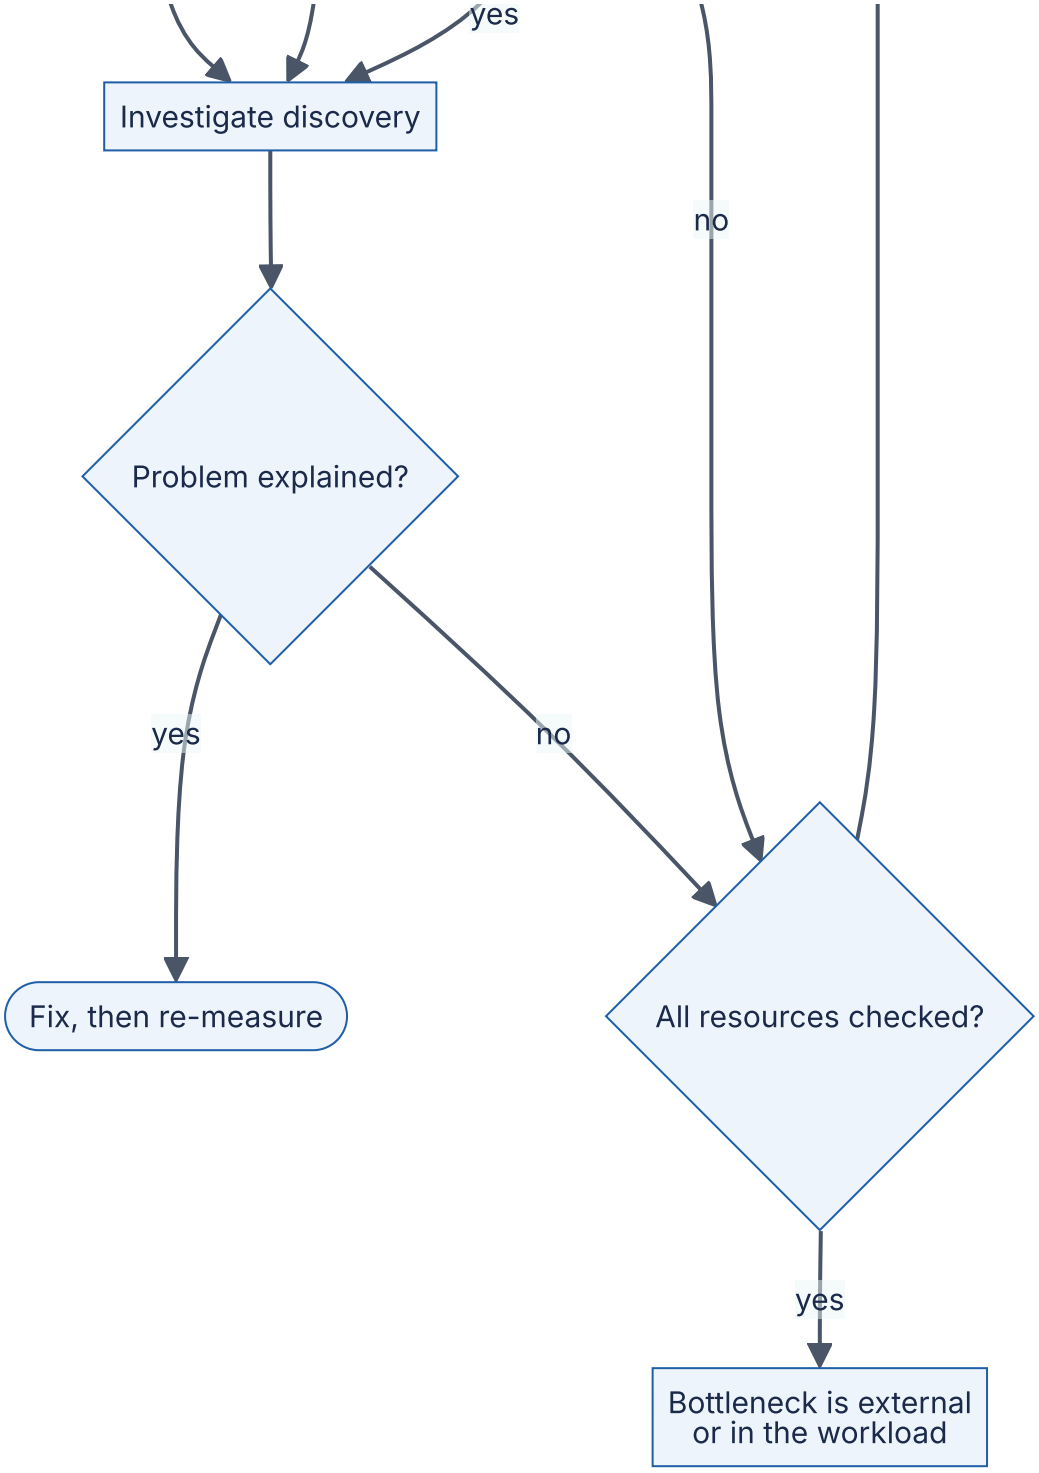
How it works internally

1. **Enumerate resources** from a block diagram of the server: CPUs, memory, disks and controllers, network interfaces, plus software resources.
2. **Check errors first.** They are quick to interpret (disk retries, NIC drops) and can explain everything else.
3. **Check utilization** per device and per CPU: an 8-core average of 25% can hide one core at 100% running a single-threaded event loop.
4. **Check saturation**: run-queue length, swapping, disk queue size, drops and retransmits, waiters on locks and pools. Sustained saturation is always a problem, because queued work is latency (§4.10).
5. **Iterate** until the problem is found or every resource is cleared.

Figure 23.1 — The USE method procedure.



Start: performance complaint
Identify resources: hardware and software
Choose next resource
Errors present?
yes
no
High utilization?
yes
no
Saturation present?
no



Reading the diagram. This is a reasoning loop, not a running system: there are no protocols or storage boundaries, and every arrow is a step the engineer takes. Iterating over a finite resource list is what makes the method complete, and each check is one counter, so a pass takes minutes. A finding must *explain* the complaint (a busy disk may be a symptom of swapping), otherwise the loop continues. The method's failure point is the resource list: a forgotten resource (a connection pool, a file-descriptor limit, a cloud API quota) can never be found. If every resource is clear, look outside the host (§23.3.3). The same checks scale to fleets per instance and resource class.

Table 23.1 — USE metrics for common resources (Linux tools in parentheses).

Resource	Utilization	Saturation	Errors
CPU	Per-CPU busy % (`mpstat -P ALL`)	Run-queue length; scheduler latency (`vmstat` r column, `runqlat`)	Machine-check events (rare)
Memory	Used vs. available (`free`)	Swapping, page scanning, OOM kills (`vmstat` si/so, `dmesg`)	Allocation failures
Disk	Busy % per device (`iostat -x`)	Average queue size; await time (`iostat -x`)	Device errors (`smartctl`, kernel log)
Network interface	Throughput vs. link speed (`sar -n DEV`)	Drops, overruns, TCP retransmits (`nstat`, `ss -ti`)	Interface errors (`ip -s link`)
Container CPU limit	CPU time vs. quota	Throttled periods (`cpu.stat` in cgroup)	—
Thread / connection pool	Busy workers / pool size	Requests waiting for a worker	Rejected tasks, acquisition timeouts
Lock	Fraction of time held	Waiting threads; contention time	Deadlock detections, timeouts

The container row deserves emphasis: a container that exhausts its CPU **quota** is **throttled** for the rest of the period even if the host is idle (§23.6.3), so host CPU looks low while latency spikes.

23.3.3 The RED method and the four golden signals

USE looks at a system from the inside; users experience it request by request. Two request-centric checklists cover that view.

DEFINITION

Definition — RED method. For every **service**, monitor **R**ate (requests per second), **E**rrors (failed requests per second) and **D**uration (the distribution of request latency, as a histogram from which percentiles are read). Tom Wilkie proposed it while at Weaveworks as a service-level complement to USE [Wilkie 2018].

DEFINITION

Definition — Four golden signals. Google's site reliability engineering guidance says that if you can measure only four metrics of a user-facing system, measure **latency** (time to serve a request, tracking successful and failed requests separately), **traffic** (demand, such as requests per second), **errors** (rate of failed requests, explicit or implicit) and **saturation** (how "full" the service is, emphasizing its most constrained resource) [Beyer et al. 2016, ch. 6].

The golden signals are RED plus saturation. Separating success and failure latency matters: a backend failing fast in 2 ms makes the latency histogram look *better* while users suffer. Saturation is the leading signal: a pool at 90% occupancy says users are *about* to hurt.

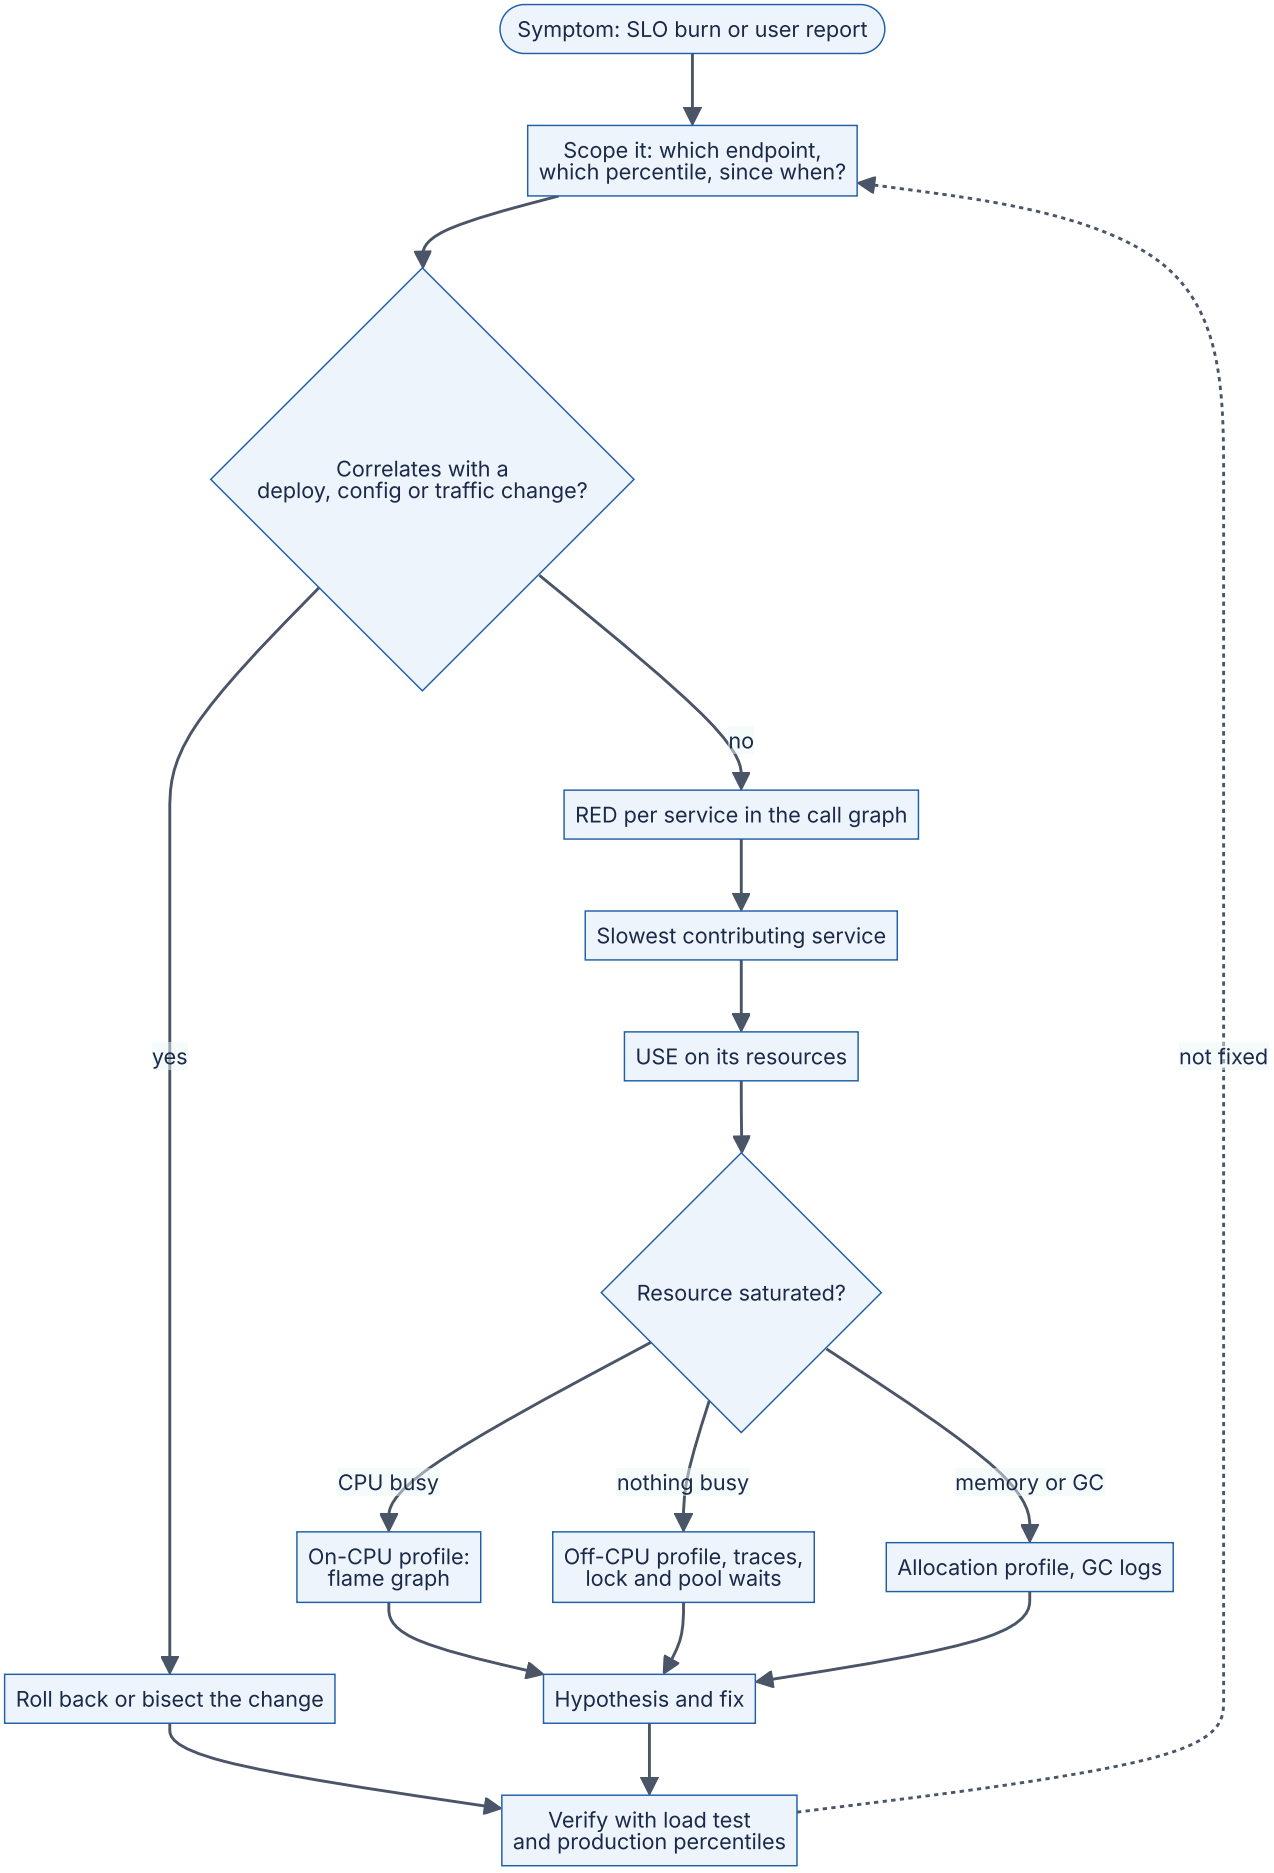
Table 23.2 — USE, RED and the four golden signals compared.

	USE	RED	Four golden signals
Unit of analysis	Resource	Service (endpoint)	User-facing service
Questions	Busy? Queued? Failing?	How much? How many fail? How long?	RED + how full?
Best for	Root-causing on one host or component	Finding *which* service in a call graph is slow	Alerting and SLOs
Typical source	OS counters, cgroup stats, pool gauges	Request middleware, service mesh, load balancer logs	Same as RED plus capacity gauges
Blind spot	Code-level causes; external dependencies	Why a service is slow	Why a service is slow
Origin	Gregg (2012 onward)	Wilkie (Weaveworks)	Google SRE book (2016)

23.3.4 From symptom to cause

A real investigation chains the checklists: RED narrows the problem to a service and endpoint, USE finds the saturated resource, a profiler (§23.4) or trace (§40.6) finds the responsible code or call, and a load test (§23.5) confirms the fix.

Figure 23.2 — Workflow from symptom to cause.



Symptom: SLO burn or user report
Scope it: which endpoint, which percentile, since when?
Correlates with a deploy, config or traffic change?
yes
no
RED per service in the call graph
Slowest contributing service
USE on its resources
Resource saturated?
CPU busy
nothing busy
memory or GC
On-CPU profile: flame graph
Off-CPU profile, traces, lock and pool waits
Allocation profile, GC logs
Roll back or bisect the change
Hypothesis and fix
Verify with load test and production percentiles
not fixed

Reading the diagram. Start from a user-visible symptom and first ask *what changed*: most regressions follow a deployment, configuration change or traffic shift, and rollback is the fastest fix. Otherwise RED metrics across the call graph (from middleware or a service mesh, over HTTP or gRPC) locate the slowest service, and USE on its resources selects the instrument: a CPU flame graph if CPUs are busy; off-CPU analysis and traces if nothing is busy but requests wait (locks, pools, dependencies); allocation profiles and GC logs if memory dominates. Solid steps are synchronous actions; the dotted edge reopens the investigation if verification fails. The main failure point is skipping scoping: “the site is slow” without an endpoint, percentile and start time cannot converge.

WORKED EXAMPLE

Worked example — Locating the bottleneck with the utilization law. RED shows the `/search` endpoint’s p99 rose from 120 ms to 900 ms at 2,400 RPS across 12 instances. USE on one instance (200 RPS) shows 8 CPUs at 35%, and a database connection pool of 16 connections reporting 14.8 busy on average with 40 waiters. Each request holds a connection for 74 ms.

1. Connection pool utilization by Little’s Law (§4.11): $L = \lambda W = 200 \times 0.074 = 14.8$ connections, so $U = 14.8/16 = 92.5\%$.
2. CPU utilization is 35% per CPU, far from saturation, and the run queue is short.
3. Saturation evidence: 40 waiters on the pool. At 92.5% utilization a queue is expected (§4.10).
4. Hypothesis: connection hold time rose. Tracing shows a new query taking 50 ms inside each request; before the change hold time was 24 ms, giving $200 \times 0.024 = 4.8$ busy connections (30%).

Interpretation. The CPU dashboard (35%) said “plenty of capacity”; the pool said “saturated”. **Engineering implication.** Software resources must be in your USE list and on your dashboards. The fix is to make the query faster or move it off the request path, not to add instances: twelve more instances would double the connection count the database must serve.

COMMON MISTAKE

Mistake — Treating utilization as the only signal. A disk at 60% utilization can still be the bottleneck if its queue is long and its requests are bursty, and a CPU at 100% may be harmless for a batch job. Utilization tells you how busy a resource is; saturation tells you whether work is *waiting* for it. Latency comes from waiting.

23.4 Profiling CPU and memory

23.4.1 Sampling versus instrumentation

DEFINITION

Definition — Profiler. A tool that attributes a resource (CPU time, wall-clock time, allocated bytes, lock wait time) to the code locations that consumed it. A **sampling profiler** interrupts the program at a fixed frequency and records the current call stack; a function's share of samples estimates its share of time. An **instrumenting** (deterministic, tracing) profiler inserts hooks at every function entry and exit and records exact call counts and durations.

First-principles explanation

To learn how a colleague spends the day you could follow them with a stopwatch (instrumentation) or glance at their desk a few hundred times at random and tally what you see (sampling). The stopwatch is exact but intrusive; the glances are cheap and give percentages accurate to a point or two. Production profiling almost always samples, because overhead is fixed by the sampling rate, not by how many functions the program calls.

How it works internally

1. A timer or hardware counter fires an interrupt or signal.
2. The handler walks the running thread's stack (via frame pointers, DWARF unwind tables or a runtime API), including kernel frames.
3. Addresses are later **symbolized** into function names, and identical stacks are counted; each count divided by the total estimates that stack's share of CPU time.

Linux `perf` typically samples at 99 Hz rather than 100 Hz to avoid lockstep with periodic activity [Gregg 2020].

FORMULA

Sampling error of a profile

$$n = f \times T \times c \qquad \hat{p} = \frac{k}{n} \qquad \mathrm{SE}(\hat{p}) = \sqrt{\frac{\hat{p}\,(1-\hat{p})}{n}}$$

Symbol	Meaning	Units
f	Sampling frequency per CPU	samples/second
T	Profiling duration	seconds
c	Number of busy CPUs sampled	count
n	Total samples collected	samples
k	Samples whose stack contains the function	samples
$\hat{p}$	Estimated fraction of CPU time in the function	dimensionless
SE	Standard error of the estimate (binomial approximation)	dimensionless

WORKED EXAMPLE

Worked example — How long to profile. A service runs on 8 busy CPUs. You sample at 99 Hz for 30 s.

1. $n = 99 \times 30 \times 8 = 23,760$ samples.
2. A function at $\hat{p} = 2\%$: $\mathrm{SE} = \sqrt{0.02 \times 0.98/23,760} = \sqrt{8.25 \times 10^{-7}} = 0.00091$, i.e. ± 0.09 percentage points; a 95% interval is about 2.0% ± 0.18%.
3. A function at $\hat{p} = 0.1\%$ (about 24 samples): $\mathrm{SE} = \sqrt{0.001 \times 0.999/23,760} = 0.000205$, a *relative* error of about 20%.

Interpretation. Thirty seconds measures anything that matters (above 1%) precisely; tiny functions are noisy, but they are not where the time is. **Engineering implication.** Profile for tens of seconds under representative load, and do not chase differences smaller than two standard errors between two profiles.

Instrumentation has exact counts but overhead proportional to call frequency: 10 million calls per second at 50 ns of hook cost adds 0.5 CPU-seconds per second, distorting exactly the small hot functions you want to measure. It suits call counts, coarse spans (distributed tracing, §40.6) and offline analysis.

23.4.2 Flame graphs

A profile of a real service contains tens of thousands of distinct stacks, far too many to read as text. Gregg's **flame graph** visualizes them [Gregg 2016]: each box is a function in a stack; the y-axis is stack depth (callers below, callees above); the **width** of a box is proportional to the number of samples containing it; boxes are sorted alphabetically along the x-axis so identical stacks merge. The x-axis is *not* time.

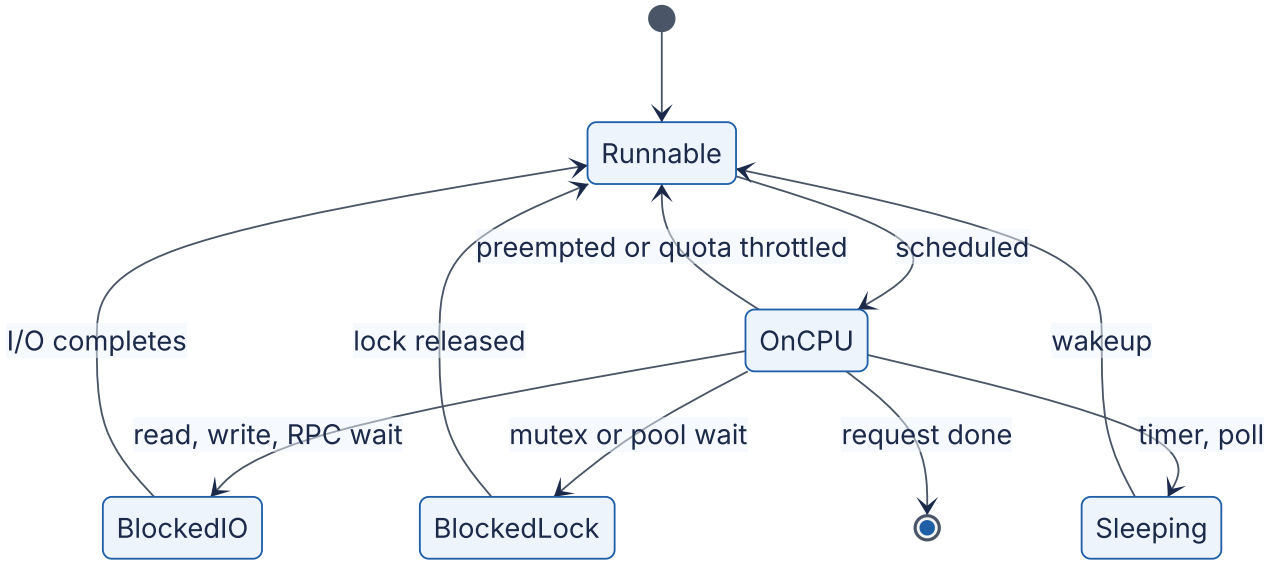
Figure 23.3 — From samples to a flame graph.

Reading the diagram. The sampler observes the service (perf and eBPF from the kernel, py-spy by reading process memory, async-profiler inside the JVM) and writes raw stacks to a profile file, the storage boundary; everything after it runs offline. Arrows are batch hand-offs, not request paths. Symbolization fails when symbols are stripped or JIT code lacks a symbol map, leaving hexadecimal frames. Collapsing merges identical stacks into counts that the flame graph draws as widths. Look first for wide **plateaus**, boxes with nothing on top, which burn CPU themselves. Continuous profiling on every host scales this to a fleet.

23.4.3 Off-CPU analysis

A CPU profile shows only time spent *running*. A request that takes 300 ms of wall-clock time but uses 5 ms of CPU is invisible to it. The missing 295 ms is **off-CPU time**: the thread was blocked on disk or network I/O, waiting for a lock, sleeping, or runnable but waiting for a CPU.

Figure 23.4 — On-CPU and off-CPU thread states.



Reading the diagram. Only `OnCPU` appears in a CPU profile. `Runnable` time is scheduler latency (CPU saturation or throttling, measured by `runqlat`); `BlockedIO` is waiting on storage or network calls; `BlockedLock` is mutex or pool contention; `Sleeping` is voluntary. Transitions out of `OnCPU` are context switches (§6.4). **Off-CPU profiling** records the stack and blocked duration at each switch-out, typically with eBPF (`offcputime`), and draws a flame graph whose width is blocked *time*. Wall-clock profilers (async-profiler's `wall` mode) sample all threads in any state. Pitfall: idle pool workers dominate off-CPU profiles, so filter to threads serving requests.

Request latency equals on-CPU plus off-CPU time. Latency problems in I/O-heavy services are usually off-CPU; throughput and cost problems usually on-CPU.

23.4.4 Tools by runtime

Table 23.3 — Common profilers (as of 2026).

Tool	Runtime	Method	Notable features
`perf`	Any (Linux)	Sampling via kernel perf events	CPU, hardware counters, kernel stacks; needs frame pointers or DWARF for user stacks
eBPF tools (BCC, bpftrace)	Any (Linux)	In-kernel programs on events	Low-overhead off-CPU, run-queue, block I/O latency histograms
py-spy	CPython	Sampling by reading process memory	No code change; attaches to a running PID; flame graph output
async-profiler	JVM	Sampling with perf events and JVM APIs	Avoids safepoint bias; CPU, allocation, lock and wall-clock modes
Java Flight Recorder	JVM	Built-in event recording	Low overhead, always-on in production; GC and lock events
pprof	Go	Built-in sampling (CPU 100 Hz), heap sampling	`net/http/pprof` endpoint; CPU, heap, goroutine, block, mutex profiles

Safepoint bias: older JVM profilers sampled threads only at **safepoints**, so time in loops without safepoints was misattributed, and a study of four Java profilers found they often disagreed about the hottest method [Mytkowicz et al. 2010]. Signal-based asynchronous profilers such as async-profiler avoid this.

23.4.5 Allocation profiling

In garbage-collected runtimes the **allocation rate** sets how often the collector runs (§23.9). Allocation profilers answer two questions: *who allocates most* (drives GC frequency) and *who holds memory now* (drives heap size); diffing heap snapshots taken minutes apart finds leaks. The program below profiles CPU with `cProfile` and memory with `tracemalloc`, counting distinct users in a request log with a list (O(n) membership test) and with a set.

```
        import cProfile
        import json
        import linecache
        import pstats
        import random
        import tracemalloc

        def make_events(n, seed=7):
            """Synthetic request log: JSON lines with a user id and a latency."""
            rng = random.Random(seed)
            return [json.dumps({"user": f"u{rng.randrange(5_000)}",
                                "ms": round(rng.lognormvariate(3, 1), 2)})
                    for _ in range(n)]

        def distinct_users_slow(events):
            seen = []                           # list: membership test is O(n)
            for line in events:
                user = json.loads(line)["user"]
                if user not in seen:
                    seen.append(user)
            return len(seen)

        def distinct_users_fast(events):
            return len({json.loads(line)["user"] for line in events})  # set: O(1)

        def report(events):
            return distinct_users_slow(events), distinct_users_fast(events)

        events = make_events(50_000)

        # 1. CPU: cProfile is a deterministic (instrumenting) profiler
        profiler = cProfile.Profile()
        profiler.enable()
        print("distinct users (slow, fast):", report(events))
        profiler.disable()
        stats = pstats.Stats(profiler)
        print(f"{'function':<22}{'calls':>8}{'self s':>9}{'total s':>9}")
        rows = sorted(((k, v) for k, v in stats.stats.items() if not k[2].startswith("
<")),
                      key=lambda kv: kv[1][3], reverse=True)[:6]       # by total time
        for (filename, line, name), (cc, nc, tottime, cumtime, _) in rows:
            print(f"{name[:21]:<22}{nc:>8}{tottime:>9.3f}{cumtime:>9.3f}")

        # 2. Memory: tracemalloc attributes live allocations to source lines
        tracemalloc.start()
        more_events = make_events(50_000)
        snapshot = tracemalloc.take_snapshot()
        tracemalloc.stop()
        for stat in snapshot.statistics("lineno")[:2]:
            frame = stat.traceback[0]
            code = linecache.getline(frame.filename, frame.lineno).strip()
            print(f"{stat.size / 1024:6.0f} KiB in {stat.count:6d} blocks: {code[:38]}")
```

Output (Python 3.13; timings vary by machine):

```
distinct users (slow, fast): (5000, 5000)
function                 calls   self s  total s
report                       1    0.000    1.486
distinct_users_slow          1    1.028    1.266
loads                   100000    0.092    0.436
decode                  100000    0.142    0.314
distinct_users_fast          1    0.021    0.220
raw_decode              100000    0.072    0.072
  3442 KiB in  50000 blocks: return _iterencode(o, 0)
   434 KiB in      3 blocks: return [json.dumps({"user": f"u{rng.ra
```

What to notice:

- **Self time versus total time.** `distinct_users_slow` has 1.03 s of *self* time: the `user not in seen` scan is an operator, not a function call, so cProfile charges it to the enclosing function. Its JSON parsing (`loads`, about 0.22 s per 50,000 calls) is the same in both versions. The fix (a set) makes the function about 6 times faster overall.
- **Call counts are exact**: 100,000 calls to `loads` (50,000 per version). A sampling profiler would give percentages but not counts.
- **Instrumentation overhead.** Each of the 100,000 `loads` calls passes through cProfile's hooks, so the absolute times are inflated; compare ratios, not absolutes.
- **tracemalloc** attributes 3.4 MiB of live memory to a line inside the JSON encoder: 50,000 strings of about 70 bytes each. The list comprehension holding them costs 434 KiB of pointers. In a production service the same view, diffed over time, finds leaks.

For a running production Python process you would use a sampling profiler instead: `py-spy record -o profile.svg --pid <PID> --duration 30` produces a flame graph without restarting or modifying the program.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Google-Wide Profiling.** Google runs continuous, low-overhead sampling profiling across its fleet, collecting CPU and heap profiles from a small random subset of machines at a time and aggregating them in a central repository. The fleet-wide view lets engineers rank the most expensive functions across all services and attribute cost to specific libraries, which guides optimization work with the largest fleet-wide payoff. Trade-off: individual profiles are sparse, so the value comes from aggregation over many machines and long periods. *Evidence: Primary* — [Ren et al. 2010]

INDUSTRY EXAMPLE

Netflix — mixed-mode flame graphs for Java. Netflix engineers produced CPU flame graphs showing Java, JIT-compiled, kernel and native frames together by running the JVM with frame pointers preserved and exporting a symbol map for JIT code so `perf` can name it. Trade-off: frame pointers cost a little CPU, accepted for the visibility. *Evidence: Primary* — [Gregg and Spier 2015]

COMMON MISTAKE

Mistake — Optimizing the function with the largest *total* time. `main` has 100% total time and nothing to optimize. Look for large *self* time (the plateaus of a flame graph). Conversely, a function with small self time but huge total time is a good target only if you can avoid *calling* the expensive callees.

23.5 Load testing and benchmarking pitfalls

23.5.1 Kinds of performance test

Table 23.4 — Performance test types.

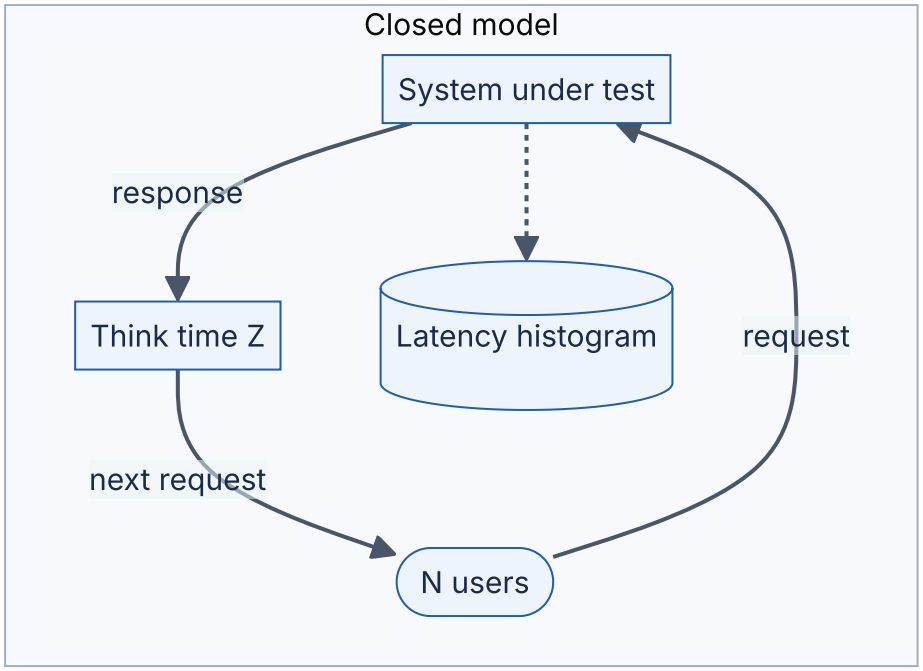
Test	Question it answers	Typical shape
Microbenchmark	How fast is this function or data structure?	Tight loop in a harness (JMH, `pytest-benchmark`, Go `testing.B`)
Load test	Does the system meet its SLO at expected peak?	Steady target rate at forecast peak for 30–60 min
Stress test	Where and how does it break?	Rate ramps until errors or latency explode
Soak (endurance) test	Does it degrade over hours?	Moderate load for 8–72 h; watch memory, handles, GC
Spike test	Does it survive a sudden surge, and recover?	Step from normal to 3–10× for minutes
Capacity benchmark	Throughput as a function of concurrency or nodes	Series of steady runs at increasing *N* (§23.10)

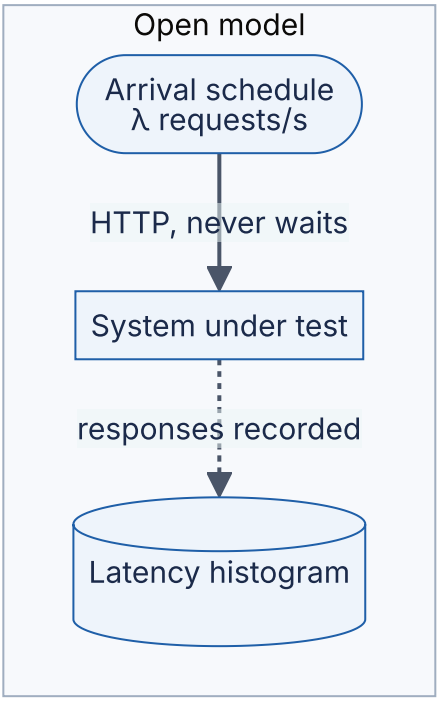
23.5.2 Open versus closed workload models

DEFINITION

Definition — Open and closed workload models. In an **open** model, new requests arrive at a rate that is independent of how fast the system answers: users on the internet do not wait for each other. In a **closed** model, a fixed population of N users (or load-generator threads) each sends a request, waits for the response, optionally pauses for a **think time** Z, and only then sends the next. A **partly open** model has sessions that arrive openly but issue several requests each, closed-loop, within the session [Schroeder et al. 2006].

Figure 23.5 — Open and closed load generators.





Reading the diagram. In the open model a scheduler issues requests (for example, HTTP) at rate λ and never waits, so when the system slows down requests pile up inside it, as real internet traffic does; responses are recorded asynchronously (dotted) into a histogram, the test's storage boundary. In the closed model each of N users loops synchronously: send, wait, think, repeat. When the system slows, users send *less*, so the generator reduces load exactly when the system struggles. That is the closed model's failure point: it cannot reach the queueing regime real users would cause. Open tests scale by

adding generator machines; closed tests by adding users, which raises load only while the system keeps up.

FORMULA

Interactive response time law (closed systems)

$$X = \frac{N}{R + Z} \qquad \Leftrightarrow \qquad R = \frac{N}{X} - Z$$

Symbol	Meaning	Units
N	Number of users (or load-generator threads) in the closed loop	count
X	Throughput	requests/second
R	Mean response time	seconds
Z	Mean think time between a response and the next request	seconds

This is Little's Law (§4.11) applied to the whole loop of users plus system [Lazowska et al. 1984].

WORKED EXAMPLE

Worked example — A closed test that cannot find the problem. A load test uses $N = 50$ threads with no think time ($Z = 0$). With $R = 10$ ms the generator produces $X = 50/0.010 = 5,000$ RPS. Production peak is 5,000 RPS, open.

1. Suppose a regression doubles service time so $R = 20$ ms at the same concurrency. The closed test now produces $X = 50/0.020 = 2,500$ RPS: it halves the offered load and reports latency of 20 ms, "a bit slower".
2. In production the 5,000 RPS keeps arriving. If capacity has fallen to about 2,500 RPS, utilization exceeds 100%, the queue grows without bound (§4.10.3), and latency rises until requests time out.

Interpretation. The closed test turns an outage into a mild regression, because it measures the system at whatever rate the system can sustain. **Engineering implication.** To check an SLO at a target rate, use an open (constant-arrival-rate) generator. Use closed tests only for systems that really are closed (a fixed pool of batch workers, a connection-limited client) or to measure capacity curves as a function of concurrency (§23.10).

Schroeder, Wierman and Harchol-Balter showed that at the same load the two models give very different response times and respond differently to scheduling policies, and that

many standard benchmarks used closed generators although web traffic is better described as open or partly open [Schroeder et al. 2006].

23.5.3 Coordinated omission

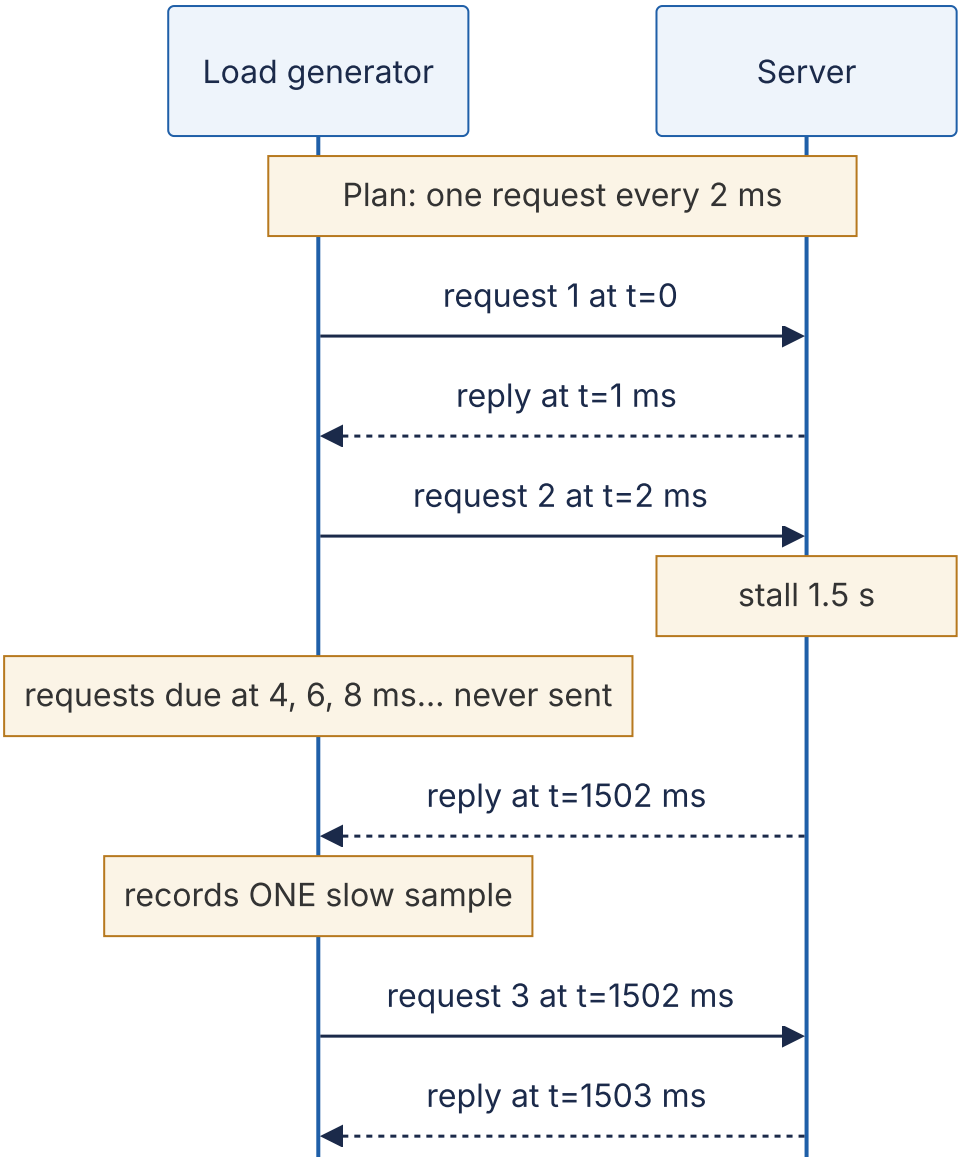
DEFINITION

Definition — Coordinated omission. A measurement error in which the load generator, by waiting for slow responses before sending more requests, fails to send (and therefore fails to measure) the requests that would have experienced the slowness. The tester and the system "coordinate" to omit the worst samples. The term and diagnosis are due to Gil Tene [Tene, How NOT to Measure Latency].

First-principles explanation

A manager measures checkout waits by sending one shopper through every two minutes. At noon the till jams for 30 minutes; the shopper reports one bad wait, and the next goes at 12:32. Fifteen real customers who would have waited 2–30 minutes were never sampled, so the report shows one bad wait in hundreds: a perfect-looking p99.

Figure 23.6 — How a closed-loop tester omits the stall.



Reading the diagram. The generator plans one request every 2 ms over a single connection and waits synchronously for each reply. When the server stalls for 1.5 s (a GC pause, a failover), request 2 waits throughout, the ~750 requests scheduled during the stall are never sent, and one 1.5 s sample is recorded. In an open model those requests would have queued at the server, and the backlog would have delayed requests after the stall too. The failure point is coupling sending to receiving; the fix is to decouple them and measure each request from its *intended* send time.

FORMULA

Damage done by a stall in an open system

$$\text{missed by closed tester} \approx \frac{T_s}{\Delta} \qquad t_{\text{drain}} = \frac{\lambda T_s}{\mu - \lambda} \qquad \text{affected requests} = \lambda (T_s + t_{\text{drain}}) = \frac{\lambda \mu T_s}{\mu - \lambda}$$

Symbol	Meaning	Units
T_s	Duration of the stall	seconds
$\Delta = 1/\lambda$	Intended interval between requests	seconds
λ	Intended (open) arrival rate	requests/second
μ	Service rate once the server resumes ($> \lambda$)	requests/second
t_{drain}	Time to drain the backlog after the stall	seconds

WORKED EXAMPLE

Worked example — A 1.5 s stall in a 60 s test. $\lambda = 500$ RPS, $\Delta = 2$ ms, $\mu = 1,000$ RPS (1 ms per request), $T_s = 1.5$ s, test length 60 s (30,000 intended requests).

1. Missed by the closed tester: $1.5/0.002 = 750$ requests (about 2.5% of the test).
2. Backlog at the end of the stall: $500 \times 1.5 = 750$ requests; it drains at the net rate $\mu - \lambda = 500$/s, so $t_{\text{drain}} = 1.5$ s.
3. Affected requests: $500 \times (1.5 + 1.5) = 1,500$, which is 5% of the test. Their latencies fall linearly from 1.5 s to about 0.
4. True p99 is the 300th worst of these: $1.5 - 300 \times (1.5/1,500) = 1.2$ s.

Interpretation. The real p99 is 1.2 s; a closed tester reports the ordinary 1–2 ms. **Engineering implication.** Generators that wait for responses under-report every percentile a stall touches, often by orders of magnitude.

The following program simulates this exact scenario with three measurement strategies: the naive closed loop, the closed loop with HdrHistogram's after-the-fact correction (which adds the "missing" samples $v - \Delta, v - 2\Delta, \ldots$ for each long sample v), and an open-loop generator that measures from the intended send time.

```
        import math
        import random

        RATE = 500                    # intended request rate, requests/second
        INTERVAL = 1 / RATE           # 2 ms between scheduled sends
        DURATION = 60.0               # seconds of test
        STALL = (30.0, 31.5)          # server freezes for 1.5 s (GC pause, failover...)

        class Server:
            """Single-threaded FIFO server; service time ~1 ms; one 1.5 s stall."""
            def __init__(self, seed=1):
                self.rng = random.Random(seed)
                self.free_at = 0.0
            def submit(self, t):
                start = max(t, self.free_at)
                if STALL[0] <= start < STALL[1]:          # frozen: wait for the stall
to end
                    start = STALL[1]
                service = 0.0008 + self.rng.expovariate(1 / 0.0002)
                if start < STALL[0] < start + service:    # stall hits mid-request
                    service += STALL[1] - STALL[0]
                self.free_at = start + service
                return self.free_at                       # completion time

        def closed_loop():
            """Naive tester: one connection; waits for each reply before sending the
            next; measures from the actual send time (like wrk or a simple script)."""
            server, t, lat = Server(), 0.0, []
            while t < DURATION:
                done = server.submit(t)
                lat.append(done - t)
                t = max(t + INTERVAL, done)               # late? just carry on from now
            return lat

        def corrected(lat):
            """HdrHistogram-style correction: a reply that took v > INTERVAL implies
            missed sends that would have seen v - INTERVAL, v - 2*INTERVAL, ..."""
            out = []
            for v in lat:
                out.append(v)
                missing = v - INTERVAL
                while missing > INTERVAL:
                    out.append(missing)
                    missing -= INTERVAL
            return out

        def open_loop():
            """Correct tester: sends on a fixed schedule whatever happens and measures
            from the *intended* send time (like wrk2, or k6 constant-arrival-rate)."""
            server, lat = Server(), []
            for i in range(int(DURATION * RATE)):
                t = i * INTERVAL
                lat.append(server.submit(t) - t)
            return lat

        def pct(sorted_ms, q):
```

```
            return sorted_ms[max(math.ceil(q / 100 * len(sorted_ms)), 1) - 1]

        print(f"{'tester':<22}{'count':>7}{'p50':>8}{'p90':>8}{'p99':>8}"
              f"{'p99.9':>8}{'max':>8}   (ms)")
        for name, lat in (("closed loop (naive)", closed_loop()),
                          ("closed + correction", corrected(closed_loop())),
                          ("open loop (truth)", open_loop())):
            ms = sorted(v * 1000 for v in lat)
            print(f"{name:<22}{len(ms):>7}" +
                  "".join(f"{pct(ms, q):>8.1f}" for q in (50, 90, 99, 99.9)) +
                  f"{ms[-1]:>8.0f}")
```

Output:

```
tester                 count     p50     p90     p99   p99.9     max   (ms)
closed loop (naive)    29245     0.9     1.3     1.7     2.1    1500
closed + correction    29994     0.9     1.3   902.2  1442.2    1500
open loop (truth)      30000     1.0     1.4  1199.8  1471.4    1501
```

What to notice:

- The naive tester sent 755 fewer requests and reports p99 = 1.7 ms. The truth is 1,200 ms, as the worked example predicted: a 700-fold understatement. Only the max (1.5 s) hints at the stall, and averages and p99 dashboards hide it.
- The correction recovers most of the tail (p99 902 ms) but not all: it reconstructs the requests missed *during* the stall but not the backlog that would have delayed requests *after* it, because the naive tester never built a queue.
- The open-loop tester's numbers are the only ones that describe what users would see. Its generator must itself never stall: real generators use many connections or asynchronous I/O so that a slow reply does not delay the next scheduled send.

23.5.4 Warm-up, think time and other pitfalls

- **Warm-up.** Early minutes run with cold caches, empty pools and interpreted code (§23.9.3). Report warm-up separately: it is what users see after every deployment.
- **Think time.** Closed tests with $Z = 0$ model nobody. Use measured think times, or an open model if you need a target rate.
- **Generator saturation.** A generator at 100% CPU delays its own sends, which is coordinated omission from the client side. Apply USE to generators too.
- **Unrealistic data.** Repeated keys hit caches; replay production traffic or sample keys from the measured popularity distribution.
- **Too-short runs.** Near saturation averages converge slowly (§4.10.3), and leaks and GC behavior appear only in soak tests.
- **Averaging percentiles.** Merge histograms, then read the percentile (§4.8.3).

23.5.5 Recording latency with HDR histograms

Fixed-width buckets lose resolution at one end of the range. **HdrHistogram** preserves a chosen number of **significant decimal digits** over a wide range by splitting power-of-two buckets into linear sub-buckets, so *relative* error stays below 10^{-d} [Tene, HdrHistogram].

FORMULA

HdrHistogram footprint (simplified from the reference implementation)

$$s = 2^{\lceil \log_2 (2 \times 10^d) \rceil} \qquad b = 1 + \lceil \log_2 \frac{H}{s \cdot L} \rceil \qquad \text{counters} = (b + 1)\frac{s}{2} \qquad \text{memory} \approx 8 \times \text{counters}$$

Symbol	Meaning	Units
d	Significant decimal digits preserved	digits
s	Sub-buckets per bucket	count
L, H	Lowest discernible and highest trackable values	e.g. µs
b	Number of power-of-two buckets	count
memory	Size with 64-bit counters	bytes

WORKED EXAMPLE

Worked example — 1 µs to 1 hour at 3 significant digits. $d = 3$, $L = 1$ µs, $H = 3.6 \times 10^9$ µs.

1. $s = 2^{\lceil \log_2 2{,}000 \rceil} = 2^{11} = 2{,}048$.
2. $H/(sL) = 3.6 \times 10^9 / 2{,}048 = 1.76 \times 10^6$; $\log_2$ of that is 20.7, so $b = 1 + 21 = 22$.
3. Counters $= 23 \times 1{,}024 = 23{,}552$; memory $= 23{,}552 \times 8 = 188{,}416$ bytes ≈ 184 KiB.

Interpretation. Under 200 KB records any latency from 1 µs to an hour with 0.1% relative error, and histograms merge by adding counters. **Engineering implication.** Record latency in HDR or similar log-linear histograms in generators and services, and ship histograms, not precomputed percentiles.

23.5.6 Load-testing tools

Table 23.5 — Load generators and their workload models (as of 2026).

Tool	Scripting	Open model	Closed model	Notes
wrk2	Lua	Yes: constant throughput, `-R` rate	—	Measures from intended send time; HdrHistogram output
k6	JavaScript	`constant-arrival-rate`, `ramping-arrival-rate` executors	`constant-vus`, `ramping-vus` executors	Documents the open/closed distinction explicitly
Gatling	Scala, Java, Kotlin	`constantUsersPerSec`, `rampUsersPerSec` injection	`constantConcurrentUsers` injection	Detailed HTML reports
Locust	Python	Approximate via `constant_throughput` per user	Default: users with `wait_time`	Easy to write; one user per greenlet
wrk (original)	Lua	—	Yes	Fast, but subject to coordinated omission

INDUSTRY EXAMPLE

Facebook — Kraken load tests with live traffic. Instead of synthetic load, Kraken shifts a controlled share of *real* user traffic onto a target cluster or region by adjusting load-balancer weights, monitors health metrics, and stops automatically if latency or errors degrade. Regular tests exposed bottlenecks synthetic tests missed. Trade-off: the "test load" is real users, so safety stops must be fast and automatic. *Evidence: Primary* — [Veeraraghavan et al. 2016]

COMMON MISTAKE

Mistake — "The load test passed at 10,000 RPS" when the generator achieved 6,000. Closed-loop generators report whatever rate the system allowed. Print the *achieved* rate next to latency results, and fail the test if it falls short.

23.6 Tail latency at scale

23.6.1 Fan-out amplification, quantified

Section 4.8.4 showed that a root waiting for N independent leaves is slow whenever *any* leaf is slow: with a leaf p99 threshold, $1 - 0.99^N$ of root requests exceed it. The same idea gives the root's whole latency distribution.

FORMULA

Percentiles of a fan-out request

$$P(T_{\text{root}} \le t) = F(t)^N \qquad t_q^{\text{root}} = F^{-1}(q^{1/N}) \qquad \text{exponential leaves: } t_q^{\text{root}} = m \ln \frac{1}{1 - q^{1/N}}$$

Symbol	Meaning	Units
$F(t)$	CDF of one leaf's latency	dimensionless
N	Number of leaves the root waits for	count
q	Desired root percentile (as a fraction)	dimensionless
t_q^{root}	Root latency at percentile q	ms
m	Mean leaf latency for exponentially distributed leaves	ms

WORKED EXAMPLE

Worked example — 100 leaves with exponential latency. Leaf latency is exponential with mean $m = 10$ ms.

1. One leaf's p99: $10 \ln 100 = 46.1$ ms.
2. Root p50 with $N = 100$: $0.5^{1/100} = 0.99309$, so $t = 10 \ln (1/0.00691) = 10 \times 4.975 = 49.8$ ms.
3. Root p99: $0.99^{1/100} = 0.9998995$, so $t = 10 \ln (1/0.0001005) = 10 \times 9.205 = 92.1$ ms.

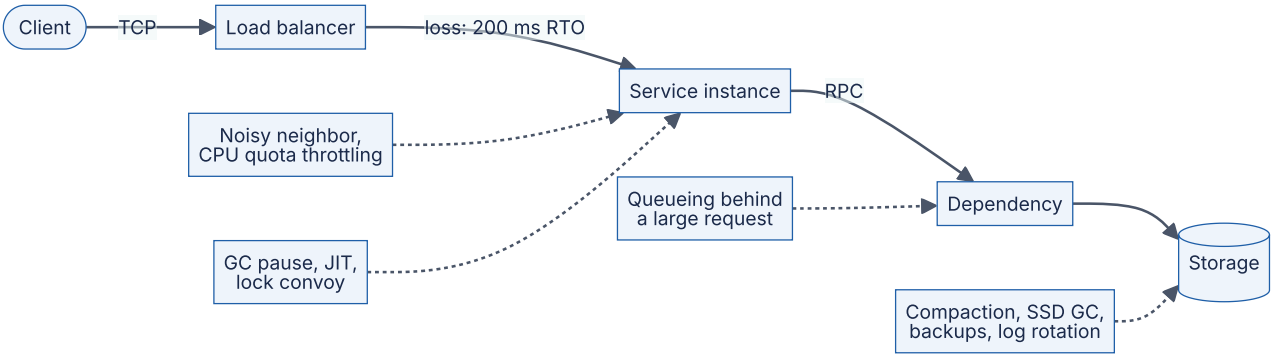
Interpretation. The root's *median* (49.8 ms) is worse than one leaf's p99 (46.1 ms). **Engineering implication.** In fan-out services the leaf tail *is* the user-facing median: engineer leaves to extreme percentiles or use tail-tolerant techniques (§23.7).

Real leaves are not fully independent: a shared cause (a switch hiccup) slows many at once. Dean and Barroso measured a large fan-out service at Google and reported that waiting for the slowest 5% of leaf requests accounted for roughly half of the root's p99 latency [Dean and Barroso 2013].

23.6.2 Sources of variability

Dean and Barroso list the usual suspects: contention with co-located work, daemons and background activities, shared global resources (switches, file systems), maintenance, queueing at many layers, power and thermal throttling, SSD garbage collection and runtime garbage collection [Dean and Barroso 2013].

Figure 23.7 — Where variability enters a request.



Reading the diagram. Solid arrows are the synchronous request path (TCP, then HTTP or RPC, then a storage read at the storage boundary). Each dotted arrow is an asynchronous disturbance that delays the request without belonging to it: a dropped packet costs a ≥ 200 ms retransmission timeout (§7.7); co-located tenants, CPU quotas (§23.6.3) and runtime pauses (§23.9) stall the instance; a request queued behind an expensive one inherits its delay; compaction (§13.9), SSD garbage collection (§5.6) and backups steal storage I/O. Every box is a tail-latency failure point, and scaling out multiplies their combined effect.

Table 23.6 — Common sources of tail latency.

Source	Typical magnitude	Detection	Mitigation
GC stop-the-world pause	1 ms – seconds	GC logs; pause histograms	Lower allocation; concurrent collector (§23.9)
Queueing behind large requests	Size of the large request	Per-request size vs. latency	Split large requests; priority classes
Background tasks (compaction, backups)	10s–100s of ms	Latency correlates with job schedule	Throttle; schedule off-peak; stagger across replicas
Noisy neighbor	10s of % slowdown	Cache misses, CPU steal time	Isolation, dedicated hosts
CPU quota throttling	Rest of a 100 ms period	`nr_throttled` in cgroup `cpu.stat`	Raise or remove limits; fewer threads
Packet loss	≥ 200 ms per retransmission	TCP retransmit counters	Avoid drops; hedging (§23.7)

23.6.3 A worked trap: CPU quota throttling

Linux enforces container CPU limits (including Kubernetes limits) with the CFS bandwidth controller: in each **period** P (100 ms by default) a cgroup may use at most its **quota** Q of CPU time across all its threads.

FORMULA

Throttling under a CPU quota

$$t_{\text{run}} = \frac{Q}{k} \qquad t_{\text{throttled}} = P - \frac{Q}{k} \qquad (\text{when } k > Q/P)$$

Symbol	Meaning	Units
P	Enforcement period	ms
Q	CPU-time quota per period (2 CPUs = $2P$)	CPU·ms
k	Threads runnable at the same time	count
t_{run}	Wall time until the quota is exhausted	ms
$t_{\text{throttled}}$	Wall time the whole cgroup is frozen	ms

WORKED EXAMPLE

Worked example — Two CPUs of quota, eight busy threads. $P = 100$ ms, $Q = 200$ ms (a limit of 2 CPUs), and a burst makes $k = 8$ threads runnable on an 8-core host.

1. $t_{\text{run}} = 200/8 = 25$ ms; $t_{\text{throttled}} = 100 - 25 = 75$ ms.
2. A request needing 40 ms of CPU on one of those threads gets 25 ms, waits 75 ms, then finishes after 15 ms more: latency 115 ms instead of 40 ms.
3. Average CPU use over the period is still only 2 cores out of 8, so host dashboards show 25%.

Interpretation. A limit expressed as an *average* (2 CPUs) is enforced over a short window, so bursty multi-threaded work is frozen for most of each period.
Engineering implication. Watch throttled-period counters, size thread pools to the quota rather than the host's core count (runtimes such as the JVM and Go read the limit for this reason in recent versions), and consider CPU requests without hard limits for latency-sensitive services.

Within a server, mitigations are **service classes** (interactive before batch), **splitting large requests**, and **managing background activity** (throttle it, or synchronize it across machines so it disturbs one short window) [Dean and Barroso 2013]. Across servers, it is often better to *tolerate* variability, as the next section shows.

23.7 Hedged and tied requests

23.7.1 Hedged requests

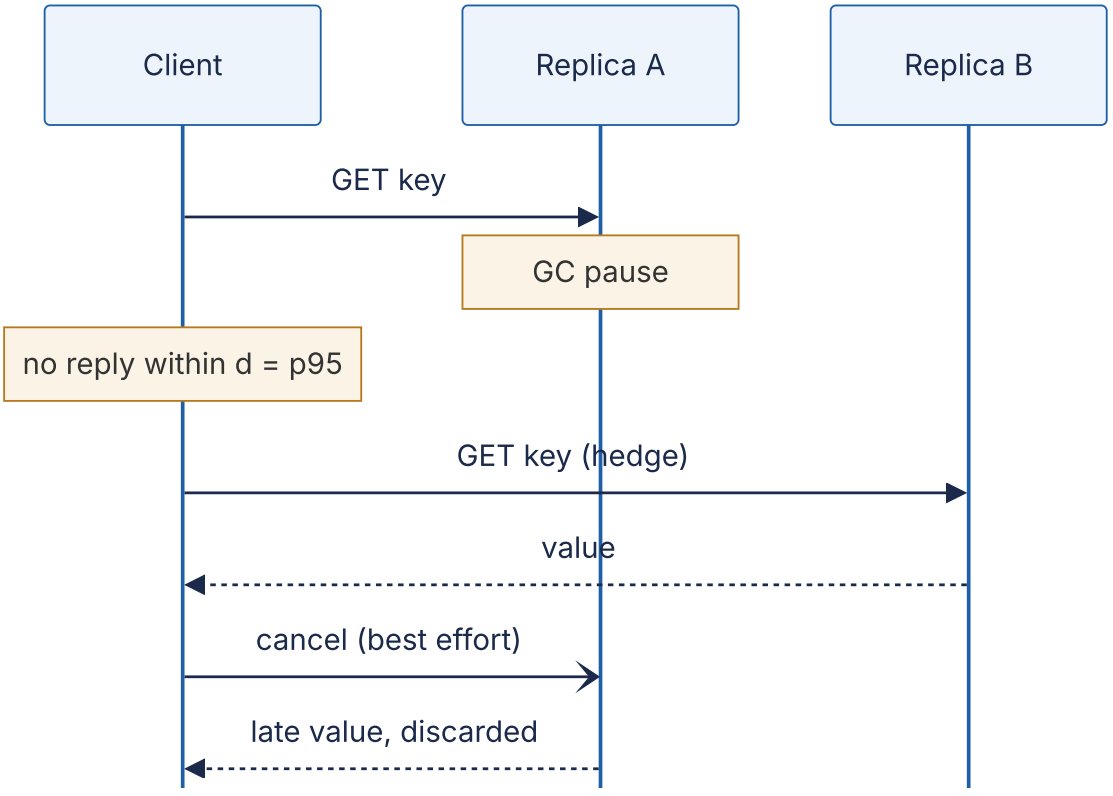
DEFINITION

Definition — Hedged request. A request sent to one replica and, if no response arrives within a **hedge delay** d, sent again to a second replica; the client uses whichever response arrives first and cancels or ignores the other [Dean and Barroso 2013].

First-principles explanation

You order a taxi through one app; if no driver accepts within five minutes, you also order through a second and take whichever car comes first. An occasional canceled booking buys protection from the rare 40-minute wait. The key choice is the delay: order from both at once and you double the load on drivers; wait too long and the hedge is useless.

Figure 23.8 — A hedged request.



Reading the diagram. The client sends a synchronous RPC to replica A, which is paused. When the hedge timer d expires, the client sends the same idempotent read to replica B and uses B's earlier answer. The cancel to A is asynchronous and best effort, so A's work may be wasted. Both replicas must hold the data (a replication boundary), and the operation must be safe to run twice (reads, or writes with an idempotency key,

§22.15). The failure point is load: if the whole system slows, many requests exceed d and hedging adds load when there is none to spare.

FORMULA

Hedged latency and extra load (independent replicas)

$$T = \min(X_1,\ d + X_2) \qquad P(T > t) = \begin{cases} P(X > t) & t < d \\ P(X > t)\,P(X > t - d) & t \geq d \end{cases} \qquad \text{extra load} = P(X > d)$$

Symbol	Meaning	Units
X_1, X_2	Latencies of the primary and the hedge, same distribution as X	ms
d	Hedge delay	ms
T	Latency seen by the client	ms
extra load	Fraction of requests that send a second copy	dimensionless

WORKED EXAMPLE

Worked example — Hedging a bimodal leaf. A replica answers in 8 ms with probability 0.98 and in 400 ms with probability 0.02 (a pause). Without hedging, p95 = 8 ms and p99 = 400 ms. Hedge after $d = 10$ ms.

1. With probability 0.98 the first reply arrives at 8 ms; no hedge is sent.
2. With probability 0.02 the hedge goes at 10 ms. It returns at $10 + 8 = 18$ ms with probability 0.98; otherwise both are slow and the reply arrives at 400 ms.
3. $P(T > 18\text{ ms}) = 0.02 \times 0.02 = 0.0004$. So p99 and p99.9 fall from 400 ms to 18 ms; only p99.96 and above remain at 400 ms.
4. Extra load $= P(X > 10\text{ ms}) = 2\%$.
5. With a 100-leaf fan-out: $P(\text{all leaves} \leq 18\text{ ms}) = (1 - 0.0004)^{100} = 0.961$, versus $0.98^{100} = 0.133$ unhedged.

Interpretation. Two percent more requests turn 87% slow fan-out queries into 4%. **Engineering implication.** Hedge idempotent operations after about the p95, bounding extra load near 5%.

23.7.2 Simulating hedging, including its cost

The worked example ignores a feedback: hedges add load, load adds queueing, and higher latency triggers more hedges. The simulation models 20 FIFO replicas with Poisson arrivals, about 1 ms of work per request, and a 50 ms hiccup on 0.1% of requests

that also delays everything queued behind it. It compares no hedging, hedging after the unhedged p95, hedging with cancellation (a copy not yet started when the original finishes is dropped), and hedging after the p50.

```
        import heapq
        import math
        import random

        SERVERS = 20
        N_REQ = 400_000

        def service_time(rng):
            """~1 ms of work; 0.1% of requests hit a 50 ms hiccup (GC, com-
paction...)."""
            t = 0.0005 + rng.expovariate(1 / 0.0005)
            if rng.random() < 0.001:
                t += 0.050
            return t

        def simulate(rho, hedge_after=None, cancel=False, seed=3):
            """FIFO replicas; Poisson arrivals; optional hedge to a second replica.
            Returns (latencies in ms, extra work as a fraction of original work)."""
            rng = random.Random(seed)
            lam = rho * SERVERS / 0.00105           # mean service time is 1.05 ms
            free_at = [0.0] * SERVERS
            events, t = [], 0.0                     # (submit_time, seq, req_id,
is_hedge, avoid)
            for i in range(N_REQ):
                t += rng.expovariate(lam)
                heapq.heappush(events, (t, i, i, False, -1))
            done = [0.0] * N_REQ
            sent = [0.0] * N_REQ
            seq, base_work, extra_work = N_REQ, 0.0, 0.0
            while events:
                now, _, rid, is_hedge, avoid = heapq.heappop(events)
                server = rng.randrange(SERVERS)
                while server == avoid:
                    server = rng.randrange(SERVERS)
                start = max(now, free_at[server])
                if is_hedge:
                    if cancel and done[rid] <= start:  # original already answered: drop
copy
                        continue
                    work = service_time(rng)
                    free_at[server] = start + work
                    extra_work += work
                    done[rid] = min(done[rid], free_at[server])
                else:
                    work = service_time(rng)
                    free_at[server] = start + work
                    base_work += work
                    sent[rid], done[rid] = now, free_at[server]
                    if hedge_after is not None and done[rid] > now + hedge_after:
                        seq += 1
                        heapq.heappush(events, (now + hedge_after, seq, rid, True,
server))
            lat = sorted((d - s) * 1000 for d, s in zip(done, sent))
            return lat, extra_work / base_work

        def pct(xs, q):
```

```
            return xs[max(math.ceil(q / 100 * len(xs)), 1) - 1]

        for rho in (0.5, 0.8):
            base, _ = simulate(rho)
            d = pct(base, 95) / 1000                # hedge after the unhedged p95
            print(f"utilization {rho:.0%}: hedge delay = p95 = {d*1000:.2f} ms")
            print(f"  {'policy':<16}{'p50':>8}{'p95':>8}{'p99':>8}{'p99.9':>8}{'extra
work':>12}")
            for name, kw in (("no hedging", {}),
                             ("hedge at p95", {"hedge_after": d}),
                             ("hedge + cancel", {"hedge_after": d, "cancel": True}),
                             ("hedge at p50", {"hedge_after": pct(base, 50) / 1000})):
                lat, extra = simulate(rho, **kw)
                print(f"  {name:<16}" + "".join(f"{pct(lat, q):>8.1f}" for q in (50, 95,
99, 99.9))
                      + f"{extra:>12.1%}")
```

Output (latencies in ms):

```
utilization 50%: hedge delay = p95 = 5.89 ms
  policy               p50     p95     p99   p99.9  extra work
  no hedging           1.3     5.9    44.6    61.0        0.0%
  hedge at p95         1.3     6.5     8.6    28.3        5.8%
  hedge + cancel       1.3     6.4     8.5    26.3        5.0%
  hedge at p50        48.6   244.1   401.8   579.2       98.7%
utilization 80%: hedge delay = p95 = 45.05 ms
  policy               p50     p95     p99   p99.9  extra work
  no hedging           2.7    45.0    68.2   127.0        0.0%
  hedge at p95      3456.8 10502.8 11149.5 11550.1       75.5%
  hedge + cancel       3.2    45.7    51.7    74.6        3.9%
  hedge at p50      7696.8 14771.3 15513.6 15978.4      100.2%
```

What to notice:

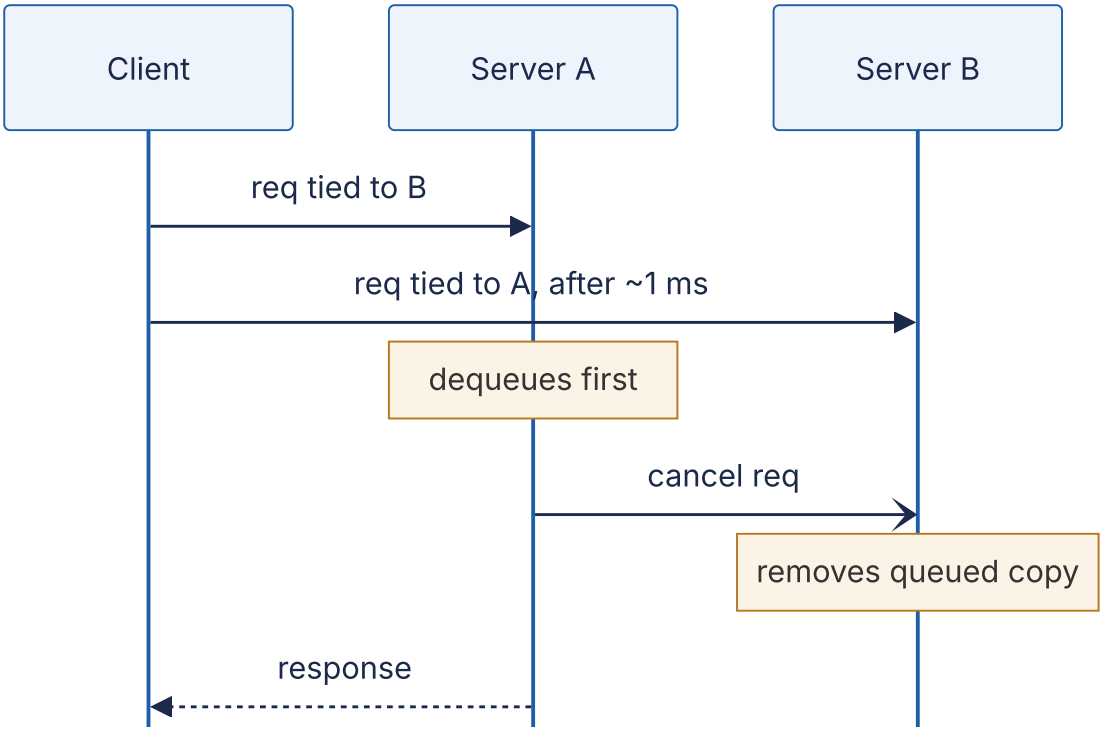
- **At 50% utilization, hedging at p95 cuts p99 from 44.6 ms to 8.6 ms** (5×) and p99.9 by more than half, for about 6% extra work. The median is untouched.
- **At 80% utilization the same policy without cancellation collapses** in a positive feedback loop: hedges raise utilization, queues grow, more requests exceed *d*. Extra work reaches 75%, demand exceeds capacity, and latency grows for as long as the run lasts. *With* cancellation the policy stays stable and still cuts the tail.
- **Hedging at p50 is a self-inflicted denial of service**, nearly doubling the work.
- The model cannot cancel a queued original; real tied requests (below) can.

23.7.3 Tied requests

Hedging waits before sending the second copy, so it helps only the slowest few percent. **Tied requests** send both copies (almost) at once, but each copy carries the identity of the other server, and whichever server *starts* executing the request first sends a cancellation to the other [Dean and Barroso 2013]. The request thus waits in the *shorter* of two

queues, which approximates a shared queue across servers (pooling, §4.10.4), and is executed only once in the common case.

Figure 23.9 — Tied requests with cross-server cancellation.



Reading the diagram. The client enqueues the request on two servers, delaying the second send by about one network message delay, and each copy names its twin. When A starts the request, it sends an asynchronous cancel to B, which drops its queued copy, so one server does the work and the client gets one response. If both dequeue before the cancel arrives, both execute (one duplicate). Unlike hedging, this needs server-side support for queue manipulation and peer messages.

Dean and Barroso report that in a BigTable benchmark, tied requests made the latency of a cluster running a concurrent large sort job nearly as good as that of an idle cluster without tied requests, at a disk-utilization cost below 1% [Dean and Barroso 2013]. They also report the hedged-request benchmark quoted in §4.8.4: hedging after 10 ms reduced the p99.9 of a 1,000-key read across 100 servers from 1,800 ms to 74 ms with 2% more requests.

Real-world industry applications

INDUSTRY EXAMPLE

Speculative execution in batch and storage systems. MapReduce schedules **backup tasks** for the last in-progress tasks of a job, taking whichever copy finishes first; the original paper reports a sort taking 44% longer with backup tasks disabled [Dean and Ghemawat 2004]. Apache Cassandra offers a per-table `speculative_retry` setting that sends a read to an extra replica when the first has not answered by a chosen percentile or fixed delay [Apache Cassandra Docs]. gRPC's retry design defines a `hedgingPolicy` with a maximum number of attempts and a hedging delay, and the server can throttle hedges with pushback [gRPC A6]. *Evidence: Primary* — [Dean and Ghemawat 2004], [Apache Cassandra Docs], [gRPC A6]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Overload spiral	Hedges add load as latency rises	Hedge rate climbs with latency	Disable hedging; shed load	Hedge budget (e.g., ≤ 5% of requests); adaptive delay
Duplicate side effects	Non-idempotent operation hedged	Duplicate records, double charges	Compensating actions	Hedge reads only, or use idempotency keys (§22.15)
No improvement	Replicas share the slow cause (same disk, same switch)	Hedge and primary equally slow	Choose replicas in other failure domains	Spread replicas across racks and zones
Hedges amplify retries	Hedging and retries both enabled at every layer	Request count ≫ user requests	Remove one layer's hedging	Hedge at one layer only, with a shared budget (§22.12)

COMMON MISTAKE

Mistake — Hedging with a fixed delay forever. A delay tuned to last quarter's p95 becomes the p60 after a regression, and the hedge rate jumps from 5% to 40%. Derive the delay from a recent latency histogram, cap the fraction of requests that may hedge, and turn hedging off when the service is overloaded.

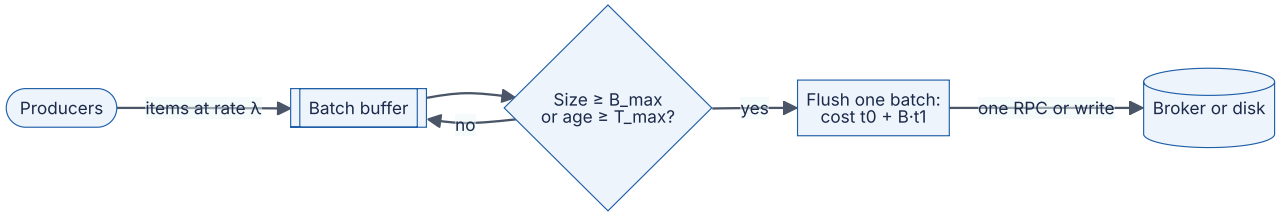
23.8 Batching, pipelining and compression

23.8.1 Batching with a size and a time limit

Section 4.18.6 modeled a batch of B items as costing $t_0 + Bt_1$: the fixed cost t_0 (a system call, a network round trip, a disk flush, a GPU kernel launch) is shared by all items. Real

batchers close a batch on whichever comes first, a **size limit** or a **time limit**, so that light traffic is not stuck waiting for a full batch. Kafka's producer `batch.size` and `linger.ms` settings are exactly this pair (§31.6).

Figure 23.10 — A batcher with size and time triggers.



Reading the diagram. Producers append asynchronously to an in-memory buffer, a failure point: its contents are lost on a crash unless callers wait for acknowledgment. Two triggers are checked on every append and by a timer; when either fires, the batch goes as one synchronous RPC or write to the sink (the storage boundary). Heavy load fills batches (maximum throughput); light load fires the timer, bounding added latency at $T_{\max}$. Scale with parallel batchers (per partition or core).

FORMULA

Batch size and latency with a time limit

$$B_{\text{eff}} \approx \min\left(B_{\max},\ \max\left(1, \lambda T_{\max}\right)\right) \qquad X_{\max} = \frac{B_{\text{eff}}}{t_0 + B_{\text{eff}}\, t_1} \qquad W_{\text{worst}} \approx T_{\max} + t_0 + B_{\text{eff}}\, t_1$$

Symbol	Meaning	Units
λ	Item arrival rate	items/second
$B_{\max}$, $T_{\max}$	Size and time limits of the batcher	items, seconds
B_{eff}	Typical batch size actually sent	items
t_0, t_1	Fixed cost per batch, marginal cost per item	seconds, seconds/item
$X_{\max}$	Throughput one sender can sustain	items/second
W_{worst}	Worst-case latency added by batching and sending	seconds

WORKED EXAMPLE

Worked example — A log shipper. Each send costs $t_0 = 0.5$ ms (round trip and system call) plus $t_1 = 10$ µs per record. Records arrive at $\lambda = 20,000$/s; one sender has one batch in flight at a time.

1. Unbatched ($B = 1$): $X_{\max} = 1/0.00051 = 1,961$/s. The sender falls 18,000 records/s behind.
2. With $T_{\max} = 5$ ms and $B_{\max} = 500$: $B_{\text{eff}} = \min(500, 20,000 \times 0.005) = 100$.
3. Batch time $= 0.5 + 100 \times 0.01 = 1.5$ ms, so $X_{\max} = 100/0.0015 = 66,667$/s: 3.3× headroom.
4. Worst-case added latency $\approx 5 + 1.5 = 6.5$ ms; the average record waits about half of $T_{\max}$, 2.5 ms.

Interpretation. A 5 ms latency budget buys a 34× throughput increase.
Engineering implication. Choose $T_{\max}$ from the latency budget, not from throughput; at high load the batch fills before the timer anyway.

The Nagle analogy. Nagle's algorithm (§7.7.8) is a batcher whose "timer" is the arrival of an acknowledgment: small writes are held while data is unacknowledged. It improves throughput for chatty senders, but combined with the receiver's delayed-ACK timer it adds tens of milliseconds to request/response traffic. The general lesson is that *two batchers in series can deadlock each other until a timer fires*. When you add batching to a client, check what the server does with small, incomplete messages.

23.8.2 Pipelining

Pipelining sends several requests on one connection without waiting for each response, overlapping network round trips with server work.

FORMULA

Sequential versus pipelined requests

$$T_{\text{seq}} = n(r + s) \qquad T_{\text{pipe}} \approx r + ns \quad (\text{window} \geq n)$$

Symbol	Meaning	Units
n	Number of requests	count
r	Network round-trip time	seconds
s	Server processing time per request	seconds

WORKED EXAMPLE

Worked example — 1,000 cache reads. $r = 0.5$ ms within a datacenter, $s = 5$ µs per GET in an in-memory store.

1. Sequential: $1,000 \times (0.5 + 0.005) = 505$ ms.
2. Pipelined: $0.5 + 1,000 \times 0.005 = 5.5$ ms, 92× faster.

Interpretation. For small operations the round trip, not the server, is the cost. **Engineering implication.** Use pipelining or multi-key commands (Redis pipelines, `MGET`) and multiplexed protocols such as HTTP/2 for many small requests. Strict in-order pipelining suffers head-of-line blocking: one slow response delays all later ones, which is why HTTP/1.1 pipelining failed and HTTP/2 multiplexes independent streams (§7.9).

23.8.3 Compression: ratio versus CPU

Compression trades CPU for bytes: it pays when bytes are the bottleneck (slow links, egress charges, storage, cache capacity).

Table 23.7 — Fast compressors on one CPU core (as of 2026; zstd project benchmark, lzbench on the Silesia corpus, Core i7-9700K).

Compressor and level	Ratio	Compression (MB/s)	Decompression (MB/s)
zstd 1.5.7, level 1	2.896	510	1,550
brotli 1.1.0, level 1	2.883	290	425
zlib 1.3.1, level 1 (gzip's DEFLATE)	2.743	105	390
lz4 1.10.0	2.101	675	3,850
snappy 1.2.1	2.089	520	1,500

Source: [Zstandard README]. Higher levels compress better and far more slowly; benchmark your own payloads.

FORMULA

When compression reduces transfer time (store-and-forward)

$$t_{\text{plain}} = \frac{S}{W} \qquad t_{\text{comp}} = \frac{S}{C_c} + \frac{S}{\rho W} + \frac{S}{C_d} \qquad \text{compress if } \frac{1}{C_c} + \frac{1}{\rho W} + \frac{1}{C_d} < \frac{1}{W}$$

Symbol	Meaning	Units
S	Uncompressed size	MB
W	Network (or disk) bandwidth	MB/s
ρ	Compression ratio (original / compressed)	dimensionless
C_c, C_d	Compression and decompression speed	MB/s

With streaming, stages overlap and time approaches the *slowest* stage rather than the sum.

WORKED EXAMPLE

Worked example — Shipping 100 MB. Use Table 23.7.

1. 1 Gb/s link ($W = 125$ MB/s): plain $= 0.80$ s. lz4: $0.148 + 100/262.6 + 0.026 = 0.148 + 0.381 + 0.026 = 0.555$ s. zstd-1: $0.196 + 100/362 + 0.065 = 0.196 + 0.276 + 0.065 = 0.537$ s. zlib-1: $0.952 + 0.292 + 0.256 = 1.50$ s.
2. 10 Gb/s link ($W = 1,250$ MB/s): plain $= 0.08$ s; lz4 $= 0.148 + 0.038 + 0.026 = 0.212$ s; zstd-1 $= 0.196 + 0.028 + 0.065 = 0.288$ s.

Interpretation. On a 1 Gb/s link, fast compressors cut transfer time by about a third and zlib nearly doubles it; on a 10 Gb/s datacenter link, compression *slows* a single-stream transfer by 2.6–3.6× (parallel compression across cores narrows the gap).
Engineering implication. Compress for slow or metered links, storage and cache capacity, and cross-region traffic (where egress is billed per byte); prefer zstd or lz4 over gzip for machine-to-machine traffic; compress batches rather than single small messages, since ratio improves with more context.

23.9 Garbage collection and runtime effects

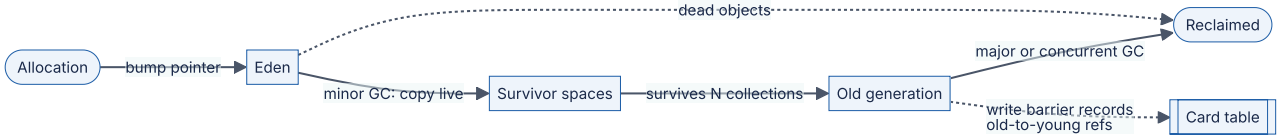
23.9.1 Generational garbage collection

DEFINITION

Definition — Garbage collection (GC). Automatic reclamation of heap memory that the program can no longer reach. A **tracing** collector finds live objects by following references from **roots** (stacks, globals, registers) and reclaims everything else. A **stop-the-world (STW) pause** is an interval in which all application threads (the **mutator**) are halted so the collector can work on a consistent heap [Jones et al. 2023].

A restaurant can clear tables while diners eat (concurrent collection) or close the room for ten minutes every hour (stop-the-world): simpler and cheaper overall, but everyone present waits. Most objects die young (request buffers, temporary strings), the **weak generational hypothesis**, which motivates **generational** collection [Ungar 1984]: allocate in a small **young generation** collected often by copying out the few survivors, and promote long-lived objects to an **old generation** collected rarely.

Figure 23.11 — Generational heap.



Reading the diagram. Allocation in Eden is a nearly free pointer bump. A minor GC copies live objects to a survivor space and reclaims the rest without touching it, so its cost scales with *survivors*, not garbage. Long-lived objects are promoted to the old generation. A **write barrier** on reference stores records old-to-young pointers in a card table (dotted bookkeeping) so minor GCs need not scan the old generation, which is collected by a major collection, stop-the-world or largely concurrent. Failure points: promotion faster than old-generation collection forces a long full STW collection; a heap too small for the live set causes back-to-back collections.

FORMULA

GC frequency and pause exposure

$$I_{\text{minor}} = \frac{E}{a} \qquad f_{\text{hit}} \approx \frac{p + w}{I_{\text{minor}}} \qquad \text{Go heap target} = H_{\text{live}} \times \left(1 + \frac{\text{GOGC}}{100}\right)$$

Symbol	Meaning	Units
E	Young-generation (Eden) size	MB
a	Allocation rate	MB/s
I_{minor}	Interval between minor collections	seconds
p	STW pause per minor collection	seconds
w	Request duration	seconds
f_{hit}	Approximate fraction of requests that overlap a pause	dimensionless
H_{live}	Live heap after the previous Go collection	MB
GOGC	Go's GC percentage setting (default 100)	percent

WORKED EXAMPLE

Worked example — GC in the tail. A JVM service allocates $a = 500$ MB/s with a 2 GB Eden; minor pauses are $p = 30$ ms. Its requests take 5 ms.

1. $I_{\text{minor}} = 2,000/500 = 4$ s between pauses.
2. Requests overlapping a pause: $f_{\text{hit}} \approx (30 + 5)/4,000 \approx 0.9\%$ (in flight when it starts, or arriving during it), each delayed by up to 30 ms.
3. So the service's p99 sits at the edge of the GC effect and its p99.9 includes most of a full pause; at 100-way fan-out, most root requests ($1 - 0.99125^{100} \approx 58\%$) see one.
4. Halving the allocation rate doubles the interval and halves the exposure. For a Go service with 1 GB live heap and GOGC = 100, the heap grows to $1 \times 2 = 2$ GB before the next cycle; GOGC = 50 caps it at 1.5 GB but runs GC twice as often.

Interpretation. GC pauses are a *rate* problem (how often) times a *size* problem (how long). **Engineering implication.** Reduce allocation first (it lowers both CPU and pause frequency), then choose a collector whose pause behavior fits the SLO.

23.9.2 Collectors in practice

Table 23.8 — Production collectors (as of 2026).

Collector	Runtime	Approach	Pause behavior	Choose when
Parallel	JVM	Generational, STW, multi-threaded	Long pauses, best throughput	Batch jobs where latency is irrelevant
G1	JVM (default since JDK 9)	Region-based, generational, mostly concurrent marking, STW evacuation	Pause-time *goal* (default 200 ms), typically tens of ms	General-purpose services
ZGC	JVM (production since JDK 15; generational since JDK 21)	Concurrent marking and relocation with load barriers	Sub-millisecond pauses independent of heap size	Large heaps with strict tail SLOs
Shenandoah	JVM (production since JDK 15, in some builds)	Concurrent compaction with barriers	Short pauses independent of heap size	Similar to ZGC
Go GC	Go	Concurrent, non-generational, non-moving mark-sweep	Short STW phases; *GC assist* slows allocating goroutines	Default; tune GOGC and GOMEMLIMIT
CPython	Python	Reference counting plus a cycle collector	Immediate frees; occasional cycle-collection pauses	Default

Concurrent collectors trade throughput and memory for short pauses: they add barriers to reference loads or stores, consume CPU for collector threads (Go's targets about 25% of available CPU during marking) and need heap headroom. Go 1.19 added `GOMEMLIMIT`, a soft limit that makes the collector run more often near it, which suits containers [Go GC Guide].

23.9.3 JIT warm-up and other runtime effects

A **just-in-time (JIT)** compiler (JVM, .NET, JavaScript engines) interprets code first, profiles it and compiles hot methods with increasing optimization, so a fresh instance runs several times slower for seconds to minutes. Every deployment and autoscaling event therefore causes a p99 spike, and tests without warm-up misstate steady-state performance. Mitigations: replay warm-up traffic before marking an instance ready, ramp traffic with load-balancer **slow start** (Chapter 19), or use ahead-of-time compilation and class-data sharing.

RECOMMENDATION

GC and runtime tuning heuristics.

- Measure before tuning: enable GC logging (`-Xlog:gc*` on the JVM, `GODEBUG=gctrace=1` in Go) and plot pause durations and frequency against latency percentiles.
- Reduce allocation rate with an allocation profiler (§23.4.5): reuse buffers, avoid boxing, stream instead of materializing.
- Give the collector headroom: a heap of a few times the live set is a common starting point; a nearly full heap means frequent collections.
- Pick the collector by goal: throughput (Parallel), balanced (G1), tail latency on large heaps (ZGC or Shenandoah).
- In containers, set the heap from the container limit (for example `-XX:MaxRAMPercentage`, or `GOMEMLIMIT` below the cgroup limit) so the runtime is not killed before it collects.

INDUSTRY EXAMPLE

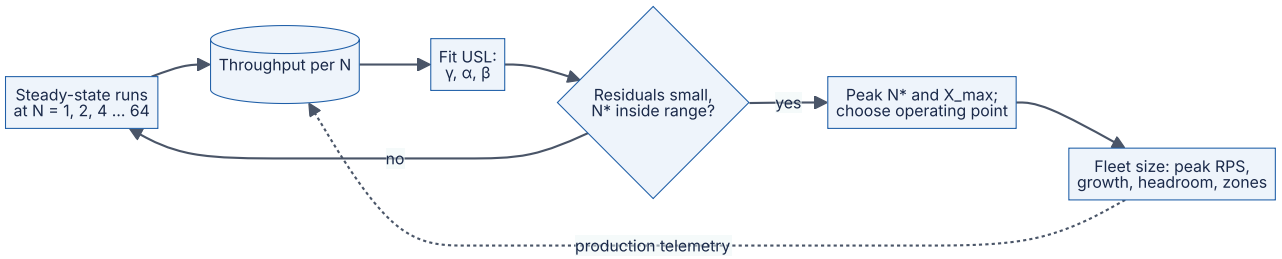
Discord — GC spikes in a Go service. Discord described a Go service holding a large in-memory cache that showed latency spikes about every two minutes. The cause was Go's forced garbage collection, which runs at least every two minutes even when little garbage exists; each cycle had to scan the large cache. Tuning reduced but did not remove the effect, and the team rewrote the service in Rust, which has no garbage collector, eliminating the spikes. Trade-off: a rewrite removed the runtime cause at significant engineering cost; reducing the number of heap pointers to scan is the usual cheaper alternative. *Evidence: Primary* — [Howarth 2020]

23.10 Capacity models from measurements

23.10.1 From benchmark to fleet

Section 4.13 introduced the Universal Scalability Law (USL) with known coefficients. In practice you *measure* throughput at several concurrency levels, *fit* the coefficients, and use the fitted model to predict the peak, choose an operating point and size the fleet [Gunther 2007].

Figure 23.12 — Capacity modeling workflow.



Reading the diagram. Each run is a warm, steady-state closed-loop test at fixed concurrency N (closed is right here, because concurrency is the independent variable); the throughputs are the stored data. If residuals are large or the fitted peak N^* lies outside the measured range, measure more points, because extrapolated peaks are unreliable. Operating point and fleet size follow by arithmetic, and production telemetry (dotted, asynchronous) refines the model.

FORMULA

USL for measured throughput, and its linearized form

$$X(N) = \frac{\gamma N}{1 + \alpha(N-1) + \beta N(N-1)} \qquad \frac{\gamma N}{X(N)} - 1 = \alpha(N-1) + \beta N(N-1)$$

Symbol	Meaning	Units
N	Concurrency (client threads, cores or nodes)	count
$X(N)$	Measured throughput at concurrency N	requests/second
γ	Throughput at $N = 1$ (the slope of ideal linear scaling)	requests/second
α, β	Contention and coherency coefficients (§4.13)	dimensionless

The right-hand form is linear in α and β, so with γ fixed at the measured $X(1)$ an ordinary least-squares fit gives a starting estimate; a nonlinear fit of all three parameters to the raw throughputs then refines it.

23.10.2 Fitting the USL in Python

The program fits benchmark data in two steps using only the standard library. The data are synthetic, generated from known coefficients ($\gamma = 950$, $\alpha = 0.03$, $\beta = 0.0004$) with 3% measurement noise, so you can see how well the fit recovers them.

```
        import math
        import random

        def usl(n, gamma, alpha, beta):
            """USL throughput: gamma = throughput at N = 1."""
            return gamma * n / (1 + alpha * (n - 1) + beta * n * (n - 1))

        def solve(a, b):
            """Solve the small linear system a x = b by Gaussian elimination."""
            n = len(b)
            m = [row[:] + [b[i]] for i, row in enumerate(a)]
            for c in range(n):
                p = max(range(c, n), key=lambda r: abs(m[r][c]))
                m[c], m[p] = m[p], m[c]
                for r in range(c + 1, n):
                    f = m[r][c] / m[c][c]
                    for k in range(c, n + 1):
                        m[r][k] -= f * m[c][k]
            x = [0.0] * n
            for r in range(n - 1, -1, -1):
                x[r] = (m[r][n] - sum(m[r][k] * x[k] for k in range(r + 1, n))) / m[r]
[r]
            return x

        def fit_linearized(ns, xs):
            """Step 1: N*gamma/X - 1 = alpha (N-1) + beta N (N-1), with gamma = X(1)."""
            gamma = xs[ns.index(1)]

        x_max = usl(n_star, g, a, b)
        print(f"R^2 = {1 - ss_res / ss_tot:.4f}   N* = {n_star:.1f}   X(N*) =
{x_max:,.0f} req/s")

        print(f"{'N':>4}{'measured':>10}{'model':>9}{'R=N/X ms':>10}{'efficiency':>12}")
        for n in ns + [96, 128]:
            model = usl(n, g, a, b)
            meas = f"{xs[ns.index(n)]:>10,}" if n in ns else f"{'-':>10}"
            print(f"{n:>4}{meas}{model:>9,.0f}{1000 * n / model:>10.2f}{model / (n *
g):>12.0%}")
```

Output:

```
linearized fit : gamma=  915.0  alpha=0.0238  beta=0.000502
nonlinear fit  : gamma=  885.4  alpha=0.0205  beta=0.000522
R^2 = 0.9983   N* = 43.3   X(N*) = 13,588 req/s
   N  measured    model  R=N/X ms  efficiency
   1       915      885      1.13        100%
   2     1,864    1,734      1.15         98%
   4     3,575    3,317      1.21         94%
   8     6,072    6,041      1.32         85%
  12     7,915    8,211      1.46         77%
  16     9,812    9,891      1.62         70%
  24    12,103   12,082      1.99         57%
  32    13,496   13,165      2.43         46%
  48    13,264   13,539      3.55         32%
  64    12,979   12,899      4.96         23%
  96         -   11,035      8.70         13%
 128         -    9,381     13.64          8%
```

What to notice:

- **The fit is excellent ($R^2 = 0.998$) yet the coefficients are off.** The true peak is at $N^* = \sqrt{0.97/0.0004} = 49$ with 13,770 req/s; the fit says 43 with 13,588 req/s. Throughput near the peak is flat, so the *location* of the peak is poorly determined while its *height* is well determined. Plan on throughput, not on the exact N^*.

- **The response-time column is Little's Law** for a closed test with no think time, $R = N/X$ (§23.5.2): latency rises more than fourfold from $N = 24$ to $N = 96$ while throughput falls.
- **Efficiency** $X(N)/(N\gamma)$ reaches 70% at $N = 16$ and 57% at 24: the knee, beyond which concurrency buys little throughput for much latency.
- Rows 96 and 128 are extrapolations; measure before relying on them.

23.10.3 Converting a model into a fleet size

FORMULA

Fleet size from per-instance capacity

$$n = \lceil \frac{\lambda_{\text{peak}}\,(1+g)}{u \cdot X_{\max}} \rceil \qquad n_{\text{zones}} = Z \cdot \lceil \frac{n}{Z-1} \rceil$$

Symbol	Meaning	Units
λ_{peak}	Forecast peak request rate	requests/second
g	Growth allowance over the planning horizon	dimensionless
$X_{\max}$	Fitted peak throughput of one instance	requests/second
u	Target fraction of $X_{\max}$ at peak (headroom for queueing and variance)	dimensionless
Z	Number of availability zones, sized to survive the loss of one	count

This is the provisioning formula of §18.11.2 with $c\,u_{target}$ replaced by the fitted $u \cdot X_{\max}$, the growth term written as one allowance g for the horizon, and the zone term rounded per zone so that every zone runs the same count (it can therefore exceed §18.11.2's $\lceil N \cdot Z/(Z-1) \rceil$ by up to $Z-2$ instances: 33 rather than 32 in the example below).

WORKED EXAMPLE

Worked example — Sizing from the fitted model. Forecast peak 150,000 RPS, growth allowance 30%, $X_{\max} = 13,588$ req/s per instance from the fit, target $u = 0.7$, three zones.

1. Per-instance planning capacity: $0.7 \times 13,588 = 9,512$ req/s. The fitted curve reaches this at $N \approx 16$, where $R \approx 1.6$ ms and efficiency is still 70%.
2. Demand with growth: $150,000 \times 1.3 = 195,000$ RPS.
3. $n = \lceil 195,000/9,512 \rceil = \lceil 20.5 \rceil = 21$ instances.
4. Survive a zone loss: each of the two remaining zones must carry the load, so $\lceil 21/2 \rceil = 11$ per zone, $3 \times 11 = 33$ instances.

Interpretation. Zone redundancy (33 vs 21) costs more than growth and headroom combined. **Engineering implication.** Re-run the benchmark and refit whenever code or instance type changes; the capacity estimate from Chapter 2 and Chapter 89 becomes a *measured* number only through this loop (§18.11 covers the planning process).

COMMON MISTAKE

Mistake — Planning to the peak of the curve. $X_{\max}$ is reached in a closed test at concurrency N^*, where latency is already several times its unloaded value; in production, arrivals are open and bursty, so running an instance near $X_{\max}$ puts it on the steep part of the queueing curve (§4.10.3). Plan to a fraction of the peak and verify the latency at that point with an open-model load test.

23.11 Summary and revision notes

SUMMARY

- **Method beats intuition.** USE (utilization, saturation, errors per resource) finds saturated resources, including locks and pools; RED and the four golden signals (rate, errors, duration, plus saturation) find the slow service. Scope the symptom, check what changed, then profile.
- **Profiling.** Sampling profilers have overhead fixed by frequency and error $\sqrt{p(1-p)/n}$; instrumenting profilers give exact counts but distort hot paths. Flame-graph width is sample share; look for wide plateaus. CPU profiles miss off-CPU time (I/O, locks, run-queue waits), which usually dominates latency problems.
- **Load testing.** Closed generators reduce load when the system slows and hide outages; use open (constant-arrival-rate) generators for SLO tests. Coordinated omission can understate p99 by orders of magnitude: measure from the intended send time. Record latency in HDR histograms and merge, never average, percentiles.
- **Tail at scale.** For N-way fan-out, root percentiles are leaf percentiles at $q^{1/N}$; the leaf tail becomes the user median. Variability comes from GC, queueing, background work, noisy neighbors, CPU throttling and packet loss.
- **Hedging.** Hedge idempotent requests after about the p95 for about 5% extra load; tied requests with cancellation do better. Without budgets and cancellation, hedging can collapse a loaded system.
- **Batching, pipelining, compression.** Bound batch latency with a timer; pipeline small requests; compress when bytes, not CPU, are the bottleneck.
- **Runtimes.** GC exposure is pause frequency (allocation rate / young size) times pause length; reduce allocation first, then choose a collector for the goal. Warm up JIT runtimes before they take traffic.
- **Capacity.** Fit the USL to measured throughput, plan to a fraction of the fitted peak, then add growth and zone redundancy.

23.12 Knowledge checkpoint

1. What are the three USE questions, and why are software resources part of the resource list?
2. How do the four golden signals differ from RED, and why should successful and failed request latencies be tracked separately?
3. A 20 s profile at 49 Hz on 4 busy CPUs shows a function in 5% of samples. What is the standard error?
4. Why can a CPU flame graph show nothing useful for a service whose p99 is 2 s?

5. State the interactive response time law and explain why a closed load test understates an overload.
6. Define coordinated omission and give two ways to avoid or correct it.
7. Why must percentiles from several load generators be computed from merged histograms?
8. Leaves have exponential latency with a 5 ms mean. What is the root's median with 50-way fan-out?
9. A container has a 1-CPU quota per 100 ms period and 4 runnable threads. How long is it throttled each period?
10. A replica answers in 5 ms with probability 0.97 and 300 ms otherwise. Hedging after 6 ms, what fraction of requests exceeds 11 ms, and what is the extra load?
11. Why did hedging without cancellation collapse at 80% utilization in the simulation of §23.7.2?
12. When does compression increase transfer time?
13. Why is the location of the USL peak N^* less reliable than its height?

Answers

1. Utilization, saturation, errors. Locks, pools and descriptor limits are finite and can saturate while hardware is idle, so omitting them hides real bottlenecks.
2. The golden signals add saturation, a leading indicator. Fast failures pull the latency distribution down, hiding user pain.
3. $n = 49 \times 20 \times 4 = 3,920$; $\mathrm{SE} = \sqrt{0.05 \times 0.95 / 3,920} = 0.0035$, i.e. ± 0.35 percentage points.
4. The time is off-CPU: waiting on I/O, locks, pools or the run queue. Use off-CPU or wall-clock profiling and traces.
5. $X = N/(R + Z)$. When R rises, a fixed population sends less, so offered load falls instead of queueing.
6. The generator waits for slow replies and so skips sends during stalls, omitting the worst samples. Use an open-model generator that measures from the intended send time (wrk2, k6 arrival-rate executors), or apply expected-interval correction.
7. Percentiles are not additive; averaging p99s from generators with different sample counts or distributions gives a number that is not the p99 of anything.
8. $0.5^{1/50} = 0.98623$; $t = 5 \ln(1/0.01377) = 5 \times 4.285 = 21.4$ ms.
9. $t_{\mathrm{run}} = 100/4 = 25$ ms, so it is throttled for 75 ms per period.
10. $P(T > 11) = 0.03 \times 0.03 = 0.0009$ (0.09%); extra load is $P(X > 6) = 3\%$.
11. Hedges raised utilization, which raised latency, which pushed more requests past the fixed hedge delay, a positive feedback loop that drove demand above capacity.
12. When CPU time to compress and decompress exceeds the bandwidth time saved: $1/C_c + 1/(\rho W) + 1/C_d > 1/W$, typically on fast links with a single stream.
13. Throughput is flat near the peak, so many values of N give nearly the same X; small noise moves N^* a lot but $X_{\max}$ little.

23.13 Interview questions

Basic

Q1. A service's average latency is fine but users complain. Where do you start? Answer. Check per-endpoint percentiles (p99, p99.9) from histograms, split by success and error, and what changed when complaints began; then RED across the call graph and USE on the slow service. Averages hide tails, and with fan-out the unlucky fraction is often most users.

Q2. What is coordinated omission? Answer. A load generator that waits for each response before sending the next stops sending during a stall, so the requests that would have suffered are never measured. Reported percentiles can be orders of magnitude too low. Use a constant-rate open generator that timestamps from the intended send time, and record into HDR histograms.

Intermediate

Q3. Design hedging for a key-value read path with a p99 problem. Answer. Hedge only idempotent reads. Set the delay from a rolling histogram near the p95, cap hedges at about 5% of requests with a token-bucket budget, choose the second replica in a different failure domain, and cancel the loser. Disable hedging when the service is overloaded (rising queue depth or error rate) to avoid feedback. Measure p99, p99.9 and hedge rate before and after; consider tied requests if the storage servers can cancel queued work.

Q4. CPU is at 30% but p99 is ten times the SLO. What could it be? Answer. Off-CPU causes: saturated pools, lock contention, slow dependencies, GC pauses, CPU quota throttling or retransmissions. Check pool waiters, cgroup `nr_throttled`, GC logs and retransmit counters, then take off-CPU profiles and traces of slow requests.

Advanced

Q5. How would you produce a capacity plan for a new service? Answer. Build a representative workload from production traces; run warm, steady-state closed tests at increasing concurrency on the target instance type; fit the USL; check residuals and that the peak lies within the measured range. Choose an operating point at a fraction of the fitted peak, verified by an open-model test at that rate against the latency SLO. Size $n = \lceil \lambda_{\text{peak}}(1+g)/(uX_{\max}) \rceil$, add zone redundancy, and refit after every major change, comparing with production telemetry.

Q6. A Java service's p99.9 spikes every few seconds. Walk through diagnosis and fixes. Answer. Correlate spikes with GC logs. If they match minor pauses, measure the allocation rate and young-generation size: frequency is E/a, and pause length scales with

survivors. Reduce allocation using an allocation profiler, size the heap with headroom, or move to a concurrent collector (ZGC or Shenandoah) for sub-millisecond pauses at some throughput and memory cost. Also rule out JIT warm-up after deployments, container throttling and background jobs.

23.14 Practical exercises

1. Run the coordinated-omission program of §23.5.3 with the stall moved to $t = 5$ s and lengthened to 5 s. Predict the true p99 with the formula of §23.5.3 before running.
2. Modify the hedging simulation to use an adaptive delay (the running p95 of the last 10,000 requests) and a budget capping hedges at 5% of requests. Does it remain stable at 80% and 90% utilization?
3. Profile a Python program of your own with `py-spy record` and with `cProfile`. Compare the hottest functions and explain any differences.
4. Use k6 with a `constant-vus` executor and then a `constant-arrival-rate` executor against a test server that sleeps 1 s every 10 s. Compare reported p99 and achieved rates.
5. Collect throughput at eight concurrency levels from any local service (for example, a database with a benchmark tool) and fit the USL with the program of §23.10.2.

23.15 Design challenges

1. **Search fan-out.** A query fans out to 200 index partitions with leaf p99 = 20 ms and p99.9 = 120 ms. The product requires root p99 ≤ 80 ms. Choose a combination of replication, hedging, tied requests and partial results, and quantify the extra load.
2. **Load-test platform.** Design an internal load-testing service for 100 teams: open-model generators, HDR histogram aggregation, safety limits for tests against shared dependencies, and automatic comparison with the previous release.

23.17 Open verification items

- RED method: confirm Wilkie’s original venue and date (Weaveworks-era talk, reportedly 2015; Grafana Labs blog 2018) and the exact title.
- Dean and Barroso (2013): confirm that the slowest 5% of leaves account for about half of root p99; the tied-request result (sort-job cluster near idle-cluster latency, disk overhead below 1%); and the hedging delay wording.
- Gregg and Spier “Java in Flames”: confirm authorship, date and URL.
- Kraken (OSDI 2016): confirm the description of traffic shifting and safety stops; no numeric claims are made.
- Discord (2020): confirm the two-minute forced-GC explanation.
- Table 23.7: values copied from the zstd README as read in 2026; re-check before publication.
- JVM collector release versions (G1 default JDK 9; ZGC and Shenandoah production JDK 15; generational ZGC JDK 21) and Go’s 25% marking CPU target.
- Tene talk: confirm a canonical venue and year.

Part V — Distributed Systems

Chapter 24 — Distributed Systems Fundamentals

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 3.5 h

Replication (Chapter 14), caching (Chapter 20) and load balancing (Chapter 19) already showed that work spread across machines behaves differently from work on one computer: replicas lag, caches go stale, failovers can leave two primaries. This chapter names the reasons. Once machines talk only by messages over a network, you lose **a consistent view of what has failed**, **a shared clock** and **guaranteed delivery**. Consistency models (Chapter 25), consensus (Chapter 26), replication and failure detection (Chapter 27) and distributed transactions (Chapter 28) all respond to those losses. This chapter supplies the vocabulary: system models, partitions and partial failures, physical and logical clocks, the FLP result and the end-to-end argument.

The running example is PhotoShare (Chapter 1), now deployed in two regions, `us-east` and `eu-west`. Its examples are *illustrative*, not a description of any real company's system.

24.1 Learning objectives

After this chapter you should be able to:

- Define a distributed system by its three essential properties and explain the two generals problem.
- Justify distribution by scale, fault tolerance, latency or data residency, and quantify replication's availability gain.
- Give a concrete failure caused by each of the eight fallacies of distributed computing.
- State a protocol's timing and failure model and compute the replicas each fault model needs.
- Distinguish complete, partial and asymmetric partitions, citing measured failure evidence.
- Explain partial and gray failures, and set a timeout from latency data.
- Calculate clock drift and NTP offset, delay and error bound; explain PTP and leap smearing; show why wall-clock last-writer-wins loses data.
- Implement and choose among Lamport clocks, vector clocks, version vectors and hybrid logical clocks.

- Explain what FLP forbids and how systems escape it, and apply the end-to-end argument.

24.2 Prerequisites

- Network latency components and the speed-of-light floor — §7.15 (message delay is never zero and is variable).
- TCP acknowledgments and retransmission — §7.7.5 (what a transport-level ACK does and does not promise).
- Primary–replica, synchronous and asynchronous replication, and multi-primary conflicts — §14.3–§14.5 (the replication settings in which clocks and partitions matter).
- Timeouts, retries and idempotency keys — §22.11–§22.15 (the request-level tools this chapter justifies).
- Probability of independent events and availability arithmetic — §4.6 and §4.14 (replication and fleet-failure calculations).
- Units: time in seconds (s), milliseconds (ms, 10^{-3} s), microseconds (µs, 10^{-6} s) and nanoseconds (ns, 10^{-9} s); drift in parts per million (ppm, 10^{-6}); storage in decimal units (1 KB = 10^{3} bytes, 1 GB = 10^{9} bytes).

24.3 What is a distributed system?

24.3.1 Definition and the three defining properties

DEFINITION

Definition — Distributed system. A set of independent computers (**nodes**) that have no shared memory and no shared clock, communicate only by exchanging messages over a network, and cooperate to provide a service. Van Steen and Tanenbaum describe it from the user's side as "a collection of autonomous computing elements that appears to its users as a single coherent system" [van Steen and Tanenbaum 2017].

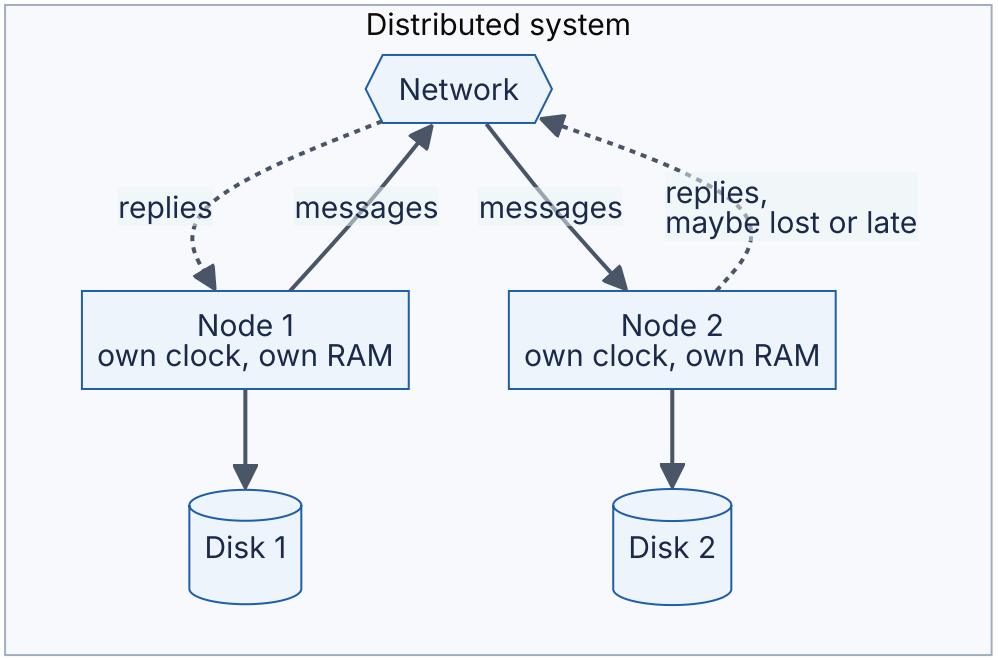
Leslie Lamport's definition is the one engineers remember. In an email of 28 May 1987 he wrote: "A distributed system is one in which the failure of a computer you didn't even know existed can render your own computer unusable" [Lamport 1987]. The joke is a precise observation: in a distributed system, your work depends on machines you cannot see, and their failures reach you in forms you did not expect.

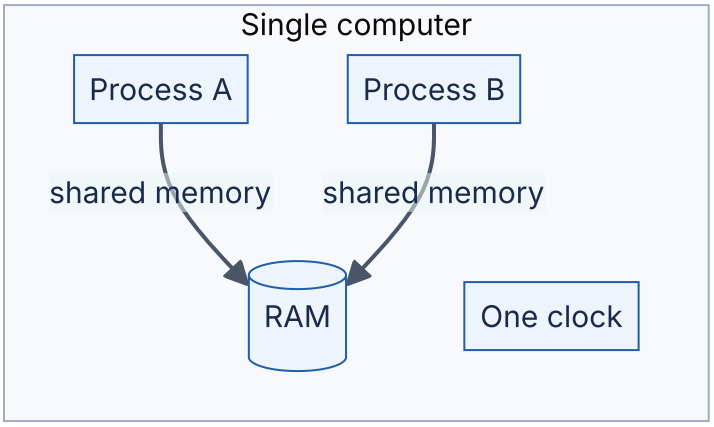
First-principles explanation

Imagine a restaurant chain whose managers communicate only by post: letters arrive late or never, no two branch clocks agree, and a manager who quits is noticed only when letters stop, which looks exactly like slow post. That chain has the three defining properties:

1. **Independent (partial) failure.** Some nodes fail while others run, and the survivors do not know exactly which failed.
2. **No global clock.** Clocks disagree, so the order of events on different nodes is not directly observable.
3. **Unreliable, asynchronous communication.** Messages may be delayed without bound, lost, duplicated or reordered, and are out of date when they arrive.

Figure 24.1 — One computer versus a distributed system.





Reading the diagram. On the left, two processes share one memory and one clock: a write is visible to the other process within nanoseconds, and if the machine fails both processes stop together. On the right, each node has its own memory, disk (a separate storage boundary) and clock; the only connection is the network. Requests travel synchronously in the sense that a caller waits, but the dotted reply paths show what the caller cannot control: a reply may arrive late or never. Failure points are each node, each disk and the network itself, and they fail independently. Scaling comes from adding nodes, at the price of more independent failure points.

24.3.2 Why this is hard: uncertainty about other nodes

Together the properties mean **a node can never be certain of another node's current state.** Silence from node 2 could mean a lost request, a slow node, a crash before or after processing, a lost reply or a reply still in flight; §24.8.1 draws all six. Every distributed algorithm is a strategy for acting correctly despite this ambiguity.

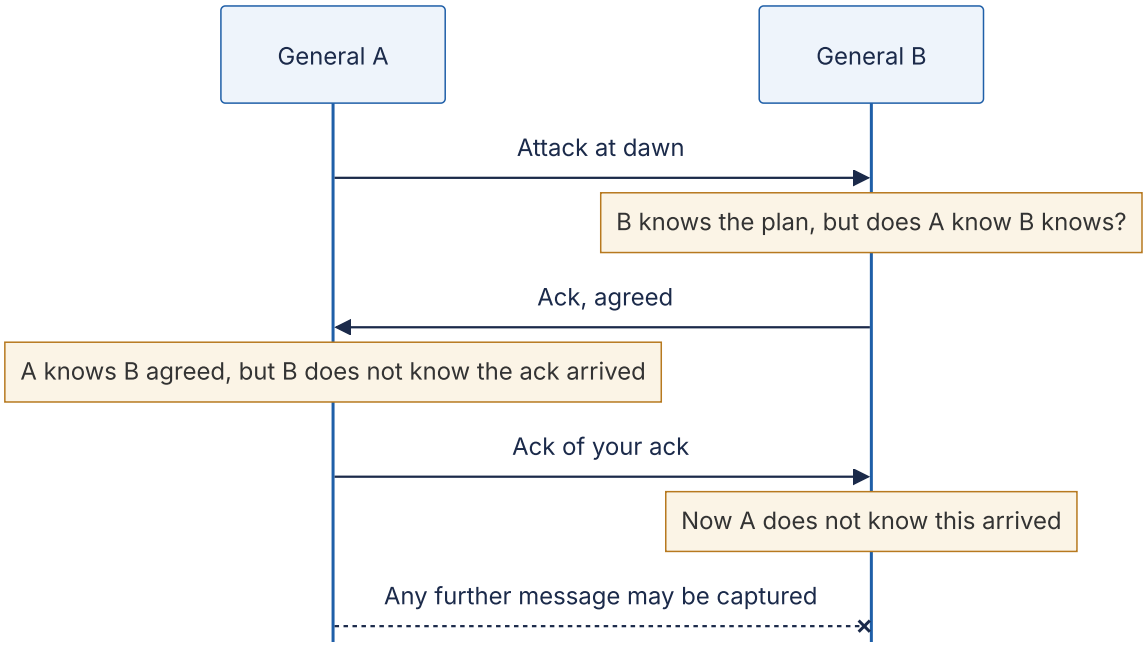
24.3.3 The two generals problem

The oldest illustration of this ambiguity is the **two generals problem**, first described by Akkoyunlu, Ekanadham and Huber [Akkoyunlu et al. 1975] and named by Jim Gray [Gray 1978].

DEFINITION

Definition — Two generals problem. Two armies camped on opposite hills must attack a city in the valley at the same time; either attacking alone is defeated. Their generals can communicate only by messengers who cross the valley and may be captured. The problem is to design a messaging protocol after which both generals are *certain* that they will attack together. No such protocol with a finite number of messages exists.

Figure 24.2 — The two generals problem: every acknowledgment needs another acknowledgment.



Reading the diagram. Solid arrows are messengers that arrived; the final arrow with a cross is a messenger captured in the valley. After each delivered message, the *sender* of the latest message is left unsure whether it arrived, so the other general's knowledge is always one level short of certainty. The failure point is the unreliable channel itself; adding more messengers raises the probability of agreement but never makes it certain, so this "protocol" does not scale toward certainty at any message count.

Why no finite protocol works

The proof is a short argument by contradiction. Suppose some protocol guarantees coordinated attack, and take the shortest such protocol, with k messages. Consider the last message. Its sender must decide to attack whether or not it arrives, because the sender cannot observe its loss. So the receiver must also decide to attack whether or not it arrives, since the protocol guarantees agreement. Then the last message affects no decision and can be removed, giving a working protocol with $k - 1$ messages. That contradicts "shortest", so no finite protocol exists.

What engineers do instead

Practical systems settle for less than certainty: **retry idempotent actions** until acknowledged (TCP, idempotency keys in §22.15); **accept high probability** (five messengers each captured with probability 0.1 all fail with probability 10^{-5}); or **persist state and allow blocking**, as two-phase commit does (§28.4).

COMMON MISTAKE

Mistake — "TCP solves the two generals problem." TCP makes delivery *reliable while the connection works,* by retransmitting. It cannot tell the sender whether its final bytes were processed by the application before the peer crashed or the connection broke (§7.7). The connection-close handshake itself has the two generals shape, which is one reason for the `TIME_WAIT` state.

24.4 Why distributed systems exist

24.4.1 Four reasons to pay the price

If distribution is this hard, why do it? Because a single computer cannot meet some requirements at all. Table 24.1 lists the four main reasons.

Table 24.1 — Why systems are distributed.

Reason	The limit of one machine	Distributed answer	What it costs
Scale	Even the largest single servers top out at hundreds of cores and a few tens of terabytes of memory (as of 2026); one disk array holds finite data	Partition data and work across nodes (§14.6, Ch 18)	Cross-node queries, rebalancing, coordination
Fault tolerance	One machine, power supply or datacenter is a single point of failure	Replicate across nodes, racks, zones and regions (Ch 14, Ch 27)	Keeping replicas consistent; failover
Latency and geography	The speed of light: New York–London RTT is at least about 56 ms over fiber (§7.15.1)	Place replicas and computation near users (Ch 21, Ch 44)	Cross-region consistency and conflicts
Data residency	Law may require that personal data stay within a jurisdiction	Region-pinned partitions and processing	Fragmented operations; per-region capacity

Some problems are also **inherently distributed** (banks in a payment network, offline edits on phones), and organizations split systems so teams deploy independently (Chapter 34). On residency, be precise: the EU GDPR does not generally require storage inside the EU, but its Chapter V restricts *transfers* of personal data outside it without safeguards [EU 2016]; some other jurisdictions mandate localization. Either way, partitions get pinned to regions.

Mathematical foundations: why replicate, and why failure is normal

FORMULA

Availability of k independent replicas, and the chance that something in a fleet fails

$$A_k = 1 - (1 - a)^k \qquad P_{\text{any}} = 1 - (1 - p)^n$$

Symbol	Meaning	Units
a	Availability of one replica (fraction of time it can serve)	dimensionless, 0–1
k	Number of replicas, any one of which can serve a request	count
A_k	Availability of the replicated service, assuming independent failures and instant failover	dimensionless
p	Probability that one node fails during a given period	dimensionless
n	Number of nodes in the fleet	count
P_{any}	Probability that at least one node fails in that period	dimensionless

WORKED EXAMPLE

Worked example — PhotoShare's metadata service.

1. One server has availability $a = 0.999$ (about 8.8 hours down per year).
2. With $k = 3$ independent replicas: $A_3 = 1 - (0.001)^3 = 1 - 10^{-9}$, nine nines on paper.
3. Now the fleet view. PhotoShare runs $n = 1,000$ nodes, each with probability $p = 0.001$ of failing on a given day. $P_{\text{any}} = 1 - 0.999^{1000}$. Since $\ln 0.999 \approx -0.0010005$, $0.999^{1000} \approx e^{-1.0005} \approx 0.368$, so $P_{\text{any}} \approx 0.632$.

Interpretation: replication makes the *service* far more available than any node, but the same scale guarantees that on about 63% of days *some* node fails. Failure is a daily routine, not an exception. Engineering implication: the nine nines are fiction, because replica failures are not independent (shared power, shared software bugs, shared network) and failover is not instant. The real gains come from placing replicas in separate failure domains and from making failover automatic and well tested, which is the subject of Chapter 27.

RECOMMENDATION

Recommendation — Distribute only for a stated reason. A single well-provisioned database with a hot standby serves many products and avoids most of this chapter's problems. When you do distribute, the reason tells you what to optimize: partitioning for scale, replication for fault tolerance, locality for latency, region pinning for residency.

24.5 The eight fallacies of distributed computing

24.5.1 Origin and the list

Around 1994, L. Peter Deutsch at Sun Microsystems listed seven false assumptions that newcomers to distributed applications make; James Gosling later added an eighth (Bill Joy and Tom Lyon are credited with the first four). The list circulated informally and was explained in detail by Rotem-Gal-Oz [Rotem-Gal-Oz 2006]. Each fallacy is the hidden assumption behind a class of outages; code that treats a remote call as a local one (§8.8) assumes several at once.

Table 24.2 — The eight fallacies and what each one breaks.

#	Fallacy	Reality	A concrete consequence	Mitigation
1	The network is reliable	Packets and connections are lost; switches and links fail daily	A payment request times out; the client retries; the customer is charged twice	Timeouts, retries with backoff, idempotency keys (§22.12, §22.15)
2	Latency is zero	Within a datacenter about 0.5 ms per round trip; across oceans 60–150 ms	A page making 100 sequential calls takes 50 ms in one region and about 7 s across regions	Batch calls, parallelize, colocate chatty services
3	Bandwidth is infinite	Links are finite and shared	Re-replicating 10 TB over a 1 Gbps link takes about 22 hours	Compress, ship deltas, throttle background traffic
4	The network is secure	Internal networks are routinely breached	Plaintext service-to-service traffic leaks credentials after one compromised host	Mutual TLS, zero trust (Ch 10)
5	Topology does not change	Nodes, routes and addresses change continuously	A client caches a server IP; the node is replaced; requests fail until restart	Service discovery, short DNS TTLs, re-resolution (§7.6)
6	There is one administrator	Many teams and providers control parts of the path	Another team changes a firewall rule or lets a certificate expire, and your service breaks	Explicit dependency contracts, certificate automation, change visibility
7	Transport cost is zero	Serialization costs CPU; providers charge for data transfer	Cross-zone chatter appears as a large line item on the cloud bill	Measure bytes per request, keep traffic zone-local where safe
8	The network is homogeneous	Mixed hardware, OS, protocol and software versions	During a rolling upgrade, v1 nodes cannot parse v2 messages and requests fail	Versioned, backward- and forward-compatible encodings

The arithmetic behind three rows: 100 calls × 0.5 ms = 50 ms, but × 70 ms = 7 s; $10 \times 10^{12} \times 8 / 10^{9} = 80{,}000$ s ≈ 22 h to copy 10 TB at 1 Gbps (which is why recovery spreads a node's data over many peers, §27.12); and at an *illustrative* $0.01/GB, 100 MB/s of cross-zone traffic is 8,640 GB/day, about $86 per day.

INDUSTRY EXAMPLE

AWS US-East, April 2011 — a topology change becomes an outage. During a network upgrade in one Availability Zone, traffic was shifted onto a lower-capacity network. Elastic Block Store (EBS) nodes lost contact with their replicas and all began re-mirroring at once; the storm exhausted capacity and degraded EBS and dependent services for days. Fallacies 1, 3 and 5 combined: a topology change made the network unreliable, and recovery traffic assumed plentiful bandwidth. *Evidence: Primary* — [AWS 2011]

COMMON MISTAKE

Mistake — "A remote procedure call is just a function call." A remote call can time out with an *unknown* outcome, take a million times longer, and run twice. Good RPC frameworks expose deadlines and status codes (§8.8, §22.11).

24.6 System models: timing and failures

24.6.1 Why a protocol needs a system model

A protocol is correct only *relative to its assumptions*: Raft (§26.7) tolerates nodes that crash but not nodes that lie, and a clock-based lease (§26.11) is safe only if drift is bounded.

DEFINITION

Definition — System model. A precise statement of what a distributed algorithm may assume about (1) **timing**: bounds on message delay, processing speed and clock drift, and (2) **faults**: how nodes and links may misbehave. Proofs of correctness hold only within the stated model.

Like a chess strategy proven under standard rules, a protocol proven for crash-stop nodes says nothing about a node that returns garbage from a corrupted disk.

24.6.2 Timing models

Table 24.3 — Timing models.

Model	What is assumed	Strength of the assumption	What it allows	Realistic?
Synchronous	Known upper bounds on message delay, processing time and clock drift	Strongest	Perfect failure detection by timeout; consensus despite failures, even Byzantine with enough nodes	Only in special hardware (avionics buses); not in commodity networks
Partially synchronous	Bounds exist but are unknown, or known bounds hold only after an unknown **global stabilization time** (GST)	Middle	Consensus that is always safe and terminates once the system behaves	Yes: the model behind Paxos, Raft and most production systems
Asynchronous	No timing bounds at all; messages are eventually delivered	Weakest	Safety-only reasoning; deterministic consensus impossible with one crash (§24.13)	Safe to assume, but too weak to build consensus on alone

The **partially synchronous** model of Dwork, Lynch and Stockmeyer [Dwork et al. 1988] fits real datacenters: usually timely, occasionally not (pauses, congestion, partitions) for an unknown time. A protocol for it must never violate **safety** (nothing bad happens) in bad periods and must make progress (**liveness**) once a good period lasts long enough.

24.6.3 Failure models

Table 24.4 — Failure models, from most benign to most severe.

Model	What a faulty node may do	Real-world example	Detectable by others?	Nodes needed to tolerate f faults in consensus	Typical systems
Crash-stop	Stops forever; until then behaves correctly	Hardware dies; VM terminated	Only by timeout (no certainty in async)	$2f + 1$	Textbook protocols; Paxos variants
Crash-recovery	Crashes, later restarts; keeps only what it wrote to stable storage	Process restart after an OOM kill; power cycle	Only by timeout	$2f + 1$, with durable logs	Raft, ZooKeeper, most databases
Omission	Fails to send or receive some messages, otherwise correct	Full NIC buffer; overloaded switch dropping packets	Only by timeout	$2f + 1$	Covered by retransmission and quorums
Timing (performance)	Responds correctly but outside the assumed time bound	30 s garbage-collection pause; fail-slow disk	Only relative to a bound	Depends on the timing model	Lease-based systems are vulnerable
Byzantine (arbitrary)	Anything: wrong values, contradictory messages to different peers, forged messages	Memory corruption, software bug, malicious operator	Not in general	$3f + 1$	Blockchains, some aerospace and financial systems

Clarifications: a **fail-stop** processor, as defined by Schlichting and Schneider, halts *detectably* [Schlichting and Schneider 1983]; plain crash-stop does not, which is the realistic case. Under **crash-recovery**, anything a node promised (a vote, an acknowledgment) must reach stable storage before the promise is sent, which is why Raft persists its term and vote (§26.7). The classic **timing** fault is a lease holder that pauses for 30 s and then writes as if it still held the lease; fencing tokens (§26.13) exist for it. **Byzantine** faults, named in [Lamport et al. 1982], include bit flips and bugs, not just malice. Links have models too: **fair-loss**, **stubborn** (retransmit forever) and **perfect** (exactly-once delivery, built with acknowledgments and duplicate suppression) [Cachin et al. 2011]; TCP approximates a perfect link only while a connection lasts.

Figure 24.3 — Failure models nest: each one includes the behaviors of those inside it.

Reading the diagram. Each arrow points to a more general model: a crash is a special omission, an omission is an infinitely late message, and everything is a special case of

Byzantine. Tolerating a model on the right tolerates all to its left, at higher cost (final box). The hierarchy is conceptual, with no protocols, storage boundaries or sync/async paths; the practical failure point is assuming a model weaker than reality.

Mathematical foundations: replicas needed per fault model

FORMULA

Minimum replicas for consensus in the partially synchronous model

$$n_{\text{crash}} \geq 2f + 1 \qquad n_{\text{Byz}} \geq 3f + 1$$

Symbol	Meaning	Units
f	Maximum number of nodes that may be faulty at once	count
n_{crash}	Nodes needed when faults are crashes or omissions	count
n_{Byz}	Nodes needed when faults may be arbitrary	count

The intuition for $2f + 1$: any decision must be backed by a **majority quorum** of $f + 1$ nodes, and any two majorities overlap in at least one node, so two conflicting decisions cannot both gather a quorum. For Byzantine faults, quorums of $2f + 1$ out of $3f + 1$ overlap in at least $f + 1$ nodes, so at least one honest node is in every overlap. Quorums in depth are in §26.4.

WORKED EXAMPLE

Worked example — How many replicas for PhotoShare's coordination service?

1. Requirement: survive one zone outage, where each zone holds one replica, so $f = 1$.
2. Crash faults: $n \geq 2(1) + 1 = 3$ replicas in 3 zones. A majority is 2, so with one zone down the other two still decide.
3. Survive two simultaneous zone losses ($f = 2$): $n \geq 5$, so 5 replicas, which needs 5 failure domains.
4. If the same service had to tolerate one *Byzantine* replica: $n \geq 3(1) + 1 = 4$, and every decision needs $2f + 1 = 3$ matching votes.

Interpretation: Byzantine tolerance costs a third more replicas at $f = 1$ and many more messages per decision. Engineering implication: inside one organization, use crash-recovery protocols plus checksums (§24.14); reserve Byzantine tolerance for mutually distrustful parties.

INDUSTRY EXAMPLE

Raft clusters such as etcd. Raft clusters typically run 3 or 5 members: 3 tolerate one failure, 5 tolerate two, and 4 still tolerate only one (a majority is 3), so even sizes add cost without tolerance. Raft assumes crash-recovery faults and partial synchrony. *Evidence: Primary* — [Ongaro and Ousterhout 2014]

24.7 Network partitions

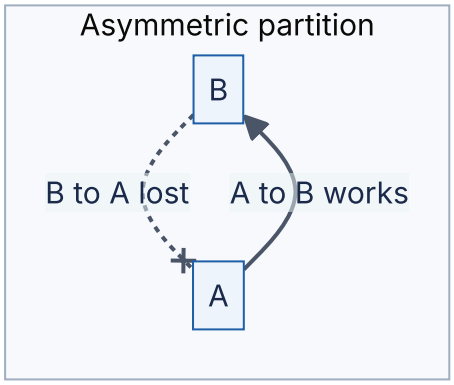
24.7.1 Definition and types

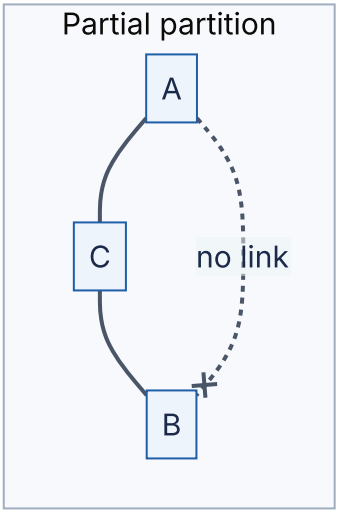
DEFINITION

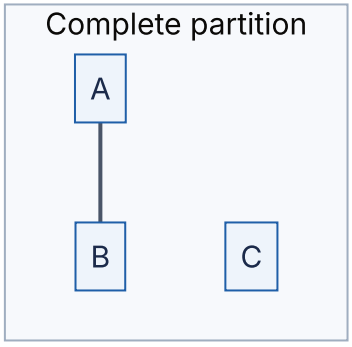
Definition — Network partition. A network fault after which some nodes that are running correctly cannot exchange messages with some other running nodes for a period of time. (This book reserves "partition" alone for a subset of data, §14.6; a network fault is always a **network partition**.)

From inside a node, a partition looks exactly like remote crashes, except that the "crashed" nodes keep running, may serve clients, and may believe *you* crashed. The less obvious shapes cause the worst bugs.

Figure 24.4 — Three kinds of network partition.







Reading the diagram. In the *complete* partition, the cluster splits cleanly: A and B talk to each other, C is cut off from both. In the *partial* partition, A and B cannot reach each other, yet both reach C, so C sees a healthy cluster while A and B each see a missing peer. In the *asymmetric* (one-way) partition, messages from A to B arrive but B's replies to A are lost. Solid lines are working links; dotted lines with crosses are failed directions. All traffic is the cluster's own heartbeat and data traffic; the failure points are the links, not the nodes, and adding nodes multiplies the number of links that can fail independently.

Table 24.5 — Partition types and the trouble each one causes.

Type	What happens	Typical cause	Why it is dangerous
Complete	The network splits into groups that cannot talk to each other	Lost uplink, failed inter-region link	Each side may elect a leader or accept writes: **split brain** (§26.12)
Partial	Some pairs cannot communicate while others can	Misconfigured firewall rule, failed link in a mesh, one bad switch port	Nodes disagree about who is alive; leadership can flap as nodes reach different peers
Asymmetric (one-way)	Traffic flows in one direction only	Saturated queue in one direction, ACL or routing asymmetry	A leader receives requests and heartbeats but its replies are lost, so it believes it is healthy while followers elect another leader
Intermittent (flapping)	Connectivity repeatedly comes and goes	Faulty optics, overloaded link	Constant failovers; each one costs work and risks inconsistency

24.7.2 How often do networks fail?

Bailis and Kingsbury's ironically titled survey "The Network is Reliable" collects the evidence [Bailis and Kingsbury 2014]:

- **Microsoft datacenters.** A measurement study of several Microsoft datacenters over a year [Gill et al. 2011] reported on average 5.2 device failures and 40.8 link failures per day, with a median time to repair of about five minutes and some failures lasting much longer. It also found that network redundancy was far less effective than hoped, improving the median traffic carried during failures by only about 43%.
- **Google clusters.** Jeff Dean's description of a typical first year of a new cluster included, among many other events, around 20 rack failures, about 5 racks that "go wonky" with half their packets lost, around 8 network maintenances of which several cause about 30 minutes of random connectivity loss, and about 3 router failures [Dean 2009].
- **Failures in deployed software.** Alquraan et al. studied 136 failures caused by network partitions in 25 widely used systems, including databases, coordination services and message brokers [Alquraan et al. 2018]. Most had catastrophic effects such as data loss, reappearance of deleted data and broken locks; many could be triggered by isolating a single node; and *partial* partitions were a significant and previously under-studied cause.

A large fleet therefore sees many small network faults every day: assume *some* pair of nodes cannot talk *right now*.

INDUSTRY EXAMPLE

Cloudflare, November 2020 — a partial partition and a Raft cluster. A partially failed switch left some members of an etcd (Raft) cluster able to reach each other and some not. The cluster could not keep a stable leader, so it could not accept writes; dependent automation that manages database primaries triggered failovers that overloaded other databases, and Cloudflare's API and dashboard were degraded for several hours. The post-mortem's title reflects that partial connectivity gave nodes contradictory views of the cluster. *Evidence: Primary* — [Lianza and Snook 2020]

24.7.3 What a partition forces you to choose

A node cut off from its peers can **refuse** (keeping consistency, losing availability on the minority side) or **answer** from local data and reconcile later (keeping availability, allowing divergence to be resolved with version vectors, §24.11, and conflict resolution, §27.14). CAP and PACELC (§25.8–§25.9) make this precise; you choose not *whether* partitions happen, only how to behave during one.

Table 24.6 — Partition failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Two primaries accept conflicting writes	Each side of a complete partition elects a leader	Two nodes report the primary role; divergent replication positions	Pick one history; reconcile or discard the other's writes	Majority quorums; fencing tokens (§26.13)
Leader flapping during a partial partition	Different nodes see different sets of peers	Election count and term number climbing quickly	Isolate the bad link or node	Pre-vote and leader-stickiness checks in Raft (§26.7); per-link health monitoring
"Healthy" leader that nobody hears	Asymmetric partition drops the leader's outbound traffic	Followers time out while the leader's own metrics look normal	Step the leader down on loss of quorum acknowledgments	Leaders check that a quorum acknowledges them within a lease period
Recovery storm after healing	All nodes resynchronize at once	Bandwidth and CPU spikes right after connectivity returns	Throttle resynchronization	Rate-limited, prioritized anti-entropy (§27.13)

COMMON MISTAKE

Mistake — "Partitions mean the cable was cut." Most partitions in practice are partial, short, or caused by software and configuration: a firewall change, a full queue, a long garbage-collection pause that makes a node unreachable for 20 s. A node that is alive but paused is, to its peers, partitioned.

24.8 Partial failures, gray failures and timeouts

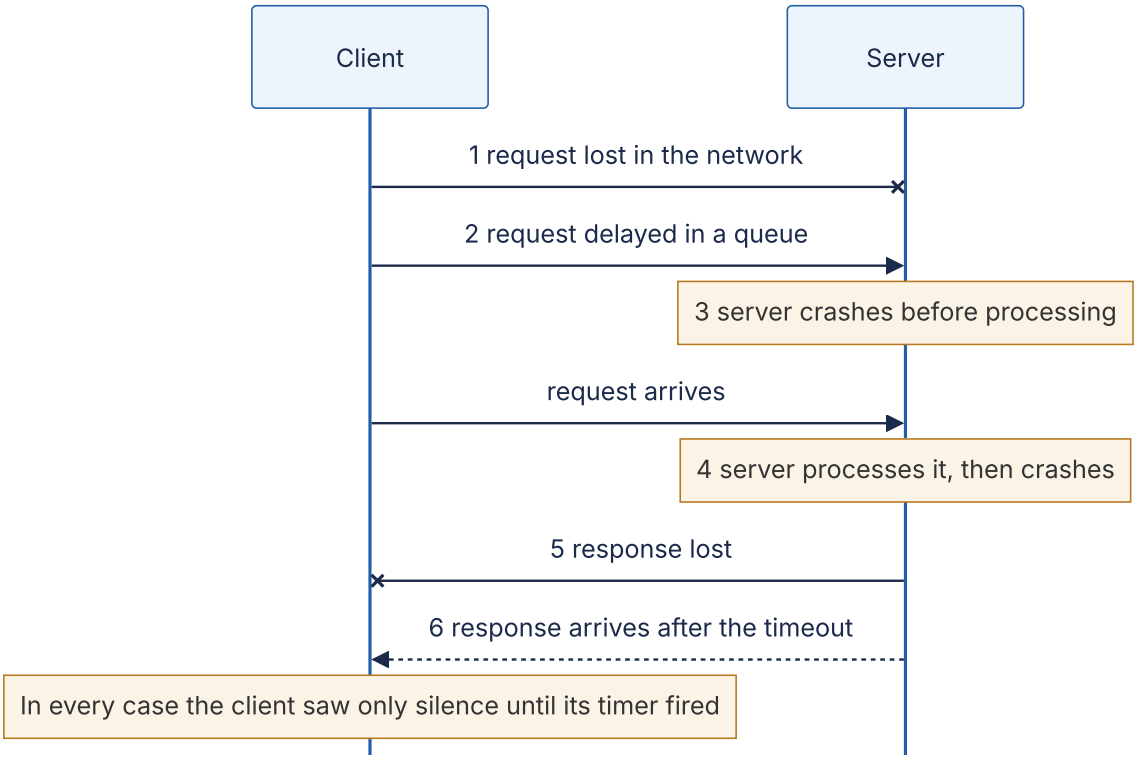
24.8.1 Partial failure

DEFINITION

Definition — Partial failure. A state in which some components of a system have failed while others continue to work, so that an operation may be applied in some places and not others, and the working components cannot reliably tell which components failed.

On one computer, partial failure is rare enough to ignore; in a fleet it is normal (§24.4.1). The hard part is the *ambiguity*.

Figure 24.5 — Six things that can happen to one request, all of which look the same to the client.



Reading the diagram. The client sends a synchronous request (solid arrows) and waits for a response (dashed arrow). Outcome 1 loses the request; 2 delays it; 3 and 4 are server crashes before and after the side effect; 5 loses the response; 6 delivers it too late to matter. Outcomes 4, 5 and 6 mean the operation *happened*; 1 and 3 mean it did not; 2 means it may still happen. The storage boundary is the server's database, which may or may not contain the effect. The failure points are the network in both directions and the server. Retrying is safe only if the operation is idempotent (§22.15), because in half of these cases the retry is a duplicate.

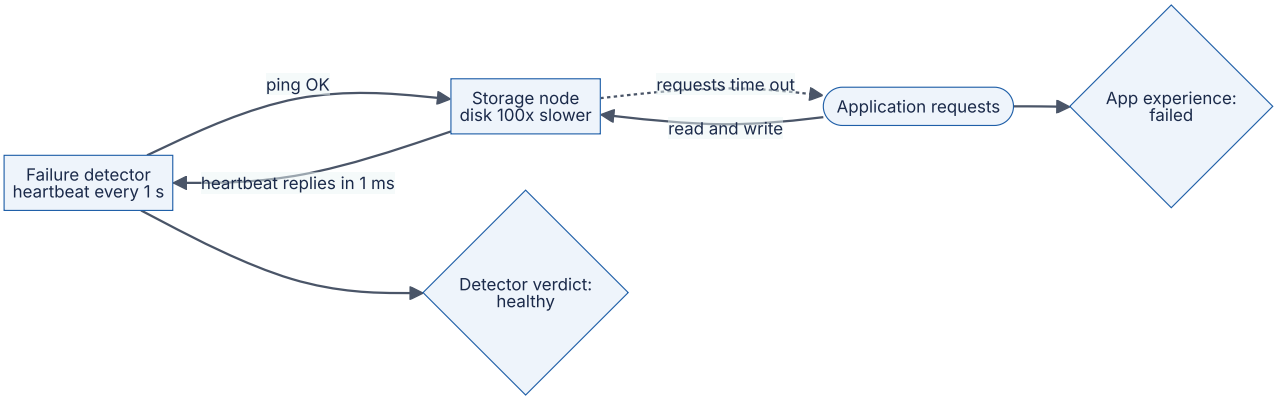
24.8.2 Gray failure

Crashes are the easy case. Huang et al. found that many serious incidents in Microsoft's cloud came from something subtler, **gray failure** [Huang et al. 2017].

> DEFINITION
>
> **Definition — Gray failure.** A component failure that is *differentially observable*: some observers (often the system's own failure detector) consider the component healthy, while others (often the applications using it) experience it as failed or badly degraded.

Examples of gray failure include a network interface that drops 1% of packets (TCP throughput collapses, §7.15.3, but pings succeed); a disk that completes every I/O but takes 500 ms instead of 5 ms (a **fail-slow** fault; Gunawi et al. collected over a hundred such hardware cases from large production systems [Gunawi et al. 2018]); and a process whose heartbeat thread runs happily while its request-handling threads are deadlocked.

Figure 24.6 — Gray failure is a disagreement between observers.



Reading the diagram. The failure detector probes the storage node with a cheap heartbeat that never touches the disk, so it gets fast replies and concludes "healthy". The application's synchronous read and write requests go through the slow disk and time out (dotted arrow: the response effectively never arrives in time). The storage boundary, the node's disk, is the failure point, and it is invisible to the probe. Because the detector says healthy, the load balancer keeps sending traffic and no failover happens; adding more nodes does not help, since the sick node still receives its share. The fix is to make the detector observe what the application observes.

Huang et al. recommend closing the observation gap: detect with what applications experience. In practice: **health checks that exercise the real dependency path**, **outlier ejection** of nodes whose client-observed errors or latency are far worse than their peers' (passive health checks, §19.5), and treating "too slow" as down.

24.8.3 Timeouts: the only failure detector you have

Without timing bounds you cannot *know* that a node crashed; you only see silence. Every failure detector, from a timeout to phi-accrual or SWIM (§27.10), turns silence into a *suspicion*.

Mathematical foundations: choosing a timeout

FORMULA

Timeout from bounded delays, and its practical percentile form

$$T = 2d + r \qquad T_{\text{practical}} = \text{RTT}_{p99.9} + r_{p99.9} + m$$

Symbol	Meaning	Units
d	Upper bound on one-way network delay	s
r	Upper bound on the time the remote node takes to process the request	s
T	Timeout after which the absence of a reply proves a fault (only if the bounds are real)	s
$\text{RTT}_{p99.9}$	Measured 99.9th-percentile round-trip time	s
$r_{p99.9}$	Measured 99.9th-percentile processing time	s
m	Safety margin for pauses (garbage collection, scheduling)	s

With real bounds, silence beyond $2d + r$ would prove a fault. Real networks have none, so the practical form accepts a small, chosen probability of mistaking slow for dead.

WORKED EXAMPLE

Worked example — Timeout for PhotoShare's metadata replicas.

1. Measured inside one region: RTT p50 = 0.4 ms, p99.9 = 4 ms; processing p99.9 = 20 ms.
2. Garbage-collection pauses on these JVM nodes reach 150 ms a few times a day; choose $m = 200$ ms.
3. $T_{\text{practical}} = 4 + 20 + 200 = 224$ ms; round to 250 ms for a request timeout.
4. For declaring a *node* dead (which triggers failover), require several consecutive misses: with heartbeats every 250 ms and 4 misses, detection takes about 1 s.

Interpretation: the pause margin, not the network, dominates. Too low a T causes false failovers that can cascade; too high leaves users waiting. Engineering implication: measure pauses and tail latency first, use a short timeout for retrying a request (§22.11) and a longer, multi-miss rule for failing over a node, and prefer adaptive detectors (§27.10).

Table 24.7 — Partial-failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate side effect after timeout	Request succeeded, response lost; client retried	Duplicate rows, double charges	Compensate or deduplicate	Idempotency keys (§22.15)
Healthy node declared dead	Timeout shorter than a garbage-collection pause	Failover events correlated with pause logs	Let the node rejoin as follower	Timeouts from measured p99.9 plus pause margin; several misses
Sick node kept in rotation	Gray failure: health check misses the slow path	Client-side p99 and error rate high for one node	Eject the node manually	Deep health checks; outlier ejection
Cascading slowness	Callers wait the full timeout on a slow dependency	Thread pools full; latency rises everywhere	Shed load; open circuit breakers	Deadlines, bulkheads, breakers (§22.11–§22.14)

COMMON MISTAKE

Mistake — "If the node answered the health check, it is up." A health check answers one narrow question. Health is what clients experience.

24.9 Physical clocks: drift, NTP, PTP and skew

24.9.1 Two clocks in every computer

DEFINITION

Definition — Time-of-day clock and monotonic clock. A **time-of-day** (wall-clock) clock returns the current date and time, for example as seconds since the Unix epoch (Linux `CLOCK_REALTIME`, Python `time.time()`). It is synchronized with other machines and *can jump* forward or backward when corrected. A **monotonic** clock (Linux `CLOCK_MONOTONIC`, Python `time.monotonic()`) only moves forward at a steady rate from an arbitrary starting point. It is meaningless across machines but correct for measuring durations on one machine.

Use the monotonic clock for timeouts, rate-limiter refill (§22.4) and latency; never assume two machines' wall clocks agree.

24.9.2 Quartz drift

A computer counts the vibrations of a quartz crystal whose frequency varies with manufacturing tolerance, temperature and age. The error is expressed in **parts per million (ppm)**: 1 ppm is 1 µs per second, or 86.4 ms per day. Commodity server oscillators typically drift by tens of ppm, and Google's Spanner design conservatively assumes a worst case of 200 ppm [Corbett et al. 2012].

FORMULA

Clock drift and the resynchronization interval

$$\Delta(t) = \rho\, t \qquad \Delta_{AB}(t) \le 2\rho\, t \qquad T_{\text{sync}} \le \frac{\varepsilon}{2\rho}$$

Symbol	Meaning	Units
ρ	Maximum drift rate of one clock	ppm (1 ppm = 10^{-6} s/s)
t	Time since the clock was last synchronized	s
$\Delta(t)$	Worst-case error of one clock relative to true time	s
$\Delta_{AB}(t)$	Worst-case skew between two clocks drifting in opposite directions	s
ε	Largest skew you can tolerate between any two clocks	s
T_{sync}	Longest interval between synchronizations that keeps skew within ε	s

WORKED EXAMPLE

Worked example — Drift on PhotoShare's servers, and Spanner's sawtooth.

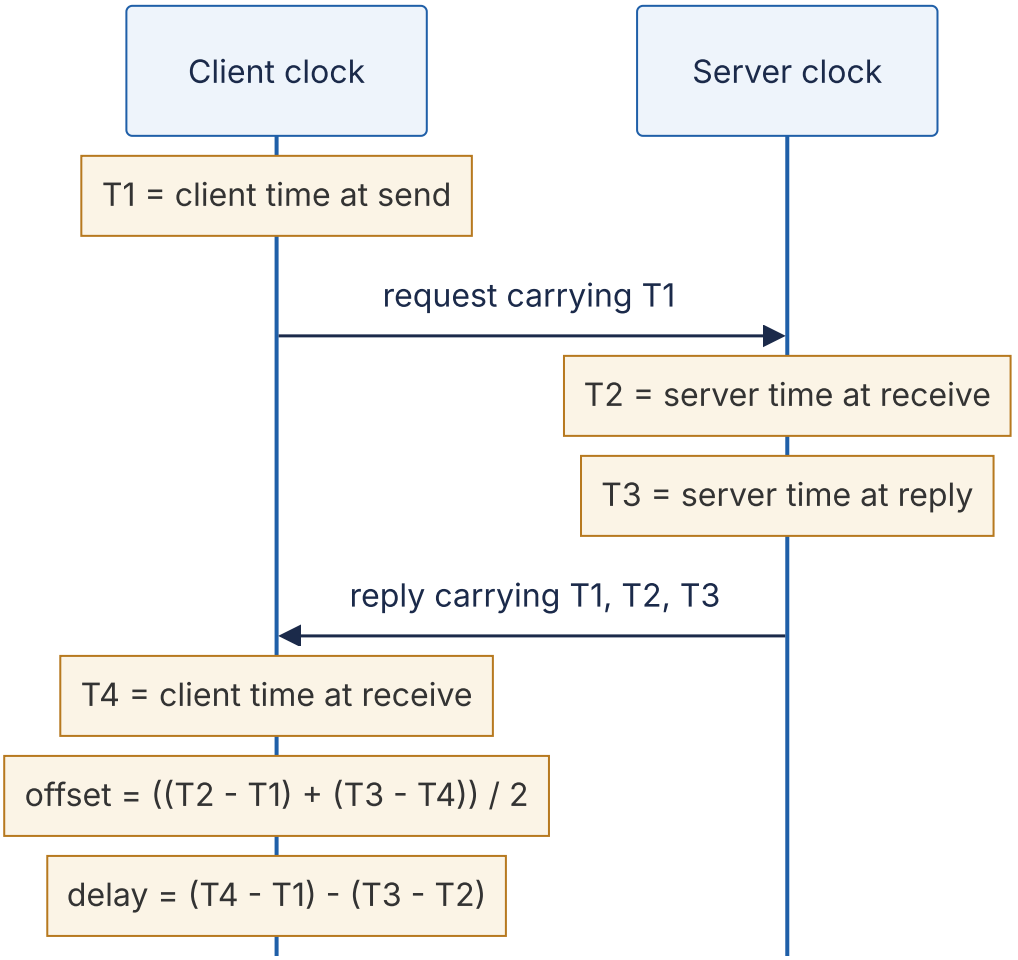
1. A server drifts at $\rho = 50$ ppm $= 50 \times 10^{-6}$ s/s. Unsynchronized for a day: $\Delta = 50 \times 10^{-6} \times 86,400 = 4.32$ s.
2. Two servers, one fast and one slow at 50 ppm, diverge at $2 \times 50 = 100$ µs per second.
3. To keep them within $\varepsilon = 1$ ms: $T_{\text{sync}} \le 0.001/(2 \times 50 \times 10^{-6}) = 10$ s.
4. Spanner: each server polls its time masters every 30 s and assumes 200 ppm, so uncertainty grows by up to $200 \times 10^{-6} \times 30 = 6$ ms between polls. Corbett et al. describe exactly this sawtooth of 0 to 6 ms on top of about 1 ms of communication delay, giving a total uncertainty ε of about 1 to 7 ms [Corbett et al. 2012].

Interpretation: drift is tiny per second but unbounded over time, so clocks must be resynchronized continually. Engineering implication: alert on *synchronization loss*, not just offset; a host that silently stopped syncing drifts further every hour.

24.9.3 NTP: synchronizing over a network

The **Network Time Protocol** (NTP), designed by David Mills and specified as NTPv4 in RFC 5905 [Mills et al. 2010], measures a round trip, assumes equal delay in both directions, and computes the offset from four timestamps.

Figure 24.7 — The NTP on-wire exchange.



Reading the diagram. One synchronous UDP request/response (port 123): T_1 and T_4 are read from the client's clock, T_2 and T_3 from the server's. No storage is involved. Failure points: asymmetric delay (biases the offset) and a wrong server clock (handled by querying several servers). NTP scales through a server hierarchy (Figure 24.8).

FORMULA

NTP offset, round-trip delay and error bound (RFC 5905)

$$\theta = \frac{(T_2 - T_1) + (T_3 - T_4)}{2} \qquad \delta = (T_4 - T_1) - (T_3 - T_2) \qquad |\theta - \theta_{\text{true}}| \le \frac{\delta}{2}$$

Symbol	Meaning	Units
T_1	Client clock when the request is sent	s
T_2	Server clock when the request arrives	s
T_3	Server clock when the reply is sent	s
T_4	Client clock when the reply arrives	s
θ	Estimated offset: server clock minus client clock; the client adds θ to correct itself	s
δ	Round-trip network delay, excluding the server's processing time	s
θ_{true}	Actual offset	s

If the request takes d_1 and the reply d_2, the error is $(d_1 - d_2)/2$, at most $\delta/2$ because $d_1 + d_2 = \delta$; hence NTP prefers low-delay samples.

WORKED EXAMPLE

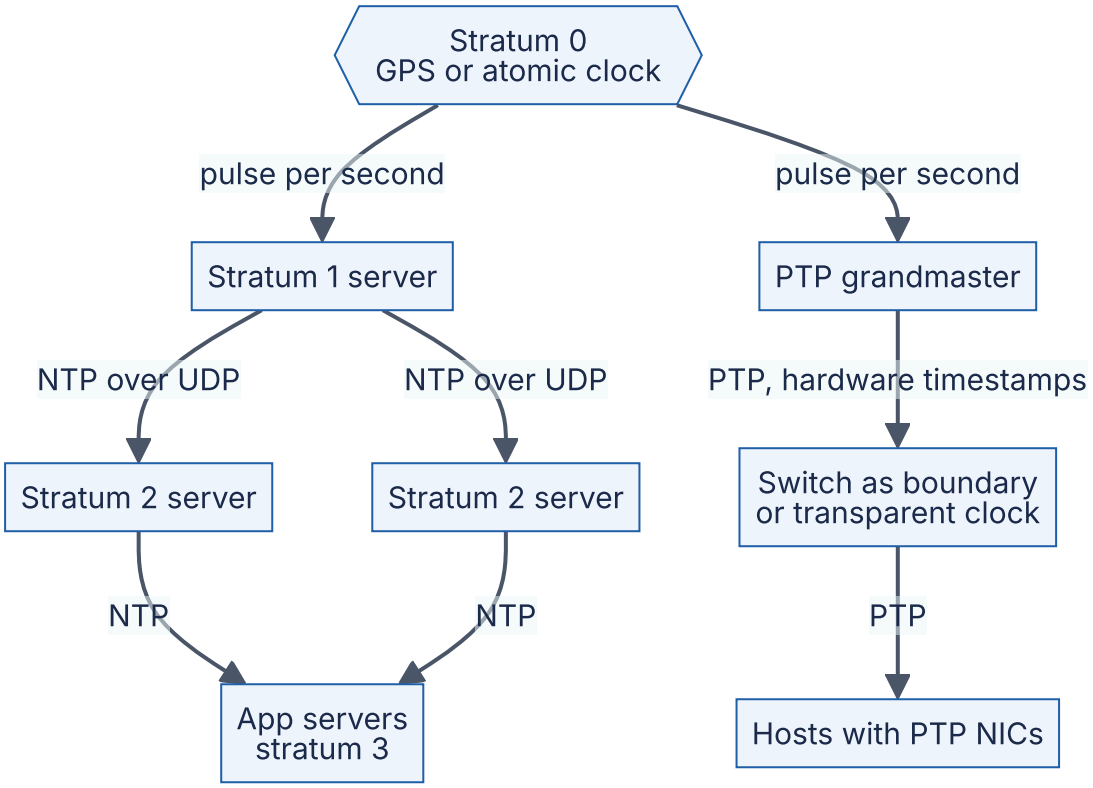
Worked example — One NTP exchange, symmetric and asymmetric.

Timestamps in seconds after 10:00:00: $T_1 = 0.000$ (client), $T_2 = 0.120$ (server), $T_3 = 0.121$ (server), $T_4 = 0.061$ (client).

1. Delay: $\delta = (0.061 - 0.000) - (0.121 - 0.120) = 0.061 - 0.001 = 0.060$ s $= 60$ ms.
2. Offset: $\theta = [(0.120 - 0.000) + (0.121 - 0.061)]/2 = (0.120 + 0.060)/2 = 0.090$ s $= 90$ ms. The client's clock is 90 ms behind the server's.
3. Check: if each direction took 30 ms and the client was 90 ms behind, the request sent at client time 0.000 (server time 0.090) arrives at server time 0.120, and the reply sent at 0.121 arrives at server time 0.151, which is client time 0.061. Both match.
4. Asymmetric case: suppose the request actually took 50 ms and the reply 10 ms (same $\delta = 60$ ms). NTP still computes 90 ms, but the true offset is $0.120 - 0.050 = 0.070$ s, an error of $(50 - 10)/2 = 20$ ms, within the bound $\delta/2 = 30$ ms.

Interpretation: NTP cannot see path asymmetry, so one sample over a 60 ms path is good only to ±30 ms. Engineering implication: run stratum-1 or stratum-2 servers inside the datacenter, where sub-millisecond round trips shrink the bound.

Figure 24.8 — The time-distribution hierarchy: NTP strata and a PTP domain.



Reading the diagram. A **stratum** is the distance from a reference clock: stratum-0 devices (GPS, atomic clocks) feed stratum-1 servers directly, and each NTP hop adds one (16 means unsynchronized). Clients query several servers so a bad one (a **falseticker**) is outvoted. The right-hand PTP domain distributes time from a grandmaster through PTP-aware switches to hosts with hardware-timestamping NICs. Arrows are periodic request/response exchanges; failure points are reference loss, falsetickers and asymmetry; the tree scales because each server serves many clients.

How an NTP client turns samples into a clock

A daemon such as `ntpd` or `chrony` (1) polls several servers repeatedly (64–1,024 s by default in `ntpd`), (2) keeps the lowest-delay samples, (3) **selects** the largest group of servers whose error intervals overlap, discarding falsetickers, (4) combines the survivors, and (5) disciplines the clock: small offsets are **slewed** (`ntpd` runs the clock at most 500 ppm fast or slow), large ones (over 128 ms by default) are **stepped**, possibly *backwards*. Typical results are milliseconds over a good wide-area path and well under a millisecond on a quiet LAN, with no hard guarantee: congestion, asymmetry or a paused virtual machine can produce offsets of seconds.

24.9.4 PTP: sub-microsecond synchronization

The **Precision Time Protocol** (PTP, IEEE 1588-2008 and its 2019 revision) [IEEE 2008; IEEE 2019] uses the same four-timestamp idea with three improvements: **hardware timestamping** in the NIC removes operating-system stack jitter, the main error in software NTP; switches act as **transparent clocks** (adding their queuing time to a correction field) or **boundary clocks** (re-serving time downstream), so asymmetry is measured rather than guessed; and **frequent exchanges** (`Sync`, `Delay_Req`, `Delay_Resp`) track drift closely. A well-built network achieves sub-microsecond synchronization, at the cost of PTP-capable NICs, switches and GPS-referenced grandmasters.

> INDUSTRY EXAMPLE
>
> **Precision time in public clouds and at Meta.** Meta has described deploying PTP across its datacenters for sub-microsecond precision [Obleukhov and Byagowi 2022]. AWS announced microsecond-accurate time from the Amazon Time Sync Service on supported instances in 2023, and publishes ClockBound, a daemon that returns the time together with an *error bound* [AWS 2023]. Applications increasingly ask “what is the time, *and how wrong could it be*?” *Evidence: Primary* — [Obleukhov and Byagowi 2022; AWS 2023]

24.9.5 Leap seconds and smearing

UTC is kept within 0.9 s of the Earth's irregular rotation by **leap seconds**: a minute ending `23:59:60` on 30 June or 31 December. Since 1972, 27 have been added, the latest at the end of 2016 (TAI − UTC = 37 s). Unix time cannot represent `23:59:60`, so systems typically repeat a second and time appears to go backwards. The 2012 leap second triggered a Linux kernel timer bug that left many Java and MySQL processes spinning at full CPU; at the end of 2016, Cloudflare's DNS software computed a negative duration and some resolutions failed [Graham-Cumming 2017]. The mitigation is **leap smearing**: servers run slightly slow over a long window, absorbing the second gradually. Google smears linearly over 24 hours, noon to noon UTC [Google: Leap Smear].

FORMULA

Leap-smear rate

$$r_{\text{smear}} = \frac{1\ \text{s}}{W} \qquad e_{\max} = 0.5\ \text{s (midpoint offset from UTC)}$$

Symbol	Meaning	Units
W	Smear window	s
r_{smear}	Rate by which smeared clocks run slow during the window	ppm
$e_{\max}$	Offset between a smeared clock and true UTC at the leap second instant	s

WORKED EXAMPLE

Worked example — Google-style 24-hour smear.

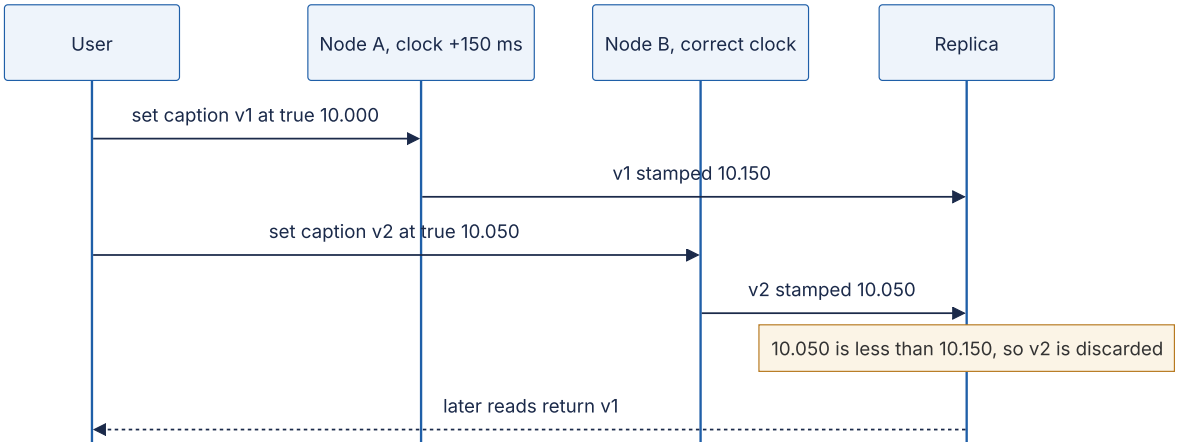
1. $W = 24 \times 3,600 = 86,400$ s.
2. $r_{\text{smear}} = 1/86,400 = 1.157 \times 10^{-5}$ s/s ≈ 11.6 ppm.
3. At the leap second, a smeared clock is half-way through: it differs from UTC by 0.5 s.

Interpretation: 11.6 ppm is an ordinary slew, so no client sees a step. Engineering implication: never mix smeared and unsmeared sources, which would disagree by up to 0.5 s. In 2022 the CGPM resolved to let UT1 − UTC grow larger by 2035, in effect ending leap seconds [BIPM 2022]; until then, systems must handle them.

24.9.6 Why wall-clock last-writer-wins loses data

Under **last-writer-wins (LWW)**, the write with the higher timestamp survives (Cassandra per cell, §12.6; many multi-primary systems, §14.5). With wall-clock timestamps, skew rather than event order decides the winner.

Figure 24.9 — Last-writer-wins discards the later write when one clock runs fast.



Reading the diagram. A user edits a PhotoShare caption through node A, then 50 ms later through node B. Each write is synchronous to its node and replicated asynchronously to the replica (the storage boundary). A's clock is 150 ms fast, so the earlier write carries the larger stamp and v2 is silently discarded. The failure point is A's clock; more replicas do not help, since all apply the same rule.

WORKED EXAMPLE

Worked example — How large is the danger window?

1. Skew between A and B: $\varepsilon = 150$ ms.
2. A write through B at true time t loses to an earlier write through A at true time $t - x$ whenever A's stamp is larger: $(t - x) + 0.150 > t$, i.e., $x < 150$ ms.
3. So any two writes to the same key through these two nodes that are less than 150 ms apart may be reordered. PhotoShare's caption edits are rare, but an inventory counter updated 50 times per second from several nodes would lose updates constantly.

Interpretation: the skew is a window within which LWW silently discards *causally later* writes. Engineering implication: use wall-clock LWW only where losing one of two near-simultaneous writes is acceptable; otherwise use logical clocks (§24.10–§24.12), version vectors (§24.11), conditional writes, or CRDTs (§27.14).

Code example

```
        """Clock arithmetic: NTP offset/delay, drift-based resync interval,
        and how last-writer-wins (LWW) loses a write when clocks are skewed."""

        def ntp_offset_delay(t1, t2, t3, t4):
            """RFC 5905 on-wire calculation (all values in seconds).
            t1, t4 are read from the client clock; t2, t3 from the server clock."""
            offset = ((t2 - t1) + (t3 - t4)) / 2   # theta: server clock minus client
clock
            delay = (t4 - t1) - (t3 - t2)          # delta: round trip minus server hold
time
            return offset, delay

        def resync_interval(max_skew_s, drift_ppm):
            """Longest interval between syncs that keeps two clocks within max_skew_s
            when each may drift up to drift_ppm in opposite directions."""
            return max_skew_s / (2 * drift_ppm * 1e-6)

        class LWWRegister:
            """A replica that keeps the value with the highest wall-clock timestamp."""

            def __init__(self):
                self.value, self.ts = None, float("-inf")

            def apply(self, value, ts):
                if ts > self.ts:
                    self.value, self.ts = value, ts
                    return "applied"
                return "discarded"

        if __name__ == "__main__":
            theta, delta = ntp_offset_delay(0.000, 0.120, 0.121, 0.061)
            print(f"NTP: offset {theta * 1000:.1f} ms, delay {delta * 1000:.1f} ms, "
                  f"error bound +/-{delta / 2 * 1000:.1f} ms")

            print(f"Resync every {resync_interval(0.001, 50):.0f} s to stay within 1 ms
at 50 ppm")

            # Node A's clock runs 150 ms fast; node B's clock is correct.
            skew = {"A": 0.150, "B": 0.000}
            writes = [  # (true time in s, node, value): the second write happens 50 ms
later
                (10.000, "A", "caption v1"),
                (10.050, "B", "caption v2"),
            ]
            replica = LWWRegister()
            for true_t, node, value in writes:
                stamp = true_t + skew[node]                    # what the node's clock
says
                print(f"t={true_t:.3f} node {node} writes {value!r:13} stamp=
{stamp:.3f}"
```

```
                    f" -> {replica.apply(value, stamp)}")
        print(f"Final value: {replica.value!r} (the later write was lost)")
```

Output:

```
NTP: offset 90.0 ms, delay 60.0 ms, error bound +/-30.0 ms
Resync every 10 s to stay within 1 ms at 50 ppm
t=10.000 node A writes 'caption v1'  stamp=10.150 -> applied
t=10.050 node B writes 'caption v2'  stamp=10.050 -> discarded
Final value: 'caption v1' (the later write was lost)
```

What to notice:

- `ntp_offset_delay` is a direct transcription of the RFC 5905 formulas; the sign convention is "server minus client".
- `LWWRegister.apply` returns `"discarded"` for the user's *latest* edit, and nothing in the system raises an error: LWW data loss is silent.
- Even if the replica received v2 first, the outcome is the same, because LWW orders by timestamp, not by arrival.

24.9.7 Clock sources and bounded uncertainty

Table 24.8 — Clock synchronization options.

Option	How it works	Typical accuracy (as of 2026)	Cost	Use when
Unsynchronized quartz	Free-running oscillator	Drifts seconds per day	None	Never for timestamps shared across machines
NTP over the Internet	Software timestamps, public servers	Milliseconds to tens of milliseconds	Free	Laptops, small fleets, logging
NTP inside a datacenter	Local stratum-1/2 servers, short paths	Sub-millisecond to a few ms	Low	Default for server fleets
PTP with hardware timestamps	NIC and switch timestamping	Sub-microsecond in a well-built LAN	PTP-capable NICs, switches, grandmasters	Finance, telecom, databases that exploit tight bounds
Bounded-uncertainty APIs	Return an interval [earliest, latest] instead of one value	Interval width of microseconds to milliseconds	Infrastructure plus discipline in using the bound	Correctness that depends on time (leases, commit wait)

The last row matters most for Part V. Google's **TrueTime** returns an interval guaranteed to contain true time, and Spanner waits out its width before making a commit visible (**commit wait**), turning bounded uncertainty into externally consistent transactions (§28.8).

Table 24.9 — Clock failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Negative durations; timeouts fire early or never	Wall clock used for durations; NTP stepped it	Negative latency metrics; stuck timers	Restart affected processes	Monotonic clocks for all durations
Lost writes under LWW	Skew larger than gap between conflicting writes	Users report edits "reverting"; audit logs disagree	Restore from log if kept	Logical or hybrid clocks, version vectors, CRDTs
Two lease holders at once	Lease holder's clock slow or process paused	Two nodes acting as owner	Fencing rejects stale owner	Fencing tokens (§26.13); bounded-uncertainty clocks
One node far off after hypervisor pause or failed sync	Synchronization stopped silently	Offset and "last sync" metrics	Step clock; quarantine node	Alert on sync loss; nodes refuse to serve when offset exceeds a bound
Leap second crash or 0.5 s disagreement	Repeated second; mixed smeared and unsmeared sources	Errors clustered at 23:59:60 UTC	Restart; fix time sources	Smear consistently across the fleet

COMMON MISTAKE

Mistake — "NTP keeps all our clocks in sync, so timestamps give a total order." NTP gives an *estimate*, usually off by milliseconds and occasionally by seconds; events closer than the skew cannot be ordered by timestamp (§17.10 makes the same point for IDs). Use logical clocks for ordering and explicit uncertainty bounds for real-time guarantees.

24.10 Logical clocks: Lamport clocks

24.10.1 Happened-before

Lamport's 1978 insight was that most systems need to know not *when* events happened but which could have *influenced* which [Lamport 1978].

DEFINITION

Definition — Happened-before (→). The smallest relation on events such that: (1) if a and b occur in the same process and a comes first, $a \to b$; (2) if a is the sending of a message and b its receipt, $a \to b$; (3) if $a \to b$ and $b \to c$, then $a \to c$. Two distinct events are **concurrent** ($a \parallel b$) if neither $a \to b$ nor $b \to a$.

Happened-before is **potential causality**: information from a *could* have reached b.

24.10.2 The algorithm

Think of a diary page counter: turn a page per event, write the page number on each letter sent, and on receiving a letter skip past its page number if higher.

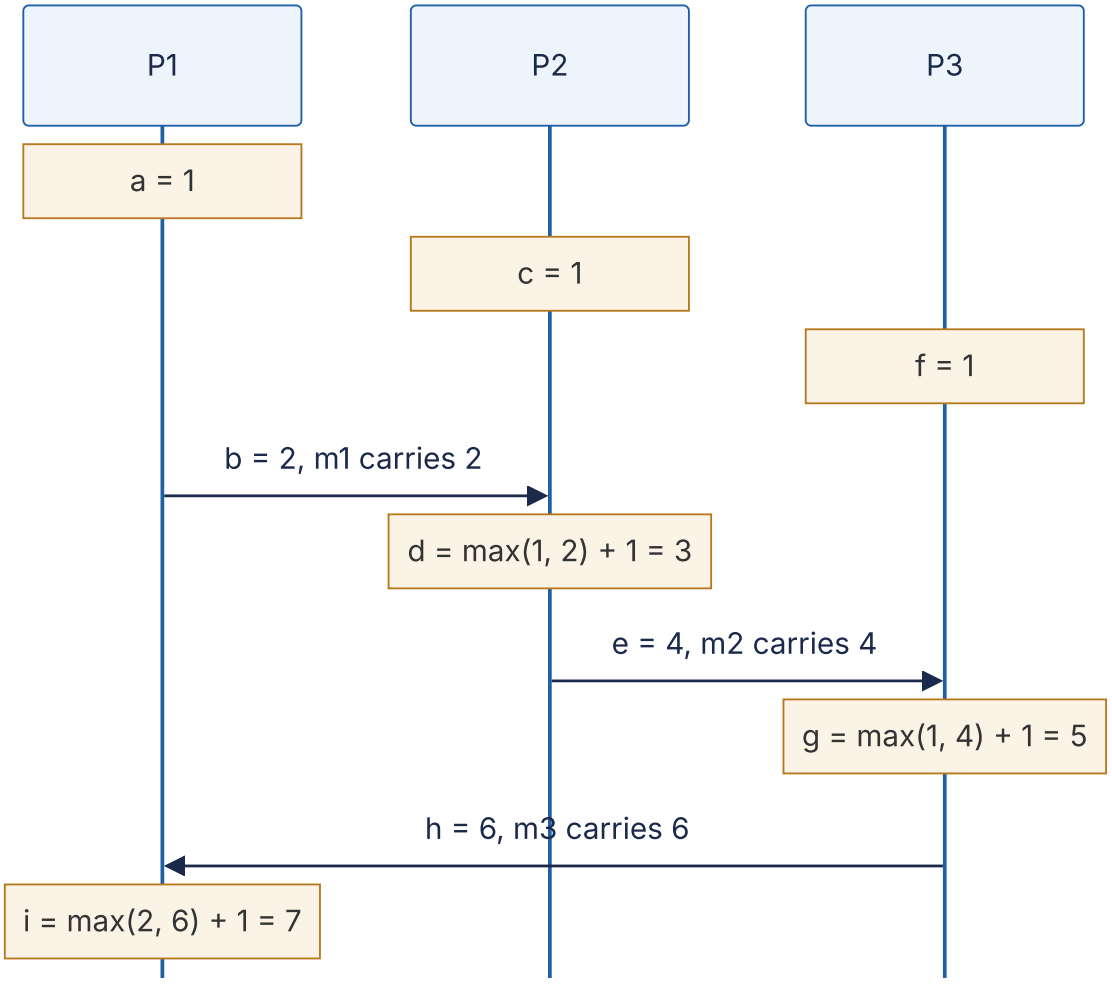
DEFINITION

Definition — Lamport clock. Each process P_i keeps an integer counter C_i, initially 0. **Rule 1:** before each event (local, send or receive), $C_i \leftarrow C_i + 1$; a send attaches the new C_i to the message. **Rule 2:** on receiving a message with timestamp t_m, set $C_i \leftarrow \max(C_i, t_m)$, then apply rule 1. The event's timestamp is the resulting C_i.

The rules guarantee the **clock condition**: if $a \to b$ then $C(a) < C(b)$. The converse does *not* hold: $C(a) < C(b)$ says only that b did not happen before a.

24.10.3 A worked trace

Figure 24.10 — Lamport timestamps on three processes.



Reading the diagram. Lifelines are processes, notes are events with timestamps, and arrows are asynchronous messages carrying the sender's timestamp. P2's receipt `d` jumps to $\max(1, 2) + 1 = 3$, and the chain continues through P3 back to P1. There is no storage or failure point; only causality is shown. Note the limitation: `c` (1) < `b` (2), yet they are concurrent. The cost is one integer per message, at any scale.

24.10.4 Code example

```
        """Lamport logical clocks: replay the trace of Figure 24.10 and derive a total
order."""

        class LamportProcess:
            def __init__(self, pid):
                self.pid, self.clock, self.log = pid, 0, []

            def _tick(self, name, kind):
                self.clock += 1                          # rule 1: increment before every
event
                self.log.append((self.clock, self.pid, name, kind))
                return self.clock

            def local(self, name):
                return self._tick(name, "local")

            def send(self, name):
                return self._tick(name, "send")          # the message carries this time-
stamp

            def receive(self, name, msg_ts):
                self.clock = max(self.clock, msg_ts)     # rule 2: jump past the sender's
time
                return self._tick(name, "receive")

        if __name__ == "__main__":
            p1, p2, p3 = LamportProcess("P1"), LamportProcess("P2"),
LamportProcess("P3")
            p1.local("a")
            m1 = p1.send("b")            # m1: P1 -> P2
            p2.local("c")
            p2.receive("d", m1)
            m2 = p2.send("e")            # m2: P2 -> P3
            p3.local("f")
            p3.receive("g", m2)
            m3 = p3.send("h")            # m3: P3 -> P1
            p1.receive("i", m3)

            events = p1.log + p2.log + p3.log
            for ts, pid, name, kind in sorted(events):  # total order: (timestamp,
process id)
                print(f"{ts:>2} {pid} {name} ({kind})")
```

Output:

```
1 P1 a (local)
1 P2 c (local)
1 P3 f (local)
2 P1 b (send)
3 P2 d (receive)
4 P2 e (send)
5 P3 g (receive)
6 P3 h (send)
7 P1 i (receive)
```

What to notice:

- Sorting by the pair (timestamp, process ID) gives a **total order** that every process can compute identically and that is consistent with causality; ties such as `a`, `c`, `f` at 1 are broken by process ID.
- The total order is *arbitrary* among concurrent events: it places `c` before `b`, though neither influenced the other.

24.10.5 Uses and limits

Lamport used this total order for distributed mutual exclusion [Lamport 1978], the seed of **state machine replication** (§26.3). Raft's **terms** behave like a Lamport clock: a node adopts any higher term it sees and rejects lower ones [Ongaro and Ousterhout 2014]; fencing tokens (§26.13) are similar. What Lamport clocks cannot do is detect concurrency.

24.11 Vector clocks and version vectors

24.11.1 The algorithm

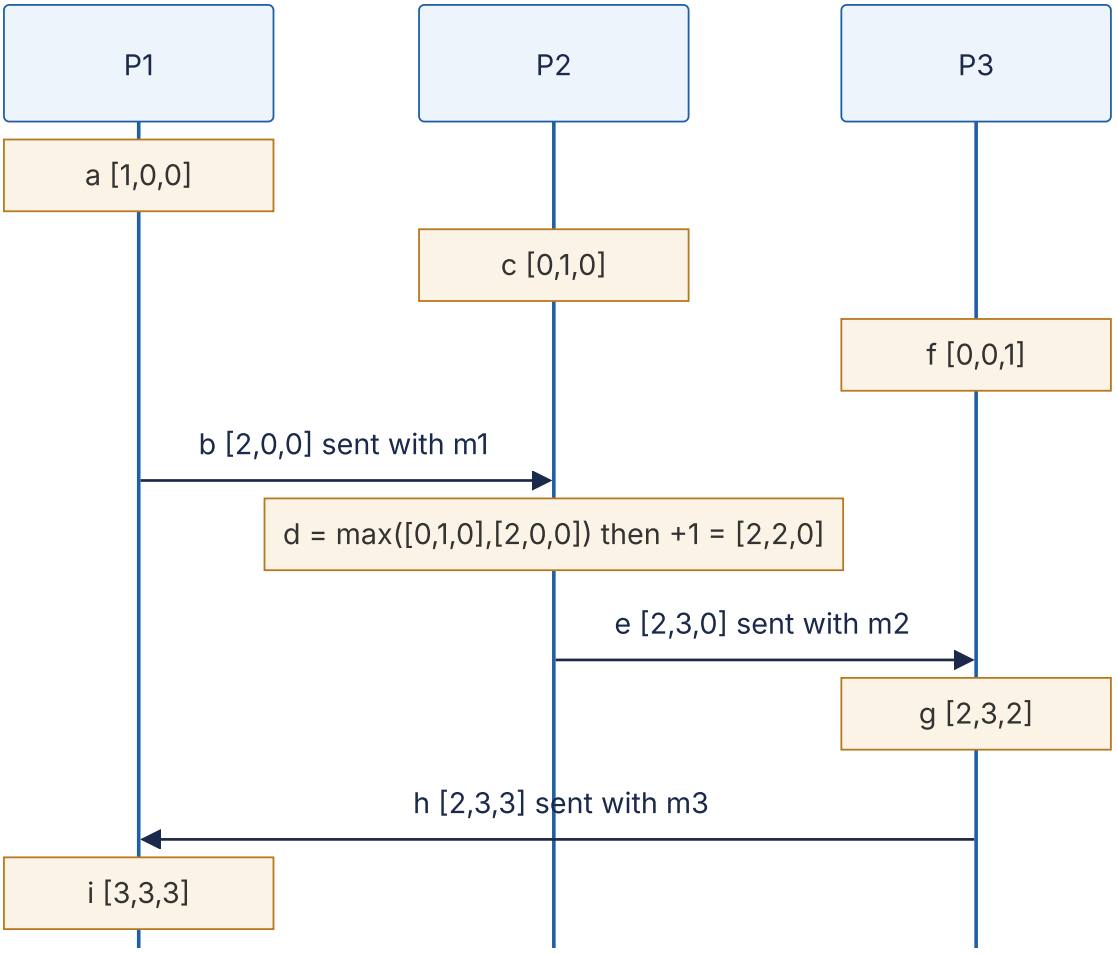
Vector clocks were introduced independently by Fidge and Mattern [Fidge 1988; Mattern 1989]. Instead of one counter, each process keeps a counter *for every process*: its knowledge of how many events each process has performed.

> DEFINITION
>
> **Definition — Vector clock.** With n processes, each process P_i keeps a vector $V_i[1..n]$, initially all zeros. Before each event, P_i increments $V_i[i]$; a send attaches a copy of V_i. On receiving a message carrying V_m, P_i sets $V_i[k] \leftarrow \max(V_i[k], V_m[k])$ for every k, then increments $V_i[i]$.

Comparison rules: $V \le W$ if $V[k] \le W[k]$ for all k; $V < W$ if $V \le W$ and $V \ne W$; $V \parallel W$ (concurrent) if neither $V \le W$ nor $W \le V$. Unlike Lamport clocks, vector clocks **characterize** causality

exactly: $a \rightarrow b$ if and only if $V(a) < V(b)$.

Figure 24.11 — Vector clocks on the same trace.



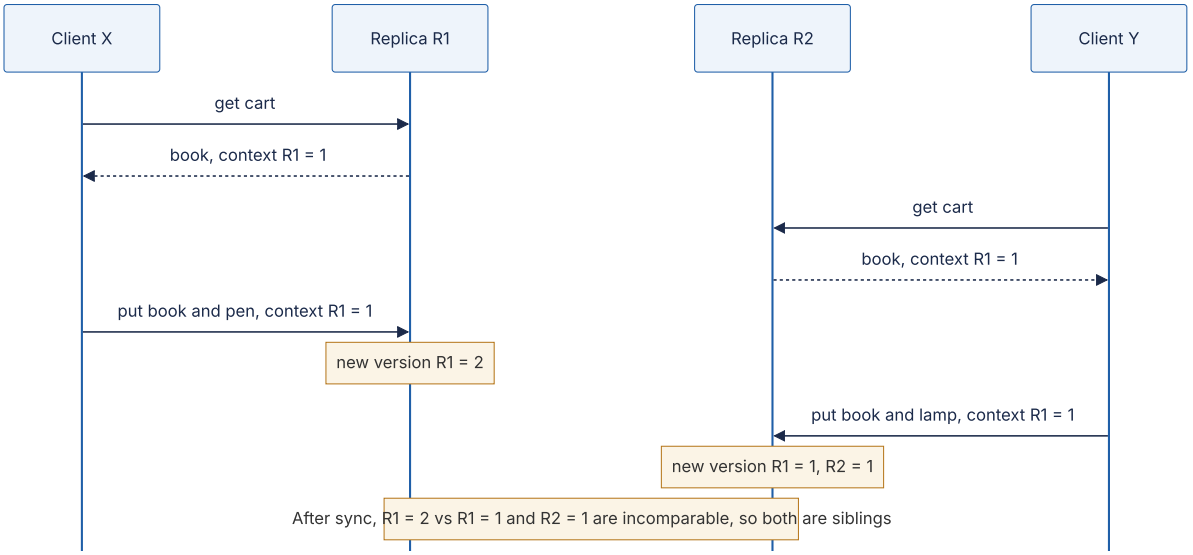
Reading the diagram. Entries are [P1, P2, P3]; each event increments its own entry, and each receipt first takes the element-wise maximum. Asynchronous messages now carry n integers. Concurrency is visible: `c` = [0,1,0] and `b` = [2,0,0] are incomparable, while `b` ≤ `g` = [2,3,2] entry by entry, so `b` → `g`. The scaling limit is vector size, which grows with the number of processes.

24.11.2 Version vectors

A **version vector** applies the same idea to *replicas of a data item* rather than to events in processes [Parker et al. 1983]. Each replica that accepts writes for a key has an entry counting the updates it has issued to that key. When two versions of a key have incomparable version vectors, they were written concurrently and are kept as **siblings** for the application (or a merge function) to reconcile; when one dominates, it replaces the other. The client passes the version vector it read (its **context**) with each write, so the store knows which versions the client had seen. This section introduces the mechanism only;

how replicated stores use siblings in practice (the Dynamo cart walk-through, Riak's causal contexts, merge functions and their pitfalls) is in §27.14.2.

Figure 24.12 — Version vectors detect a concurrent shopping-cart update.



Reading the diagram. Both clients read context {R1: 1} and write synchronously through different replicas, which later synchronize asynchronously. Neither {R1: 2} nor {R1: 1, R2: 1} dominates, so both values are kept as siblings; the next reader gets both and writes back a merge. The storage boundary is each replica's copy. Unlike LWW (Figure 24.9), nothing is silently lost, at the cost of application merging.

24.11.3 Code example

```
        """Vector clocks: comparison, the Figure 24.11 trace, and sibling detection with
version vectors."""

        def compare(v, w):
            """Return 'equal', 'before' (v happened before w), 'after' or 'concur-
rent'."""
            keys = set(v) | set(w)
            le = all(v.get(k, 0) <= w.get(k, 0) for k in keys)
            ge = all(v.get(k, 0) >= w.get(k, 0) for k in keys)
            if le and ge:
                return "equal"
            if le:
                return "before"
            if ge:
                return "after"
            return "concurrent"

        def merge(v, w):
            return {k: max(v.get(k, 0), w.get(k, 0)) for k in sorted(set(v) | set(w))}

        class VCProcess:
            def __init__(self, pid):
                self.pid, self.vc, self.events = pid, {}, {}

            def _tick(self, name):
                self.vc = dict(self.vc)
                self.vc[self.pid] = self.vc.get(self.pid, 0) + 1   # increment own entry
                self.events[name] = self.vc
                return self.vc

            def local(self, name):
                return self._tick(name)

            def send(self, name):
                return self._tick(name)                # the message carries a copy of
vc

            def receive(self, name, msg_vc):
                self.vc = merge(self.vc, msg_vc)       # element-wise maximum, then in-
crement
                return self._tick(name)

        class VersionedStore:
            """One key replicated with version vectors keyed by replica id. Concurrent
            writes are kept as siblings instead of being silently overwritten."""

            def __init__(self):
                self.siblings = []                     # list of (version_vector,
value)
```

```
            def get(self):
                context = {}
                for vv, _ in self.siblings:
                    context = merge(context, vv)
                return [val for _, val in self.siblings], context

            def put(self, replica, value, context):
                new_vv = dict(context)
                counter = max((vv.get(replica, 0) for vv, _ in self.siblings),
default=0)
                new_vv[replica] = counter + 1           # replica issues its next
counter value
                # Keep only siblings that the new write did not causally overwrite.
                self.siblings = [(vv, val) for vv, val in self.siblings
                                 if compare(vv, new_vv) == "concurrent"]
                self.siblings.append((new_vv, value))

        def fmt(v):
            return "[" + ",".join(str(v.get(p, 0)) for p in ("P1", "P2", "P3")) + "]"

        if __name__ == "__main__":
            p1, p2, p3 = VCProcess("P1"), VCProcess("P2"), VCProcess("P3")
            p1.local("a"); m1 = p1.send("b")
            p2.local("c"); p2.receive("d", m1); m2 = p2.send("e")
            p3.local("f"); p3.receive("g", m2); m3 = p3.send("h")
            p1.receive("i", m3)
            ev = {**p1.events, **p2.events, **p3.events}
            for name in "abcdefghi":
                print(name, fmt(ev[name]))
            for x, y in [("b", "g"), ("c", "b"), ("f", "e"), ("a", "i")]:
                print(f"{x} vs {y}: {compare(ev[x], ev[y])}")

            store = VersionedStore()
            store.put("R1", "cart=[book]", {})
            _, ctx = store.get()                            # both clients read the same
version
            store.put("R1", "cart=[book, pen]", ctx)        # client 1 writes via replica
R1
            store.put("R2", "cart=[book, lamp]", ctx)       # client 2 writes via R2 con-
currently
            values, ctx = store.get()
            print("siblings:", values, "context:", ctx)
            store.put("R1", "cart=[book, pen, lamp]", ctx) # client merges and writes
back
            print("after merge:", store.get())

            # Pitfall: two clients write concurrently through the SAME replica.
            store = VersionedStore()
            store.put("R1", "v0", {})
            _, ctx = store.get()
            store.put("R1", "from client X", ctx)           # gets {R1: 2}
            store.put("R1", "from client Y", ctx)           # gets {R1: 3}, which domi-
nates {R1: 2}
            print("same-replica concurrent writes:", store.get()[0])
```

Output:

```
a [1,0,0]
b [2,0,0]
c [0,1,0]
d [2,2,0]
e [2,3,0]
f [0,0,1]
g [2,3,2]
h [2,3,3]
i [3,3,3]
b vs g: before
c vs b: concurrent
f vs e: concurrent
a vs i: before
siblings: ['cart=[book, pen]', 'cart=[book, lamp]'] context: {'R1': 2, 'R2': 1}
after merge: (['cart=[book, pen, lamp]'], {'R1': 3, 'R2': 1})
same-replica concurrent writes: ['from client Y']
```

What to notice:

- `compare` treats missing entries as 0, so vectors can be sparse maps rather than fixed arrays.
- The merged write carries the merged context {R1: 2, R2: 1}, so its new vector {R1: 3, R2: 1} dominates both siblings and replaces them.
- The last case is a real flaw of per-replica version vectors: two *concurrent* writes through the same replica get {R1: 2} and {R1: 3}, the second appears to dominate the first, and client X's write is lost. Dotted version vectors (§24.11.5) fix this.

24.11.4 Size growth

FORMULA

Vector clock metadata size

$$S = n(b_{\text{id}} + b_{\text{ctr}}) \qquad M = K \cdot S$$

Symbol	Meaning	Units
n	Number of entries (processes, replicas or clients that have written)	count
b_{id}	Bytes to identify an entry's owner	bytes
b_{ctr}	Bytes per counter	bytes
S	Metadata per version	bytes
K	Number of keys stored	count
M	Total version metadata	bytes

WORKED EXAMPLE

Worked example — Server IDs versus client IDs.

1. Entries keyed by replica: $n = 3$, 8-byte IDs and 8-byte counters. $S = 3 \times 16 = 48$ bytes. For $K = 10^9$ keys, $M = 48 \times 10^9$ bytes = 48 GB, acceptable next to the data.
2. Entries keyed by *client*, for a popular key written by 10,000 distinct users: $S = 10,000 \times 16 = 160,000$ bytes = 160 KB of metadata on one key, transferred on every read and write.
3. Over a fleet of 1,000 processes tracking event causality: $S = 1,000 \times 16 = 16$ KB on *every message*.

Interpretation: size grows with the number of writers, and Charron-Bost proved no smaller timestamp can characterize causality in general [Charron-Bost 1991]. Engineering implication: key vectors by a small, stable set of replicas; if you must prune entries, accept occasional false conflicts.

INDUSTRY EXAMPLE

Amazon Dynamo. Dynamo tracked versions of shopping-cart objects with vector clocks of (node, counter) pairs, returned divergent versions to the client for semantic reconciliation, and truncated the vector by removing the oldest pair when it exceeded a threshold (about 10 pairs), accepting the small risk of losing causality information [DeCandia et al. 2007]. *Evidence: Primary* — [DeCandia et al. 2007]

24.11.5 Dotted version vectors

Dotted version vectors (DVVs) fix the same-replica flaw [Preguiça et al. 2010]. A DVV pairs the writer's causal context with a **dot**, the (replica, counter) pair naming *this* write. Writes through R1 with dots (R1, 2) and (R1, 3) are recognized as concurrent because neither context contains the other's dot. DVVs stay bounded by the replica count while avoiding lost updates and client-keyed "sibling explosion"; Riak adopted them in version 2.0 [Riak Docs: Dotted Version Vectors].

Table 24.10 — Logical clocks compared.

Clock	Size	Detects concurrency?	Close to real time?	Typical use
Lamport	1 integer	No	No	Total order, terms, fencing tokens
Vector clock	*n* entries (processes)	Yes	No	Causality tracking, debugging, causal broadcast
Version vector	*n* entries (replicas) per key	Yes	No	Conflict detection in replicated stores
Dotted version vector	Replica entries plus one dot	Yes, including same-replica writes	No	Riak-style key-value stores
Hybrid logical clock	64 bits	No	Yes, within skew	Timestamps for MVCC and snapshot reads

24.12 Hybrid logical clocks

24.12.1 Why combine physical and logical time

Multi-version databases need timestamps that (1) respect causality, (2) stay close to real time so "read as of 10:00" means something, and (3) fit in 64 bits. Lamport clocks miss (2); physical clocks miss (1). Kulkarni et al.'s **hybrid logical clock** (HLC) provides all three [Kulkarni et al. 2014].

DEFINITION

Definition — Hybrid logical clock. A timestamp (l, c) where l is the largest physical clock value the node has seen (from its own clock or from any message) and c is a logical counter that orders events sharing the same l. Timestamps compare lexicographically: first by l, then by c.

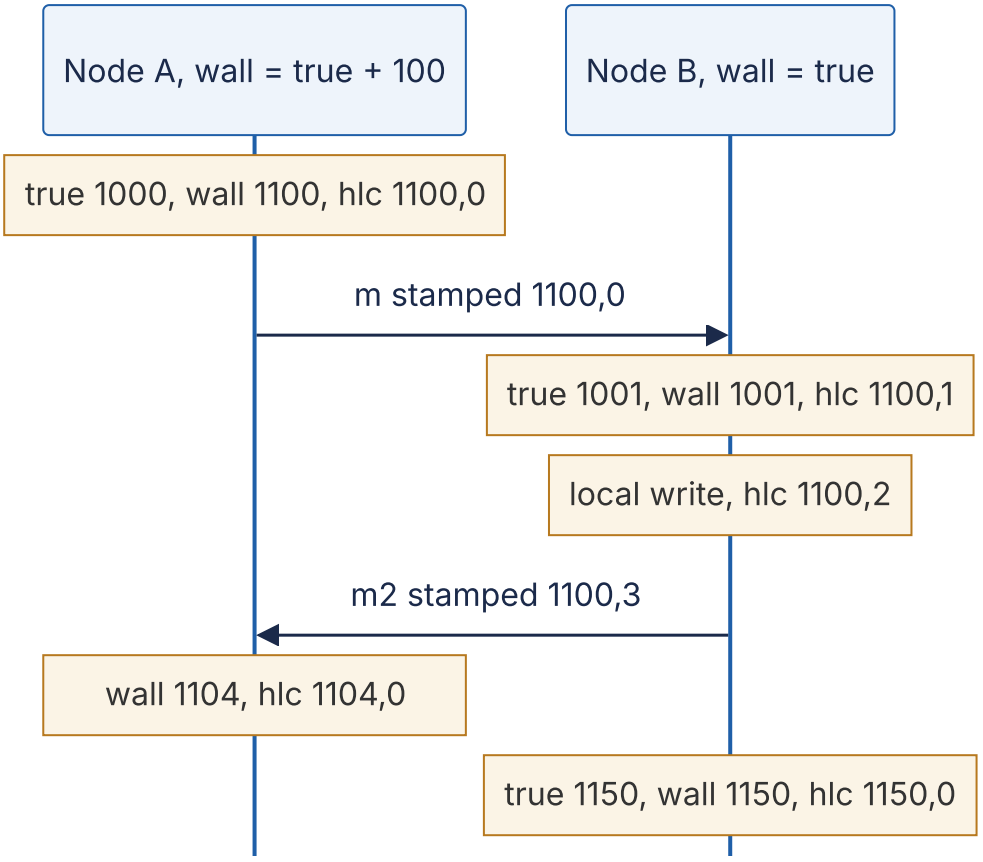
24.12.2 The algorithm

For a local or send event at a node with physical clock pt: set $l' \leftarrow l$, $l \leftarrow \max(l', pt)$; if $l = l'$ then $c \leftarrow c + 1$, else $c \leftarrow 0$.

For a receive of a message stamped (l_m, c_m): set $l \leftarrow \max(l', l_m, pt)$; then $c \leftarrow \max(c, c_m) + 1$ if l equals both l' and l_m; $c \leftarrow c + 1$ if $l = l'$ only; $c \leftarrow c_m + 1$ if $l = l_m$ only; otherwise $c \leftarrow 0$.

The paper proves that $e \rightarrow f$ implies $\mathrm{hlc}(e) < \mathrm{hlc}(f)$, that $l - pt \le \varepsilon$ (the clock skew) because l is always some node's clock reading, and that c stays small, so 48 bits of l plus 16 bits of c fit a 64-bit time field.

Figure 24.13 — HLC keeps causal order when node A's clock runs 100 ms fast.



Reading the diagram. Times are in milliseconds. A's message reaches B when B's wall clock reads 1001, *before* the send stamp 1100; physical timestamps would invert the order. B's HLC adopts $l = 1100$ and counts with c, ordering the receipt and B's next write after the send. Messages are asynchronous; the clock has no storage boundary. At 1150, l returns to physical time. The failure point is unbounded skew: one wildly fast clock drags every HLC forward, so production systems bound and monitor offsets.

24.12.3 Code example

```
        """Hybrid logical clock (Kulkarni et al. 2014) on two nodes whose clocks dis-
agree by 100 ms."""

        class HLC:
            def __init__(self, physical_clock):
                self.pt = physical_clock      # function returning this node's wall
clock, in ms
                self.l, self.c = 0, 0         # l: largest physical time seen; c: logi-
cal counter

            def now(self):
                """Timestamp a local or send event."""
                old_l = self.l
                self.l = max(old_l, self.pt())
                self.c = self.c + 1 if self.l == old_l else 0
                return (self.l, self.c)

            def update(self, msg):
                """Timestamp a receive event for a message stamped msg = (l_m, c_m)."""
                l_m, c_m = msg
                old_l = self.l
                self.l = max(old_l, l_m, self.pt())
                if self.l == old_l == l_m:
                    self.c = max(self.c, c_m) + 1
                elif self.l == old_l:
                    self.c += 1
                elif self.l == l_m:
                    self.c = c_m + 1
                else:
                    self.c = 0
                return (self.l, self.c)

        def pack(ts):
            """48 bits of milliseconds plus a 16-bit counter fit in one 64-bit inte-
ger."""
            l, c = ts
            assert c < 2**16
            return (l << 16) | c

        if __name__ == "__main__":
            true_ms = 1000
            a = HLC(lambda: true_ms + 100)    # node A's clock runs 100 ms fast
            b = HLC(lambda: true_ms)          # node B's clock is correct

            def show(event, node, ts, wall):
                print(f"true={true_ms} {event:<15} {node}: wall={wall}  hlc={ts}")

            ts = a.now()
            show("A sends m", "A", ts, true_ms + 100)
            true_ms += 1
            ts = b.update(ts)
```

```
            show("B receives m", "B", ts, true_ms)
            true_ms += 1
            ts = b.now()
            show("B local write", "B", ts, true_ms)
            true_ms += 1
            ts = b.now()
            show("B sends m2", "B", ts, true_ms)
            true_ms += 1
            ts = a.update(ts)
            show("A receives m2", "A", ts, true_ms + 100)
            true_ms = 1150
            ts = b.now()
            show("B local", "B", ts, true_ms)
            print("packed:", hex(pack(ts)), "->", ts == (pack(ts) >> 16, pack(ts) &
0xFFFF))
```

Output:

```
true=1000 A sends m       A: wall=1100  hlc=(1100, 0)
true=1001 B receives m    B: wall=1001  hlc=(1100, 1)
true=1002 B local write   B: wall=1002  hlc=(1100, 2)
true=1003 B sends m2      B: wall=1003  hlc=(1100, 3)
true=1004 A receives m2   A: wall=1104  hlc=(1104, 0)
true=1150 B local         B: wall=1150  hlc=(1150, 0)
packed: 0x47e0000 -> True
```

What to notice:

- `update` is the only place causality enters: taking the maximum with l_m guarantees the receipt is stamped after the send.
- l never runs ahead of the fastest physical clock (1100 here), so HLC timestamps stay within the skew of real time.
- Like a Lamport clock, an HLC is a scalar and cannot detect concurrency.

24.12.4 HLC in production: uncertainty intervals

HLC orders causally related events, but two *unrelated* transactions on different nodes are ordered only up to the clock skew. CockroachDB, which uses HLC timestamps, handles this with a configured **maximum clock offset** (500 ms by default, as of 2026) and an **uncertainty interval** [Cockroach Labs Docs; Kimball 2016].

FORMULA

Read uncertainty interval

$$t_r < t_w \le t_r + \varepsilon_{\max} \;\Rightarrow\; \text{restart the read at } t_w$$

Symbol	Meaning	Units
t_r	The reading transaction's HLC timestamp	s
t_w	Commit timestamp of a value found by the read	s
$\varepsilon_{\max}$	Configured maximum clock offset between any two nodes	s

Such a value *might* have committed before the read began in real time (the writer's clock may have been ahead), so the read moves up to t_w and retries.

WORKED EXAMPLE

Worked example — A read meets uncertain writes.

1. $\varepsilon_{\max} = 500$ ms; a read starts at $t_r = $ 10:00:00.000.
2. It finds a value at 10:00:00.300: inside $(t_r, t_r + 0.5]$, so it restarts at $t_r' = $ 10:00:00.300 and returns that value.
3. A value at 10:00:00.700 lies beyond the window: it definitely happened after the read began, and is ignored.

Interpretation: correctness depends on the configured bound holding, so CockroachDB nodes monitor their offset against peers and shut down rather than serve near the maximum. Engineering implication: better synchronization buys performance; halving $\varepsilon_{\max}$ halves the restart window. Spanner goes further with TrueTime (§28.8).

INDUSTRY EXAMPLE

MongoDB and CockroachDB. MongoDB's causal consistency sessions use a cluster-wide logical clock of the hybrid type, a (seconds, counter) pair gossiped on every message and signed to prevent malicious advancement [Tyulenev et al. 2019]. CockroachDB stamps every transaction with an HLC and uses the uncertainty interval above. *Evidence: Primary* — [Tyulenev et al. 2019; Cockroach Labs Docs]

24.13 The FLP impossibility result

24.13.1 The statement

DEFINITION

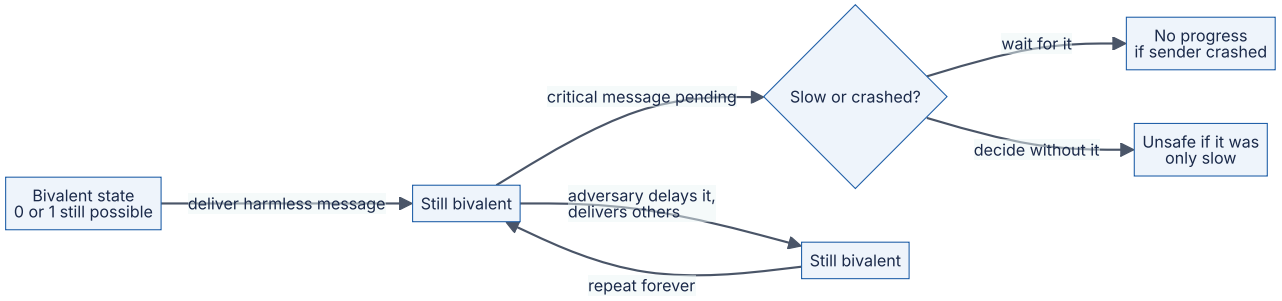
Definition — FLP impossibility. In a fully asynchronous message-passing system with reliable links, no *deterministic* protocol can solve **consensus** (all correct processes decide the same value, the value was proposed by some process, and every correct process eventually decides) if even one process may crash-stop [Fischer et al. 1985].

The assumptions are generous (no lost messages, one clean crash); only a delay bound is missing.

24.13.2 Intuition

Call a system state **bivalent** if both decisions (0 and 1) are still reachable, and **univalent** once the outcome is fixed. FLP shows that (1) some initial state is bivalent, and (2) from any bivalent state, an adversarial scheduler can always deliver messages in an order that keeps the state bivalent. The key step is that there is always some pending message whose delivery would decide the outcome; the scheduler delays it. Because the system is asynchronous, a delayed message is indistinguishable from a crashed sender, so the protocol cannot safely decide without it, and the scheduler can repeat the trick forever.

Figure 24.14 — The adversary keeps the protocol undecided.



Reading the diagram. Nodes are global states of the protocol; edges are message deliveries chosen by the adversarial scheduler, which is how the asynchronous network is modeled. When a critical message is pending, the protocol faces the decision box: waiting risks blocking forever if the sender crashed, deciding risks disagreement if the sender was merely slow. The adversary always picks the delivery that keeps the system bivalent. There are no storage boundaries; the failure point is the inability to tell slow from crashed, and adding processes does not help.

24.13.3 What FLP does and does not forbid

Table 24.11 — Reading FLP correctly.

FLP forbids	FLP does not forbid	How real systems escape
A deterministic protocol that *guarantees* termination in every asynchronous execution with one crash	Protocols that are always *safe* and terminate when the network behaves	**Partial synchrony** [Dwork et al. 1988]: Paxos and Raft never decide inconsistently and make progress after GST
	Protocols that terminate with probability 1	**Randomization** [Ben-Or 1983]: coin flips defeat the adversarial schedule
	Protocols that use an oracle to suspect failures	**Failure detectors** [Chandra and Toueg 1996]: an eventually accurate detector suffices
	Solving weaker problems	Eventual consistency and CRDTs avoid consensus altogether (§27.14)

In practice, a Raft cluster may fail to elect a leader during a storm of slow messages, stays *safe* throughout, and recovers once messages flow; its randomized election timeouts break symmetry, though they are not Ben-Or's algorithm [Ongaro and Ousterhout 2014].

COMMON MISTAKE

Mistake — "FLP proves consensus is impossible, so systems like etcd cannot work." FLP rules out a *guarantee of termination* in a purely asynchronous model. Real systems keep safety unconditionally and obtain liveness from timeouts, i.e., from the assumption that the network is eventually timely. FLP is also distinct from CAP (§25.8), which concerns availability of reads and writes during a partition.

24.14 The end-to-end argument

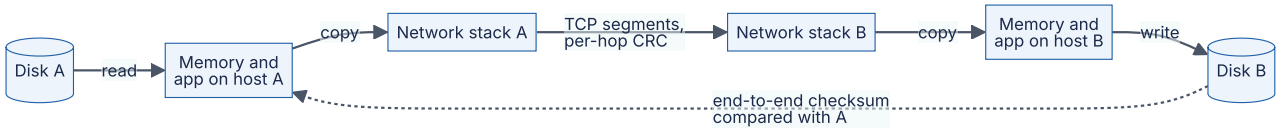
24.14.1 The principle

Saltzer, Reed and Clark's 1984 paper asks where in a layered system a function such as reliable delivery should be implemented [Saltzer et al. 1984]. Their answer, paraphrased: a function that can be implemented completely and correctly only with knowledge held by the application at the endpoints cannot be provided as a feature of the communication system alone. A lower layer may still provide a partial version, but only as a *performance optimization*.

Their example is **careful file transfer** from A's disk to B's disk. A reliable network still cannot prevent corruption in A's memory, a buffer copy or B's disk; only an application

check at both ends (compare checksums of the stored and original file, retry on mismatch) covers every step.

Figure 24.15 — Where errors can enter a file transfer, and which check covers them.



Reading the diagram. Data flows left to right between two storage boundaries (the disks) through several copies; every arrow is a failure point. TCP and link-layer checks protect only the middle arrow. The dotted arrow is the asynchronous end-to-end verification, which covers every step and scales at one checksum per file regardless of path length.

FORMULA

Undetected-corruption probability over many transfers

$$P_{\text{bad}} = 1 - (1 - q)^{N}$$

Symbol	Meaning	Units
q	Probability that one transfer suffers corruption no lower layer catches	dimensionless
N	Number of transfers	count
P_{bad}	Probability that at least one transfer is silently corrupted	dimensionless

WORKED EXAMPLE

Worked example — Rare errors at fleet scale.

1. Assume, for illustration, that one transfer in 10^{10} suffers corruption missed by TCP and link checks: $q = 10^{-10}$.
2. PhotoShare's replication moves $N = 10^9$ blocks per day: $P_{\text{bad}} = 1 - (1 - 10^{-10})^{10^9} \approx 1 - e^{-0.1} \approx 0.095$.
3. Over a year: $N = 3.65 \times 10^{11}$, $P_{\text{bad}} \approx 1 - e^{-36.5} \approx 1$.

Interpretation: a probability that looks negligible per transfer becomes a near-certainty at scale. Engineering implication: verify integrity end to end (checksums stored with the data and checked on read). Stone and Partridge measured that real Internet traffic contains errors the TCP checksum fails to catch at rates far above what checksum theory predicts [Stone and Partridge 2000].

INDUSTRY EXAMPLE

Amazon S3, July 2008. A single corrupted bit in messages of S3's internal gossip protocol, which carried no checksum of its own, spread incorrect server-state information through the system and caused a multi-hour outage. AWS's remedy included adding checksums to that internal state and its messages [AWS 2008]. *Evidence: Primary* — [AWS 2008]

24.14.2 Applying the argument

- **Delivery versus processing.** A TCP acknowledgment means the peer's kernel buffered the bytes (§7.7), not that the application processed them. A message broker should be acknowledged *after* processing (Chapters 30–31).
- **Exactly-once effects.** No network can deliver exactly once; the endpoint achieves *effectively-once* processing with at-least-once delivery plus deduplication by idempotency key (§22.15).
- **Security.** Encryption hop by hop leaves data exposed at every intermediary; end-to-end encryption does not (Chapter 10).
- **Where lower layers still help.** Wi-Fi retransmits frames locally because an end-to-end retransmission would be far slower: the permitted "performance optimization".

COMMON MISTAKE

Mistake — "The network (or storage system) is reliable, so the application needn't check." Each layer's guarantee covers only that layer. If the requirement is "the user's photo is stored intact and saved once", only the application can verify it.

24.15 Summary and revision notes

SUMMARY

- Distributed systems have **independent failures, no global clock and unreliable messages**; the **two generals problem** shows certainty of agreement over a lossy channel is impossible.
- Distribute for **scale, fault tolerance, latency or data residency**. Replication gives $A_k = 1 - (1 - a)^k$ under independence, but fleets fail daily: $P_{\text{any}} = 1 - (1 - p)^n$.
- Each of the **eight fallacies** maps to a class of outages.
- State a **system model**: timing (synchronous, partially synchronous, asynchronous) and faults (crash-stop, crash-recovery, omission, timing, Byzantine). Consensus needs $2f + 1$ nodes for crashes, $3f + 1$ for Byzantine faults.
- **Network partitions** are complete, partial or asymmetric, and occur daily in large fleets; partial ones cause many catastrophic bugs.
- A timeout means **unknown outcome**. **Gray failures** are differentially observable; detect them with what clients experience. Set timeouts from measured p99.9 plus pause margin.
- Quartz drifts (1 ppm = 86.4 ms/day); NTP estimates $\theta = [(T_2 - T_1) + (T_3 - T_4)]/2$ with error up to $\delta/2$; PTP with hardware timestamps reaches sub-microsecond. Use monotonic clocks for durations; smear leap seconds consistently.
- **Wall-clock LWW** silently discards causally later writes that fall within the skew window.
- **Lamport clocks**: $a \to b \Rightarrow C(a) < C(b)$, total order with tie-breaking, no concurrency detection. **Vector clocks** characterize causality exactly at $O(n)$ size; **version vectors** detect concurrent writes as siblings; **dotted version vectors** fix same-replica lost updates.
- **HLC** (l, c) is causal, within skew of real time, and 64 bits; real-time guarantees still need bounded skew (uncertainty intervals, TrueTime in §28.8).
- **FLP**: no deterministic asynchronous consensus guarantees termination with one crash; systems stay safe always and live under partial synchrony, randomization or failure detectors.
- **End-to-end argument**: integrity, deduplication and processing acknowledgments belong at the endpoints; lower layers only optimize.

24.16 Knowledge checkpoint

1. Name the three properties that make a system distributed.
2. Why can no finite protocol solve the two generals problem?
3. One server is 99.9% available. What is the availability of 3 independent replicas, and why is that number optimistic?

4. Give a concrete consequence of the fallacy “latency is zero”.
5. How many nodes does consensus need to tolerate 2 crash faults? 2 Byzantine faults?
6. What is the difference between a partial and an asymmetric partition?
7. Define gray failure and give one example.
8. A clock drifts at 20 ppm. How far off can it be after one hour?
9. NTP timestamps: $T_1 = 0$, $T_2 = 50$, $T_3 = 52$, $T_4 = 22$ ms. Compute offset, delay and error bound.
10. Under LWW, node A’s clock is 80 ms fast. Which writes through node B can A’s earlier writes override?
11. Lamport timestamps $C(a) = 3$, $C(b) = 5$. What can you conclude?
12. Compare [2,1,0] and [1,2,0]; then [1,1,0] and [2,1,3].
13. What problem do dotted version vectors solve?
14. Does FLP mean Raft can lose data? Explain.
15. State the end-to-end argument and give one application.

Answers

1. Independent (partial) failure, no shared clock, communication only by unreliable messages with unbounded delay.
2. The sender of the last message cannot know whether it arrived, so both must decide the same way without it; the message is then unnecessary, contradicting the assumption of a shortest protocol.
3. $1 - 0.001^3 = 1 - 10^{-9}$. Failures are correlated (shared power, network, software) and failover is not instant.
4. A chatty page with 100 sequential calls takes 50 ms at 0.5 ms per call in one region but about 7 s at 70 ms per call across regions.
5. $2f + 1 = 5$; $3f + 1 = 7$.
6. Partial: some pairs cannot communicate while others can (A and B both reach C but not each other). Asymmetric: one direction works and the other does not.
7. A failure seen by some observers but not others, e.g., a disk 100× slower that passes the heartbeat health check while application requests time out.
8. $20 \times 10^{-6} \times 3,600 = 0.072$ s $= 72$ ms.
9. $\delta = (22 - 0) - (52 - 50) = 20$ ms; $\theta = [(50 - 0) + (52 - 22)]/2 = 40$ ms (client behind by 40 ms); bound ± 10 ms.
10. Any B write within 80 ms after an A write to the same key.
11. Only that $b \not\rightarrow a$; a may have happened before b or they may be concurrent.
12. [2,1,0] and [1,2,0] are concurrent; [1,1,0] < [2,1,3], so the first happened before the second.
13. Concurrent writes through the same replica, which per-replica version vectors misorder as one dominating the other, losing a write.
14. No. Raft is always safe; FLP only means that in bad asynchronous periods it may fail to make progress (elect a leader or commit).

15. A function that needs endpoint knowledge must be implemented at the endpoints; lower layers can only optimize. Example: checksum the stored file end to end, or deduplicate by idempotency key.

24.17 Interview questions

Basic

Q1. Why is building a distributed system harder than a single-machine one? Answer. Three losses: partial failure (some parts fail, others continue, and nobody knows exactly which), no global clock (events on different machines cannot be ordered by time) and unreliable messaging (loss, delay, duplication). A timeout cannot distinguish a slow node from a dead one or tell whether a write happened, so designs need idempotency, quorums and logical ordering.

Q2. Can you use server timestamps to order events across machines? Answer. Only coarsely. NTP skew is milliseconds and occasionally seconds; clocks can step backwards. Events closer together than the skew may be misordered, which makes LWW lose writes. Use Lamport or hybrid logical clocks for causal order, vector clocks to detect concurrency, or a single sequencer; use bounded-uncertainty clocks when real-time order matters.

Intermediate

Q3. Design conflict handling for a shopping cart replicated across two regions. Answer. Avoid LWW, which drops items. Track versions with version vectors keyed by replica (or dotted version vectors), keep concurrent versions as siblings, and merge on read (union of adds); represent removals with tombstones or use an observed-remove set CRDT (§27.14) so deletions are not resurrected. Discuss metadata size, sibling limits and the user experience of merges.

Q4. A node passes health checks, yet its clients see 30% errors. What is happening and what would you change? Answer. A gray failure: the probe does not exercise the failing path (disk, dependency, thread pool). Make health checks exercise real dependencies, add client-side outlier detection that ejects nodes with abnormal error rates or latency, and alert on client-observed rather than self-reported health.

Advanced

Q5. Explain FLP and how Raft copes with it. Answer. In an asynchronous system no deterministic consensus protocol can guarantee termination if one process may crash, because a slow process is indistinguishable from a crashed one and an adversarial schedule

can keep the system undecided. Raft keeps safety unconditionally (majority quorums, term checks, persisted votes) and gets liveness from partial synchrony: timeouts detect leader failure, and randomized election timeouts break split votes. During a bad network period it may stall, but never diverges.

Q6. Your database uses HLC timestamps and a 500 ms maximum offset. Why do some reads restart, and how would you reduce restarts? Answer. A read at t_r that finds a value committed in $(t_r, t_r + 500\ \text{ms}]$ cannot tell whether it committed before the read in real time, so it moves its timestamp forward and retries. Reduce restarts by improving clock synchronization (PTP or a precise cloud time service) and lowering the configured maximum offset, by monitoring offsets so nodes with bad clocks are removed, and by reducing contention on hot keys.

24.18 Practical exercises

1. Extend the Lamport listing with Lamport's mutual-exclusion algorithm (request, reply, release) for three processes and check that the lock is granted in timestamp order.
2. Modify the version-vector store to use dotted version vectors and show that the "same-replica" case keeps both writes as siblings.
3. Simulate 10 nodes with random drift between −50 and +50 ppm and NTP corrections every 64 s with ±2 ms error. Plot the maximum pairwise skew and count LWW inversions for writes 10 ms apart.
4. Run `chronyc tracking` (or `ntpq -p`) on a Linux machine; identify the stratum, offset, root delay and root dispersion, and explain each in terms of §24.9.3.
5. Using `tc netem` on two containers, create a one-way partition and observe how an etcd or Redis Sentinel cluster behaves.

24.19 Design challenges

1. **Global event log.** PhotoShare wants a per-user activity feed assembled from events produced in three regions, ordered so that a reply never appears before the comment it answers. Choose clocks (Lamport, HLC, vector), state the system model, quantify metadata overhead per event, and describe behavior during an inter-region partition.
2. **Clock-safe leases.** Design a leader lease for a job scheduler whose nodes use NTP with up to 50 ms skew and may pause for 2 s during garbage collection. Size lease duration and renewal interval, and explain why fencing tokens (§26.13) are still needed.

Chapter 25 — Consistency and Availability

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

A customer changes her shipping address and presses “Place order”. The order service reads the address from a replica in another zone that has not yet received the change, and the parcel goes to her old flat. Nothing crashed, no disk failed and every component did exactly what its documentation promised. The bug is a mismatch between the guarantee the code assumed (“I will read what was just written”) and the guarantee the database gave (“replicas converge eventually”).

This chapter gives you a precise vocabulary for those guarantees. A **consistency model** is a contract between a data store and its clients: it says which values a read is allowed to return, given the writes that happened before or alongside it. Strong models make replicated data behave like a single copy and cost latency and availability. Weak models are fast and always answer, but let clients observe anomalies. Between the two lie sequential consistency, causal consistency and the session guarantees, each of which forbids a specific set of anomalies at a specific price.

Transaction isolation (§11.13) is a different axis; §25.3.1 and §25.7.5 keep the two apart. Three runnable Python programs accompany the chapter: a brute-force linearizability checker, a version-vector implementation of session guarantees, and a Monte Carlo simulation of probabilistically bounded staleness.

25.1 Learning objectives

After this chapter you should be able to:

- Define linearizability through real-time order and a legal sequential history, locate linearization points, and decide by hand or with a checker whether a register history is linearizable.
- Explain why a linearizable read or write costs at least one round trip to a quorum, and compute that latency for a given replica placement.
- Distinguish sequential consistency from linearizability with a concrete history, and explain why sequential consistency is not compositional.
- Define causal consistency, give an anomaly it prevents, and describe how COPS tracks and checks dependencies.
- State the four session guarantees of Terry et al., draw the anomaly each prevents and implement each with sticky routing, version tokens or log positions.

- Quantify eventual consistency with probabilistically bounded staleness (PBS) using a closed form and a simulation.
- State the CAP theorem as Gilbert and Lynch proved it, define its terms formally, and refute “pick two” and “CA system” claims.
- Classify real systems with PACELC, including configuration caveats, and choose consistency settings in Cassandra, DynamoDB, Cosmos DB, MongoDB and Spanner.
- Describe how Jepsen records histories, injects faults and checks them with Knossos-style and Elle-style checkers, and summarize published findings accurately.

25.2 Prerequisites

- Replication, replication lag and the two lag anomalies — §14.3, §14.4 (this chapter formalizes them).
- Transactions, isolation levels and anomalies — §11.12, §11.13 (to keep isolation and consistency separate).
- System models, network partitions and partial failures — §24.6–§24.8 (the CAP proof is a statement about an asynchronous network that can lose messages).
- Lamport clocks, the happens-before relation and vector clocks — §24.10, §24.11 (causal consistency is defined by happens-before; session guarantees are implemented with version vectors).
- Clock skew and NTP — §24.9 (why “latest” cannot simply be decided by wall-clock timestamps).
- Percentiles and latency distributions — §4.8 (PBS is a statement about latency distributions).

25.3 Linearizability

25.3.1 Histories, objects and two kinds of guarantee

Before defining any model you need the material every model is stated over: a **history**.

DEFINITION

Definition — Operation, history. An **operation** is one call by a client on a shared object, such as `write(x, 1)` or `read(x)`. It has an **invocation** event (the client sends the request, at real time t_{inv}) and, if the client hears back, a **response** event (at t_{resp}, carrying the return value). A **history** is the sequence of invocation and response events observed in one execution. An operation without a response is **pending**: it may or may not have taken effect.

Two operations are **concurrent** if their intervals $[t_{\text{inv}}, t_{\text{resp}}]$ overlap. If operation *a* responds before operation *b* is invoked ($a.t_{\text{resp}} < b.t_{\text{inv}}$), then *a* **precedes** *b* in **real-time order**. Notice that real time is the time of an imaginary global observer; no node needs to know it, but the definitions use it.

A consistency model is a set of allowed histories; a store "provides" it if every history it can produce, under every allowed fault, is in the set [Viotti & Vukolić 2016]. This turns vague adjectives ("strongly consistent") into a test you can run.

Models come in two families that are often confused.

Table 25.1 — Single-object consistency models versus transaction isolation models.

	Single-object (non-transactional) consistency	Transaction isolation
Unit of reasoning	One operation on one object (register, key, queue)	A transaction: a group of operations on many objects
Question answered	Which value may a read return, given writes by others and real time?	Which interleavings of concurrent transactions are allowed?
Classic strongest model	Linearizability [Herlihy & Wing 1990]	Serializability [Papadimitriou 1979]
Weaker models	Sequential, causal, session guarantees, eventual	Snapshot isolation, repeatable read, read committed
Mentions real time?	Linearizability does; sequential and causal do not	Plain serializability does not; strict serializability does
Typical anomalies	Stale read, reading back in time, missing own write	Dirty read, lost update, write skew (§11.13)
Where in this book	This chapter	§11.13–§11.15; distributed transactions Ch 28

The two meet at **strict serializability**: transactions are serializable *and* the serial order respects real time. Strict serializability is to transactions what linearizability is to single operations; Spanner calls it **external consistency** [Corbett et al. 2012]. A database can be serializable without being linearizable (a serializable replica that serves a consistent but stale snapshot), and linearizable without being serializable (a key-value store whose single-key operations are linearizable but which has no multi-key transactions). Keep the two axes apart in interviews and designs: "Which isolation level?" and "Which consistency model?" are separate questions.

25.3.2 The definition

DEFINITION

Definition — Linearizability. A history is **linearizable** if each operation can be assigned a single instant, its **linearization point**, somewhere between its invocation and its response, such that (1) the operations, ordered by these points, form a **legal sequential history** of the object (every read returns the value of the most recent preceding write), and (2) therefore whenever *a* precedes *b* in real time, *a* comes before *b* in that order. Pending operations may be either included (with a linearization point after their invocation) or dropped. An object is linearizable if all its histories are [Herlihy & Wing 1990].

First-principles explanation

Imagine a single notebook on a table in a room. People walk in, write a value or read the latest value, and walk out. Each visit takes a moment, and two visitors can be in the room at once, but the notebook itself is changed at one instant. Anyone who arrives after you left must see your entry or a later one. Linearizability is the promise that a replicated system behaves *exactly* like that single notebook, even though behind the scenes there are five copies on three continents. Kleppmann calls this the **single-copy illusion** [Kleppmann 2017].

Consequently, once any client has read a new value, no client can afterwards read an older one, and "afterwards" is real time as observed by anybody, including a colleague you phone to say "I've just paid; can you see it?"

Why does this exist?

Herlihy and Wing introduced linearizability in 1990 as a correctness condition for concurrent objects (queues, counters, registers) in shared-memory multiprocessors [Herlihy & Wing 1990]. Distributed systems adopted it because many problems require a single, agreed, up-to-date value: a lock or lease must have one holder; a username must be unique; a bank balance must not be spent twice; a leader must be the only leader. In each case a stale read leads to two parties acting on contradictory information. Linearizability is also what makes higher-level protocols easy to reason about: a linearizable compare-and-set register is enough to build leader election and fencing tokens (Chapter 26).

Herlihy and Wing also proved that linearizability is **local** (compositional): a history over many objects is linearizable if and only if each object's sub-history is. Independently linearizable partitions therefore compose into a linearizable store. Section 25.4 shows that sequential consistency lacks this property.

25.3.3 Linearization points and checking a history

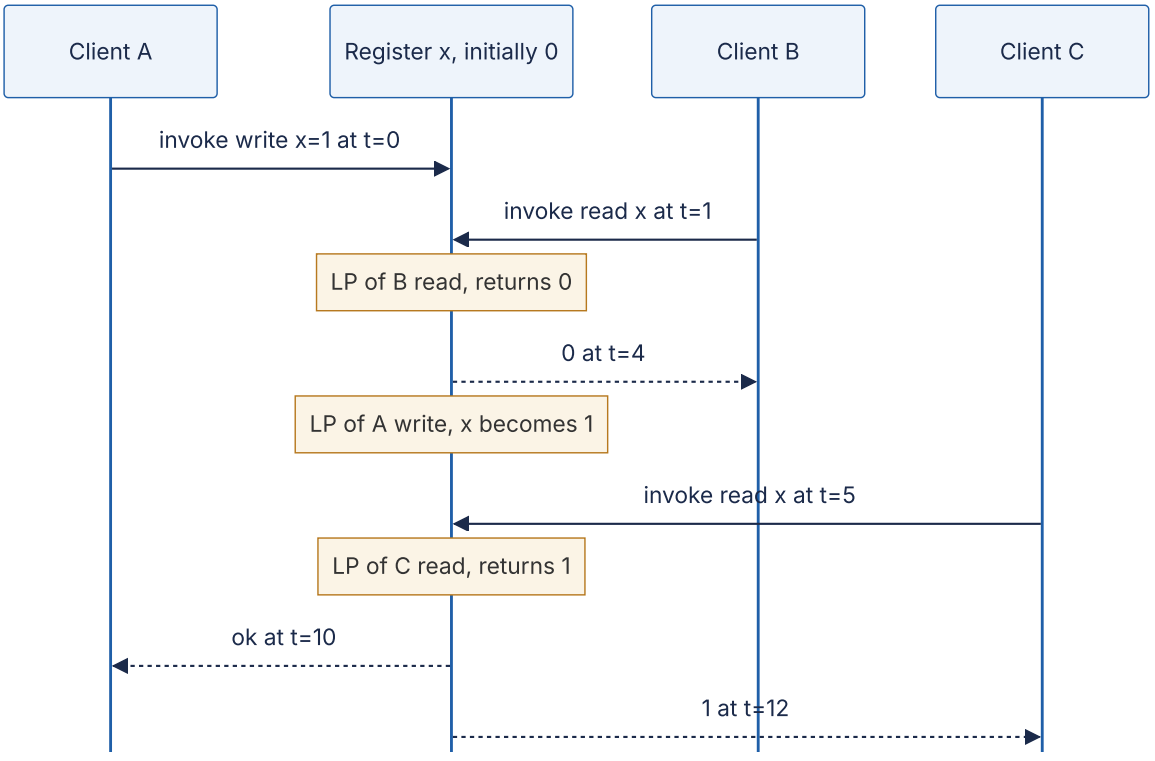
How it works internally

To check a history by hand:

1. Draw each operation as an interval on a timeline, one row per client.
2. For every operation, you may place its linearization point anywhere inside its interval.
3. Look for a placement in which reads return the latest preceding write. If one exists, the history is linearizable; the placement is a **witness**.
4. If every placement fails, the history is not linearizable.

The search is exponential in the worst case: Gibbons and Korach showed that checking whether a history of a read/write register is linearizable is NP-complete in general [Gibbons & Korach 1997]. Practical checkers prune aggressively and handle histories of thousands of operations when concurrency is modest (§25.11).

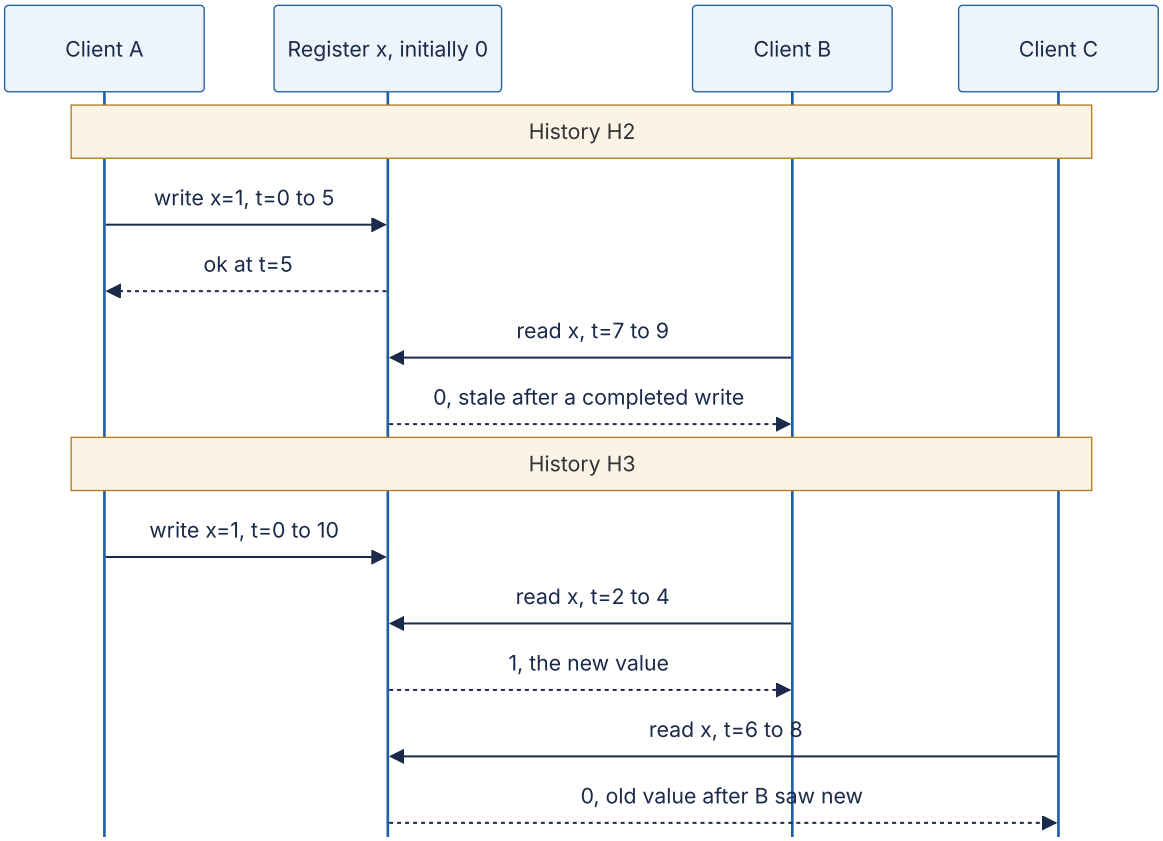
Figure 25.1 — A linearizable history and its linearization points.



Reading the diagram. Time runs downward; solid arrows are invocations and dashed arrows responses, all synchronous request/response calls on one logical register. Client A's write lasts from t = 0 to t = 10, so it is concurrent with both reads. "LP" marks a chosen linearization point. B's read (t = 1 to 4) can be linearized before the write takes effect, so returning the old value 0 is legal; C's read (t = 5 to 12) is linearized after the write, so returning 1 is legal. The register behind the arrows may be five replicas, but the

history is indistinguishable from one copy. The failure point to watch is a read that starts *after* a completed write or *after* another read that saw the new value; Figure 25.2 shows both.

Figure 25.2 — Two non-linearizable histories: a stale read, and a new-then-old inversion.



Reading the diagram. In H2 the write has *completed* (acknowledged at t = 5) before B's read begins at t = 7, so real-time order forces the write before the read; a read returning 0 has no legal placement. This is the classic asynchronous-replica bug: the write was acknowledged by the primary and the read went to a lagging replica. H3 is subtler: the write is still in progress, so either value is individually allowed, but once B has returned 1 (its linearization point is after the write's), C's read, which begins after B finished, must also see 1. Returning 0 means the system "un-wrote" a value someone already observed. H3 happens in leaderless quorum stores when a write has reached one replica but not a quorum, and two readers contact different replica sets (§25.3.4).

Code example

The program below is a brute-force checker for histories of read/write registers. It tries to build a legal sequential order one operation at a time, allowing an operation to go next only if no unplaced operation must precede it. With `real_time=True` the precedence rule is real-time order (linearizability); with `real_time=False` it is only each client's program or-

der (sequential consistency, §25.4). Memoizing on the set of placed operations and the register state is the core idea of the Wing–Gong–Lowe family of checkers used by Knossos and Porcupine [Wing & Gong 1993; Lowe 2017].

```
        """Brute-force checker: is a history of register operations linearizable,
        or at least sequentially consistent? Each operation is
            (process, kind, key, value, invoke_time, response_time)
        kind is "w" (write value) or "r" (read that returned value).
        response_time None means the client never heard back (the op may or may not
        have taken effect). All registers start at 0."""
        from functools import lru_cache

        INF = float("inf")

        def check(history, real_time=True):
            ops = [(p, k, key, v, inv, INF if resp is None else resp)
                   for p, k, key, v, inv, resp in history]
            n = len(ops)
            done = frozenset(i for i in range(n) if ops[i][5] != INF)

            def must_precede(a, b):
                """True if op a has to be ordered before op b."""
                if real_time:                       # linearizability: real-time order
                    return ops[a][5] < ops[b][4]
                # sequential consistency: only each process's own program order
                return ops[a][0] == ops[b][0] and ops[a][4] < ops[b][4]

            @lru_cache(maxsize=None)
            def search(placed, state):              # placed: bitmask; state: sorted
(key, value) pairs
                if all(placed >> i & 1 for i in done):
                    return ()                       # every completed op is placed
                regs = dict(state)
                for i in range(n):
                    if placed >> i & 1:
                        continue
                    # i can go next only if no unplaced op must precede it
                    if any(not placed >> j & 1 and j != i and must_precede(j, i)
                           for j in range(n)):
                        continue
                    p, kind, key, v, _, _ = ops[i]
                    if kind == "r" and regs.get(key, 0) != v:
                        continue                    # read would return the wrong value
                    new = dict(regs)
                    if kind == "w":
                        new[key] = v
                    rest = search(placed | 1 << i, tuple(sorted(new.items())))
                    if rest is not None:
                        return (i,) + rest
                return None

            order = search(0, ())
            return None if order is None else [ops[i][:4] for i in order]

        def describe(name, h):
            lin, sc = check(h, real_time=True), check(h, real_time=False)
            print(f"{name}: linearizable={lin is not None}, sequential={sc is not
None}")
            if lin:
                print("   linearization:", " -> ".join(f"{p}:{k}({key}={v})" for p, k,
```

```
key, v in lin))
            elif sc:
                print("   sequential order:", " -> ".join(f"{p}:{k}({key}={v})" for p,
k, key, v in sc))

        H1 = [("A", "w", "x", 1, 0, 10),   # write overlaps both reads
              ("B", "r", "x", 0, 1, 4),
              ("C", "r", "x", 1, 5, 12)]
        H2 = [("A", "w", "x", 1, 0, 5),    # write finished at t=5 ...
              ("B", "r", "x", 0, 7, 9)]    # ... yet a later read sees the old value
        H3 = [("A", "w", "x", 1, 0, 10),   # new-then-old inversion during a write
              ("B", "r", "x", 1, 2, 4),
              ("C", "r", "x", 0, 6, 8)]
        H4 = [("A", "w", "x", 1, 0, 2),    # a process misses its own write
              ("A", "r", "x", 0, 3, 4)]
        H5 = [("A", "w", "x", 1, 0, 2), ("A", "r", "y", 0, 3, 4),   # store buffering
              ("B", "w", "y", 1, 0, 2), ("B", "r", "x", 0, 3, 4)]
        H6 = [("A", "w", "x", 1, 0, None), # write timed out: outcome unknown
              ("B", "r", "x", 1, 5, 6),
              ("C", "r", "x", 1, 7, 8)]

        for name, h in [("H1", H1), ("H2", H2), ("H3", H3), ("H4", H4), ("H5", H5),
("H6", H6)]:
            describe(name, h)
        x_only = [op for op in H5 if op[2] == "x"]
        y_only = [op for op in H5 if op[2] == "y"]
        print("H5 per key sequential:", check(x_only, False) is not None, check(y_only,
False) is not None)
```

Running it prints:

```
H1: linearizable=True, sequential=True
   linearization: B:r(x=0) -> A:w(x=1) -> C:r(x=1)
H2: linearizable=False, sequential=True
   sequential order: B:r(x=0) -> A:w(x=1)
H3: linearizable=False, sequential=True
   sequential order: C:r(x=0) -> A:w(x=1) -> B:r(x=1)
H4: linearizable=False, sequential=False
H5: linearizable=False, sequential=False
H6: linearizable=True, sequential=True
   linearization: A:w(x=1) -> B:r(x=1) -> C:r(x=1)
H5 per key sequential: True True
```

What to notice:

- `must_precede` is the only difference between the two models. Linearizability constrains order by real time across all clients; sequential consistency only by each client's own program order.
- H2 and H3 (Figure 25.2) fail linearizability but pass sequential consistency: the checker reorders B's or C's stale read before the write, which is legal when real time does not count.

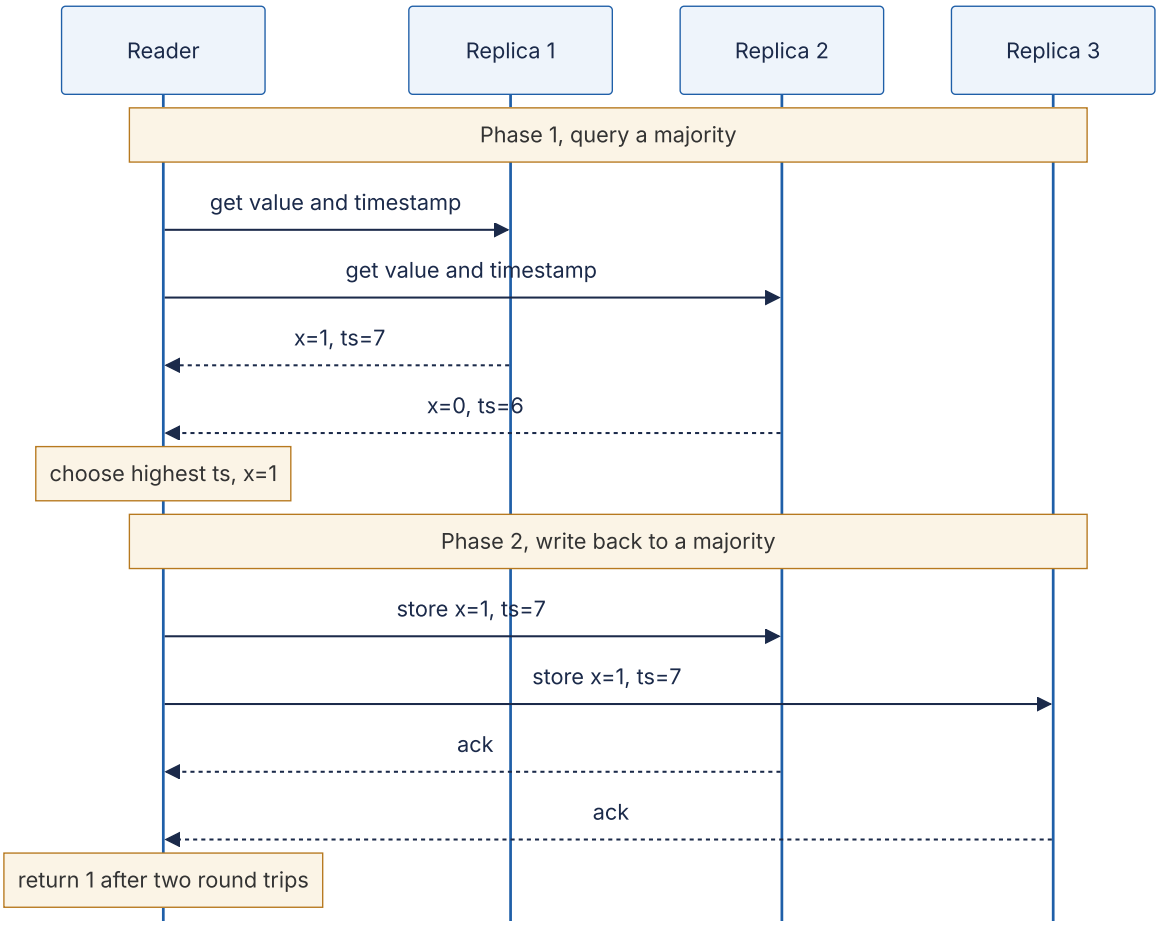
- H6 contains a write whose client timed out. The checker may include it (it evidently took effect, since reads return 1). Treating timeouts as failures would wrongly flag this history; real checkers model them as **indeterminate**, exactly as here.
- H5 is discussed in §25.4.

25.3.4 Implementing linearizability

You can obtain linearizability in three ways, all of which route every operation through some point of agreement:

1. **Single copy or single leader with synchronous reads.** All reads and writes go to one node (a single PostgreSQL server, or the leader of a partition). It is linearizable as long as there is exactly one such node. After failover, the old leader must be prevented from serving, which needs leases or a consensus round (Chapter 26). A leader that serves reads from local state without confirming it is still leader can return stale data after a new leader has been elected elsewhere.
2. **Consensus-replicated log.** Raft, Multi-Paxos and ZAB (Chapter 26) order writes through a majority. Linearizable reads either go through the log too, or the leader confirms its leadership with a quorum heartbeat (Raft's ReadIndex) or relies on a time-based lease bounded by clock-drift assumptions [Ongaro 2014].
3. **Quorum registers without a leader.** The **ABD** algorithm of Attiya, Bar-Noy and Dolev [Attiya et al. 1995] implements a linearizable read/write register over N replicas tolerating $f < N/2$ crashes, with no leader and no consensus. Each value carries a timestamp. A write sends (value, timestamp) to all replicas and waits for a majority to acknowledge. A read asks a majority for their (value, timestamp), picks the highest, and **writes it back** to a majority before returning.

Figure 25.3 — ABD quorum read with write-back on three replicas.



Reading the diagram. All calls are synchronous RPCs; the reader waits for two of three replies in each phase. Replica 1 holds a write that has reached only one node, the partial-write situation of history H3. Without phase 2, this reader returns 1 but a later reader querying Replicas 2 and 3 would return 0, an inversion. Phase 2 makes sure that any value a reader returns is stored on a majority, so every later majority overlaps it. The failure points are replica crashes (tolerated while a majority answers) and a network partition that leaves the reader with only a minority (the read blocks: this is the C-over-A choice of §25.8). Scaling is per object: different registers can live on different replica groups because linearizability is compositional.

Mathematical foundations

Every one of the three approaches needs a message exchange with a majority (or with a leader that has itself confirmed a majority) on the critical path. That is the price of linearizability.

FORMULA

Latency of a quorum operation

$$T_{\text{op}} \approx k \times \text{RTT}_{(q)} + T_{\text{proc}}, \qquad q = \lfloor N/2 \rfloor + 1$$

Symbol	Meaning	Units
T_{op}	Latency of one linearizable read or write as seen by the client	ms
k	Sequential round trips the protocol needs (ABD read: 2; ABD single-writer write: 1; Raft write via leader: 1 to the followers plus the client-to-leader trip)	count
$\text{RTT}_{(q)}$	Round-trip time to the q-th closest replica, counting the coordinator itself if it holds a replica	ms
q	Majority quorum size for N replicas	replicas
N	Number of replicas	replicas
T_{proc}	Processing and disk flush time	ms

WORKED EXAMPLE

Worked example — Five replicas across regions. A register is replicated in five regions. From the coordinator in Virginia, the RTTs are: Virginia 0 ms (local replica), Ohio 12 ms, Oregon 65 ms, Ireland 75 ms, Frankfurt 90 ms. Take $T_{\text{proc}} = 1$ ms.

1. $q = \lfloor 5/2 \rfloor + 1 = 3$. Sorted RTTs: 0, 12, 65, 75, 90. The third smallest is $\text{RTT}_{(3)} = 65$ ms (Oregon).
2. One-round-trip write: $T \approx 1 \times 65 + 1 = 66$ ms.
3. ABD read with write-back: $T \approx 2 \times 65 + 1 = 131$ ms.
4. Now move the Oregon replica to a second Virginia zone (RTT 1 ms). Sorted: 0, 1, 12, 75, 90; $\text{RTT}_{(3)} = 12$ ms. Write ≈ 13 ms; read ≈ 25 ms.

Interpretation. Quorum latency is set by the *median* replica's distance, not the nearest one (the same order statistic appears as $\text{RTT}_{(q-1)}$ over followers for Raft commits in §26.4.2 and for *R/W* quorums in §27.8.3). Clustering a majority close together makes linearizable operations cheap for nearby clients, at the cost of a region failure taking down the majority. **Engineering implication.** Linearizable global data pays a cross-region round trip somewhere; you choose where. Spanner and CockroachDB place leaders and voting replicas near the dominant writers for that reason (§25.10, Chapter 28).

Is this cost an artifact of particular algorithms, or fundamental? Lipton and Sandberg, and later Attiya and Welch, proved lower bounds in a model where message delays are between $d - u$ and d [Lipton & Sandberg 1988; Attiya & Welch 1994].

FORMULA

Lower bound for sequentially consistent and linearizable registers

$$t_{\text{read}} + t_{\text{write}} \geq d$$

Symbol	Meaning	Units
t_{read}	Worst-case time for a read to return	ms
t_{write}	Worst-case time for a write to return	ms
d	Maximum one-way message delay between replicas	ms

The bound holds already for sequential consistency, and linearizability, being stronger, inherits it. Attiya and Welch also showed that sequential consistency can make *either* reads *or* writes fast (local), while linearizability requires both reads and writes to wait for time proportional to the delay uncertainty. Causal consistency, by contrast, can be implemented with purely local reads and writes (§25.5). Kleppmann uses exactly this distinction to argue that latency, not partitions, is the more useful lens on consistency [Kleppmann 2015].

WORKED EXAMPLE

Worked example — What the bound forbids. Two data centers are 35 ms apart one way ($d = 35$ ms). A team wants a sequentially consistent register with 5 ms reads and 5 ms writes everywhere.

1. $t_{\text{read}} + t_{\text{write}} = 5 + 5 = 10$ ms.
2. $10 < 35$, so the bound is violated: no algorithm can achieve this, however clever.
3. Options: make writes slow ($t_{\text{write}} \geq 30$ ms, keeping 5 ms reads), make reads slow, or weaken the model to causal consistency, which allows both to be local.

Interpretation. This is an impossibility, not an engineering gap. **Engineering implication.** Push back early on “strongly consistent and single-digit-millisecond everywhere” and ask which operations truly need it.

Real-world industry applications

INDUSTRY EXAMPLE

Amazon S3 strong read-after-write consistency (2020). S3 historically offered eventual consistency for overwrites and listings. In December 2020 it moved to strong read-after-write consistency for all PUTs and LISTs at no extra cost, using a cache-coherence protocol in which a witness component tracks object changes so front ends can tell when cached metadata is stale (§15.4). The change removed a whole class of data-lake bugs in which a job listed a prefix and missed files just written. *Evidence: Primary* — [Vogels 2021; AWS Docs: S3 Consistency]

INDUSTRY EXAMPLE

etcd and Kubernetes. Kubernetes stores cluster state in etcd, a Raft-replicated key-value store. Leader election among controllers relies on linearizable compare-and-set on a lease object. Jepsen's 2020 analysis found etcd's key-value operations, including multi-key transactions, to be strictly serializable under partitions, pauses, crashes and clock skew, while its lock API could not guarantee mutual exclusion (§25.11). *Evidence: Primary* — [Kingsbury 2020a]

Failure scenarios

Table 25.2 — Failure scenarios that break linearizability.

What goes wrong	Why	Detection	Recovery	Prevention
Stale read from a deposed leader	Old leader is partitioned but still believes it leads and serves reads locally	Jepsen-style test with partitions; two nodes claim leadership	Step down on lease expiry	ReadIndex or quorum reads; leases with bounded clock drift
Read from asynchronous replica	Write acknowledged before replica applied it	Read-after-write probes; replica lag metrics	Route to primary	Synchronous apply, LSN-tracked reads (§25.6)
New-old inversion in quorum store	Partial write visible to one reader's quorum, not the next	Linearizability checker on recorded histories	Read repair	Write-back on read (ABD), or a consensus-replicated log
Clock-based "latest" wins	Last-writer-wins by wall clock picks a write that happened earlier	Lost-update tests with clock skew	Restore from log	Logical or hybrid timestamps (§24.12); consensus ordering

Common misconceptions

COMMON MISTAKE

Mistake — "$R + W > N$ makes a Dynamo-style store linearizable." Overlapping quorums guarantee that a read sees the latest *completed* write in the absence of failures, but they do not prevent the new-then-old inversion of H3 when a write is still in flight or partially failed, and sloppy quorums (§27.9) and last-writer-wins conflict resolution break the overlap entirely. Linearizability needs write-back on read or a consensus protocol on top of the quorum [Kleppmann 2017].

COMMON MISTAKE

Mistake — "Linearizability means operations take effect when they are sent." The linearization point may be anywhere between invocation and response. A client that sent a write and timed out does not know whether it happened; a correct client treats the outcome as unknown and retries idempotently (§22.15).

25.4 Sequential consistency

25.4.1 Definition and contrast with linearizability

DEFINITION

Definition — Sequential consistency. A history is **sequentially consistent** if there is a single total order of all operations that is a legal sequential history of the objects and that respects each client's **program order** (the order in which that client issued its own operations). In Lamport's words, "the result of any execution is the same as if the operations of all the processors were executed in some sequential order, and the operations of each individual processor appear in this sequence in the order specified by its program" [Lamport 1979].

First-principles explanation

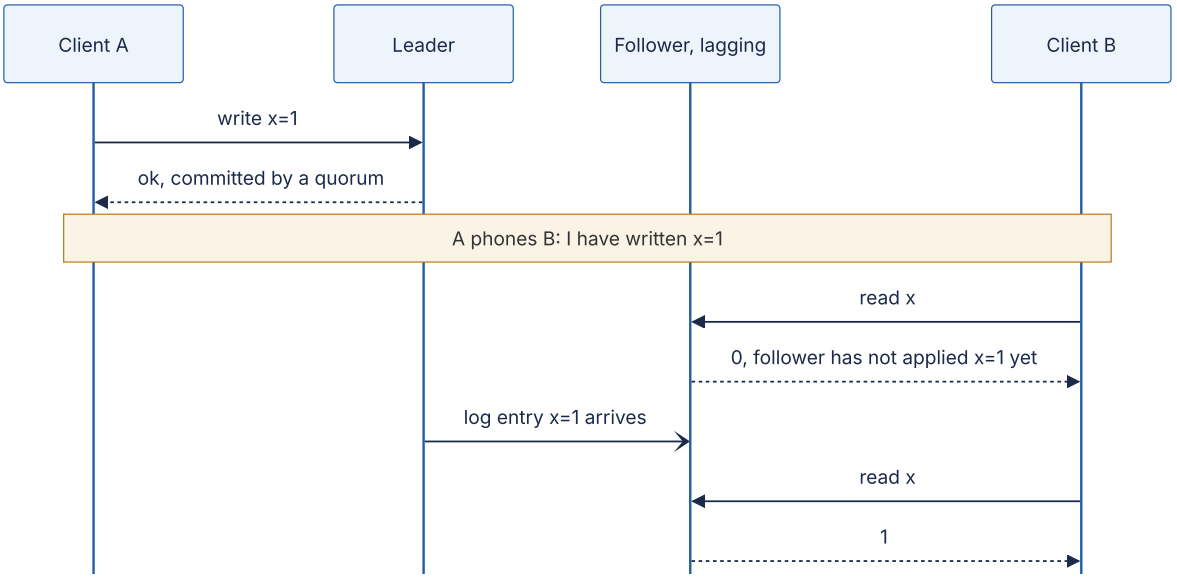
Go back to the notebook. Sequential consistency still promises that everyone sees the *same story*, entries in one order, and that each person's own entries appear in the order that person wrote them. What it drops is the clock on the wall. The story may be told late: you may read the notebook as it was ten minutes ago, as long as everyone agrees on the sequence and you never see your own entries out of order. Linearizability is sequential consistency plus the rule that the agreed order must also match real time.

Lamport defined it in 1979 for multiprocessor memory. Most modern processors provide something weaker (x86-TSO, Arm's relaxed model) and offer fence instructions to recover it where needed (cache coherence, the layer underneath, is §5.4.6).

How it works internally

A common implementation in replicated stores is: **writes go through a single ordered log; reads are served by any replica that has applied a prefix of the log, and a client never reads from a replica behind the point it has already seen.** Every replica applies the same writes in the same order, so all clients see one sequence, but a replica may lag, so a read can return a value that is already overwritten elsewhere. That is the gap between Figures 25.1 and 25.4.

Figure 25.4 — A sequentially consistent but not linearizable history (follower read).



Reading the diagram. Writes are synchronous to a quorum through the leader; log shipping to this follower (open arrowhead) is asynchronous. B's first read starts after A's write completed in real time, so returning 0 violates linearizability. But the history is sequentially consistent: the total order "B reads 0, A writes 1, B reads 1" respects each client's program order. The out-of-band phone call is the failure point: it carries causality the storage system cannot see. Followers scale reads horizontally; the cost is exactly this staleness.

ZooKeeper behaves like this by design. Writes are linearizable through the ZAB atomic broadcast, but reads are served locally by whichever server the client is connected to, so reads may be stale. ZooKeeper guarantees that each client's operations are applied in FIFO order and that a client never sees an older state after a newer one, even after reconnecting to a different server. A client that needs the latest value calls `sync` before

reading, which makes the server catch up with the leader at that moment [Hunt et al. 2010].

25.4.2 Sequential consistency is not compositional

Unlike linearizability, sequential consistency is not local: two objects can each be sequentially consistent while the system as a whole is not. History H5 from the checker of §25.3.3 is the textbook case, called **store buffering**:

- Client A writes `x = 1`, then reads `y` and gets 0.
- Client B writes `y = 1`, then reads `x` and gets 0.

Restricted to `x` alone (A's write, B's read of 0), the history is sequentially consistent: order B's read first. The same holds for `y` alone. The checker confirms both (`H5 per key sequential: True True`). But no single order works for both: whichever write comes first in the total order precedes, in program order, the other client's read, which must then return 1. The checker reports `sequential=False` for the combined history. Real multiprocessors produce exactly this outcome because each write sits in a store buffer while the following read goes to memory.

The consequence: sequentially consistent shards do not make a sequentially consistent store without cross-shard coordination, whereas linearizable shards do make a linearizable one.

INDUSTRY EXAMPLE

ZooKeeper reads and `sync`. ZooKeeper's paper describes reads served from a server's local replica as the source of its read throughput, which scales with the number of servers, while writes go through the leader. Applications that need a fresh read after an external signal (Figure 25.4's phone call) issue `sync` first, paying one leader round trip only on the paths that need it. *Evidence: Primary* — [Hunt et al. 2010]

COMMON MISTAKE

Mistake — "Sequential consistency is the same as serializability." Sequential consistency orders individual operations on objects and says nothing about grouping operations into atomic transactions. Serializability orders transactions and, in its plain form, says nothing about real time or about each client's sessions. Neither implies the other.

25.5 Causal consistency

25.5.1 Definition

Recall from §24.10 Lamport's **happens-before** relation: $a \to b$ if a and b are on the same process and a comes first, or a is the sending of a message and b its receipt, or by transitivity. For a data store, the messages are writes and reads: if a client reads a value written by w, every later operation of that client is causally after w.

DEFINITION

Definition — Causal consistency. Writes that are **causally related** must be seen by every client in their causal order; writes that are **concurrent** (neither happens before the other) may be seen in different orders by different clients. Formally, each client's view must be a legal sequential history that respects the causal order induced by program order and reads-from [Ahamad et al. 1995].

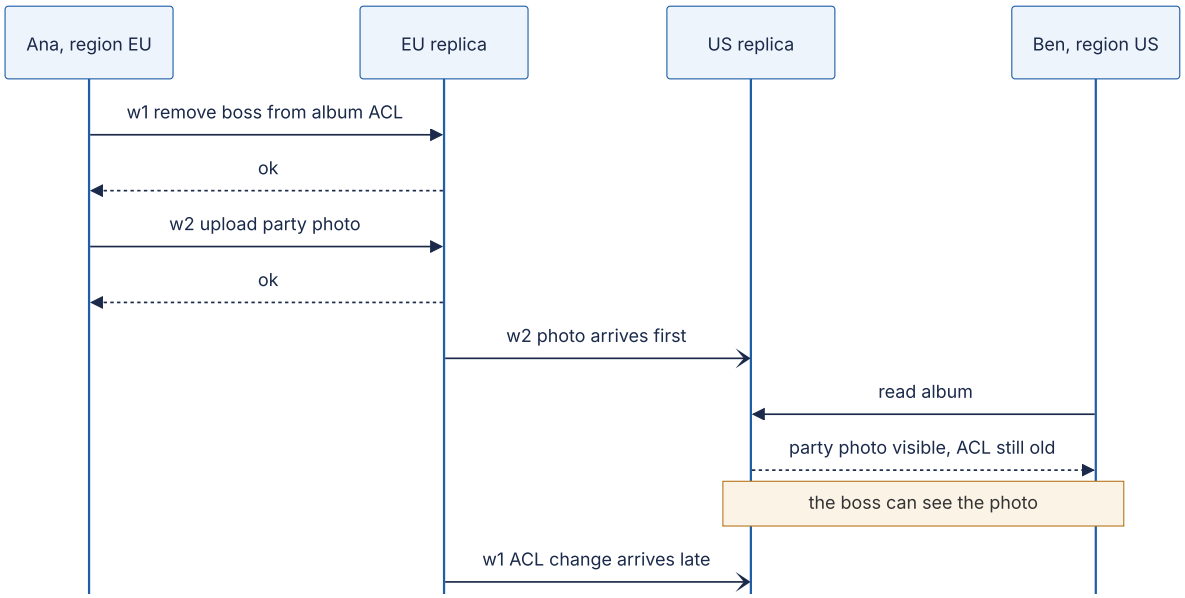
First-principles explanation

Picture a group chat. Ana asks "Who wants pizza?" and Ben replies "Me!". Causality says nobody may ever see Ben's reply without Ana's question above it, because Ben wrote it *after reading* the question. But if Ana and Chen post unrelated messages at the same moment, some phones may show Ana's first and others Chen's first; nothing is wrong with that. Causal consistency enforces the first rule and allows the second. It forbids exactly the anomalies that confuse humans (answers before questions, a comment on a photo that does not exist yet) while letting unrelated updates flow independently.

Why does this exist?

Causal consistency is a sweet spot for geo-replicated systems. It can be implemented so that every read and write completes at the local data center, with no cross-region wait, and it remains available during network partitions as long as a client stays connected to the same replica (it is **sticky available**, §25.7.5). Mahajan, Alvisi and Dahlin argued that no consistency model stronger than a variant they call real-time causal consistency can be both available under partitions and convergent [Mahajan et al. 2011]. Causal consistency is, in that sense, about the strongest model you can have while still choosing A in CAP.

Figure 25.5 — A causality violation across regions.



Reading the diagram. Ana's two writes go synchronously to her local EU replica; replication to the US (open arrowheads) is asynchronous and, here, reorders them because they travel on different partitions or connections. Ana issued w1 before w2, so w1 happens before w2. A replica that applies w2 without w1 lets the photo leak to the boss. The storage boundary is between the regions; the failure point is applying a write before its causal dependencies. A causally consistent store would hold w2 at the US replica until w1 is applied, and the scaling challenge is doing that check without serializing all writes.

25.5.2 How COPS tracks dependencies

COPS (Clusters of Order-Preserving Servers) is a geo-replicated key-value store from Lloyd, Freedman, Kaminsky and Andersen that provides **causal+ consistency**: causal consistency plus **convergent conflict handling**, so that replicas that receive concurrent writes to the same key resolve them identically and converge [Lloyd et al. 2011]. Its design shows the general recipe.

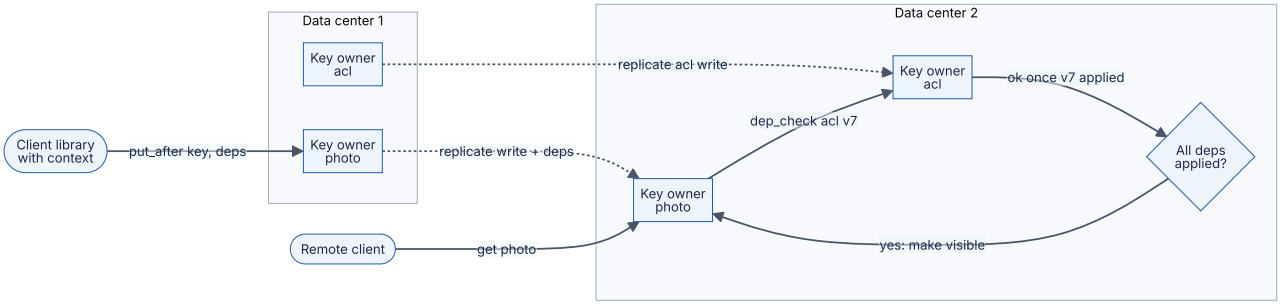
How it works internally

1. **The client library keeps a context.** Every value the client reads or writes adds an entry (key, version) to the client's context. These are the operations its next write may depend on.
2. **Writes carry dependencies.** A `put` is sent to the local cluster as `put_after(key, value, deps)`, where `deps` is the context. The local cluster applies it immediately, assigns it a version (a Lamport timestamp, so concurrent writes have a deterministic winner) and returns. The write is local: no cross-region wait.
3. **Nearest dependencies only.** Tracking every ancestor would grow without bound. Because dependencies are transitive, a write needs to list only its **nearest** depen-

dencies; COPS clears the client's context after each put and replaces it with the new write, since that write already depends on everything before it.

4. **Remote clusters check before applying.** When a replicated write arrives at a remote cluster, the node owning that key issues `dep_check` calls to the nodes owning each dependency. Each call returns once that dependency (or a later version) is applied locally. Only then is the write made visible.
5. **Reads are local.** `get` returns whatever the local cluster has; every visible value already has its dependencies visible.
6. **COPS-GT** adds read-only **get transactions** that return a causally consistent snapshot of several keys.

Figure 25.6 — COPS: local writes, asynchronous replication, dependency checks.



Reading the diagram. The client's write is acknowledged by the local key owner synchronously; replication between data centers (dotted) is asynchronous. In data center 2 the owner of `photo` asks the owner of `acl` whether version 7, the nearest dependency, is applied; the `dep_check` call blocks until it is. Only then does the photo become visible to remote clients, so no reader sees the photo without the ACL change. Each data center is a storage boundary holding a full replica, partitioned by consistent hashing within it. Failure points: a partition between data centers delays visibility of new writes there but never blocks local reads or writes. Scaling is horizontal because dependency checks touch only the partitions named in the dependency list, not a global sequencer.

Advantages and disadvantages

Causal consistency gives local-latency reads and writes in every region, survives partitions between regions, and forbids the anomalies users notice most. Its costs are metadata (dependency lists or vector clocks on every write), extra checks on the remote apply path, and **visibility delay**: a write whose dependency is stuck in a slow partition waits, so a hot dependency can hold up many writes. It also cannot enforce invariants such as uniqueness: two regions can concurrently register the same username, because concurrent writes are, by definition, allowed. Such operations still need coordination, so systems typically combine causal consistency for most data with linearizable operations for a few keys.

INDUSTRY EXAMPLE

MongoDB causally consistent sessions. Since version 3.6, MongoDB clients can open a causally consistent session. The driver carries an `operationTime` and `clusterTime` from each response into the next request, and a secondary that has not yet reached that time waits before answering. With read concern `majority` and write concern `majority`, the session provides read-your-writes, monotonic reads, monotonic writes and writes-follow-reads even when reads go to secondaries. *Evidence: Primary* — [MongoDB Docs: Causal Consistency and Read and Write Concerns]

COMMON MISTAKE

Mistake — "Causal consistency needs synchronized clocks." It needs *logical* ordering: Lamport timestamps, vector clocks or explicit dependency lists (§24.10–§24.11). Physical clocks, or hybrid logical clocks (§24.12), are sometimes added to make versions human-meaningful or to support snapshot reads, but correctness does not depend on clock accuracy.

25.6 Session guarantees

25.6.1 Four promises to one client

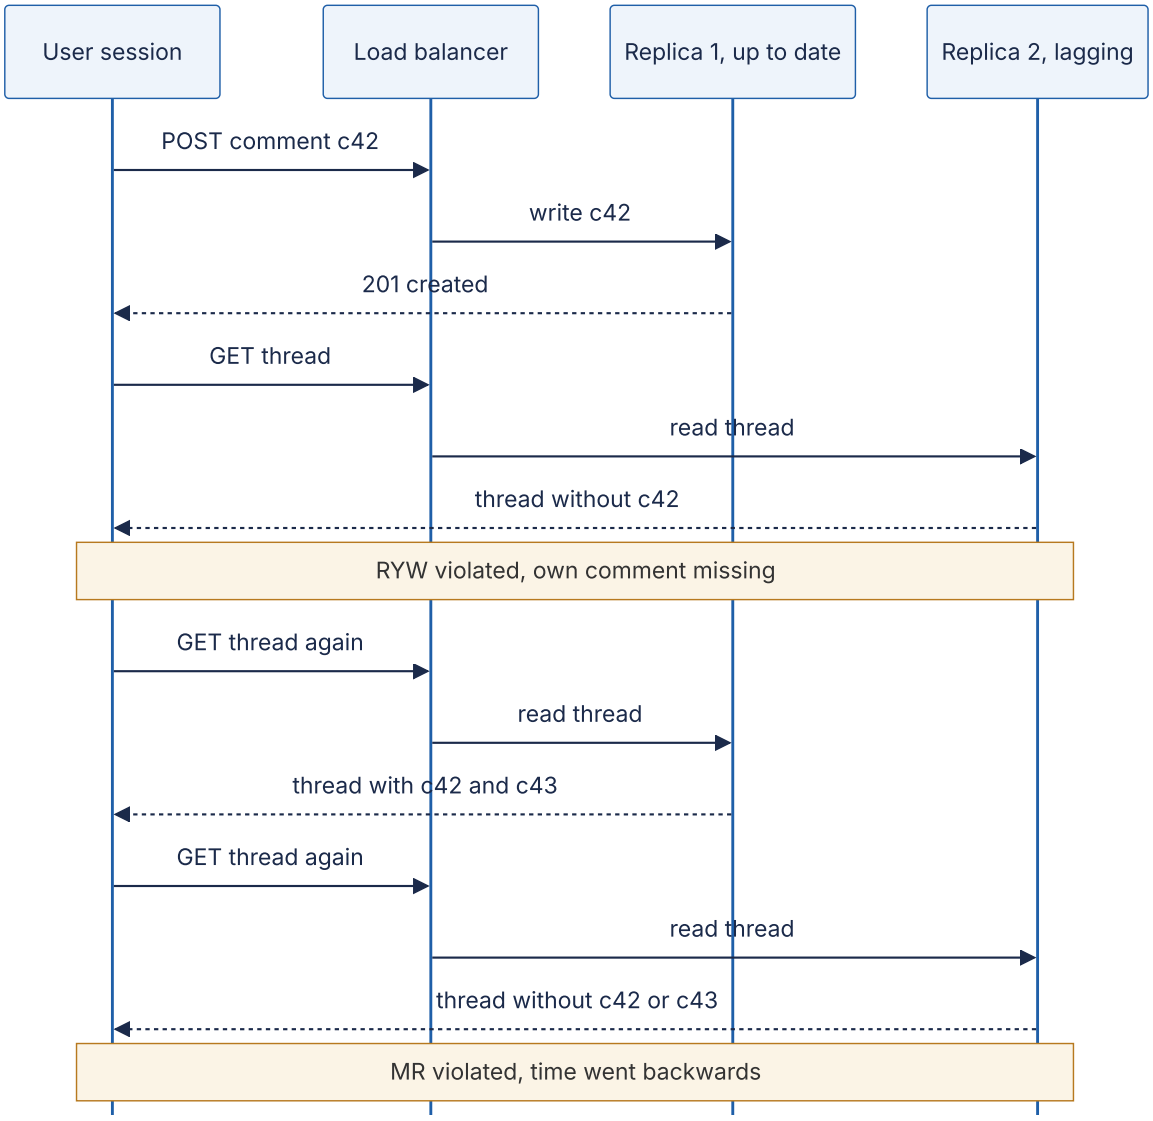
Global models constrain what *all* clients see. Often a weaker, cheaper promise suffices: that the system looks sensible *to each client individually*. Terry and colleagues, building the Bayou weakly connected replicated storage system at Xerox PARC, defined four such **session guarantees** [Terry et al. 1994]. A **session** is the sequence of operations a single client (an application instance, a browser tab, a user) performs; the guarantees hold within it.

DEFINITION

Definition — Session guarantees. Read-your-writes (RYW): if a session writes w and later reads, the read reflects w (or a later write). **Monotonic reads (MR):** if a session reads a value reflecting a set of writes, later reads reflect at least that set; the session never sees time go backwards. **Monotonic writes (MW):** a session's writes are applied at every replica in the order the session issued them. **Writes-follow-reads (WFR):** if a session reads a value produced by write w_1 and then writes w_2, every replica applies w_1 before w_2 (the new write is ordered after what the session saw).

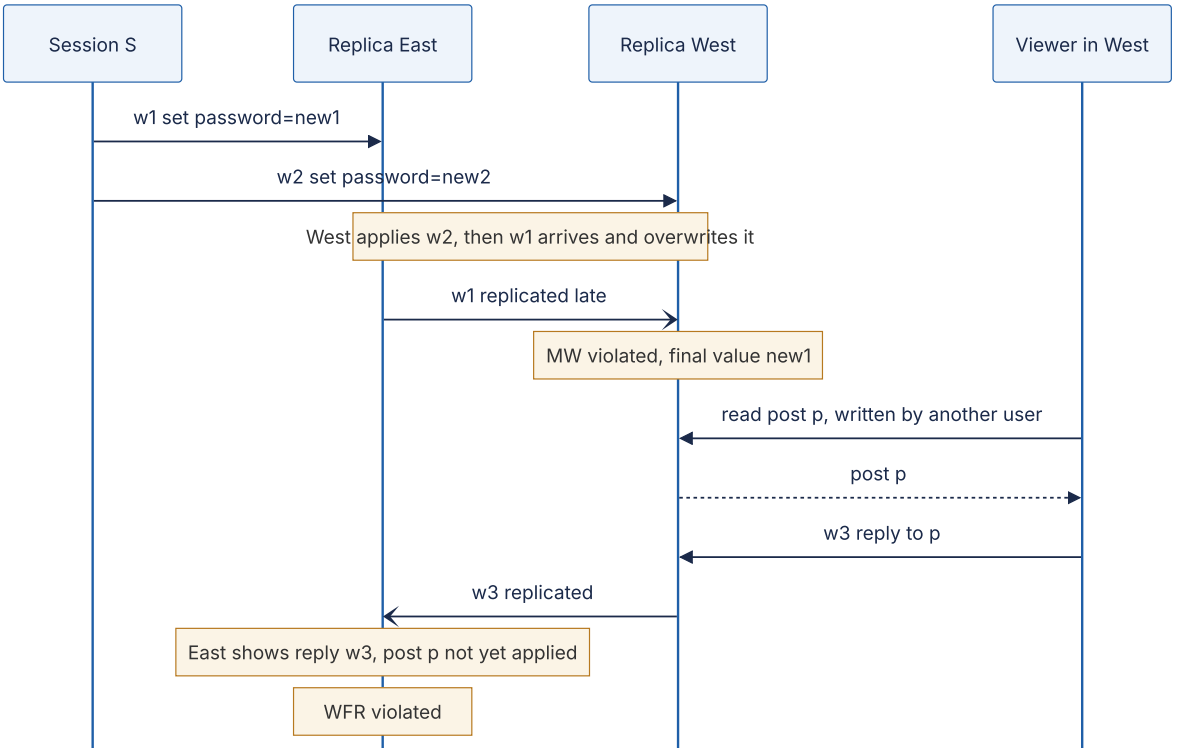
Together the four guarantees give each session a causally consistent view of its own interactions; causal consistency (§25.5) extends the same ordering across sessions that communicate through the data. Chapter 14 showed the first two failing with lagging read replicas (Figure 14.3). Figure 25.7 shows them in a multi-region setting, and Figure 25.8 shows the two write-side guarantees.

Figure 25.7 — Read-your-writes and monotonic-reads violations behind a load balancer.



Reading the diagram. All calls are synchronous HTTP requests; replication between the replicas (not drawn) is asynchronous. The load balancer is the failure point: by choosing a replica per request with no memory of the session, it can send any read to the lagging replica. Adding replicas makes the anomaly more likely, not less. The fixes below constrain routing per session, not globally, so they keep most of the read scaling.

Figure 25.8 — Monotonic-writes and writes-follow-reads violations.



Reading the diagram. Writes go synchronously to whichever replica the session reaches; replication between regions (open arrowheads) is asynchronous and unordered. In the first half, the session's two writes arrive at West in the wrong order, so West ends with the older password: the session's own write order was not preserved. In the second half, the viewer's reply depends on a post it read, but East receives the reply before the post, so readers in East see an answer to nothing. Both failures sit in the replication path; the fix is to carry ordering metadata with writes so replicas delay out-of-order ones.

25.6.2 Implementation techniques

Terry et al. implemented all four guarantees with two sets per session, stored at the client: the **write-set** (identifiers of writes the session issued) and the **read-set** (identifiers of writes that produced values the session read). Compressed as **version vectors** (one counter per origin replica, §24.11), each set is small. A replica may serve a request only if its own vector *dominates* the required one:

- RYW: before a read, the replica must cover the write-set.
- MR: before a read, the replica must cover the read-set.
- MW: before a write, the replica must cover the write-set (so earlier writes are applied first).
- WFR: before a write, the replica must cover the read-set.

If no reachable replica qualifies, the client waits or tries another replica. Production systems use the same idea in simpler forms.

Table 25.3 — Session guarantees and practical implementation techniques.

Guarantee	Anomaly prevented	Sticky sessions	Version token / LSN tracking	Other technique
Read-your-writes	Own write missing	Works only if writes and reads hit the same replica	Client keeps the commit LSN or GTID of its last write; read from a replica with applied LSN ≥ token, else wait or go to primary	Read from primary for a fixed window after a write (fails if lag exceeds window)
Monotonic reads	Data moving backwards	Pin a session to one replica: sufficient while it is up	Keep the highest LSN or vector observed; never read from a replica behind it	—
Monotonic writes	Own writes reordered	Single primary for the key already orders them	Sequence number per session; replica buffers out-of-order writes	Route all of a session's writes to one leader
Writes-follow-reads	Reply before the post it answers	—	Attach read-set vector to the write; remote replica delays apply until covered	Single-leader log orders all writes anyway

Two practical points matter. First, **single-leader systems give MW and WFR for free** within one partition, because one log orders all writes; the session problems there are RYW and MR on followers (Chapter 14). Multi-leader and leaderless systems need all four. Second, **tokens must travel with the session**, not the connection: a user who writes on a phone and reads on a laptop gets RYW only if the token is stored server-side with the user or carried in a cookie.

Code example

The program below implements the Bayou approach with version vectors. A `Session` records the vectors of what it wrote and read; a replica may serve it only if its vector dominates what the enabled guarantees require.

```
        """Bayou-style session guarantees with version vectors (after Terry et al.
1994).
        A replica's vector counts how many writes from each origin it has applied.
        The session remembers the vectors of what it wrote and what it read, and a
        replica may serve the session only if its vector dominates the required one."""

        def dominates(a, b):
            return all(a.get(k, 0) >= v for k, v in b.items())

        def merge(a, b):
            return {k: max(a.get(k, 0), b.get(k, 0)) for k in a.keys() | b.keys()}

        class Replica:
            def __init__(self, name):
                self.name, self.vv, self.log = name, {}, []
            def apply(self, origin, seq, item):        # anti-entropy delivers writes in
order
                if self.vv.get(origin, 0) == seq - 1:
                    self.vv[origin] = seq
                    self.log.append(item)
            def local_write(self, item):
                seq = self.vv.get(self.name, 0) + 1
                self.apply(self.name, seq, item)
                return self.name, seq

        class Session:
            def __init__(self, ryw=True, mr=True, mw=True, wfr=True):
                self.ryw, self.mr, self.mw, self.wfr = ryw, mr, mw, wfr
                self.read_vv, self.write_vv = {}, {}

            def can_read(self, rep):
                need = {}
                if self.ryw: need = merge(need, self.write_vv)   # see my own writes
                if self.mr:  need = merge(need, self.read_vv)    # never go backwards
                return dominates(rep.vv, need)

            def can_write(self, rep):
                need = {}
                if self.mw:  need = merge(need, self.write_vv)   # my writes stay in or-
der
                if self.wfr: need = merge(need, self.read_vv)    # writes after what I
read
                return dominates(rep.vv, need)

            def read(self, replicas):
                for rep in replicas:                             # try nearest first
                    if self.can_read(rep):
                        self.read_vv = merge(self.read_vv, rep.vv)
                        return rep.name, list(rep.log)
                return None, "no replica is fresh enough: wait or go to another site"

            def write(self, replicas, item):
                for rep in replicas:
                    if self.can_write(rep):
                        origin, seq = rep.local_write(item)
                        self.write_vv = merge(self.write_vv, {origin: seq})
```

```
                        return rep.name
                return None

        def own_write_then_read(**g):
            east, west = Replica("east"), Replica("west")
            s = Session(**g)
            s.write([east], "name=Ada")            # write lands in east
            return s.read([west, east])            # next request is routed to west
first

        def read_twice(**g):
            east, west = Replica("east"), Replica("west")
            east.local_write("comment 1")          # another user's write, not yet in
west
            s = Session(**g)
            first = s.read([east])
            second = s.read([west, east])          # load balancer prefers west now
            return first, second

        off = dict(ryw=False, mr=False, mw=False, wfr=False)
        print("RYW off:", own_write_then_read(**off))
        print("RYW on :", own_write_then_read())
        print("MR off :", read_twice(**off))
        print("MR on  :", read_twice())
```

Output:

```
RYW off: ('west', [])
RYW on : ('east', ['name=Ada'])
MR off : (('east', ['comment 1']), ('west', []))
MR on  : (('east', ['comment 1']), ('east', ['comment 1']))
```

What to notice:

- `read_vv` absorbs the *whole* vector of the replica read, a conservative over-approximation of what the session saw. Bayou did the same; precise tracking would need per-write dependencies, as in COPS.
- Replacing the vector with a single log sequence number (LSN) gives the single-leader version used with PostgreSQL and MySQL replicas (§14.4.4): one counter suffices because there is one origin.

INDUSTRY EXAMPLE

Azure Cosmos DB session consistency. Cosmos DB's default consistency level, *session*, gives read-your-writes, monotonic reads, monotonic writes and writes-follow-reads within a session by returning a **session token** with every write; the SDK sends it with later reads, and a replica that has not caught up to the token either waits or the request is retried elsewhere. Clients that share a token (for example, by passing it between web servers) share the session. *Evidence: Primary* — [Microsoft Docs: Cosmos DB Consistency Levels]

COMMON MISTAKE

Mistake — "Sticky sessions give read-your-writes." They give monotonic reads while the pinned replica is healthy. If writes go to a primary and reads to the pinned replica, the replica may not yet have the session's own write. And when the pinned replica fails, the session moves to another replica that may be further behind, breaking monotonic reads too, unless a token travels with it.

25.7 Eventual consistency

25.7.1 Definition: a liveness promise, not a safety promise

DEFINITION

Definition — Eventual consistency. If no new updates are made to an object, eventually all reads return the last updated value [Vogels 2009]. Equivalently, replicas that have received the same set of updates **converge** to the same state. **Strong eventual consistency** strengthens this: replicas that have received the same updates are in the same state immediately, with no further coordination, which is what conflict-free replicated data types (CRDTs) guarantee (§27.14).

Eventual consistency is a **liveness** property ("something good eventually happens") with no **safety** content ("nothing bad ever happens"). It says nothing about what you read *while* updates are flowing, and no bound on how long "eventually" is. A store that returned arbitrary values for an hour and then converged would technically comply [Bailis & Ghodsi 2013]. The engineering question is therefore quantitative: **how stale, how often?**

Eventual consistency also needs a **conflict resolution** rule for concurrent writes to the same key: last-writer-wins by timestamp (which silently discards one write), application merge (the Dynamo shopping cart unions concurrent versions [DeCandia et al. 2007]), or

CRDTs. Chapter 27 (§27.13–§27.14) covers anti-entropy, read repair and conflict resolution.

25.7.2 Probabilistically bounded staleness

Bailis, Venkataraman, Franklin, Hellerstein and Stoica introduced **probabilistically bounded staleness (PBS)** to answer "how eventual?" for Dynamo-style stores with N replicas, write quorum W and read quorum R [Bailis et al. 2012]. When $R + W \le N$ (a **partial quorum**), a read may miss the latest write. PBS predicts two quantities:

- **t-visibility:** the probability that a read issued t ms after a write commits returns that write (or a newer one).
- **k-staleness:** the probability that a read returns a value no more than k versions old.

Mathematical foundations

The simplest model assumes a write has reached exactly W of N replicas when it commits and has not spread further, and that a read contacts R replicas chosen uniformly at random.

FORMULA

Probability that a partial-quorum read misses the latest write

$$p_s = \frac{\binom{N-W}{R}}{\binom{N}{R}}, \qquad P(\text{older than all } k \text{ most recent versions}) = p_s^k$$

Symbol	Meaning	Units
p_s	Probability that all R replicas read hold none of the latest write's W copies	probability
N	Replication factor	replicas
W	Replicas that acknowledged the write when it committed	replicas
R	Replicas whose responses the read waits for	replicas
k	Number of most recent versions, any one of which counts as fresh enough (the read may miss $k-1$ of them)	versions

WORKED EXAMPLE

Worked example — Closed-form staleness for common settings.

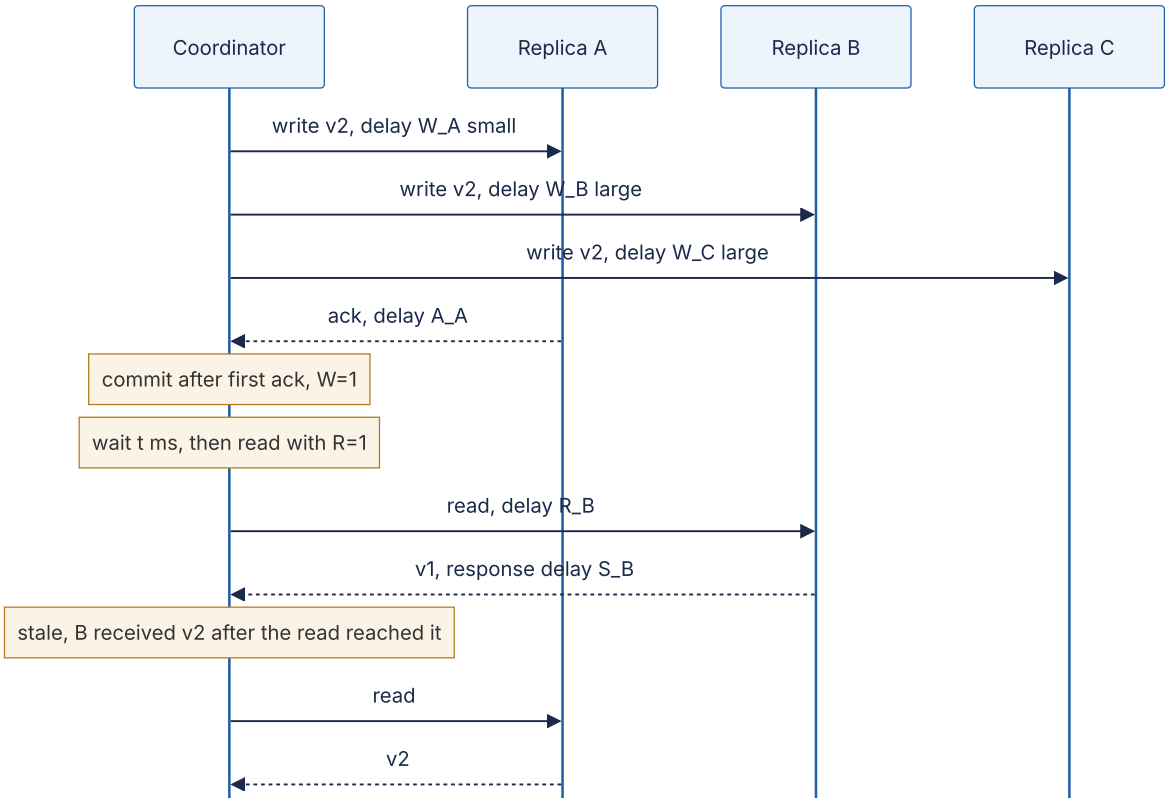
1. $N = 3$, $R = W = 1$: $p_s = \binom{2}{1}/\binom{3}{1} = 2/3 \approx 0.667$. Right after commit, two reads in three could miss the write if nothing propagates further.
2. $N = 3$, $R = 1$, $W = 2$: $p_s = \binom{1}{1}/\binom{3}{1} = 1/3$.
3. $N = 3$, $R = W = 2$: $\binom{1}{2} = 0$, so $p_s = 0$: the quorums overlap ($R + W > N$).
4. $N = 5$, $R = W = 2$: $p_s = \binom{3}{2}/\binom{5}{2} = 3/10 = 0.3$.
5. k-staleness for case 1 with $k = 3$ (the read may miss the last two versions but not three in a row): $p_s^3 = (2/3)^3 = 8/27 \approx 0.30$. With a newer write every few milliseconds, a $R = W = 1$ read lands on a replica missing three consecutive writes about 30% of the time in this pessimistic model.

Interpretation. The closed form is a worst case: it ignores the fact that the write keeps propagating to the other $N - W$ replicas after commit. **Engineering implication.** To get realistic numbers you must model propagation latency, which is what the Monte Carlo below does. The closed form is still useful for one thing: it shows that partial quorums are stale immediately after commit far more often than intuition suggests.

How it works internally: the WARS model

PBS models four latency distributions per replica, which give it its name, **WARS**: **W** (write request reaches the replica and is applied), **A** (the acknowledgment returns to the coordinator), **R** (a later read request reaches the replica), **S** (the replica's response returns). The write commits when the W-th acknowledgment arrives. A read starting t ms later returns the first R responses; it is consistent if at least one of those replicas had applied the write before the read request reached it.

Figure 25.9 — The WARS model of a partial-quorum write and read (N = 3, W = 1, R = 1).



Reading the diagram. All messages are asynchronous one-way deliveries with random delays; the coordinator only waits for the first W acknowledgments and the first R read responses. The write is applied at A quickly and at B and C later. The read happens to be answered first by B, which had not yet applied v2, so it returns v1. Had the coordinator waited for two responses ($R = 2$), A's v2 would have been included and the higher version returned. Staleness depends on the race between write propagation (W) and the read's arrival (t + R), which is why t-visibility improves with t and with slower reads. Failure points: a replica with a slow disk widens W; scaling the number of replicas without raising R or W makes misses more likely.

Code example

```
        """PBS-style Monte Carlo (WARS model, after Bailis et al. 2012): probability
        that a read issued t ms after a write commits returns that write (or newer)."""
        import random
        from math import comb

        def one_trial(n, r, w, t, lat):
            W = [lat("W") for _ in range(n)]           # write reaches replica i
            A = [lat("A") for _ in range(n)]           # replica i's ack returns
            commit = sorted(W[i] + A[i] for i in range(n))[w - 1]   # w-th ack
            R = [lat("R") for _ in range(n)]           # read request reaches replica i
            S = [lat("S") for _ in range(n)]           # replica i's response returns
            first_r = sorted(range(n), key=lambda i: R[i] + S[i])[:r]
            # consistent if some responder already had the write when the read arrived
            return any(W[i] <= commit + t + R[i] for i in first_r)

        def lat(kind, rng=random.Random(7)):
            if kind == "W":                            # propagate + apply: slow tail
                return 1.0 + rng.expovariate(1 / 4.0)  # mean 5 ms
            return 0.25 + rng.expovariate(1 / 0.5)     # A, R, S: mean 0.75 ms

        def p_consistent(n, r, w, t, trials=100_000):
            return sum(one_trial(n, r, w, t, lat) for _ in range(trials)) / trials

        if __name__ == "__main__":
            n = 3
            print("closed form, no propagation after commit: P(stale) = C(N-
W,R)/C(N,R)")
            for r, w in [(1, 1), (1, 2), (2, 1), (2, 2)]:
                print(f"  N={n} R={r} W={w}: {comb(n - w, r) / comb(n, r):.3f}")
            ts = [0, 1, 2, 5, 10, 20]
            print("\nMonte Carlo P(consistent read) by delay t after commit (ms)")
            print("R W  " + "".join(f"{t:>8}" for t in ts))
            for r, w in [(1, 1), (1, 2), (2, 1), (2, 2)]:
                row = [p_consistent(n, r, w, t) for t in ts]
                print(f"{r} {w}  " + "".join(f"{p:8.4f}" for p in row))
```

Output (about 10 seconds; the seed makes it reproducible):

```
closed form, no propagation after commit: P(stale) = C(N-W,R)/C(N,R)
  N=3 R=1 W=1: 0.667
  N=3 R=1 W=2: 0.333
  N=3 R=2 W=1: 0.333
  N=3 R=2 W=2: 0.000

Monte Carlo P(consistent read) by delay t after commit (ms)
R W         0       1       2       5      10      20
1 1    0.5000  0.6100  0.6975  0.8579  0.9600  0.9964
1 2    0.7568  0.8089  0.8514  0.9299  0.9792  0.9985
2 1    0.8253  0.8928  0.9354  0.9853  0.9989  1.0000
2 2    1.0000  1.0000  1.0000  1.0000  1.0000  1.0000
```

What to notice:

- The latency distributions are **illustrative**, not measurements: write application has a 1 ms floor plus an exponential tail with a 4 ms mean, network legs 0.25 ms plus a 0.5 ms exponential. Bailis et al. fitted distributions from production traces; with your own system, replace `lat` with samples from your latency histograms.
- At $t = 0$, $R = W = 1$ is consistent 50% of the time, better than the closed form's $1 - 2/3 = 33\%$, because propagation continues while the read is in flight.
- $R = 2, W = 1$ beats $R = 1, W = 2$ at every t here even though both have $R + W = 3$: waiting for two read responses samples more replicas *after* propagation has progressed. Which is better depends on whether reads or writes dominate your latency budget.

WORKED EXAMPLE

Worked example — Reading the simulation as an SLO. A product team accepts that a profile edit may be invisible to *other* users for a short while, but wants at least 99% of reads issued 10 ms or more after a write to be fresh. With $N = 3$:

1. From the table, at $t = 10$ ms: $(R, W) = (1, 1)$ gives 0.9600, $(1, 2)$ gives 0.9792, $(2, 1)$ gives 0.9989.
2. Only $(2, 1)$ meets 99%. It also keeps writes at one acknowledgment.
3. Cost: every read waits for the second-fastest of three responses, which raises read p99. The author's own writes still need read-your-writes (§25.6).

Interpretation. PBS turns "eventually" into a curve you can put in a service level objective. **Engineering implication.** Measure the four WARS distributions in your deployment, rerun the simulation and choose (R, W) per table; revisit when disks, load or topology change.

25.7.3 Where eventual consistency fits

Eventual consistency is the right default for data where a short window of staleness is harmless and availability or latency dominates: counters of likes and views, recommendation features, product catalogs, DNS, caches, shopping carts with merge semantics. It is the wrong choice for anything whose correctness depends on a single current value: balances, inventory reservations, uniqueness, locks. Many systems combine the two per operation, which is the theme of §25.10.

COMMON MISTAKE

Mistake — "Eventual consistency means data is usually stale." Most reads are usually fresh. The danger is *unbounded* staleness during incidents (a partitioned replica, a stalled replication stream) and the anomalies the bare model permits. Add session guarantees and monitor replication lag.

25.7.4 Models compared

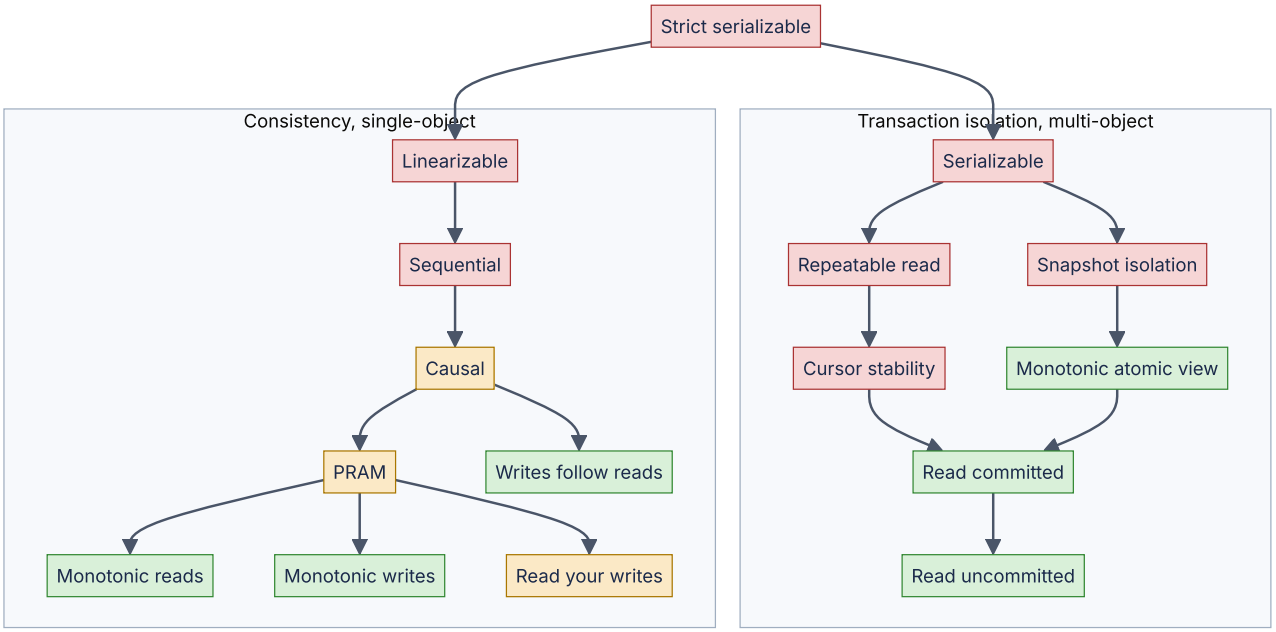
Table 25.4 — Single-object consistency models compared.

Model	What it guarantees	Allows	Latency of reads and writes	Available under partition?
Linearizable	One copy, real-time order	Nothing beyond concurrency	Quorum or leader round trip for both	No
Sequential	One agreed order, program order	Stale reads (order in the past)	One of reads or writes can be local	No
Causal	Causal order seen by all	Concurrent writes seen in different orders	Both local	Sticky available
Session guarantees (PRAM and friends)	Sensible view per session	Cross-session staleness and reordering	Local unless the replica is behind the token	Sticky or totally available
Eventual	Convergence when writes stop	Anything in between	Both local	Totally available

25.7.5 The map of consistency models

The models of §25.3–§25.7 and the isolation levels of §11.13 form a partial order: model *A* is **stronger** than *B* if every history allowed by *A* is allowed by *B*. Figure 25.10 draws that order after Jepsen's map of consistency models, which is itself based on Viotti and Vukolić and on Bailis et al.'s work on highly available transactions [Kingsbury: Consistency Models; Viotti & Vukolić 2016; Bailis et al. 2014].

Figure 25.10 — The consistency hierarchy: transactional isolation (left) and single-object consistency (right).



Reading the diagram. An arrow from *A* to *B* means *A* implies *B* (every *A* history is a *B* history); strength decreases downward. The left subgraph holds transaction isolation models, which constrain groups of operations over many objects; the right holds single-object consistency models; strict serializable at the top is the meeting point (serializable plus real time). Colors give availability under network partition as classified by Bailis et al. and Jepsen: red models cannot be totally available (some requests must block or fail in a partition); amber models are **sticky available**, meaning available as long as each client keeps talking to the same replicas; green models are **totally available**, so any non-failed replica can answer. Eventual consistency, a liveness property, is not drawn; it can be combined with any green or amber model. PRAM (pipelined RAM, [Lipton & Sandberg 1988]) is the combination of read-your-writes, monotonic reads and monotonic writes.

Two lessons from the map are worth memorizing. First, **the red-amber boundary is exactly the CAP boundary**: everything at or above sequential consistency cannot stay available in a partition, while causal consistency and below can (§25.8). Second, **isolation and consistency are orthogonal** until the very top: a serializable system can serve stale reads, and a linearizable key-value store can have no transactions at all.

25.8 The CAP theorem

25.8.1 The precise statement

Brewer conjectured in a 2000 keynote that a web service cannot be simultaneously consistent, available and partition-tolerant [Brewer 2000]. Gilbert and Lynch turned the conjecture into a theorem by defining each word [Gilbert & Lynch 2002].

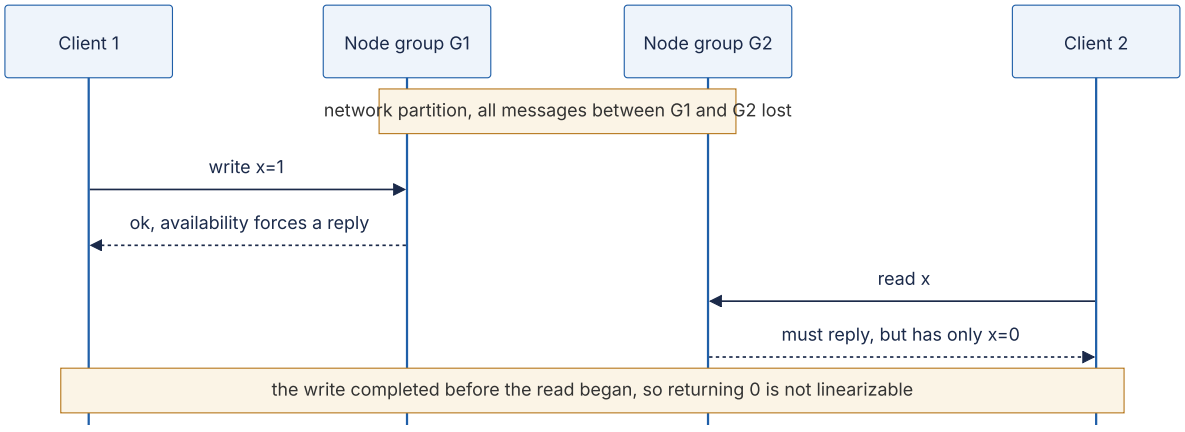
DEFINITION

Definition — CAP theorem (Gilbert and Lynch). In an asynchronous network model, where messages may be delayed arbitrarily and there are no clocks, it is impossible to implement a read/write data object that guarantees both of the following in all fair executions, including those in which messages are lost: **Consistency (C):** the object is **atomic**, that is, linearizable (§25.3). **Availability (A):** every request received by a non-failing node must eventually result in a response. **Partition tolerance (P)** is not a property the system chooses; it is the assumption that the network may lose arbitrarily many messages between nodes.

Each term is narrower than its everyday meaning. “C” is linearizability of a single register, not ACID consistency. “A” requires *every* non-failing node to answer, with no time bound: a system that answers 99.99% of requests in 100 ms but refuses the minority side is not CAP-available, and one that answers after an hour is. “P” is a network fault, not a design option.

How the proof works

Figure 25.11 — The CAP proof scenario.



Reading the diagram. The nodes are split into two groups whose messages to each other are lost. Requests are synchronous from each client’s point of view. Availability forces G1 to acknowledge the write without contacting G2, and forces G2 to answer the read without contacting G1. G2 cannot know about the write, so it returns the old value after the write completed: a violation of linearizability. The only escapes are for G1 to withhold its acknowledgment or G2 to withhold its answer until the partition heals, which gives up availability. Gilbert and Lynch also show the result holds in a partially synchronous model with local clocks.

25.8.2 Common misreadings

COMMON MISTAKE

Mistake — "Pick two of three." You cannot "pick" P: partitions happen whether you choose them or not, so the real choice is what each operation does *during* a partition, C or A. When there is no partition, CAP says nothing, and a system can be both linearizable and available [Brewer 2012]. Drawing CAP as a triangle with three equal corners is the source of most confusion.

COMMON MISTAKE

Mistake — "Our database is CA." A single-node database is not partition-tolerant in any useful sense; it is simply not distributed. A distributed system that claims CA means "we assume partitions don't happen," and when one does, it will in fact sacrifice C or A, usually without having designed which [Kleppmann 2015].

COMMON MISTAKE

Mistake — "System X is CP" or "AP" as a whole. Most systems are neither in the strict sense. A Raft-based store is not CAP-available (the minority side refuses requests), but its follower reads are not CAP-consistent either. A Dynamo-style store with quorum reads and writes is not linearizable even without partitions (§25.3.4). Kleppmann argues that the labels should be dropped in favor of naming the actual consistency model and failure behavior of each operation [Kleppmann 2015].

25.8.3 Brewer's "CAP twelve years later"

In 2012 Brewer revisited the theorem [Brewer 2012]. His main points:

1. **Partitions are rare**, so systems should not give up C or A when there is no partition.
2. **The choice is fine-grained**: per operation, per data item, per user, and it can change over time. A system can refuse to sell the last seat during a partition while still letting users browse.
3. **Partitions should be managed explicitly in three steps**: *detect* the partition (typically by timeout), enter a **partition mode** that limits some operations, then *recover* by merging state and **compensating** for mistakes, for example by refunding an oversold item. CRDTs and commutative operations make the merge mechanical.
4. **Latency and partitions are the same thing in practice**: a timeout is the only way to detect a partition, so every timeout decision is a small CAP decision.

Earlier, Fox and Brewer had framed the trade-off as **harvest** (the fraction of the data reflected in an answer) versus **yield** (the fraction of requests answered), pointing out that degrading harvest, such as a search result missing one shard, is often better than failing the request [Fox & Brewer 1999].

25.8.4 What CAP leaves out

Kleppmann's critique identifies the gaps [Kleppmann 2015]. CAP covers one consistency model (linearizability), one fault (a partition), and one notion of availability that no real system measures. It says nothing about latency, about crashed nodes, or about any model weaker than linearizability. His proposed alternative is to state, for each operation, how its latency depends on network delay d: linearizable operations take time proportional to d, causal operations can complete in constant time. This is the same insight as the lower bound of §25.3.4 and the motivation for PACELC.

INTERVIEW TIP

Interview tip — Answer CAP questions in three sentences. (1) CAP says that during a network partition a replicated register cannot be both linearizable and able to answer on every node. (2) So the real decision is per operation: refuse or delay (consistency) versus answer possibly stale or conflicting (availability), plus a plan to reconcile. (3) Outside partitions the trade-off is latency versus consistency, which is PACELC.

25.9 PACELC

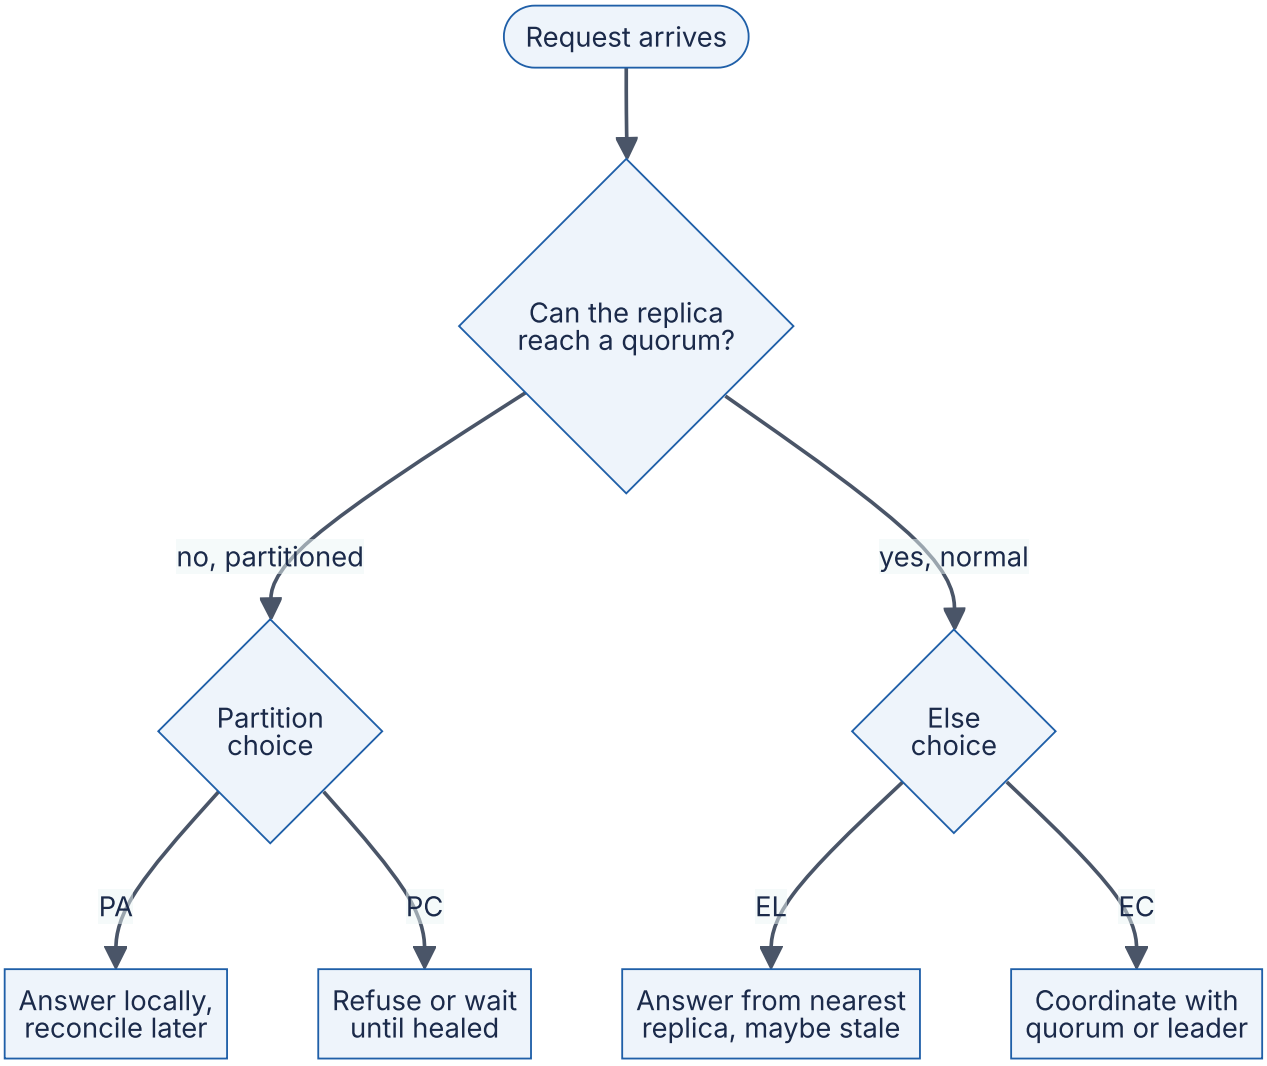
25.9.1 The formulation

Abadi observed that the consistency trade-off most systems actually make has nothing to do with partitions [Abadi 2012]. Keeping replicas synchronized costs round trips on every request, partition or not.

DEFINITION

Definition — PACELC. If there is a **P**artition, how does the system trade off **A**vailability and **C**onsistency; **E**lse, when the system is running normally, how does it trade off **L**atency and **C**onsistency? A system is labeled by its two choices, for example PA/EL or PC/EC.

Figure 25.12 — The PACELC decision for one operation.



Reading the diagram. A request takes the left branch only while the replica cannot reach the nodes it needs; that is the CAP decision. The right branch is the everyday path, where the choice is between answering from the closest replica (low latency, possibly stale) and paying a synchronous round trip for consistency. Both decisions are made per operation and are often configurable. The failure point is the “can it reach a quorum?” test itself, which in practice is a timeout.

25.9.2 Classifying real systems

Abadi’s 2012 paper labeled Dynamo, Cassandra and Riak as PA/EL; VoltDB/H-Store and Megastore as PC/EC; MongoDB as PA/EC; and Yahoo’s PNUTS as PC/EL [Abadi 2012]. Configurations have changed since; Table 25.5 gives labels for typical settings as of 2026. Treat every label as a statement about a configuration, not about a product.

Table 25.5 — PACELC classification of real systems, by configuration (as of 2026).

System	Typical configuration	P choice	E choice	Caveat
Cassandra	`ONE` or `LOCAL_ONE` reads and writes	PA	EL	`QUORUM` both ways gives PC/EC per request; lightweight transactions use Paxos (PC/EC)
DynamoDB (single region)	Default eventually consistent reads	PA	EL	`ConsistentRead=true` reads the leader replica: EC, and fails rather than serve stale data
DynamoDB global tables	Multi-Region eventual consistency (default)	PA	EL	Multi-Region strong consistency mode (GA 2025) is PC/EC, chosen at table creation
Cosmos DB	Session (default)	PA	EL within session rules	Strong is PC/EC; bounded staleness is PC within its bound
MongoDB	`w: majority`, reads from primary	PC	EC	Reads from secondaries are EL; `w: 1` (pre-5.0 default) risks rollback
Spanner	Read-write transactions, strong reads	PC	EC	Stale reads at a past timestamp are EL
CockroachDB	Default	PC	EC	Follower reads with `AS OF SYSTEM TIME` are EL
etcd, ZooKeeper	Default	PC	EC for writes	ZooKeeper reads are local (EL) unless preceded by `sync`; etcd serializable reads are EL
PostgreSQL with async replicas	Reads routed to replicas	PC for writes (one primary)	EL	Failover to an async replica can lose acknowledged writes

Mathematical foundations

The cost of “EC” can be priced directly. DynamoDB bills reads in **read capacity units (RCUs)**: one RCU is one strongly consistent read per second of an item up to 4 KB, or two eventually consistent reads [AWS Docs: DynamoDB Read Consistency].

FORMULA

DynamoDB read capacity for a read rate

$$\text{RCU} = r \times \left\lceil \frac{s}{4\ \text{KB}} \right\rceil \times f, \qquad f = \begin{cases} 1 & \text{strongly consistent} \\ 0.5 & \text{eventually consistent} \end{cases}$$

Symbol	Meaning	Units
RCU	Provisioned read capacity needed	RCU
r	Read rate	reads/s
s	Item size	KB
f	Consistency factor	RCU per 4 KB read

WORKED EXAMPLE

Worked example — Paying for EC. A profile service reads 20,000 items per second, each 6 KB.

1. Size factor: $\lceil 6/4 \rceil = 2$.
2. Eventually consistent: $20,000 \times 2 \times 0.5 = 20,000$ RCU.
3. Strongly consistent: $20,000 \times 2 \times 1 = 40,000$ RCU.
4. If only the 5% of reads that follow the user's own edit need RYW and use strong reads: $20,000 \times 2 \times (0.95 \times 0.5 + 0.05 \times 1) = 40,000 \times 0.525 = 21,000$ RCU.

Interpretation. Strong reads double read cost; applying them only where a session guarantee needs them costs 5% more than all-eventual. **Engineering implication.** Choose consistency per call site, not per table; the latency and cost difference is a property of each operation.

25.10 Consistency trade-offs in real databases

25.10.1 Tunable consistency

Modern databases rarely offer one model; they offer knobs, usually per request.

- **Cassandra** sets a consistency level per statement: `ONE`, `QUORUM`, `LOCAL_QUORUM` (a majority in the local data center), `EACH_QUORUM`, `ALL`, and `SERIAL` / `LOCAL_SERIAL` for Paxos-based lightweight transactions such as `INSERT ... IF NOT EXISTS` [Apache Cassandra Docs]. `LOCAL_QUORUM` reads and writes are the common production choice: overlapping quorums within a region, asynchronous replication to other regions (EL across regions).

- **DynamoDB** makes reads eventually consistent by default; `ConsistentRead=true` makes a `GetItem`, `Query` or `Scan` strongly consistent within a region, at twice the read cost (§25.9.2). Global secondary indexes support only eventually consistent reads [AWS Docs: DynamoDB Read Consistency].
- **MongoDB** combines write concern (`w: 1`, `w: majority`), read concern (`local`, `majority`, `linearizable`, `snapshot`) and read preference (primary or secondaries). `linearizable` read concern on the primary confirms with a majority before returning [MongoDB Docs: Read Concern].
- **Follower reads.** CockroachDB and Spanner let a query read a slightly old, consistent snapshot from the nearest replica: CockroachDB with `AS OF SYSTEM TIME follower_read_timestamp()`, Spanner with **bounded-staleness** or **exact-staleness** reads [CockroachDB Docs: Follower Reads; Google Cloud Docs: Spanner Reads]. The read is serializable but not linearizable: it is a correct view of the past.

25.10.2 Cosmos DB's five levels

Azure Cosmos DB exposes five named levels, which map neatly onto this chapter's models [Microsoft Docs: Cosmos DB Consistency Levels].

Table 25.6 — Azure Cosmos DB consistency levels (as of 2026).

Level	Guarantee	Closest model in this chapter	Notes
Strong	Reads see the latest committed write	Linearizable	Writes wait for a majority in every region; not offered with multiple write regions
Bounded staleness	Reads lag writes by at most K versions or T seconds	Linearizable outside the window; consistent prefix inside it	Minimum bounds depend on single- or multi-region writes
Session (default)	RYW, MR, MW, WFR within a session token	Session guarantees (§25.6)	Other sessions see consistent prefix
Consistent prefix	Never see writes out of order or with gaps	Ordered prefix of a single log, no recency bound	Reads may be arbitrarily old
Eventual	Convergence only	Eventual	Lowest latency and cost

25.10.3 External consistency in Spanner

Spanner provides **external consistency**, which is strict serializability for transactions: if transaction T_1 commits before T_2 starts, T_1's commit timestamp is smaller [Corbett et al. 2012]. It achieves this with TrueTime, a clock API that returns an interval guaranteed to contain true time, and a **commit wait**: a transaction does not report success until its timestamp is definitely in the past everywhere. The cost is a commit wait of about twice the clock uncertainty (about 8 ms at the paper's typical uncertainty of 4 ms), which over-

laps the Paxos round trip that logs the commit, so a commit takes roughly the larger of the two. Chapter 28 (§28.8.2) treats the mechanism.

INDUSTRY EXAMPLE

Amazon DynamoDB global tables with multi-Region strong consistency. Global tables historically replicated asynchronously between regions with last-writer-wins resolution. In June 2025 AWS made a multi-Region strong consistency (MRSC) mode generally available, so that strongly consistent reads in any participating region return the latest write, with a recovery point objective of zero. The mode is selected when the table is created; writes pay cross-region replication latency. *Evidence: Primary* — [AWS 2025: DynamoDB MRSC]

RECOMMENDATION

Recommendation — Choose consistency per operation. List each operation and ask: does a stale or reordered answer cause a wrong decision (money, inventory, uniqueness, authorization) or only a cosmetic glitch? Give the first group linearizable operations (leader reads, quorum reads, conditional writes, strong reads); give user-facing reads of a user's own data session guarantees; serve everything else eventually consistent from the nearest replica. Write the choice into the API documentation.

25.11 Jepsen-style testing

25.11.1 Why test consistency?

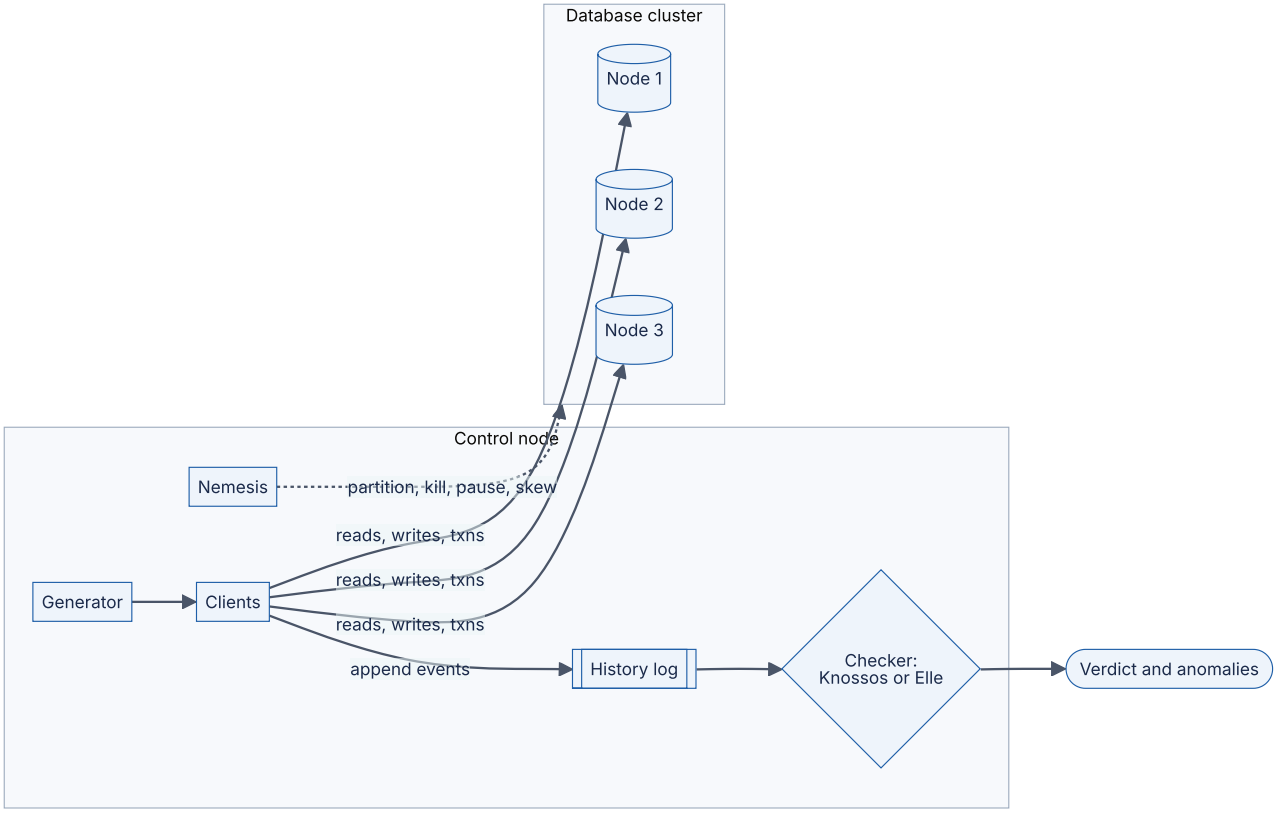
A consistency model is a claim about *all* histories under *all* allowed faults. Unit tests exercise a handful of interleavings without faults, where most systems behave linearizably. Bugs live in rare windows: a leader paused by garbage collection while a new one is elected, a partition during a membership change, a clock jump during lease renewal. Kyle Kingsbury's **Jepsen** project, started in 2013, tests real databases by generating concurrent operations, injecting faults, recording the history, and checking it against a model [Kingsbury: Jepsen].

How it works internally

1. **Set up** a cluster (typically five nodes) and a control node that runs the test.
2. **Generate** a workload: many concurrent clients issue randomized operations, such as reads, writes and compare-and-set on registers, or transactions appending to lists.
3. **Inject faults** with a **nemesis**: network partitions (via firewall rules), process crashes and pauses (`SIGSTOP`), clock skew, disk faults, membership changes.

4. **Record a history**: every invocation and completion with its result, marking timed-out operations as **indeterminate** (`:info`), exactly like H6 in §25.3.3.
5. **Check** the history: a linearizability checker for single-object workloads, or a transactional checker for isolation levels.

Figure 25.13 — Architecture of a Jepsen test.



Reading the diagram. The generator schedules operations for many client threads, which call the database over its native protocol synchronously. The nemesis acts asynchronously on the nodes over SSH. Every event goes to the history log (the storage boundary for test evidence), and the checker analyzes it offline after the run. Failure points are deliberate: the nemesis creates them. The checker is the scaling bottleneck: linearizability checking is NP-complete, so tests keep concurrency and history length modest or partition the history by key.

25.11.2 Checkers

Table 25.7 — History checkers.

Checker	What it checks	Method	Notes
Knossos	Linearizability of single objects	Search for a linearization, Wing–Gong–Lowe style	Jepsen's original checker (Clojure); cost grows quickly with concurrency
Porcupine	Linearizability	Same family, optimized, with per-key partitioning	Go; used in MIT 6.824 labs
Elle	Transaction isolation, from read uncommitted to strict serializable	Infers write-read, write-write and read-write dependencies, then finds cycles (Adya's phenomena)	Linear-time on suitable workloads such as list-append [Kingsbury & Alvaro 2020]

Elle's key idea is to design the workload so that the history *reveals* the version order: if each transaction appends unique values to lists, a read of `[1, 2, 5]` proves that the append of 2 came before the append of 5. Dependency graphs can then be built directly, and any cycle is a named anomaly (G0, G1c, G-single, G2-item) [Adya 1999; Kingsbury & Alvaro 2020].

25.11.3 Published findings

Jepsen reports are public and detailed. Three examples show the range:

INDUSTRY EXAMPLE

etcd 3.4.3 (2020). Key-value operations, including multi-key transactions, appeared strictly serializable under partitions, pauses, crashes, clock skew and membership changes, and watches delivered changes in order apart from an undocumented edge case. etcd's locks, however, could not guarantee mutual exclusion in an asynchronous network, a fundamental limitation of lease-based locks that needs fencing tokens (§26.13). *Evidence: Primary* — [Kingsbury 2020a]

INDUSTRY EXAMPLE

MongoDB 4.2.6 (2020). Even with the strongest read and write concerns, transactions exhibited read skew, cyclic information flow, duplicate writes and internal consistency violations, so they did not provide snapshot isolation; under default settings transactions could lose writes. MongoDB changed the default write concern to `majority` in version 5.0. *Evidence: Primary* — [Kingsbury 2020b; MongoDB Docs: Jepsen]

INDUSTRY EXAMPLE

PostgreSQL 12.3 (2020). Using Elle, Jepsen found that the SERIALIZABLE level allowed G2-item anomalies (anti-dependency cycles) in healthy clusters without any faults, a bug in serializable snapshot isolation that the PostgreSQL developers then fixed. The same report noted that PostgreSQL's REPEATABLE READ is snapshot isolation. *Evidence: Primary* — [Kingsbury 2020c]

RECOMMENDATION

Recommendation — Test your own system's claims. Record histories in integration tests (client, operation, invocation and completion time, result), run them through Porcupine, Knossos or Elle, and add fault injection: partition the leader, pause it beyond its lease, skew clocks. Treat every timeout as indeterminate. A single non-linearizable history with a short witness is worth more than months of green dashboards.

25.12 Summary and revision notes

SUMMARY

- **Two axes.** Single-object consistency models (linearizable, sequential, causal, session, eventual) say which values reads may return; isolation levels (§11.13) say which transaction interleavings are allowed. Strict serializability is where they meet.
- **Linearizability** = a linearization point inside each operation's interval, giving a legal sequential history that respects real time; the single-copy illusion. It is compositional. Checking is NP-complete in general; brute force with memoization works for small histories. It costs a round trip to a quorum or a confirmed leader ($T \approx k \cdot \mathrm{RTT}_{(q)}$), and $t_{\text{read}} + t_{\text{write}} \geq d$ already for sequential consistency.
- **Sequential consistency** drops real time but keeps one agreed order and program order; follower reads in ZooKeeper behave like this. It is not compositional (store buffering).
- **Causal consistency** orders only causally related writes, allows local reads and writes and is sticky available; COPS carries nearest dependencies and checks them before applying remote writes.
- **Session guarantees** (RYW, MR, MW, WFR) are implemented with read-sets and write-sets as version vectors, LSN tokens or sticky routing; tokens must travel with the session.
- **Eventual consistency** is liveness only. PBS quantifies it: $p_s = \binom{N-W}{R} / \binom{N}{R}$ immediately after commit, and a WARS simulation gives t-visibility curves you can put in an SLO.
- **CAP** (Gilbert and Lynch): in an asynchronous network that can lose messages, no register is both linearizable and available on every non-failed node. Not "pick two"; no meaningful "CA"; choose per operation what happens during a partition.
- **PACELC** adds the everyday trade-off: else, latency versus consistency. Labels describe configurations, not products.
- **Jepsen** records histories under injected faults and checks them with Knossos/Porcupine (linearizability) or Elle (isolation, via dependency cycles). Treat timeouts as indeterminate.

25.13 Knowledge checkpoint

1. What makes two operations concurrent, and when does a precede b in real time?
2. Why is history H3 (a read returns 1 during a write, a later read returns 0) not linearizable, even though each read alone could be?

3. State the locality property of linearizability and why it matters for partitioned stores.
4. Give a history that is sequentially consistent but not linearizable.
5. Why does $R + W > N$ not by itself give linearizability?
6. Five replicas have RTTs 0, 2, 30, 80 and 85 ms from the coordinator. What is the latency of an ABD read?
7. Which session guarantee does a sticky replica provide, and which does it fail to provide?
8. In COPS, why does a client need to track only nearest dependencies?
9. Compute p_s for $N = 5$, $R = 1$, $W = 2$.
10. What exactly do C, A and P mean in Gilbert and Lynch's proof?
11. Why is "CA system" a misleading label?
12. Classify Cassandra at `LOCAL_ONE` and Spanner strong reads in PACELC.
13. What does Elle need from a workload to infer the version order?
14. Why must a Jepsen history record timed-out operations as indeterminate?

Answers

1. Their invocation–response intervals overlap. *a* precedes *b* if *a*'s response happens before *b*'s invocation.
2. Once B returned 1, B's linearization point is after the write's. C's read starts after B finished, so its point is later still and must see 1.
3. A history is linearizable if and only if each object's sub-history is. Independently linearizable partitions compose into a linearizable store without cross-partition coordination for single-object operations.
4. H2: A writes $x = 1$ and completes; afterwards B reads 0. The order "B reads, then A writes" respects program order.
5. Partial writes, in-flight writes, sloppy quorums and last-writer-wins can let one reader see a new value and a later reader an old one; write-back or consensus is needed.
6. $q = 3$, $\mathrm{RTT}_{(3)} = 30$ ms; two round trips, about 60 ms plus processing.
7. Monotonic reads while the replica is healthy; not read-your-writes if writes go elsewhere, and not monotonic reads across failover.
8. Dependencies are transitive: the nearest dependency already depends on everything before it, and the remote cluster applied it only after its own dependencies.
9. $\binom{3}{1}/\binom{5}{1} = 3/5 = 0.6$.
10. C: linearizable read/write register. A: every request to a non-failing node eventually gets a response. P: the network may lose arbitrarily many messages.
11. Partitions are not optional in a distributed system; a "CA" system just has not decided whether it will lose C or A when one happens.
12. Cassandra `LOCAL_ONE`: PA/EL. Spanner strong reads: PC/EC.
13. A way to recover each object's version order from reads, for example appends of unique values to lists, so dependencies can be inferred directly.

14. The operation may have taken effect; treating it as failed produces false alarms, and treating it as succeeded can hide real anomalies.

25.14 Interview questions

Basic

Q1. What is the difference between linearizability and serializability? Answer. Linearizability is a recency guarantee for single operations on single objects: each operation appears to take effect at one instant between its call and return, respecting real time. Serializability is an isolation guarantee for transactions over many objects: the outcome equals some serial order, which need not respect real time. Strict serializability combines both.

Q2. A user updates her profile and the page still shows the old one. What happened and how do you fix it? Answer. The read went to a lagging replica, violating read-your-writes. Return the commit LSN or a session token with the write and read only from replicas that have applied it, or read from the primary for that user's own profile after a write.

Intermediate

Q3. Explain CAP precisely and say what your design does during a partition. Answer. In an asynchronous network that can lose messages, a register cannot be both linearizable and answer on every non-failing node. Per operation, I decide: payments and inventory decrements refuse on the minority side (PC); browsing, carts and likes keep serving locally with merge or compensation afterwards (PA). Outside partitions, PACELC's latency–consistency choice applies: strong reads where a stale value causes a wrong decision, nearest-replica reads elsewhere.

Q4. How would you implement monotonic reads across a fleet of read replicas? Answer. Track, per session, the highest LSN (or version vector) it has observed; route reads only to replicas at or beyond it, waiting briefly or falling back to the primary otherwise. Sticky routing alone fails on replica failure.

Advanced

Q5. Your team wants a globally replicated, linearizable key-value store with 5 ms reads and writes on three continents. Respond. Answer. Impossible: for sequential consistency already $t_r + t_w \geq d$, and cross-continent d is tens of milliseconds. Offer alternatives: place each key's quorum near its main writer (fast for local users, slow for others);

linearizable writes with follower reads that are bounded-stale; or causal consistency with local operations plus linearizable operations only for uniqueness and money.

Q6. How would you test that a new replicated store is linearizable? Answer. Jepsen-style: concurrent clients on a small key set doing reads, writes and compare-and-set; a nemesis partitioning, pausing and killing leaders and skewing clocks; record every invocation and completion, timeouts as indeterminate; check with Porcupine or Knossos per key. For transactions, use list-append workloads and Elle. Minimize failing histories and turn them into regression tests.

25.15 Practical exercises

1. Extend the checker of §25.3.3 with a compare-and-set operation and construct a history in which two CAS operations both succeed but the history is not linearizable.
2. Add a third replica and a write-side scenario to the session-guarantee program that demonstrates a monotonic-writes violation when `mw=False`.
3. Modify the PBS simulation so one of the three replicas has a 10× slower write path. How do the curves for $(R,W) = (1,1)$ and $(2,1)$ change?
4. Run Porcupine on histories produced by a toy key-value store with an asynchronous replica, and find the shortest non-linearizable history.

25.16 Design challenges

1. **Global collaborative documents.** Users in three regions edit shared documents. Choose consistency models for document contents, access control lists and document names (which must be unique per folder), and justify the latency each user sees.
2. **Ticketing.** A concert ticketing service must never oversell seats but must keep browsing available during a regional network partition. Describe partition detection, partition mode and recovery in Brewer's terms.

25.18 Open verification items

- Attiya and Welch (1994): confirm the exact bounds attributed in §25.3.4 ($t_r + t_w \geq d$ for sequential consistency, credited also to Lipton and Sandberg; linearizability needing both operations to wait in proportion to delay uncertainty).
- Mahajan et al. (2011): confirm the precise statement of the real-time causal result.
- Jepsen map (Figure 25.10): re-check edges and availability colors against the current jepsen.io page (jepsen.io was unreachable from the build environment).
- PostgreSQL 12.3: confirm the fix release (believed 12.4).
- Cosmos DB: confirm minimum bounded-staleness K/T values and that strong consistency is unavailable with multiple write regions.
- Spanner commit-wait magnitude (about $2\bar{\varepsilon} \approx 8$ ms, as derived in §28.8.2 from the paper’s average ε of about 4 ms); Brewer 2012 page numbers.

Chapter 26 — Consensus and Coordination

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 7 h

At 02:14 a database primary stops answering heartbeats. The failover controller promotes a replica. Ninety seconds later the old primary finishes a long garbage-collection pause, finds its network link healthy again, and keeps accepting writes, because nothing told it that it had been replaced. For a few minutes two nodes both believe they are the primary, and customers who wrote to the "wrong" one lose their orders when the clusters are reconciled. Nothing here was a bug in the usual sense: every node acted correctly on the information it had. The failure was a missing *agreement* about who was in charge.

This chapter is about that agreement. **Consensus** gets unreliable machines to decide one thing and never change their minds; **coordination** builds on it: leader election, locks, leases, configuration and membership. You will learn why majority quorums work, how Paxos and Raft agree despite crashes and lost messages, how ZooKeeper, etcd and Chubby package consensus as a service, and why even a correct lock service cannot stop a paused client unless storage checks a **fencing token**.

26.1 Learning objectives

After this chapter you should be able to:

- State the consensus problem (agreement, validity, termination) and explain how a replicated state machine turns single-value consensus into a fault-tolerant service.
- Compute quorum sizes, fault tolerance, availability and commit latency for 3-, 5- and 7-node clusters, and explain flexible quorums.
- Compare bully, ring and lease-based leader election and explain why electing a leader does not, by itself, give safety.
- Trace single-decree Paxos through prepare/promise and accept/accepted, including competing proposers, and explain how Multi-Paxos removes phase 1 from the common path.
- Explain Raft's terms, elections, log replication, log matching, commit rule and the "commit only current-term entries" subtlety; size election timeouts; describe snapshots, membership changes, ReadIndex and lease reads; and run a Raft simulator.
- Use ZooKeeper, etcd, Consul and Chubby primitives (ephemeral nodes, watches, revisions, leases, sequencers) to build election, locks and barriers.

- Evaluate distributed-lock designs, including the Redlock debate, and design leases with an explicit clock-safety margin.
- Diagnose split brain and prevent it with quorums, witnesses, STONITH and fencing tokens.

26.2 Prerequisites

- System models, partial failure and network partitions — §24.6–§24.8 (consensus algorithms are defined relative to a failure model).
- Physical clocks and clock skew — §24.9 (leases and lease reads depend on bounded clock drift).
- FLP impossibility — §24.13 (explains why every practical algorithm needs timeouts).
- Linearizability — §25.3 (the consistency level consensus-backed services provide).
- Primary–replica replication and failover — §14.3–§14.4 (consensus fixes the failover problems introduced there).
- Write-ahead logs and `fsync` — §13.5, §13.12 (every vote and log entry must be durable before it is acknowledged).

26.3 The consensus problem

26.3.1 Agreement, validity, termination

> DEFINITION
>
> **Definition — Consensus.** A set of processes, each of which may **propose** a value, must **decide** on a single value such that: **agreement** — no two correct processes decide differently; **validity** (integrity) — the decided value was proposed by some process; **termination** — every correct process eventually decides. Once decided, a value never changes.

First-principles explanation

Picture five friends choosing a restaurant by text message. Messages arrive late or not at all, and any friend's phone may die mid-conversation. They want three things. Everyone who chooses must choose the *same* restaurant (agreement). The chosen restaurant must be one somebody actually suggested, not a default made up by the protocol (validity). And they must eventually stop arguing and eat (termination). The first two are **safety** properties: "nothing bad ever happens." The third is a **liveness** property: "something good eventually happens."

The difficulty is that a silent phone is ambiguous: is Dana's phone dead, or her reply just slow? Wait forever and the group may never decide; decide without her and Dana may later act on an older, different decision. Every consensus algorithm is a careful answer to this ambiguity.

Why does this exist?

Many problems reduce to consensus: choosing one leader, committing or aborting a distributed transaction, granting a lock to one client, agreeing on membership, and ordering writes to a replicated database. Solve consensus once and you can build all of these, which is why it sits underneath ZooKeeper, etcd, Consul, Chubby, Spanner, CockroachDB, TiKV and Kafka's KRaft controller (Chapter 31).

The impossibility result and how practice escapes it

Section 24.13 introduced the **FLP result** [Fischer, Lynch and Paterson 1985]: in a fully *asynchronous* system, where message delays have no upper bound, no deterministic algorithm can guarantee consensus if even one process may crash. The reason is exactly Dana's silent phone: the algorithm can never distinguish "crashed" from "slow," and an adversarial schedule can keep it undecided forever.

Practical algorithms **never compromise safety** under any timing, and guarantee **termination only when the network behaves** for long enough, a model called **partial synchrony** [Dwork, Lynch and Stockmeyer 1988]. Paxos and Raft use timeouts to suspect failures; a wrong suspicion costs time, never correctness.

> KEY CONCEPT
>
> **Key insight — Safety from quorums, liveness from timers.** In Paxos, Raft and ZAB, the rules preventing two different decisions depend only on counting votes from overlapping majorities; timeouts only decide *when to try again*. A badly tuned timeout makes these systems slow, never inconsistent. Designs that use clocks for safety (leases, §26.11) need separate scrutiny.

The failure model matters. Paxos and Raft assume **crash-recovery** faults (§24.6): nodes stop, may restart with their durable state intact, and never lie. Tolerating **Byzantine** nodes that send arbitrary or malicious messages needs different algorithms and $3f + 1$ nodes; that is the subject of Chapter 45.

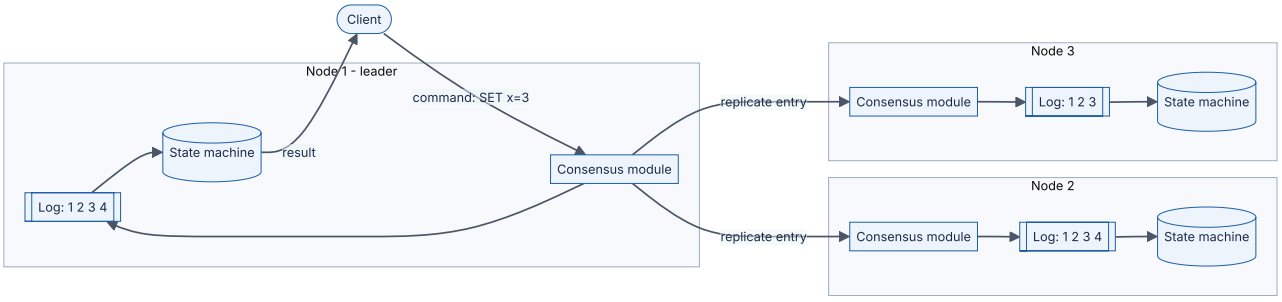
26.3.2 Replicated state machines

DEFINITION

Definition — Replicated state machine (RSM). A service implemented as a deterministic state machine that is copied onto several nodes. Each node applies the same sequence of commands, taken from a replicated **log**, in the same order, so every node passes through the same sequence of states and produces the same outputs [Schneider 1990].

Single-value consensus decides one thing. A database needs to decide millions of things in order. The **replicated state machine** approach bridges the gap: run one instance of consensus per log position (slot 1, slot 2, …). Slot *i* decides "the *i*-th command." Because each replica is deterministic and applies the same commands in the same order, the replicas stay identical without ever comparing their states.

Figure 26.1 — A replicated state machine built on a consensus log.



Reading the diagram. The client sends a command to the consensus module on the leader (Node 1). The module appends the command to its durable log (subroutine shape) and replicates it, over RPC, to the modules on the other nodes, which append it to their own logs. When a majority of logs contain the entry, it is **committed**; each node then feeds committed entries, in order, to its state machine (cylinder), and the leader returns the result. Write-path arrows are synchronous: the client waits until a majority has stored the entry. Node 3 is one entry behind, which is allowed, because a majority (Nodes 1 and 2) holds entry 4. Storage: each node owns its log and state; nothing is shared. Failure points: if Node 1 crashes, Nodes 2 and 3 elect a new leader whose log contains every committed entry. Scaling: adding nodes improves fault tolerance but not write throughput, because every node stores every entry.

Two consequences follow. The state machine must be **deterministic** (no local clock, random numbers or unordered iteration inside `apply`; the leader writes such values into the command). And the log is the source of truth; state is a cache of "the log applied so far," which is why snapshots (§26.7.8) can replace the log prefix.

COMMON MISTAKE

Misconception — "Consensus makes the system faster or more scalable." Consensus makes a service *fault-tolerant*, not fast. Every write waits for a majority round trip and a disk flush, and every node does every write. A 5-node etcd cluster has lower write throughput than a single node. Systems that need scale partition the data into many independent consensus groups (CockroachDB ranges, TiKV regions, Spanner splits), each small (§14.6, §28.10).

26.4 Quorums

26.4.1 Majority quorums and the intersection property

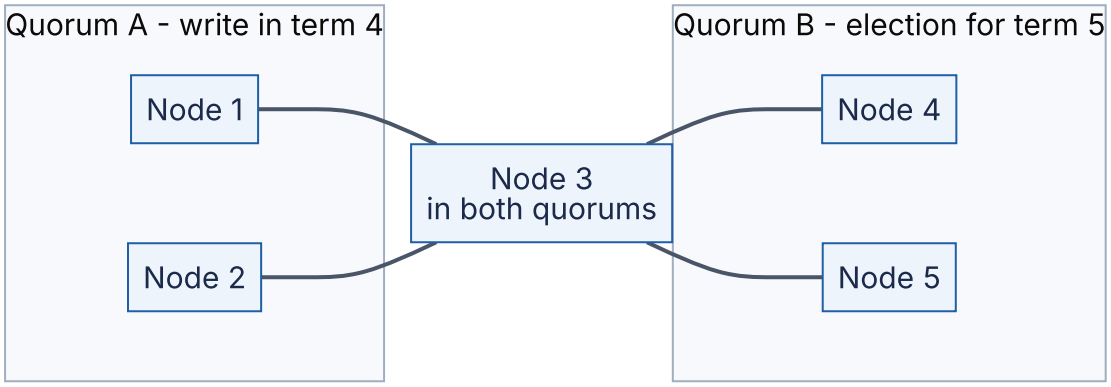
DEFINITION

Definition — Quorum. A set of nodes whose agreement is sufficient for an operation to take effect. A **majority quorum** in a cluster of N voting nodes is any set of more than $N/2$ nodes. The essential **intersection property**: any two majority quorums share at least one node.

First-principles explanation

Think of a committee of five where a decision needs three signatures. Two rival decisions would need six signatures from five members, so someone signed both. If no member signs two conflicting decisions, conflicts are impossible. The overlapping member is the system's memory: whoever comes later meets at least one node that saw what came before.

Figure 26.2 — Two majority quorums in a five-node cluster always intersect.



Reading the diagram. Quorum A is {1, 2, 3}, the nodes that stored a write in term 4. Quorum B is {3, 4, 5}, the nodes that voted in a later election. Links show membership

only; no data flows. Both quorums have three of five members, so they share a node, here Node 3. Node 3 carries the term-4 write into the term-5 election: Raft's voting rule lets it refuse any candidate whose log lacks that write (§26.7.6). The failure point the figure guards against is the **minority partition**: {4, 5} alone cannot form a quorum, so it can neither elect a leader nor commit writes. Scaling the cluster changes the arithmetic but not the principle.

Mathematical foundations

FORMULA

Majority quorum size and fault tolerance

$$q = \lfloor \frac{N}{2} \rfloor + 1 \qquad f = N - q = \lfloor \frac{N-1}{2} \rfloor \qquad \Leftrightarrow \qquad N = 2f + 1$$

Symbol	Meaning	Units
N	Number of voting nodes	nodes
q	Majority quorum size	nodes
f	Crash failures tolerated while still able to form a quorum	nodes

WORKED EXAMPLE

Worked example — 3, 4, 5 and 7 nodes.

1. $N = 3$: $q = \lfloor 1.5 \rfloor + 1 = 2$; $f = 3 - 2 = 1$.
2. $N = 4$: $q = 2 + 1 = 3$; $f = 4 - 3 = 1$.
3. $N = 5$: $q = 2 + 1 = 3$; $f = 5 - 3 = 2$.
4. $N = 7$: $q = 3 + 1 = 4$; $f = 7 - 4 = 3$.

Interpretation. The fourth node buys nothing: a 4-node cluster tolerates one failure, like a 3-node cluster, but needs three acknowledgments instead of two and has one more machine that can fail. **Engineering implication.** Run an odd number of voters: 3 for most services, 5 when you want to survive one failure *during* planned maintenance of another, 7 rarely. Add read capacity with non-voting members (ZooKeeper observers, etcd learners) rather than voters.

Fault tolerance is not the same as availability. If each node is independently available with probability a, the cluster is available when at least q nodes are up.

FORMULA

Availability of a majority-quorum cluster (independent failures)

$$A_{\text{cluster}} = \sum_{k=q}^{N} \binom{N}{k} a^{k} (1-a)^{N-k}$$

Symbol	Meaning	Units
A_{cluster}	Probability that a quorum of nodes is up	dimensionless
a	Availability of one node	dimensionless
N, q	Cluster size and quorum size	nodes
$\binom{N}{k}$	Number of ways to choose which k nodes are up	count

WORKED EXAMPLE

Worked example — nodes that are each 99% available.

1. $N = 3$, $q = 2$:
   $A = a^3 + 3a^2(1-a) = 0.970299 + 3 \times 0.9801 \times 0.01 = 0.970299 + 0.029403 = 0.999702$.
   Unavailability 2.98×10^{-4}, about 157 minutes per year.
2. $N = 5$, $q = 3$:
   $A = 0.99^5 + 5 \times 0.99^4 \times 0.01 + 10 \times 0.99^3 \times 0.01^2 = 0.950990 + 0.048030 + 0.000970 = 0.999990$.
   About 5.2 minutes per year.
3. $N = 7$, $q = 4$: $A \approx 0.99999966$, about 0.18 minutes (11 seconds) per year.
4. $N = 4$, $q = 3$: $A = 0.99^4 + 4 \times 0.99^3 \times 0.01 = 0.960596 + 0.038812 = 0.999408$, worse than $N = 3$.

Interpretation. Each step from 3 to 5 to 7 multiplies unavailability by roughly 0.03. **Engineering implication.** These numbers assume independent failures; a shared switch, zone outage or bad configuration push breaks that. Place voters in distinct failure domains, or the arithmetic is fiction.

Table 26.1 — Majority quorums at a glance.

Voters N	Quorum q	Failures tolerated f	Unavailability at $a = 0.99$	Typical use
1	1	0	1.0×10^{-2}	Development only
3	2	1	3.0×10^{-4}	Default for etcd, ZooKeeper, Consul
4	3	1	5.9×10^{-4}	Avoid: worse than 3
5	3	2	9.9×10^{-6}	Critical control planes, Chubby cells
7	4	3	3.4×10^{-7}	Rare; write latency and load grow

26.4.2 The latency trade-off

Larger clusters are more available but slower to commit, because the leader must wait for more acknowledgments. The leader waits only for the fastest $q - 1$ followers (it counts itself), so commit latency is an **order statistic** of follower round-trip times.

FORMULA

Quorum commit latency

$$L_{\text{commit}} \approx t_{\text{fsync}} + \text{RTT}_{(q-1)}$$

Symbol	Meaning	Units
L_{commit}	Time from the leader receiving a write to the entry being committed	ms
t_{fsync}	Time to flush the entry to durable storage (leader and followers flush in parallel)	ms
$\text{RTT}_{(k)}$	The k-th smallest round-trip time from the leader to its followers, including the followers' flush	ms
q	Quorum size	nodes

WORKED EXAMPLE

Worked example — a cluster spread across regions. The leader is in Virginia. Candidate replica sites have round-trip times of 12 ms (Ohio), 25 ms (Montreal), 70 ms (Oregon), 140 ms (Frankfurt), 150 ms (London) and 210 ms (Tokyo). Assume $t_{\text{fsync}} = 1$ ms.

1. $N = 3$ (Virginia, Ohio, Montreal): $q - 1 = 1$ follower needed; fastest RTT is 12 ms; $L \approx 1 + 12 = 13$ ms.
2. $N = 5$ (add Oregon, Frankfurt): $q - 1 = 2$; second-fastest is 25 ms; $L \approx 26$ ms.
3. $N = 7$ (add London, Tokyo): $q - 1 = 3$; third-fastest is 70 ms; $L \approx 71$ ms.

Interpretation. Going from 3 to 7 replicas multiplies commit latency by about 5.5, because the quorum must now reach across the continent. **Engineering implication.** Choose voter placement as carefully as voter count, for example 5 voters in three nearby regions (2 + 2 + 1), and place the leader where $\text{RTT}_{(q-1)}$ is smallest.

26.4.3 Flexible quorums

A majority is sufficient for intersection, but it is not *necessary*. Howard, Malkhi and Spiegelman observed that Paxos uses quorums in two different phases: **phase 1** (leader election, “who is in charge and what might already be decided?”) and **phase 2** (replication, “store this value”). Safety only requires that *every phase-1 quorum intersects every phase-2 quorum*; two phase-2 quorums need not intersect, because only one leader issues phase-2 requests for a given proposal number [Howard, Malkhi and Spiegelman 2016].

FORMULA

Flexible Paxos quorum condition

$$|Q_1| + |Q_2| > N$$

Symbol	Meaning	Units
$\lvert Q_1 \rvert$	Size of a leader-election (phase-1) quorum	nodes
$\lvert Q_2 \rvert$	Size of a replication (phase-2) quorum	nodes
N	Number of acceptors	nodes

WORKED EXAMPLE

Worked example — 7 acceptors.

1. Majority quorums: $|Q_1| = |Q_2| = 4$; $4 + 4 = 8 > 7$. Each write waits for 3 followers; elections and replication each tolerate 3 failures.
2. Flexible choice: $|Q_2| = 3$, so $|Q_1| \geq 7 - 3 + 1 = 5$. Check: $3 + 5 = 8 > 7$.
3. With a stable leader, each write now waits for only 2 followers (the second-fastest RTT instead of the third), and replication continues while the leader and any 2 other nodes are up, tolerating 4 failures among the followers.
4. A leader change needs 5 of 7 nodes, so it tolerates only 2 failures.

Interpretation. Flexible quorums move fault tolerance from the rare path (elections) to the common path (writes). **Engineering implication.** Useful when leader changes are rare and write latency dominates; risky when failures are correlated (a zone loss kills the leader *and* several nodes), so most production systems keep majorities.

26.5 Leader election

26.5.1 Election algorithms

DEFINITION

Definition — Leader election. A protocol by which the nodes of a group choose one node, the **leader**, to coordinate some activity (ordering writes, running a scheduler, owning a partition), and choose a replacement when it fails. The goal is *at most one* leader at a time (safety) and *eventually some* leader (liveness).

Why does this exist?

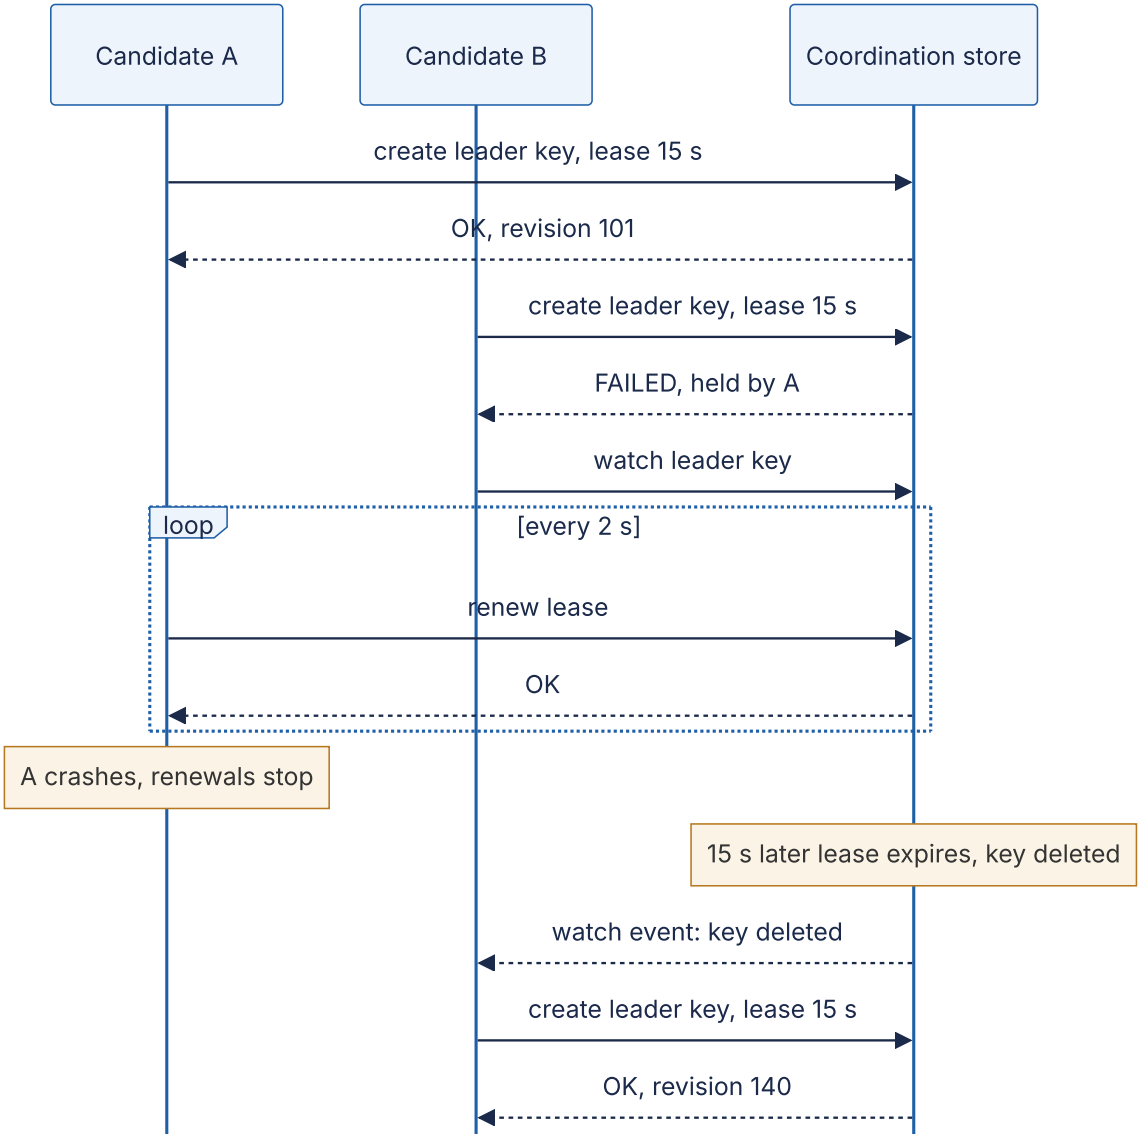
Most replicated systems are far simpler with one coordinator. A single leader can order writes without conflicts, assign work without double assignment, and answer "what is the latest value?" from its own memory. The cost is that the leader is a single point of failure, so the group needs a way to replace it quickly and without ever having two.

How it works internally: three classic approaches

1. **Bully algorithm** [Garcia-Molina 1982]. A node that suspects the leader has failed sends `ELECTION` to all higher-ID nodes. If none answers within a timeout, it announces itself with `COORDINATOR`; otherwise a higher node takes over. The highest-ID live node wins. Worst case $O(n^2)$ messages; it assumes reliable failure detection, which real networks do not provide.

2. **Ring algorithm** [Chang and Roberts 1979]. IDs travel clockwise around a logical ring; each node forwards only IDs larger than its own. A node that receives its own ID back is the maximum and announces itself. Average $O(n \log n)$ messages, worst case $O(n^2)$; a single broken link stalls it.
3. **Lease-based election on a consensus store.** Candidates race to create or acquire a key (say `/services/scheduler/leader`) in ZooKeeper, etcd or Consul. The store, itself replicated by consensus, lets exactly one candidate succeed and attaches a **lease** (a time-limited grant, §26.11). The winner renews the lease periodically; if it stops, the lease expires and another candidate wins. This is how almost every production system elects leaders today, including Kubernetes controllers (§26.9).

Figure 26.3 — Lease-based leader election through a coordination service.



Reading the diagram. Both candidates call the coordination store with synchronous RPCs (solid: request; dashed: response). The store is a consensus-backed cluster whose

atomic “create if absent” guarantees a single winner. A’s lease is renewed every 2 s; when A crashes, nothing deletes the key until the 15 s lease expires. B learns of the expiry through a **watch** (an asynchronous notification it registered earlier) rather than by polling. The revision numbers (101, 140) increase with every write and can serve as fencing tokens (§26.13). Failure points: if A is merely *paused* rather than crashed, it may still believe it is leader after its lease expired; the store cannot reach into A to stop it. Scaling: one store cluster can host thousands of election keys for different services.

26.5.2 Why election alone does not give safety

Every algorithm above produces a node that *believes* it leads; none can make a deposed leader *stop believing it*. A partitioned, paused or slow old leader overlaps with its successor, and if both act on shared state you have split brain (§26.12).

Safe systems therefore add one of two mechanisms on top of election:

- **Every action is itself checked by a quorum.** In Raft and Paxos, a leader cannot commit anything without a majority acknowledging it *in its current term*. A deposed leader’s requests carry an old term, and any majority contains at least one node that has seen the newer term and rejects them. The old leader may *believe* it leads, but it cannot *do* anything.
- **Every action carries an epoch the resource can check.** When the protected resource is outside the consensus group (a database, a file in object storage), the leader must present a monotonically increasing token, and the resource rejects stale ones. This is fencing (§26.13).

> COMMON MISTAKE
>
> **Misconception — “Once we have leader election, only one node acts as leader.”** Election guarantees at most one leader *per term or lease epoch* as seen by the election service. It says nothing about what an old leader does with its stale belief. Without quorum-checked actions or fencing, two nodes will eventually act as leader at the same time.

26.6 Paxos

Leslie Lamport described Paxos as the legislature of a fictional Greek island whose part-time legislators wander in and out of the chamber [Lamport 1998]. The paper was written around 1990 and published in 1998; its allegory made it famously hard to read, and Lamport later restated the algorithm, beginning: “The Paxos algorithm, when presented in plain English, is very simple” [Lamport 2001]. This section follows that plain-English version.

26.6.1 Single-decree Paxos

DEFINITION

Definition — Single-decree (basic) Paxos. A consensus algorithm in which **proposers** suggest values, **acceptors** vote on them and **learners** find out the decided value. A value is **chosen** when a majority of acceptors has accepted it with the same proposal number. Paxos guarantees safety under any message delays, loss or reordering, and makes progress whenever one proposer can run both phases without interference from another.

First-principles explanation

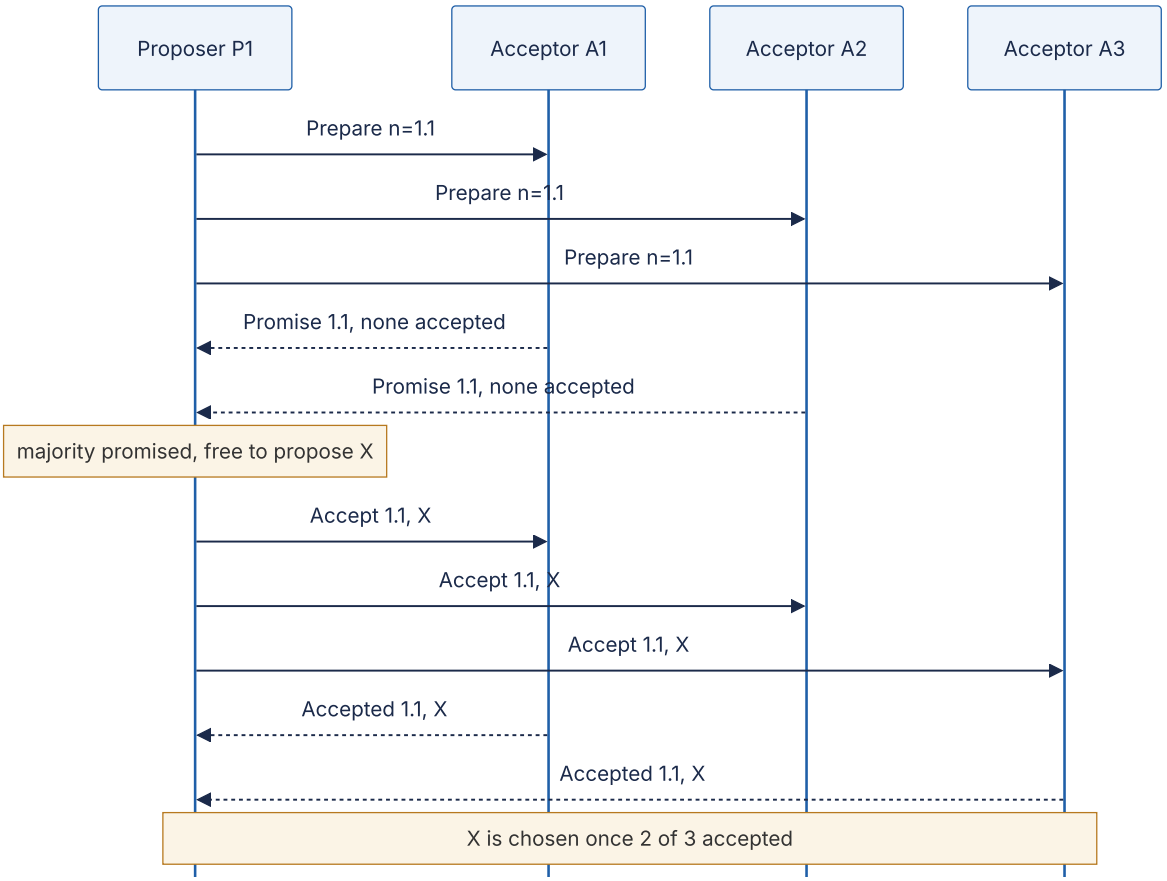
Imagine booking a room through five receptionists, each with a paper diary. A rival may be asking a different three at the same moment, so you first present a *ticket number* higher than any they have seen ("promise to ignore lower tickets") and ask whether they have already written a booking. If any has, you must *finish that booking* instead of yours. Only after a majority promises do you ask them to write the booking under your ticket. The first step discovers and protects the past; the second decides.

How it works internally

Each acceptor stores, durably: `promised_n` (highest proposal number it promised) and `(accepted_n, accepted_v)` (the last proposal it accepted, if any). Proposal numbers must be unique and totally ordered; the usual construction is a pair `(round, proposer_id)` compared lexicographically, so proposers never collide.

1. **Phase 1a — Prepare.** A proposer picks a proposal number n higher than any it has used and sends `Prepare(n)` to the acceptors.
2. **Phase 1b — Promise.** An acceptor that receives `Prepare(n)` with $n >$ `promised_n` sets `promised_n = n`, writes it to disk, and replies `Promise(n, accepted_n, accepted_v)`. Otherwise it ignores the request or replies with a rejection containing `promised_n` (a useful hint).
3. **Value selection.** If the proposer receives promises from a majority, it looks at the accepted proposals they reported. If any acceptor reported one, the proposer **must** propose the value v of the highest-numbered accepted proposal. Only if none reported anything may it propose its own value.
4. **Phase 2a — Accept.** The proposer sends `Accept(n, v)` to the acceptors.
5. **Phase 2b — Accepted.** An acceptor that receives `Accept(n, v)` with $n \geq$ `promised_n` records `(accepted_n, accepted_v) = (n, v)` durably and replies `Accepted(n, v)` to the proposer and the learners. Otherwise it rejects.
6. **Learning.** When a learner sees `Accepted(n, v)` from a majority for the same n, the value v is chosen.

Figure 26.4 — Single-decree Paxos without contention.



Reading the diagram. P1 uses proposal number 1.1 (round 1, proposer 1). All arrows are point-to-point RPCs; each acceptor must persist its promise or acceptance before replying, so every reply implies a disk flush. Two promises out of three form a majority, so P1 does not wait for A3's promise. Because no promise reported an accepted value, P1 may propose its own value X. Two `Accepted` replies (from A1 and A3) form a majority, and X is chosen at that instant, even before anyone knows it. Failure points: one acceptor can fail without blocking progress; if the proposer fails, a later proposer's phase 1 discovers X. Cost: two round trips and two durable writes per value.

Why the value-adoption rule makes Paxos safe

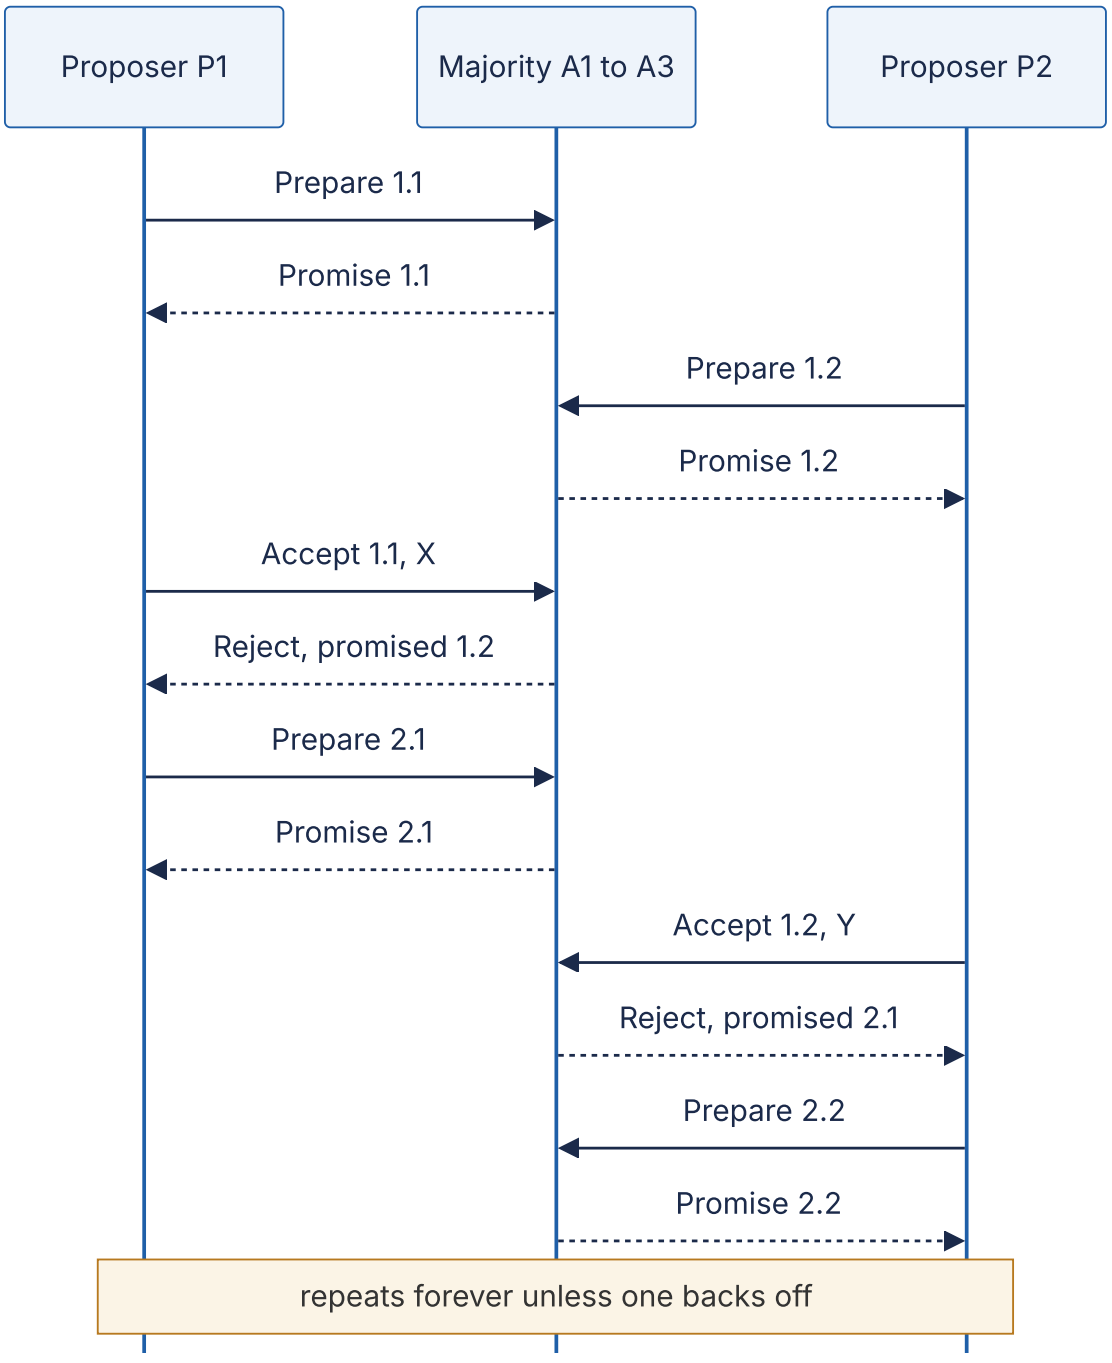
Suppose X was chosen with proposal 1.1, meaning a majority accepted it. Any later proposer with number $n > 1.1$ must collect promises from a majority, and that majority intersects the accepting majority (§26.4.1). So at least one promise reports "I accepted (1.1, X)." The adoption rule then forces the new proposer to propose X again. By induction on proposal numbers, every proposal after X was chosen carries X. Lamport's invariant: *if a value v is chosen with number n, every higher-numbered proposal issued has value v* [Lamport 2001].

Note that a value can be chosen without its proposer knowing (replies lost), and an acceptor may hold an accepted value that is never chosen; neither breaks safety.

Dueling proposers

Paxos is safe but not guaranteed to terminate, and the classic way it stalls is two proposers repeatedly pre-empting each other.

Figure 26.5 — Dueling proposers: safe but not live.



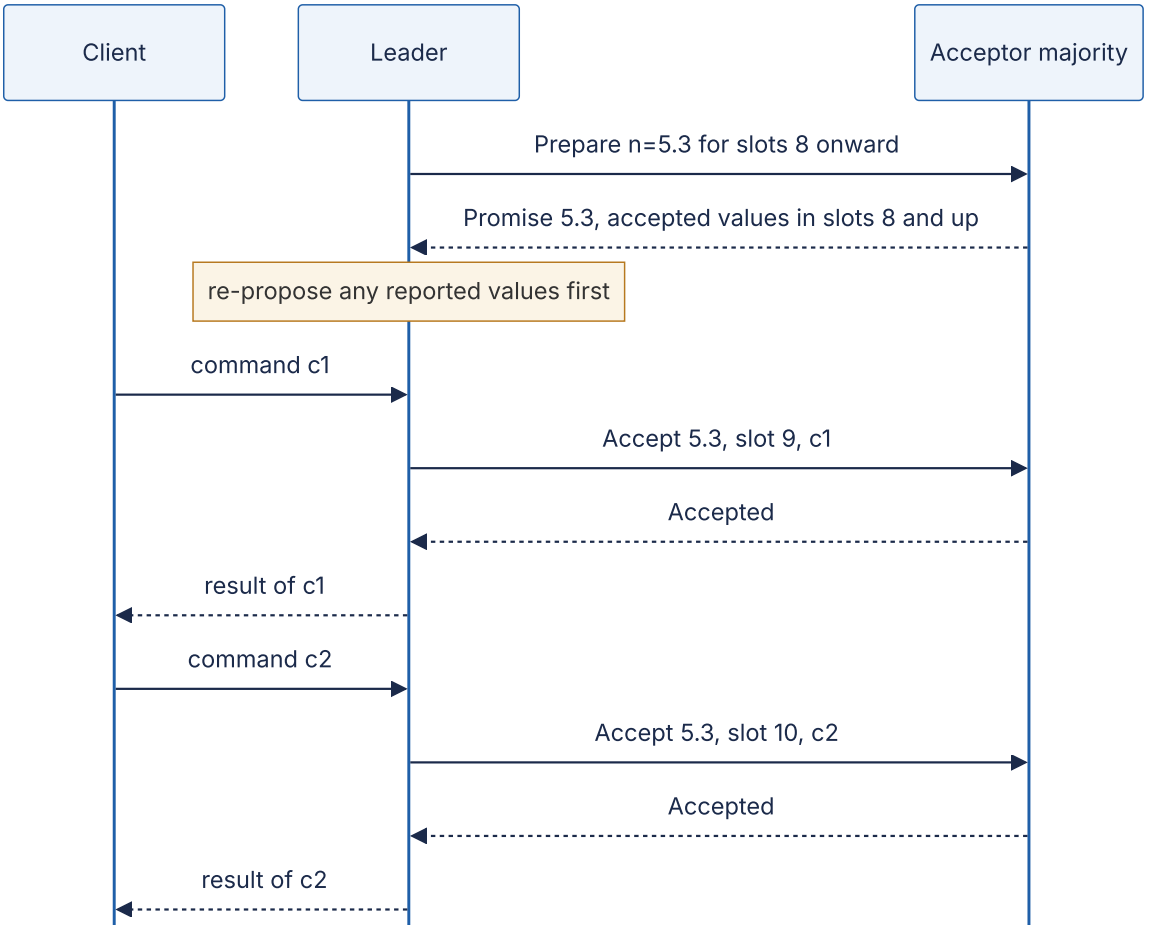
Reading the diagram. The acceptors are drawn as one participant; each arrow stands for messages to and replies from a majority. Before P1's accept arrives, P2's higher prepare (1.2) raises every promise, so P1's accept is rejected; P1's retry (2.1) then invalidates P2's accept, and so on. Nothing wrong is decided, but nothing is decided at all: the FLP adversarial schedule (§24.13) made concrete. The fixes are liveness mechanisms:

randomized back-off and, above all, a single **distinguished proposer** (leader), which Multi-Paxos and Raft provide.

26.6.2 Multi-Paxos

Running two round trips per log slot is expensive. **Multi-Paxos** observes that phase 1 does not depend on the value, so a stable leader can run phase 1 *once* for all future slots: `Prepare(n)` for "slot *i* and every slot after it." Each acceptor's promise covers all those slots and reports any values it accepted in them. From then on, each new command needs only phase 2: one round trip and one durable write, the same cost as Raft's AppendEntries.

Figure 26.6 — Multi-Paxos: phase 1 once, then one round trip per command.



Reading the diagram. The new leader (5.3) prepares every slot from 8 onward in one synchronous exchange with a majority. Promises report values already accepted there; slot 8 had one, so the leader re-proposes it first. Each client command then costs one `Accept` / `Accepted` round trip plus a durable write per acceptor, and the leader applies commands in slot order. Failure point: a successor leader must fill **gaps** (slots never chosen) with no-ops. Scaling: batch commands per slot and pipeline slots.

Paxos in production

Google's **Paxos Made Live** is the best antidote to the idea that knowing the algorithm is enough [Chandra, Griesemer and Redstone 2007]. Building Chubby's replicated log needed additions the papers did not specify: master leases for local reads, epoch numbers to detect leader changes mid-operation, disk-corruption handling (a replica that lost its state must not vote as if it remembered its promises), snapshots, membership changes and extensive randomized testing. The authors conclude that there are significant gaps between the algorithm's description and a real system's needs.

> INDUSTRY EXAMPLE
>
> **Google Chubby's replicated log.** Problem: a lock service for thousands of machines that must survive replica failures. Architecture: five replicas per cell running Multi-Paxos with a leader ("master") holding a lease; the replicated log stores the lock-service database. Why chosen: safety without timing assumptions. Trade-off: most engineering effort went outside the core algorithm. *Evidence: Primary* — [Chandra, Griesemer and Redstone 2007]; [Burrows 2006]

Table 26.2 — Paxos family vocabulary mapped to Raft.

Concept	Paxos / Multi-Paxos	Raft	ZAB
Leader identity epoch	Proposal number (round, id)	Term	Epoch (high 32 bits of zxid)
Phase 1	Prepare / Promise	RequestVote (plus log check)	Discovery and synchronization
Phase 2	Accept / Accepted	AppendEntries	Proposal / Ack / Commit
Log position	Slot (may have gaps)	Index (no gaps)	Counter (low 32 bits of zxid)
Who can become leader	Anyone; must learn and adopt prior values	Only a node with an up-to-date log	Node with the highest zxid, then synchronizes followers

26.7 Raft

Raft was designed by Diego Ongaro and John Ousterhout with **understandability** as its primary goal [Ongaro and Ousterhout 2014]. It matches Multi-Paxos in fault tolerance and performance, but splits consensus into leader election, log replication and safety, and removes freedoms Paxos allows, such as log gaps or a leader with a stale log. etcd, Consul, CockroachDB, TiKV, Vault's integrated storage and Kafka's KRaft (Chapter 31) all use Raft or close variants. Ongaro's thesis adds membership changes, compaction, client interaction and read optimizations [Ongaro 2014].

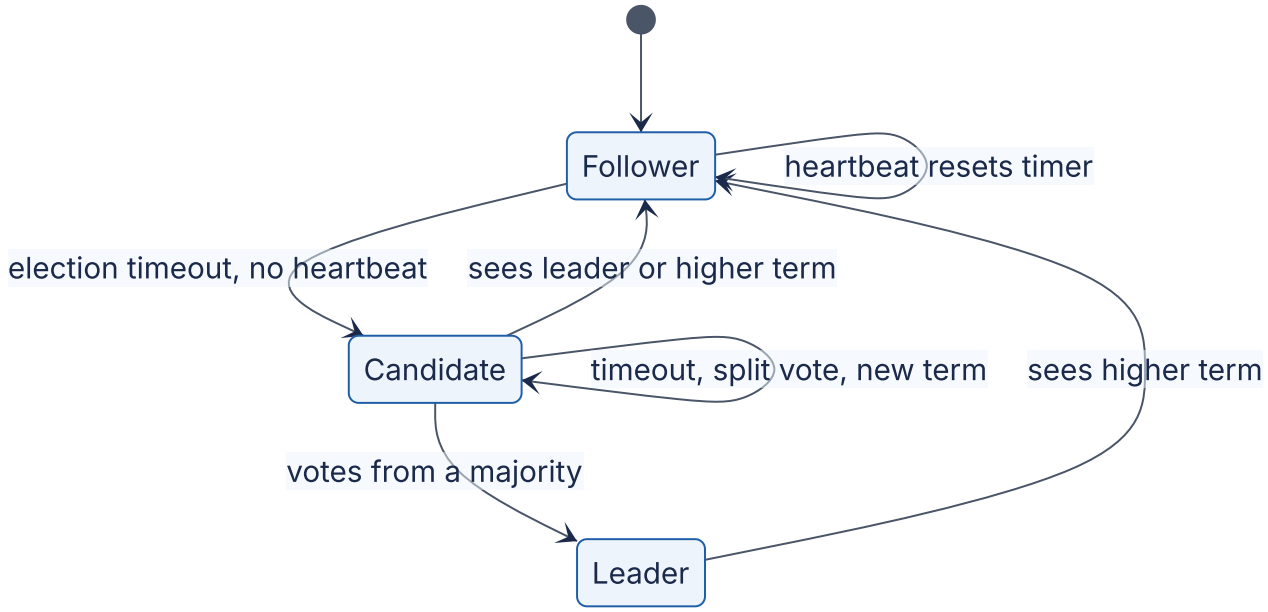
26.7.1 Terms, roles and state

DEFINITION

Definition — Raft term. A logical clock that divides time into consecutive, numbered periods. Each term begins with an election; if a candidate wins, it is the **leader** for the rest of the term, and there is at most one leader per term. Every RPC carries the sender's term; a node that sees a higher term immediately adopts it and becomes a follower; a request with a lower term is rejected.

Every node is in one of three roles: **follower** (passive; answers RPCs), **candidate** (seeking votes) or **leader** (handles all client writes and replicates the log). Each node persists `currentTerm`, `votedFor` (the candidate it voted for in this term, if any) and its log, and must flush them to disk *before* replying to any RPC that changed them. Volatile state includes `commitIndex` (highest entry known committed) and `lastApplied`; leaders also keep `nextIndex[]` and `matchIndex[]` per follower.

Figure 26.7 — Raft role transitions.



Reading the diagram. Every node starts as a follower. A follower that hears no leader for its randomized election timeout increments its term and becomes a candidate. A candidate becomes leader with a majority of votes, reverts to follower on hearing a legitimate leader or a higher term, and starts a new term if its timeout expires first (typically after a split vote). A leader steps down only on seeing a higher term. All transitions are local decisions from messages and timers. Failure point: a leader that is partitioned away stays leader in its own view, but cannot commit anything, and steps down as soon as it hears the higher term.

26.7.2 Leader election

1. A follower's election timer expires. It increments `currentTerm`, votes for itself, persists both, and sends `RequestVote(term, candidateId, lastLogIndex, lastLogTerm)` to all peers.
2. A node grants its vote if the candidate's term is at least its own, it has not voted for someone else in this term, and the **candidate's log is at least as up-to-date** as its own: the candidate's last entry has a higher term, or the same term and an index at least as large. Each node votes for at most one candidate per term, first come, first served.
3. A candidate with votes from a majority becomes leader and immediately sends empty `AppendEntries` heartbeats to assert authority.
4. If two candidates split the vote, both time out and retry in a higher term. Raft makes this rare by drawing each timeout at random, for example uniformly from 150–300 ms, the range the paper recommends [Ongaro and Ousterhout 2014].

Raft's timing requirement is broadcastTime ≪ electionTimeout ≪ MTBF: heartbeats must arrive well within the timeout, and the timeout must be far shorter than the mean time between failures.

FORMULA

Raft election timing and expected failover time

$$h \approx \mathrm{RTT}_{\mathrm{typ}}, \qquad T_{\min} \geq 10 \times \mathrm{RTT}_{\mathrm{typ}}, \qquad T_{\mathrm{failover}} \approx T_{\min} + \frac{W}{n+1} - \frac{h}{2} + \mathrm{RTT} + t_{\mathrm{fsync}}$$

Symbol	Meaning	Units
h	Heartbeat interval	ms
$\mathrm{RTT}_{\mathrm{typ}}$	Typical round-trip time between members	ms
$T_{\min}, W$	Election timeout is drawn uniformly from $[T_{\min}, T_{\min} + W]$	ms
n	Followers still alive after the leader fails	nodes
T_{failover}	Expected time from leader crash to a new leader	ms

The heartbeat and 10× rules are the etcd tuning guidance [etcd Docs: Tuning]. The failover estimate adds three pieces: the earliest of n uniform timers fires on average $W/(n+1)$ after $T_{\min}$; timers were last reset by a heartbeat on average $h/2$ before the crash; and the winner then needs one vote round trip with a disk flush.

WORKED EXAMPLE

Worked example — two deployments.

1. *Single data center*, RTT about 0.5 ms, Raft-paper settings: $h = 50$ ms, $T_{\min} = 150$ ms, $W = 150$ ms, 5 nodes so $n = 4$ survivors.
   $T_{\text{failover}} \approx 150 + 150/5 - 50/2 + 0.5 + 1 = 150 + 30 - 25 + 1.5 = 156.5$ ms.
2. *Cross-region*, RTT 70 ms: $h = 100$ ms (etcd's default), and $T_{\min} \geq 10 \times 70 = 700$ ms, so keep etcd's default of 1,000 ms; etcd's Raft library randomizes over $[T, 2T)$, so $W = 1,000$ ms. $T_{\text{failover}} \approx 1,000 + 1,000/5 - 50 + 70 + 1 = 1,221$ ms.

Interpretation. The simulator in §26.7.7, which uses the first deployment's settings, measures a median failover of 155 ms over 200 seeded runs, matching the estimate. **Engineering implication.** Failover time is dominated by the election timeout, which must grow with network RTT. Lowering it below about 10 RTTs trades faster failover for spurious elections whenever a p99.9 network hiccup or GC pause delays heartbeats.

Randomization does not eliminate competing candidates; it makes them unlikely.

FORMULA

Probability that a second candidate starts before the first's votes arrive

$$P_{\text{contend}} = 1 - \left(1 - \frac{\delta}{W}\right)^{n}$$

Symbol	Meaning	Units
δ	Time for the first candidate's RequestVote to reach the others (one-way delay plus flush)	ms
W	Width of the randomized timeout range	ms
n	Number of followers whose timers are running	nodes
P_{contend}	Probability that the gap between the first two timeouts is below δ	dimensionless

WORKED EXAMPLE

Worked example — choosing the randomization width. With $n = 4$ and $\delta = 10$ ms:

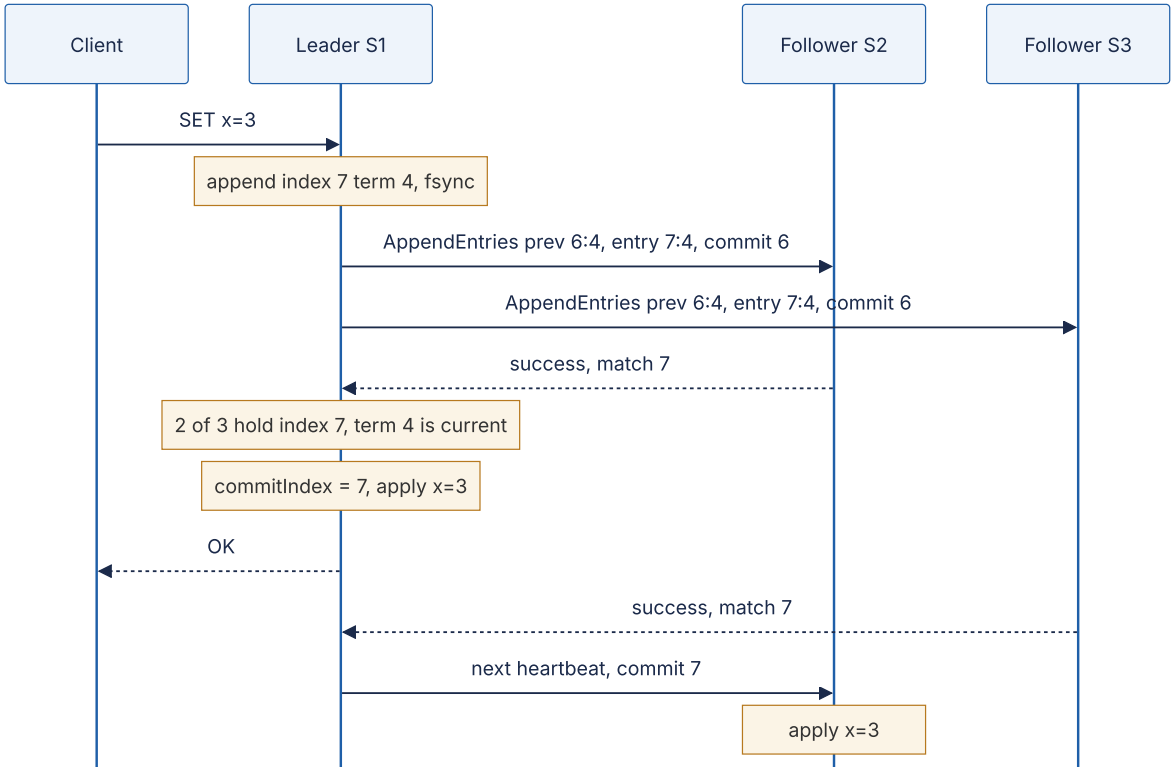
1. $W = 150$ ms: $1 - (1 - 10/150)^4 = 1 - 0.9333^4 = 1 - 0.7588 = 0.241$.
2. $W = 1,000$ ms: $1 - 0.99^4 = 1 - 0.9606 = 0.039$.
3. $W = 150$ ms but $\delta = 2$ ms (fast LAN, NVMe flush): $1 - 0.98667^4 = 0.052$.

Interpretation. This bounds split votes from above; contention does not always split the vote. **Engineering implication.** Keep W at least an order of magnitude above δ. A 200,000-trial Monte Carlo check of the first case gives 0.241, matching the formula.

26.7.3 Log replication

Once elected, the leader accepts client commands, appends each as a new log entry `(term, index, command)`, and replicates it with `AppendEntries(term, leaderId, prevLogIndex, prevLogTerm, entries[], leaderCommit)`. Heartbeats are simply AppendEntries with no entries.

Figure 26.8 — Replicating and committing one entry.



Reading the diagram. The client's write goes synchronously to the leader, which appends entry 7 (term 4) and flushes it. AppendEntries carries `prev 6:4`: "my entry before this one is index 6 with term 4"; a follower accepts only if its own log has that entry. As

soon as one follower plus the leader (a majority of three) hold the entry, the leader advances `commitIndex`, applies the command and answers the client; S3's slower reply is not needed. Followers learn the new commit index on the next AppendEntries (asynchronous to the client) and apply then. Each log is on its node's own disk. Failure points: if the leader crashes after committing but before replying, the client must retry, so commands should be idempotent or deduplicated by client ID and sequence number (§22.15). Scaling: leaders batch many commands per AppendEntries and pipeline requests without waiting for replies.

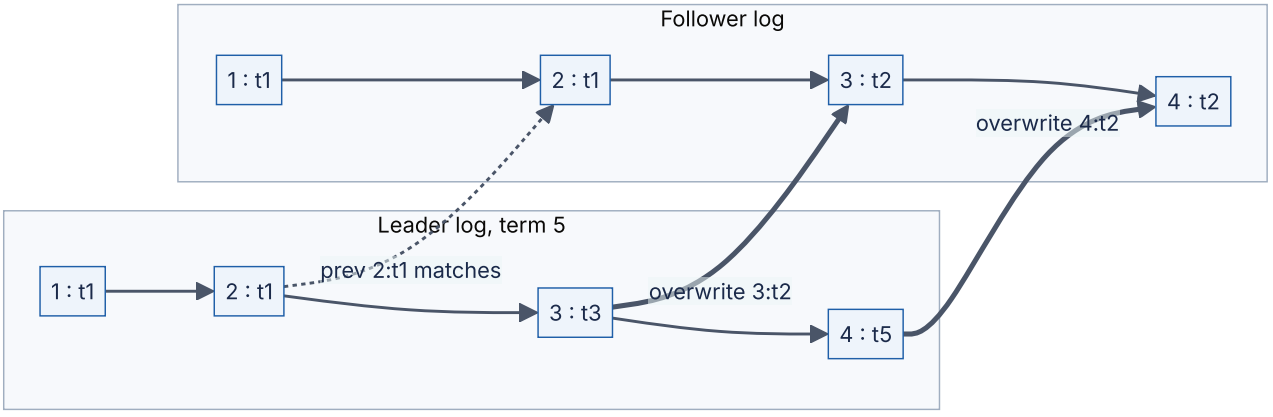
26.7.4 The log matching property

DEFINITION

Definition — Log matching property. If two logs contain an entry with the same index and term, then (1) the entries store the same command, and (2) the logs are identical in all preceding entries.

Part (1) holds because a leader creates at most one entry per index in its term and never changes it. Part (2) is enforced inductively by the **consistency check**: a follower accepts AppendEntries only if it has an entry matching `(prevLogIndex, prevLogTerm)`. When the check fails, the leader decrements `nextIndex` for that follower and retries until they find the last point of agreement; the follower then deletes everything after that point and appends the leader's entries. The leader never deletes or overwrites its own entries (**leader append-only**).

Figure 26.9 — Repairing a divergent follower log.



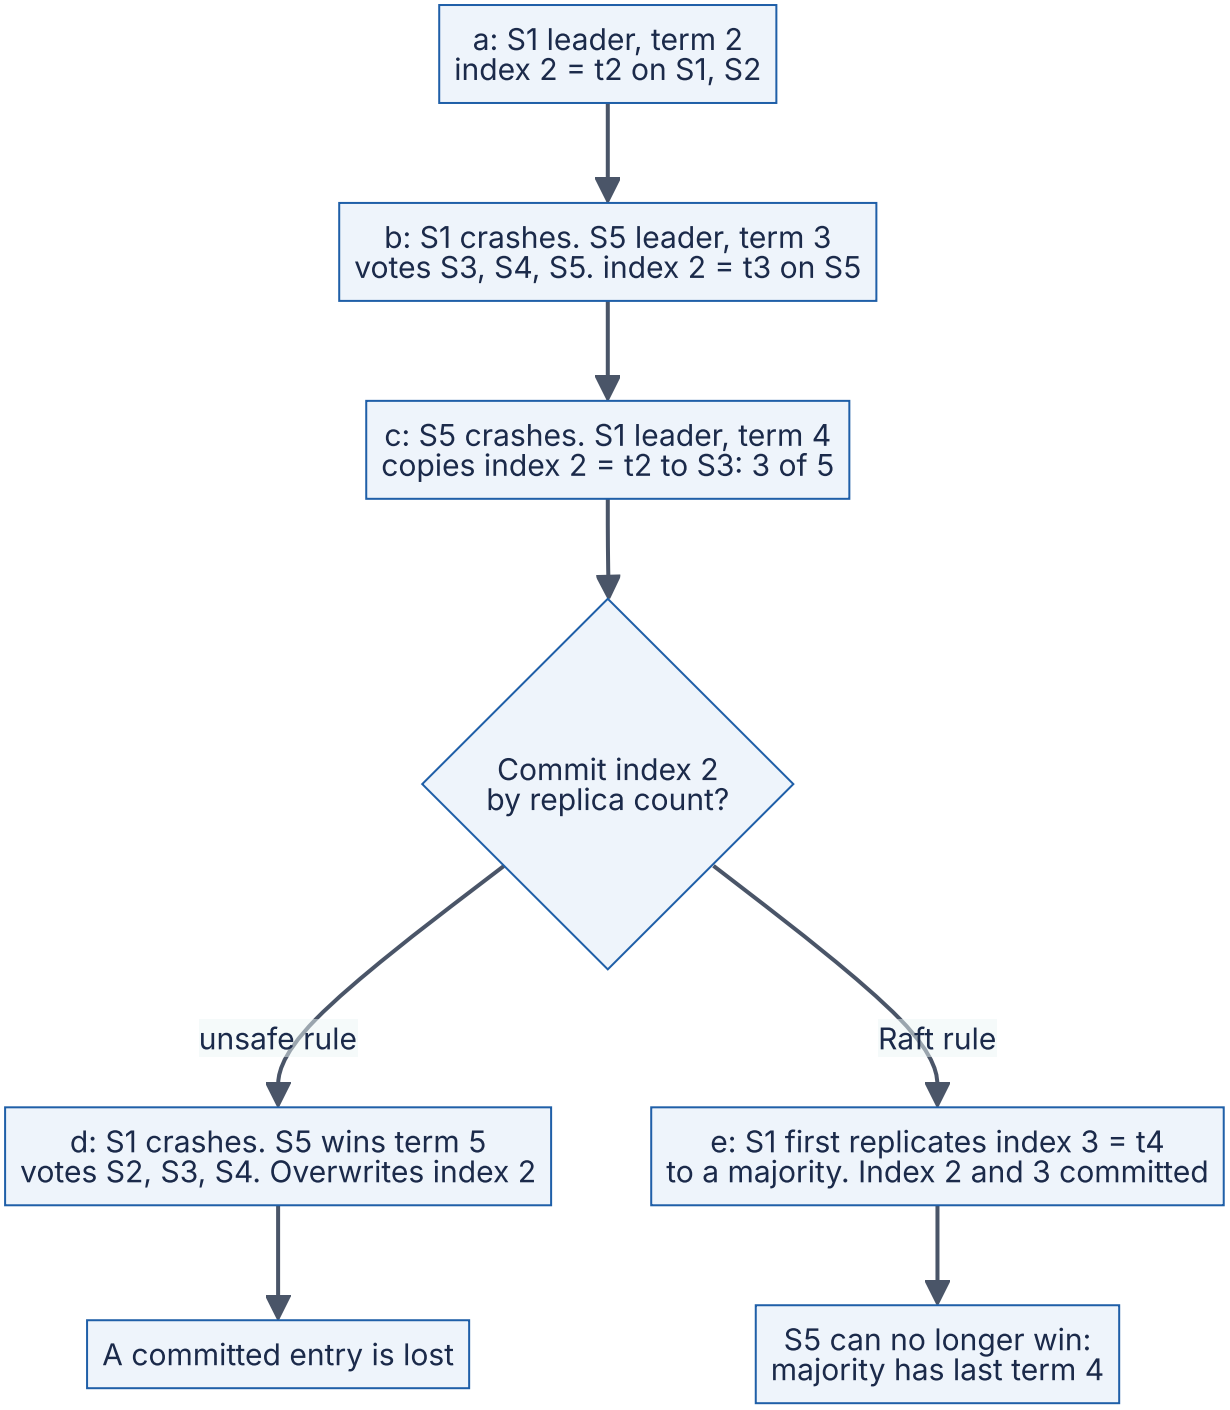
Reading the diagram. Each box is a log entry labeled `index : term`. The follower holds uncommitted entries 3 and 4 from a term-2 leader that crashed. The leader's AppendEntries with `prev 4:t5` fails, then `prev 3:t3` fails, then `prev 2:t1` succeeds (dotted arrow). The follower truncates after index 2 and takes the leader's entries 3 and 4 (thick arrows). Data flows only leader to follower. Failure point: backing off one entry per

round trip is slow for long-lagging followers, so implementations skip a whole conflicting term per round trip or send a snapshot (§26.7.8).

26.7.5 The commit rule and the “current term only” subtlety

A leader marks an entry committed when it is stored on a majority, **but only if the entry is from the leader’s current term**. Entries from earlier terms are never committed by counting replicas; they become committed *indirectly* when a later current-term entry after them commits, by the log matching property. This is the scenario in Figure 8 of the Raft paper.

Figure 26.10 — Why a leader must not commit old-term entries by counting replicas.



Reading the diagram. Read top to bottom. In (c), the term-2 entry at index 2 sits on a majority (S1, S2, S3), so a naive leader would call it committed. But S5's last entry has term 3, "more up-to-date" than term 2, so in (d) S5 wins votes from S2, S3 and S4 and overwrites index 2: the "committed" entry vanishes. Under Raft's rule (e), S1 first puts a term-4 entry on a majority; those nodes refuse to vote for S5, and index 2 commits safely as a prefix of index 3. Hence a new leader immediately appends a **no-op entry** in its term, as the simulator in §26.7.7 does.

26.7.6 Why Raft is safe

The core guarantee is **state machine safety**: if any node has applied a log entry at index i, no node ever applies a different entry at i. It follows from a chain of properties [Ongaro and Ousterhout 2014]:

1. **Election safety.** At most one leader per term, because each node votes once per term and two majorities intersect.
2. **Leader append-only** and **log matching** (§26.7.4).
3. **Leader completeness.** If an entry is committed in term T, it is present in the logs of all leaders of terms greater than T. Sketch: the entry is on a majority M_1; a later winner received votes from a majority M_2; some voter is in both; that voter only votes for a candidate whose log is at least as up-to-date as its own; with the current-term commit rule, “at least as up-to-date” implies the candidate’s log contains the entry.
4. Since every future leader contains every committed entry, and followers only take entries from leaders, nodes apply the same entry at each index.

The thesis includes a formal proof of the single-node algorithm, and the authors model-checked a TLA+ specification [Ongaro 2014].

26.7.7 A runnable Raft simulator

The program below implements Raft’s election and replication rules in a deterministic, tick-based simulation of five nodes. Messages take 2–8 ms, timeouts are drawn from 150–300 ms, heartbeats are sent every 50 ms (new entries ride on the next heartbeat), and a seeded random generator makes every run reproducible. It omits snapshots, membership changes and client sessions.

```
        """A simplified, deterministic Raft simulator: leader election + log replica-
tion.

        Time advances in 1 ms ticks. Messages take 2-8 ms. Nodes can crash and restart
        (persistent state survives a crash; volatile state does not). Not production
code:
        no snapshots, no membership changes, no client sessions.
        """
        import random

        HEARTBEAT_MS = 50
        ELECTION_MIN_MS, ELECTION_MAX_MS = 150, 300

        class Node:
            def __init__(self, nid, peers, rng):
                self.id, self.peers, self.rng = nid, peers, rng
                # Persistent state (survives crashes)
                self.term, self.voted_for, self.log = 0, None, []   # log entries:
(term, command)
                self.up = True
                self.reset_volatile(now=0)

            def reset_volatile(self, now):
                self.role, self.commit, self.votes = "follower", 0, set()
                self.next_idx, self.match_idx = {}, {}
                self.reset_election_timer(now)

            def reset_election_timer(self, now):
                self.deadline = now + self.rng.randint(ELECTION_MIN_MS, ELECTION_MAX_MS)

            def last_index(self):
                return len(self.log)

            def term_at(self, index):          # log indices are 1-based; index 0 has
term 0
                return self.log[index - 1][0] if index > 0 else 0

        class Cluster:
            def __init__(self, n=5, seed=7):
                self.rng = random.Random(seed)
                ids = list(range(1, n + 1))
                self.nodes = {i: Node(i, [p for p in ids if p != i], self.rng) for i in
ids}
                self.inbox, self.now = [], 0                       # (deliver_at, dst,
msg)

            def log_event(self, text):
                print(f"t={self.now:5d} ms  {text}")

            def send(self, src, dst, msg):
                msg["src"] = src
                self.inbox.append((self.now + self.rng.randint(2, 8), dst, msg))

state machine safety holds: True
200 seeded runs: safety violations=0, failover ms: median=155, p95=276, max=360
```

What to notice:

- **Persistent versus volatile state.** `term`, `voted_for` and `log` survive `crash()`; `reset_volatile` wipes role, commit index and leader bookkeeping, as a real restart would. n4 rejoins with term 1, adopts term 2 from the first message it sees, and is brought up to date by the consistency check.

- **The up-to-date check** is one tuple comparison, `(last_term, last_index) >= (...)`, which compares terms first and indices second.
- **The commit rule** in `advance_commit` requires both a majority and `term_at(idx) == n.term`; each new leader appends a `no-op` so earlier entries commit through it (index 4 commits indices 1–4 for n3).
- **Writes wait for the next heartbeat** (400 ms write, 426 ms commit), a simplification; real leaders send AppendEntries immediately and batch.
- **Failover statistics** (median 155 ms) match the formula in §26.7.2. Change `ELECTION_MIN_MS` or the message delays and rerun to see the trade-offs.

26.7.8 Snapshots and log compaction

A log that grows forever exhausts disk and makes restarts replay hours of history. Each node independently takes a **snapshot** of its state machine at some applied index, records the `lastIncludedIndex` and `lastIncludedTerm` (needed for the consistency check of the next entry), and discards the log prefix. When a follower is so far behind that the leader has already discarded the entries it needs, the leader sends **InstallSnapshot** chunks instead of AppendEntries. Snapshotting must not block the state machine for long: implementations use copy-on-write structures or the storage engine's own consistent snapshot (etcd snapshots its bbolt database; CockroachDB and TiKV ship RocksDB-family SST files). Snapshot frequency is a trade-off between disk space and the cost of each snapshot; etcd, for example, triggers one after a configurable number of applied entries.

26.7.9 Membership changes

Changing the voter set changes the quorum definition. Switching all nodes at once is unsafe: during the transition some nodes count old-configuration majorities and others new ones, and two disjoint majorities could elect two leaders in one term.

- **Joint consensus** (Raft paper). The leader first commits a configuration entry $C_{\text{old,new}}$; while it is in effect, every election and every commit needs a majority of C_{old} *and* a majority of C_{new}. Once $C_{\text{old,new}}$ is committed, the leader commits C_{new}. Any change, including replacing several nodes at once, is safe.
- **Single-server changes** (thesis). If you add or remove only *one* voter at a time, every majority of the old configuration intersects every majority of the new one, so no joint phase is needed. Each configuration takes effect as soon as it is appended (not committed), and only one change may be in progress. In 2015 Ongaro reported a bug in the original single-server description that could lose a committed entry when changes overlapped with leader changes; the fix is that a new leader must commit an entry in its own term (the same no-op as in §26.7.5) before starting a membership change.

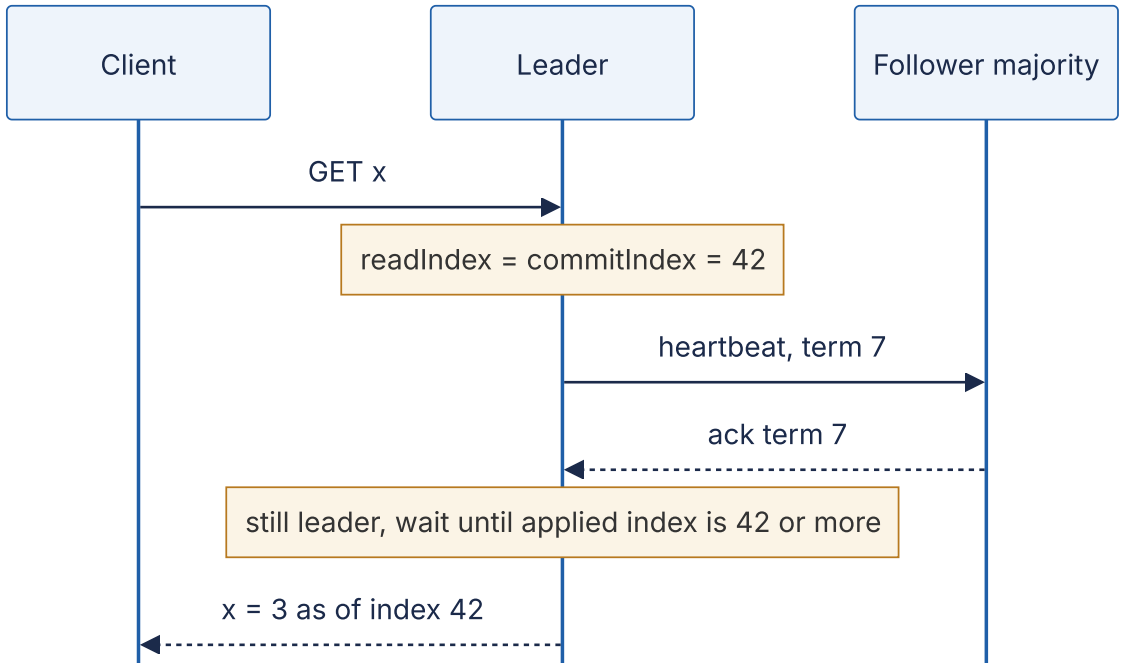
Production systems add **learners** (etcd) or observers (ZooKeeper): a new node catches up without affecting the quorum and is promoted when current. Otherwise adding an empty fourth node (quorum 3) plus one unrelated failure blocks all writes.

26.7.10 Linearizable reads: ReadIndex and lease reads

A read from the leader's local state is *not* automatically linearizable (§25.3): a partitioned leader may not know it was replaced and return a value already overwritten. Three remedies exist [Ongaro 2014]:

1. **Log reads.** Append the read to the log like a write. Correct, but costs a disk write per read.
2. **ReadIndex.** The leader records its current `commitIndex` as the read index, confirms it is still leader by exchanging a heartbeat round with a majority, waits until its state machine has applied up to the read index, then answers locally. Cost: one round trip, no disk write. Followers can serve reads the same way by asking the leader for a read index. A new leader must first commit its no-op entry, or its `commitIndex` may be stale.
3. **Lease reads.** After a successful heartbeat round started at time t, the leader assumes no other leader can exist before $t + T_{\text{min}}$ (followers will not start an election sooner), shortened by a clock-drift margin. Within that window it answers reads with no network round trip. This trades a timing assumption for latency: a long pause on the leader, or clock rates that differ more than the margin, can return stale data.

Figure 26.11 — ReadIndex: linearizable reads without writing to the log.



Reading the diagram. The leader notes the commit index (42) when the read arrives. The synchronous heartbeat round to a majority proves no newer leader existed then: a majority would have a higher term and reject it. The leader waits to apply index 42, so the read reflects every earlier committed write, and replies from memory. Nothing is written to disk. Failure point: if the heartbeat round fails, the leader aborts the read rather than risk staleness. Scaling: one heartbeat round can confirm leadership for a whole batch of pending reads.

etcd uses ReadIndex for its default linearizable reads and also offers **serializable** reads, served from any member's local state without a round trip, which may be stale [etcd Docs: API guarantees].

Failure scenarios

Table 26.3 — Raft failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Repeated elections	Timeout below network, GC or `fsync` jitter	Term climbing	Raise timeout; faster dedicated disks	Size timeouts from p99.9 RTT and flush latency
Disruptive rejoining node	A partitioned node's inflated term forces the leader to step down	Term jumps after healing	Automatic, after an extra election	**Pre-vote** [Ongaro 2014]: campaign only if a majority would vote
Writes blocked	Quorum lost	Commit index stalls	Restore nodes; else rebuild from backup, accepting loss	5 voters across 3 zones; learners
Stale reads	Local reads on a deposed leader	Jepsen-style tests (§25.11)	Switch to ReadIndex	ReadIndex, or lease reads with margin
Data loss after crash	Acknowledged before `fsync`	Divergent committed logs	Rebuild replica from peers	Never disable `fsync`; checksums

26.8 ZooKeeper and ZAB

26.8.1 The coordination-kernel idea

DEFINITION

Definition — ZooKeeper. A replicated coordination service that exposes a small, file-system-like tree of data nodes (**znodes**) with linearizable writes, FIFO per-client ordering, ephemeral and sequential nodes, and change notifications (**watches**). Applications build locks, leader election, barriers and configuration management on top of these primitives [Hunt et al. 2010].

Before ZooKeeper (built at Yahoo!, now an Apache project), each distributed system wrote its own, usually buggy, election and membership code. ZooKeeper deliberately offers no locks; it offers a **wait-free** API (no operation blocks on another client) from which clients compose **recipes**.

How it works internally

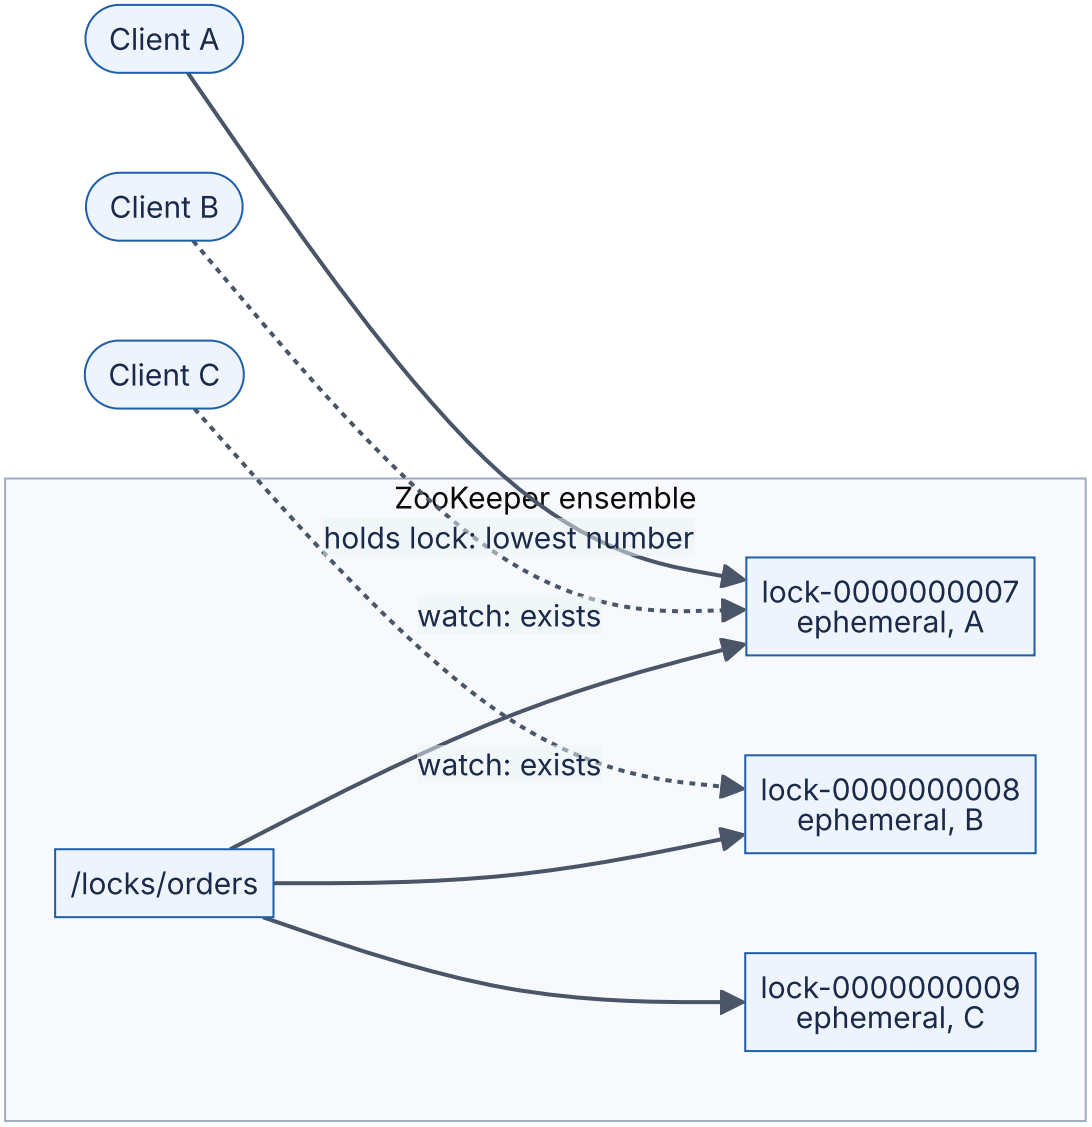
- **Znodes.** Each holds a small blob of data (the default limit is about 1 MB; coordination data should be bytes to kilobytes) plus a version number used for conditional updates (`setData(path, data, expectedVersion)`).
- **Ephemeral znodes** exist only while the client **session** that created them is alive. A session is kept alive by heartbeats; if the server ensemble hears nothing for the session timeout, it expires the session and deletes its ephemeral nodes. This is ZooKeeper's failure detector.
- **Sequential znodes** get a monotonically increasing 10-digit suffix from their parent, for example `lock-0000000007`, giving a total order among competing clients.
- **Watches** are one-time triggers set by a read (`getData`, `exists`, `getChildren`); the server sends one notification when the node changes, and the client must re-read and re-arm. Version 3.6 added persistent and recursive watches.
- **Ordering guarantees.** Writes are linearizable and go through the leader. Reads come from the connected server's local replica, fast but possibly stale; call `sync()` first to read the latest. Each client's operations execute in issue order, and a client sees a watch notification before the data that triggered it.
- **Observers** are non-voting servers that receive committed updates and serve reads, adding read capacity without slowing writes.

26.8.2 ZAB: ZooKeeper Atomic Broadcast

ZooKeeper replicates its tree with **ZAB**, an atomic broadcast protocol designed for primary–backup systems [Junqueira, Reed and Serafini 2011]. Each update is a state change produced by the leader (not the client's original request), labeled with a 64-bit **zxid**: the high 32 bits are the leader's **epoch**, the low 32 bits a counter. In the broadcast phase the leader sends a proposal, followers write it to disk and acknowledge, and the leader commits once a quorum has acknowledged, much like Raft's AppendEntries. After a leader failure, ZAB runs **discovery** (the new leader learns the latest epoch and history from a quorum) and **synchronization** (it brings followers to its history) before broadcasting again. ZAB's distinguishing guarantee is **primary order**: all of a leader's changes are delivered in order, and a new leader's changes come after every change from previous leaders that was delivered. ZooKeeper's paper reports that read-dominated workloads reach tens to hundreds of thousands of operations per second [Hunt et al. 2010].

26.8.3 Recipes: leader election, locks and barriers

Figure 26.12 — The ZooKeeper lock recipe with sequential ephemeral znodes.



Reading the diagram. Each client creates an ephemeral sequential child of `/locks/orders` (synchronous write through the ZooKeeper leader) and lists the children. A's node has the lowest number, so A holds the lock. B and C do not poll: each sets a watch (dotted, asynchronous notification) on the node *immediately below its own*. When A releases the lock by deleting its node, or A's session expires and ZooKeeper deletes it, only B is notified; B re-lists the children, sees it is lowest, and proceeds. Watching only the predecessor avoids the **herd effect** (every waiter waking on every release). The waiter queue lives inside the replicated tree. Failure point: A can be paused past its session timeout and still believe it holds the lock; the node's creation zxid should be passed to the protected resource as a fencing token (§26.13).

- **Leader election** is the same recipe: the candidate with the lowest sequential node under `/election` is leader, and each other candidate watches its predecessor.
- **Barrier.** Workers wait until a node `/barrier/ready` exists (watch on `exists`); the coordinator creates it to release everyone. A **double barrier** has workers register ephemeral children on entry and waits until the count reaches *k*, then waits for all to leave.
- **Configuration and group membership.** Store configuration in a znode and watch it; each live member registers an ephemeral child under `/members`.

> INDUSTRY EXAMPLE
>
> **Apache HBase, Hadoop HDFS and Kafka.** HBase uses ZooKeeper to elect its active master and track live region servers; HDFS high availability uses it to elect and fence the active NameNode (§15.5.2). Kafka historically stored cluster metadata and its controller election in ZooKeeper, then replaced it with KRaft, a Raft-based metadata quorum; Kafka 4.0 (2025) removed ZooKeeper mode entirely (Chapter 31). The trend reflects operational cost: running a separate ZooKeeper ensemble alongside every cluster was a frequent source of outages and configuration mistakes. *Evidence: Primary* — [Apache HBase Reference Guide]; [Apache Kafka KIP-500]

26.9 etcd

etcd is a distributed key–value store replicated with Raft, created at CoreOS and now a Cloud Native Computing Foundation project. It is best known as the database behind Kubernetes [etcd Docs].

26.9.1 Data model: revisions, watches, leases and transactions

- **Flat, ordered key space.** Keys are byte strings; range queries over prefixes replace ZooKeeper's tree.
- **MVCC and revisions.** The store keeps a single cluster-wide **revision** counter that increases with every modification. Each key records `create_revision`, `mod_revision` and `version`. You can read any key "as of" an older revision until **compaction** removes history older than a chosen revision.
- **Watches** start from a revision and stream every subsequent change, so a client that reconnects at revision *r* misses nothing (unless *r* was compacted). This fixes ZooKeeper's classic one-shot watch gap.
- **Leases.** A lease has a TTL; keys can be attached to it; the client renews with `LeaseKeepAlive`. When the lease expires, all its keys are deleted, the equivalent of ephemeral znodes.
- **Transactions.** `Txn(If compare..., Then ops..., Else ops...)` executes atomically, enabling compare-and-swap on a key's value, version or revision.

- **Consistency.** Writes are linearizable through Raft; reads are linearizable by default (ReadIndex, §26.7.10) or serializable on request.

The `concurrency` package of the Go client implements election and mutexes from these primitives: each contender writes a key under a common prefix attached to its lease, and the contender whose key has the lowest `create_revision` holds the lock; the others watch the key just before theirs, mirroring Figure 26.12. That revision is a natural fencing token.

26.9.2 etcd in Kubernetes

The Kubernetes API server is etcd's only client. Objects live under keys such as `/registry/pods/<namespace>/<name>`, `resourceVersion` derives from etcd's revision, and every controller's **watch** is an etcd watch multiplexed by the API server. etcd's health defines the control plane's; Kubernetes documentation recommends running an odd number of members (typically 3 or 5) on dedicated, low-latency disks [Kubernetes Docs: etcd]. The default storage quota is 2 GB; keeping the dataset small (compaction, defragmentation, no large blobs) is a standing task.

> INDUSTRY EXAMPLE
>
> **Kubernetes controller leader election.** Only one replica of `kube-controller-manager` or `kube-scheduler` acts at a time. Rather than etcd leases, they compete to update a `coordination.k8s.io Lease` object through the API server, with optimistic concurrency on `resourceVersion`. The defaults are a 15 s lease duration, a 10 s renew deadline and a 2 s retry period, so a crashed leader is replaced in roughly 15–17 s. Trade-off: this is coarse failover, chosen to avoid churn, and it relies on clocks running at similar rates. *Evidence: Primary* — [Kubernetes Docs: Leases]; [Kubernetes Docs: kube-controller-manager]

26.10 Distributed locks

26.10.1 Why distributed locks are hard

A single-process lock is simple because the kernel sees every thread. A distributed lock has no such comfort:

1. **The holder can fail silently.** So locks need an expiry (a lease), or a crashed client holds the lock forever.
2. **Expiry means the holder can lose the lock without knowing.** A process paused for 20 s (garbage collection, VM migration, page faults on a swapped heap, a `SIGSTOP`) resumes believing it still holds a lock that expired 10 s ago.

3. **Messages are delayed.** A write sent while holding the lock can arrive at the storage system after the lock has passed to someone else.

Kleppmann distinguishes two purposes [Kleppmann 2016]. An **efficiency lock** prevents duplicate work (two workers computing the same report); an occasional double holder costs some wasted CPU. A **correctness lock** protects an invariant (two writers corrupting one file); a double holder causes data loss. The right design depends on which you have.

26.10.2 The Redlock debate

The Redis documentation describes **Redlock**, an algorithm for a lock across *N* independent Redis primaries (typically 5) with no replication between them [Redis Docs: Distributed Locks]:

1. Record the current time. Try to acquire the lock on each instance in turn with `SET resource random_value NX PX ttl` and a short per-instance timeout.
2. The lock is acquired if a majority (3 of 5) succeeded and the total elapsed time is less than the TTL. The remaining **validity time** is the TTL minus the elapsed time minus an allowance for clock drift.
3. Otherwise, release on all instances (a script deletes the key only if it still holds `random_value`) and retry after a random delay.

In 2016 Martin Kleppmann published “How to do distributed locking,” arguing that Redlock is unsuitable for correctness locks [Kleppmann 2016]. Salvatore Sanfilippo (antirez), Redis’s creator, replied in “Is Redlock safe?” [Sanfilippo 2016]. The debate is a good model of how to reason about timing assumptions, so both sides are summarized here.

Table 26.4 — The Redlock debate in brief.

Issue	Kleppmann's argument	antirez's reply
Paused or delayed clients	Any lease-based lock can expire while the holder is paused; Redlock offers no **fencing token** (the random value is not monotonic), so storage cannot reject the stale holder	This affects every lock with auto-release; Redlock checks elapsed time after acquisition, and the unique random value can be used for check-and-set at the resource
Timing assumptions	Safety depends on bounded network delay, bounded pauses and bounded clock drift; a clock jump on one instance (for example, an NTP step) can let two clients hold a majority	Redlock needs bounded clock *rate* error, not synchronized clocks; operators should configure time sync to slew, not step
What to use instead	For efficiency, a single Redis node is enough; for correctness, use a consensus system (ZooKeeper, etcd) **with fencing tokens**	If the resource can check tokens, it is already a linearizable store; Redlock with its assumptions is adequate for many uses

A fair reading: both agree an auto-expiring lock cannot alone protect a resource from a paused holder; they disagree about how realistic the timing failures are. Redlock is reasonable as an efficiency lock, though one Redis instance is simpler. For correctness, use a consensus-backed lock and pass a monotonic token to the resource, or make the resource itself the arbiter (a conditional write such as compare-and-set on a version).

RECOMMENDATION

Recommendation — Choosing a lock. (1) Can you avoid the lock? An idempotent operation, a conditional write or a single-writer partition (§14.6) is usually better. (2) If you need a lock for efficiency, a single Redis `SET NX PX` with a sensible TTL is fine. (3) If you need it for correctness, use etcd, ZooKeeper or Consul, and make the protected resource check a fencing token (§26.13). (4) Never hold a lock across an unbounded operation without renewing it and checking validity before each side effect.

26.11 Leases

26.11.1 Leases and clocks

DEFINITION

Definition — Lease. A time-bounded grant of a right (to cache data, to act as leader, to hold a lock) from a grantor to a holder. Within the term the holder may act without consulting the grantor; after the term, the right lapses automatically, even if the holder has crashed or is unreachable [Gray and Cheriton 1989].

First-principles explanation

A lease is a library loan: you keep the book until the due date without phoning in, and if you vanish the loan simply ends. Gray and Cheriton introduced leases for cache consistency in the V file system: a server could update a file once every client lease on it expired, even if a client was unreachable. Leases turn “wait forever” into “wait at most T,” at the price of depending on clocks: holder and grantor each measure T with their own oscillator.

Mathematical foundations

The holder should start its timer *before* sending the request (so network delay counts against it), and the grantor starts its timer when it grants. Both clocks may run fast or slow relative to real time by at most a rate ρ.

FORMULA

Lease safety margin

$$T_{\text{holder}} = T(1-\rho) - d_{\max} \qquad T_{\text{grantor}} = T(1+\rho)$$

Symbol	Meaning	Units
T	Nominal lease duration	s
ρ	Maximum clock rate error relative to real time (drift bound)	dimensionless (e.g. 10^{-4} = 100 ppm)
$d_{\max}$	Maximum time between the holder checking validity and its action taking effect (processing, network, budgeted pause)	s
T_{holder}	Local elapsed time after which the holder must stop acting	s
T_{grantor}	Local elapsed time after grant before the grantor may grant the right to someone else	s

WORKED EXAMPLE

Worked example — a 10 s leader lease. $T = 10$ s, $\rho = 10^{-4}$ (100 ppm, a generous bound for server oscillators), $d_{max} = 0.5$ s.

1. Holder: $T(1-\rho) = 10 \times 0.9999 = 9.999$ s; minus d_{max}: $9.999 - 0.5 = 9.499$ s.
2. Grantor: $T(1+\rho) = 10 \times 1.0001 = 10.001$ s.
3. Real-time gap: the holder stops at most $9.499/(1-\rho) + 0.5 \approx 10.0$ s after its request was sent; the grantor reassigns no earlier than $10.001/(1+\rho) = 10.0$ s after granting, which is later than the request was sent. The intervals do not overlap.
4. Renewal: renew about every $T/3$ (3.3 s), so two consecutive renewals can fail before the lease lapses at 9.5 s; renewing every $T/2$ (5 s) tolerates only one.

Interpretation. Clock drift contributes only about 1 ms of margin over 10 s; the 500 ms action budget dominates. **Engineering implication.** The real enemy is not drift but **unbounded pauses**: a 15 s GC pause between the validity check and the write blows through any margin. That is why leases need fencing tokens (§26.13) whenever the action has effects outside the holder's process, and why clock *steps* (an NTP correction that jumps time) must be prevented on lease holders.

Leases appear throughout this book: GFS chunk leases (§15.5.1), Chubby sessions (§26.14), etcd and Consul session TTLs, Raft lease reads (§26.7.10), Kubernetes `Lease` objects (§26.9.2) and the idempotency-key claims of §22.15.

26.12 Split brain

26.12.1 Causes and prevention

DEFINITION

Definition — Split brain. A failure in which two or more parts of a cluster each believe they are the authoritative primary (or leader) and accept conflicting writes, so the system's state diverges.

Causes

- **Failover without a quorum.** A two-node pair loses its heartbeat link and each side promotes itself; neither can tell a partition from a crash.
- **A paused primary** resumes after being replaced and keeps serving (the chapter opening).
- **Asymmetric partitions.** A reaches B but not vice versa, so they disagree about who is alive.

- **Operator error.** Promoting a replica while the old primary is still reachable.

Prevention

1. **Quorum.** Only a side holding a majority may act; the minority stops.
2. **Witness (tie-breaker).** Two-site deployments add a lightweight third vote in a third location (a file-share or cloud witness in Windows Server Failover Clustering, an arbiter in MongoDB, a third etcd member), so one site can form a majority.
3. **STONITH ("shoot the other node in the head").** Before taking over, the survivor *forcibly* powers off or isolates the old primary through an out-of-band channel: a power distribution unit, a server management controller (IPMI), or a cloud API that stops the instance. Brutal, but it turns "maybe still running" into "definitely off."
4. **Resource-level fencing.** Revoke the old primary's access to shared storage (SCSI persistent reservations, revoking a volume attachment) or have the resource reject stale epochs (§26.13).

INDUSTRY EXAMPLE

GitHub, October 2018. A 43-second loss of connectivity between GitHub's East Coast network hub and its primary East Coast data center led the cluster-management tool Orchestrator, which uses Raft among its own nodes, to promote MySQL primaries in the West Coast data center. Writes accepted on the East Coast during the brief window had not replicated West, so both sites now held writes the other lacked; GitHub chose data integrity over availability and spent about 24 hours reconciling and restoring service. The lesson: consensus among the *failover controllers* does not prevent divergence in the *data* they manage, and topology-aware failover policies matter. *Evidence: Primary* — [GitHub 2018]

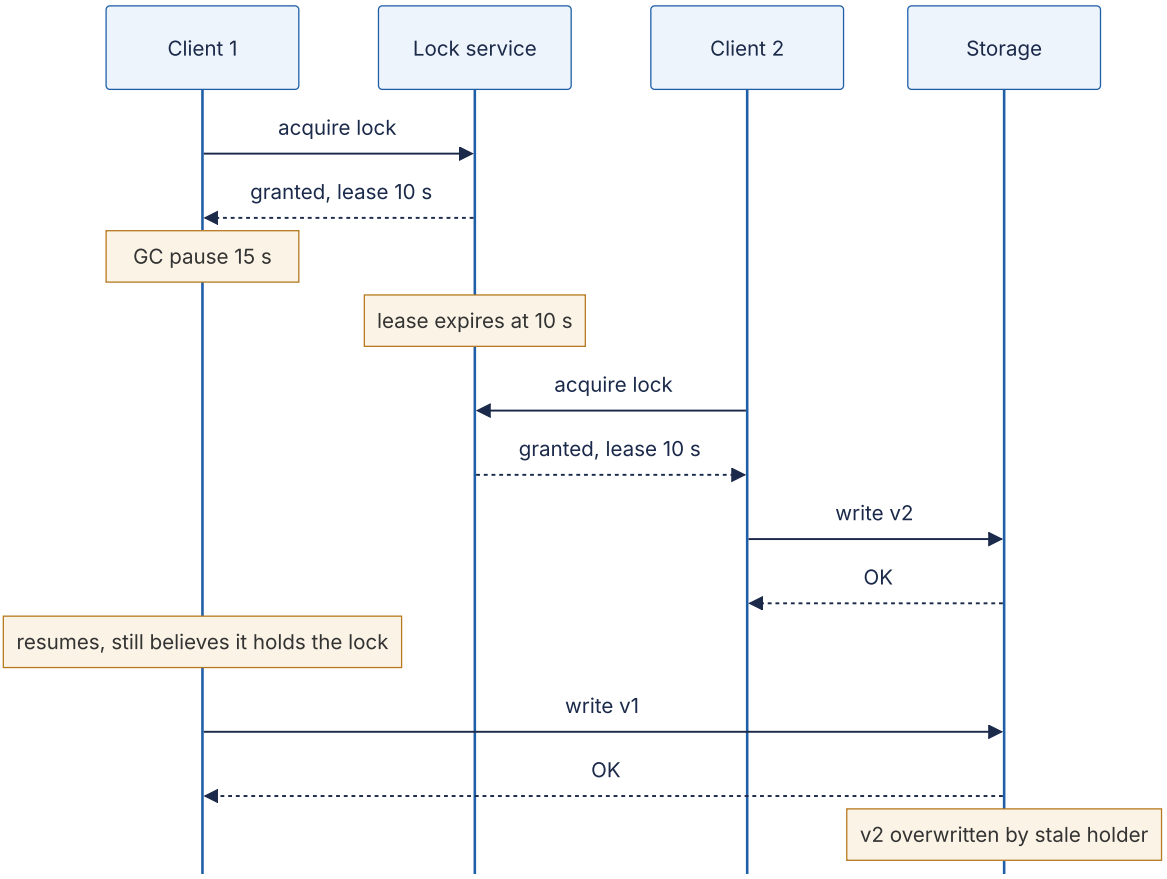
26.13 Fencing tokens

DEFINITION

Definition — Fencing token. A number, increasing with every grant of a lock or lease, that the holder attaches to every request to the protected resource. The resource remembers the highest token it has accepted and rejects any request carrying a lower one.

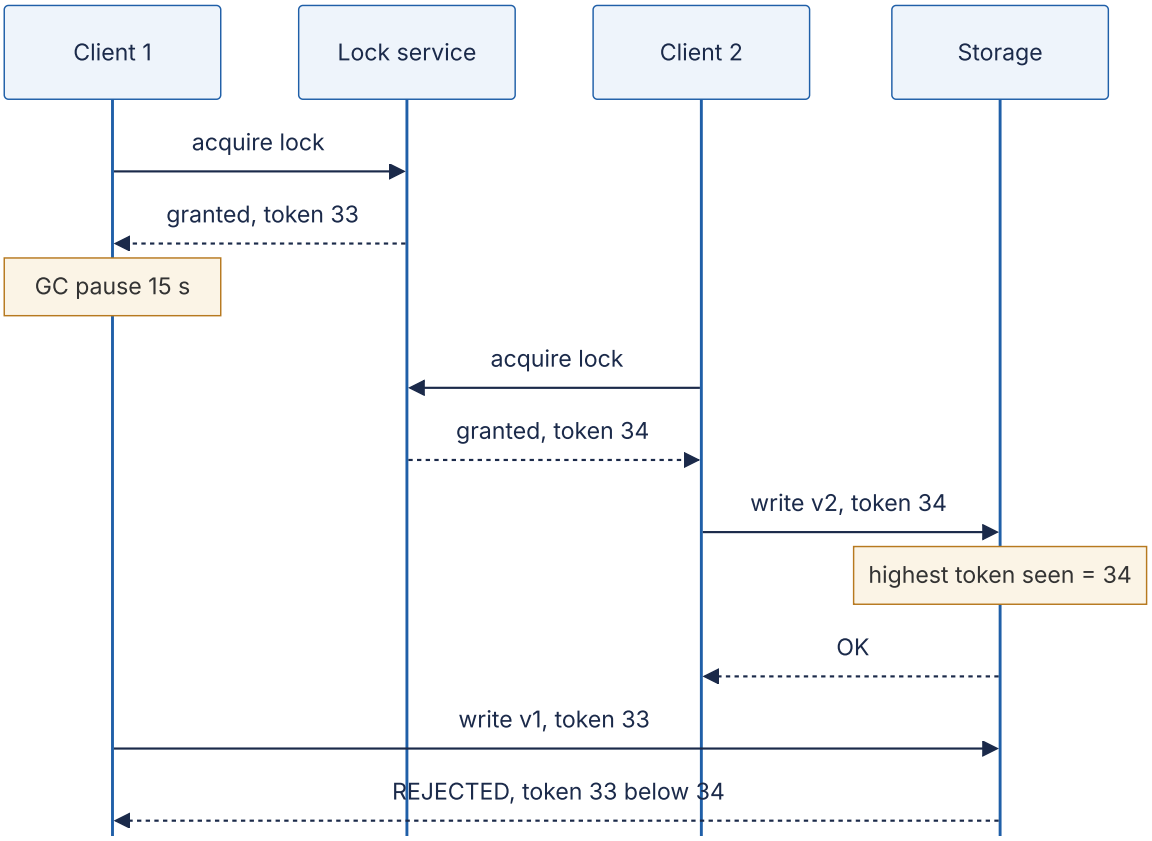
Fencing moves the final safety check from the client, which cannot know it has been paused, to the resource, which sees requests in the order they actually arrive. The two diagrams below follow Kleppmann's example [Kleppmann 2016].

Figure 26.13 — Without fencing: a paused client corrupts storage.



Reading the diagram. All arrows are synchronous RPCs. Client 1 holds a valid lease, then stops for 15 s without being able to observe its pause. The lock service correctly grants the lock to Client 2, which writes. Client 1 resumes and writes; storage cannot distinguish this from a legitimate write. Every component behaved correctly, yet Client 2's update is lost. The failure point is the gap between "checked the lock" and "write took effect," which no lock service can close from outside the client.

Figure 26.14 — With fencing: the storage service rejects the stale holder.



Reading the diagram. The lock service now hands out increasing tokens (33, then 34). Storage records the highest token it has accepted, durably and atomically with the write. Client 1's late write carries 33, which is lower than 34, so it is rejected and Client 1 learns it lost the lock. Ordering is decided at the storage boundary, where requests serialize. Failure points: storage must check and record tokens atomically, and every path to the resource must carry the token. Had Client 1's write arrived *before* Client 2's, accepting it would be correct.

Good token sources are values the consensus system already increments: a Raft or ZAB index, a ZooKeeper zxid or znode version, an etcd revision, a Chubby **sequencer**, or a Kubernetes-style generation number. If the resource cannot check tokens (a legacy file server, an external payment API), fencing is impossible and you must fall back to idempotency keys (§22.15), STONITH or long lock-delays, accepting the residual risk.

COMMON MISTAKE

Misconception — "A random lock value works as a fencing token." A random value lets the holder release only its own lock, but storage cannot tell whether value `a9f3` is newer or older than `71c2`. Fencing needs a *monotonic* order. The alternative is for the resource to support compare-and-set against the exact current owner value, which makes the resource itself the lock.

26.14 Coordination services in practice

26.14.1 Chubby

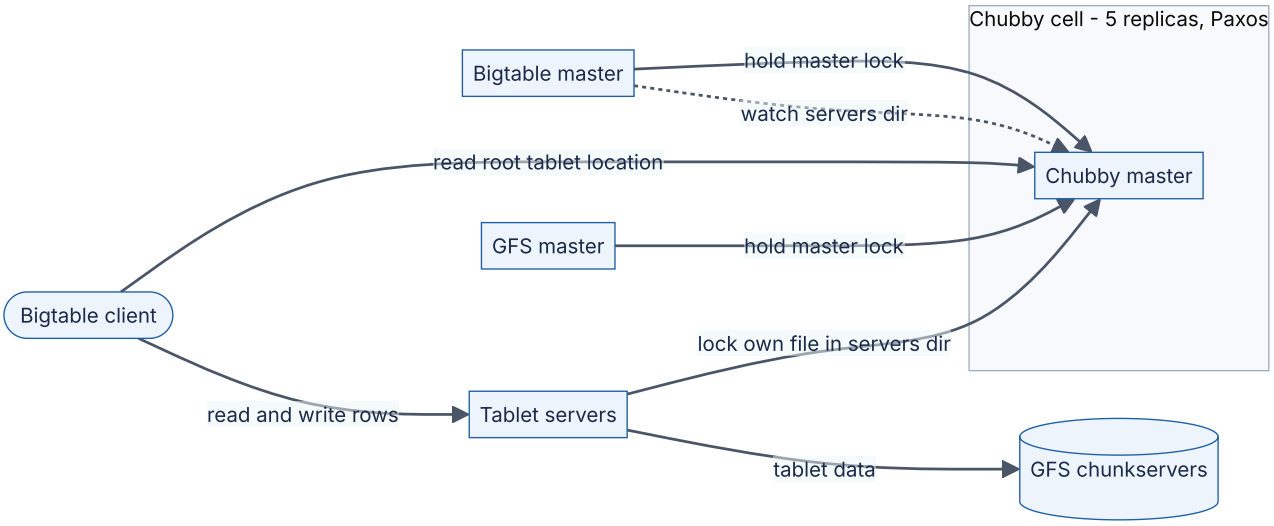
DEFINITION

Definition — Chubby. Google's lock service, providing coarse-grained advisory locks and small files in a file-system-like namespace, replicated across a five-node **cell** with Paxos, and used chiefly for leader election, naming and storing small amounts of configuration [Burrows 2006].

Burrows chose a *lock service* over a consensus library deliberately: taking a lock and writing a file was far easier to add to existing programs than embedding Paxos. Key design points:

- **Coarse-grained locks**, held for hours or days, not milliseconds, so load is low and brief outages do not disturb current holders.
- **Sessions and KeepAlives.** Each client session has a lease; the master holds each KeepAlive RPC until the lease nears expiry, then replies with a new lease (12 s by default) plus cache invalidations and events. If the lease lapses, the client enters **jeopardy**, disables its cache, and waits a **grace period** (45 s by default) for a new master before declaring the session lost.
- **Master election and master leases.** Replicas elect a master through Paxos; the master holds a lease of a few seconds during which no other master can be elected, letting it serve reads locally.
- **Consistent client caching** with invalidation: the master blocks a write until every caching client has invalidated, so reads are almost always local.
- **Sequencers and lock-delay.** A lock holder can obtain a **sequencer** (lock name, mode and generation number) and pass it to servers, which check it with Chubby: fencing tokens under another name. For servers that cannot check sequencers, Chubby imposes a **lock-delay** (up to one minute) before a lock released by a failed holder can be re-acquired.

Figure 26.15 — How Bigtable and GFS use Chubby.



Reading the diagram. Solid arrows are synchronous RPCs; the dotted arrow is an asynchronous event subscription. Bigtable's and GFS's masters each hold an exclusive lock so at most one master acts. Each tablet server locks a uniquely named file in a servers directory; the Bigtable master watches it to discover servers and, when one loses its lock, deletes its file and reassigns its tablets. Clients read the root tablet's location from Chubby, then talk to tablet servers, which store data in GFS; Chubby is off the data path. Failure point: if Chubby is unavailable for long, Bigtable becomes unavailable; the Bigtable paper measured this effect as small but nonzero [Chang et al. 2006]. Scaling: clients cache Chubby data, and Chubby proxies can aggregate KeepAlives.

INDUSTRY EXAMPLE

Chubby as Google's name service. Burrows reports that Chubby's most popular use was not locking but naming: storing small files mapping service names to addresses, where Chubby's consistent caching outperformed time-based DNS caching. Trade-off: this concentrated a great deal of read load on one service, handled by caching and proxies. *Evidence: Primary* — [Burrows 2006]

26.14.2 Choosing a coordination service

Table 26.5 — ZooKeeper vs etcd vs Consul vs Chubby (as of 2026).

	ZooKeeper	etcd	Consul	Chubby
What it is	Apache coordination service; hierarchical znodes	CNCF key–value store; Kubernetes' database	HashiCorp service-discovery and KV platform	Google-internal lock service
How it works	ZAB; leader orders writes; any server serves (possibly stale) reads	Raft; MVCC revisions; gRPC API	Raft among servers; gossip (Serf) among agents	Multi-Paxos in a 5-replica cell; master lease
Advantages	Mature recipes (Apache Curator); ephemeral and sequential nodes; observers	Revision-based watches; leases; transactions; linearizable reads by default	Health checks, DNS interface, multi-datacenter federation, sessions with lock-delay	Sequencers; lock-delay; consistent client caching
Disadvantages	JVM tuning; one-shot watches (before 3.6); stale reads unless `sync`	Dataset must stay small (2 GB default quota); sensitive to disk latency	KV is secondary to discovery; more moving parts	Not available outside Google
Performance	Reads scale with servers; writes bounded by leader and quorum	Writes bounded by leader, quorum and `fsync`	Similar to etcd for KV; gossip scales membership	Designed for low load: coarse locks, cached reads
Operational complexity	Medium–high (separate JVM ensemble)	Medium (defrag, compaction, backups)	Medium–high (servers plus agent on every node)	Run by a central team
Cost	Open source; 3–5 dedicated nodes	Open source; 3–5 nodes with fast SSDs	Open source plus commercial edition	Internal
Use cases	Hadoop, HBase, older Kafka, Solr	Kubernetes, CoreDNS, Vitess topology, many cloud-native systems	Service mesh, discovery, config, locks	GFS, Bigtable master election; naming
Choose when	You run the Hadoop ecosystem or need its recipes	You build on Kubernetes or need watches with history	You need discovery and health checking with locks	(Model for your designs)

Many systems now **embed** a Raft library (etcd's `raft`, HashiCorp's `raft`) instead of running an external service, as Kafka did with KRaft; and conditional writes in managed stores can serve as leases or fencing points without running a quorum yourself.

26.15 Summary and revision notes

SUMMARY

- **Consensus**: agreement, validity, termination. FLP forbids guaranteed termination under asynchrony, so algorithms keep safety always and liveness under partial synchrony: *safety from quorums, liveness from timeouts*.
- A **replicated state machine** runs one consensus decision per log slot; deterministic replicas applying the same log stay identical.
- **Majority quorums** intersect. $N = 2f + 1$ tolerates f crashes; use 3 or 5 voters, never an even number. Commit latency is the $(q - 1)$-th fastest follower RTT, so placement matters as much as count. Flexible Paxos needs only $|Q_1| + |Q_2| > N$.
- **Leader election** yields a node that *believes* it leads; safety needs quorum-checked actions or fencing.
- **Paxos**: prepare/promise discovers and locks out the past; accept/accepted decides; a proposer must adopt the highest-numbered accepted value it hears. Dueling proposers can livelock; Multi-Paxos uses a stable leader and skips phase 1.
- **Raft**: terms, randomized election timeouts, RequestVote with an up-to-date check, AppendEntries with a consistency check (log matching), commit only current-term entries (Figure 8), no-op on election, snapshots, joint or single-server membership changes, ReadIndex or lease reads.
- **ZooKeeper** (ZAB) offers znodes, ephemeral and sequential nodes and watches for recipes; **etcd** offers revisions, history-preserving watches, leases and transactions and backs Kubernetes; **Chubby** pioneered coarse-grained locks, sessions, KeepAlives, sequencers and lock-delay.
- **Expiring locks** cannot stop a paused holder; the Redlock debate centers on timing assumptions and missing fencing. **Leases** need margins for drift and, above all, pauses.
- **Split brain** is prevented by quorums, witnesses, STONITH and **fencing tokens**, which let the resource reject stale holders.

26.16 Knowledge checkpoint

1. Which consensus properties are safety properties and which is a liveness property?
2. How many failures does a 6-voter cluster tolerate, and why is it a poor choice?
3. Five voters have follower RTTs of 2, 3, 40 and 45 ms. What is the commit latency with 1 ms flushes?
4. With $N = 9$ and $|Q_2| = 3$, what is the minimum phase-1 quorum in Flexible Paxos?
5. In Paxos, a proposer receives promises reporting accepted proposals (2.1, A) and (3.2, B). Which value must it propose?

6. Why can dueling proposers prevent Paxos from deciding, and what fixes it?
7. A Raft node's last entry is (index 9, term 3). A candidate's last entry is (index 12, term 2). Does the node grant its vote?
8. Why does a new Raft leader append a no-op entry?
9. What does the log matching property guarantee, and which check enforces it?
10. Why are single-server membership changes safe without joint consensus?
11. How does ReadIndex make a leader read linearizable without writing to the log?
12. Why do ZooKeeper lock waiters watch their predecessor rather than the lock holder?
13. A lease is 6 s, $\rho = 2 \times 10^{-4}$, $d_{\max} = 1$ s. When must the holder stop?
14. Why is a random lock value not a fencing token?

Answers

1. Agreement and validity are safety; termination is liveness.
2. $q = 4$, $f = 2$, the same as 5 voters, with one more machine to fail and a larger quorum to wait for.
3. $q - 1 = 2$ followers; the second-fastest RTT is 3 ms; $L \approx 1 + 3 = 4$ ms.
4. $|Q_1| \geq 9 - 3 + 1 = 7$.
5. B, the value of the highest-numbered accepted proposal (3.2).
6. Each proposer's higher prepare invalidates the other's pending accept, forever. A single distinguished leader plus randomized back-off.
7. No. The node's last term (3) is higher than the candidate's (2), so its log is more up-to-date regardless of length.
8. Entries from earlier terms can only be committed indirectly; committing a current-term entry commits them and enables ReadIndex.
9. Equal (index, term) implies identical prefixes; the AppendEntries `(prevLogIndex, prevLogTerm)` consistency check.
10. Any majority of a configuration with N voters intersects any majority of one with $N \pm 1$ voters.
11. It fixes the commit index at the read's start, confirms leadership with a heartbeat round to a majority, and waits to apply up to that index.
12. To avoid the herd effect: each release wakes exactly one waiter.
13. $6 \times (1 - 0.0002) - 1 = 5.9988 - 1 = 4.9988$ s after sending the request.
14. Storage cannot order random values, so it cannot tell a newer holder from a stale one.

26.17 Interview questions

Basic

Q1. Why do consensus clusters usually have 3 or 5 nodes? Answer. A majority quorum lets $2f + 1$ nodes tolerate f crashes. Three tolerates one, five tolerates two (one failure during maintenance of another). Even sizes add cost and latency without extra tolerance, and more than five adds write latency and leader load for little availability gain under correlated failures.

Q2. What is a fencing token and when do you need one? Answer. A monotonically increasing number issued with each lock or lease grant; the protected resource rejects requests with a token lower than the highest it has seen. You need it whenever a lock protects correctness and the resource is outside the lock service, because a paused or delayed holder can act after its lock expired.

Intermediate

Q3. Walk through a Raft leader failure and recovery. Answer. Followers stop receiving heartbeats; the first whose randomized timeout fires increments its term and requests votes. Nodes vote once per term, only for candidates whose log is at least as up-to-date. With a majority, it becomes leader, appends a no-op, and repairs followers' logs through AppendEntries consistency checks. Uncommitted entries from the old leader may be overwritten; committed ones survive by leader completeness. Failover takes roughly one election timeout plus a round trip.

Q4. Design leader election for a fleet of cron schedulers. Answer. Use a lease-based election in etcd or ZooKeeper: create a key with a lease (for example, 15 s, renewed every 5 s), watch it if you lose. The leader checks lease validity before each job, carries the key's revision as a fencing token into the job store, and the store rejects stale tokens. Make jobs idempotent to tolerate the rare double run. State the failover time (about one lease duration).

Advanced

Q5. A team proposes Redlock to guard writes to a shared S3 object. Critique it. Answer. Redlock's safety depends on bounded pauses, delays and clock drift, and its random values cannot fence. A GC pause can let two clients write. Instead use conditional writes on the object (compare an ETag or version, where supported) so the store itself arbitrates, or a consensus-backed lock whose revision the writer stores and checks atomically. If a lock is only for efficiency, a single Redis node suffices.

Q6. Explain the Raft "Figure 8" problem and its fix. Answer. A leader of term 4 replicates an entry from term 2 to a majority, then crashes. A node holding a conflicting term-3 entry can still win the next election, because term 3 is more up-to-date than term 2, and overwrite the "majority-replicated" entry. Raft therefore commits only entries from the leader's current term by counting replicas; earlier entries commit indirectly, which is why new leaders write a no-op immediately.

26.18 Practical exercises

1. Modify the simulator of §26.7.7 to partition the leader with one follower (a minority) for 500 ms. Verify that the minority leader cannot commit and that a new leader is elected on the majority side.
2. Remove the `n.term_at(idx) == n.term` check from `advance_commit` and construct a schedule reproducing Figure 26.10. Does `check_safety` detect the violation?
3. Set the election timeout range to 150–155 ms and measure split votes and failover times over 200 seeds; compare with the formula in §26.7.2.
4. Start a three-member etcd cluster locally, take a lock with `etcdctl lock`, pause the holder with `kill -STOP`, and observe the lease expiry and the next holder's revision.
5. Implement the ZooKeeper lock recipe with Apache Curator or `kazoo`, and verify that a release wakes only one waiter.

26.19 Design challenges

1. **Global configuration service.** Store feature flags read by 50,000 servers in three regions, updated a few times per hour. Choose voter count and placement, decide which reads must be linearizable, design watch fan-out (proxies or caches), and estimate commit latency and availability.
2. **Fenced job runner.** Design a system in which exactly one worker processes each partition of a queue, workers can pause for up to 30 s, and the output database supports conditional writes. Specify lease duration, renewal, fencing and recovery after a pause.

- antirez reply URL (`antirez.com/news/101`) and the Redis documentation URL for Redlock.
- ZooKeeper throughput phrasing in Hunt et al. 2010; persistent recursive watches introduced in 3.6.0.
- etcd defaults as of 2026: 100 ms heartbeat, 1,000 ms election timeout, randomization over $[T, 2T)$, 2 GB quota; tuning guidance (heartbeat ≈ RTT, election ≥ 10 × RTT).
- Kubernetes controller defaults (15 s / 10 s / 2 s) as of 2026.
- Chubby defaults (12 s lease extension, 45 s grace, lock-delay up to 1 min) and Bigtable’s measured Chubby-caused unavailability.
- Kafka 4.0 (2025) removing ZooKeeper mode.

Chapter 27 — Replication and Fault Tolerance

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

Chapter 14 introduced replication as a database scaling tool: one primary, a few read replicas, and a choice between synchronous and asynchronous commit (§14.3–§14.5). That picture stops being enough when you ask harder questions. What happens when the primary dies at the wrong moment? How does anyone *know* it died? Can a store keep accepting writes while half its nodes are unreachable, and what does it give up to do so? When two copies disagree, which one is right?

This chapter surveys the five families of replication strategy, works through primary–backup, chain, multi-leader and leaderless replication, and then treats the machinery that keeps replicas alive and consistent: quorums, hinted handoff, failure detection, failover, recovery, anti-entropy and conflict-free replicated data types (CRDTs). Consensus belongs to Chapter 26, consistency definitions to Chapter 25 and distributed transactions to Chapter 28.

27.1 Learning objectives

After this chapter you should be able to:

- Choose among primary–backup, chain, multi-leader, leaderless and consensus-based replication for a workload, and justify the choice.
- Compute asynchronous failover loss, chain write latency and CRAQ read capacity, and estimate multi-leader conflict rates.
- State what $R + W > N$ does and does not guarantee, and compute quorum latency from the k-th fastest replica.
- Size hinted handoff, compute phi-accrual suspicion, SWIM detection time and gossip rounds, and build failover and recovery time budgets.
- Use read repair and Merkle anti-entropy, choose among last-writer-wins, version vectors and CRDTs, and implement and test four CRDTs.

27.2 Prerequisites

- Primary–replica replication, replication modes and lag — §14.3–§14.5 (this chapter builds on them rather than repeating them).

- Consistent hashing, virtual nodes and preference lists — §14.8 (leaderless stores place replicas on a ring).
- Merkle trees — §17.8 (the data structure behind anti-entropy).
- Availability, MTBF/MTTR and durability arithmetic — §4.14–§4.16 (every redundancy argument here reduces to them).
- Percentiles and tail latency — §4.8 (quorum latency is an order statistic).
- Failure models, partial failures, clocks and version vectors — §24.6–§24.11 (what can fail, and how causality is tracked).

27.3 Replication strategies overview

27.3.1 Five ways to keep copies

DEFINITION

Definition — Replication strategy. The rule that decides *which* replicas may accept a write, *in what order* the replicas apply writes, and *when* a write counts as done. The five families are **primary-backup**, **chain replication**, **multi-leader**, **leaderless** and **consensus-based** replication.

First-principles explanation

A family shares a shopping list on several phones. One person can forward every change (primary–backup); changes can pass along a line of phones, with the last one answering questions (chain); everyone can edit locally and sync later (multi-leader); anyone can write to any two of three phones and read any two (leaderless quorums); or the family can vote on each change (consensus). Each rule trades latency, availability during failures and how surprising the list looks to a reader.

Why does this exist?

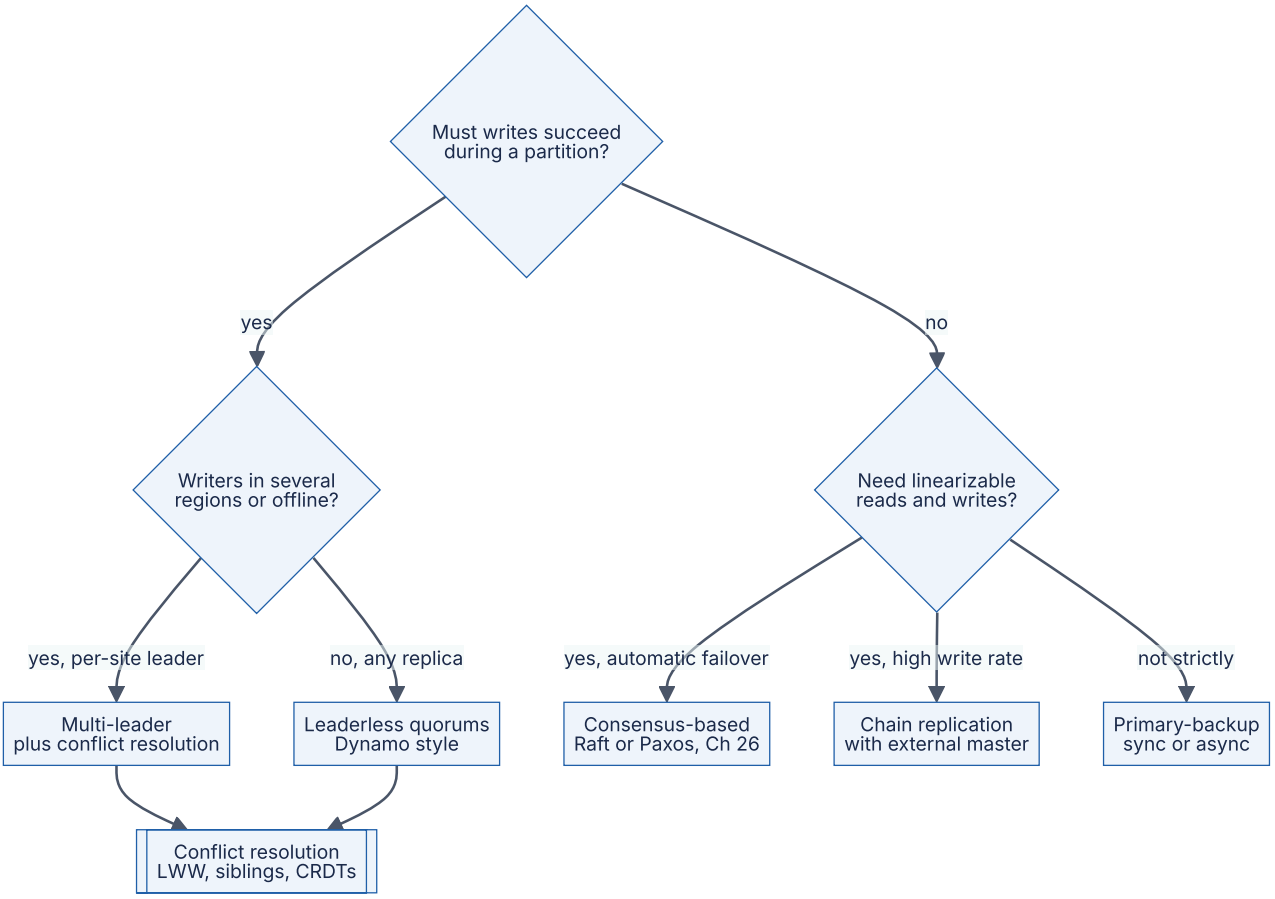
Replication exists for three reasons: **fault tolerance** (survive node, disk and zone failures), **latency** (serve users from a nearby copy) and **throughput** (spread reads, and sometimes writes, over more machines). No single strategy optimizes all three, because a write that must reach distant copies before it is acknowledged is slow, and a write that is acknowledged before reaching them can be lost or can conflict.

Decision table

Table 27.1 — Replication strategies compared.

	Primary–backup	Chain	Multi-leader	Leaderless	Consensus-based
Who accepts writes	One primary	Head of chain	Every leader	Any replica, via a coordinator	Elected leader
Ordering	Primary's order	Chain order	None globally; conflicts	None; version vectors or timestamps	Agreed log
Write done when	Backups ack (sync) or at once (async)	Tail has it	Local leader commits	W of N ack	Majority ack
Strong reads	From primary	From tail	No	No (not even with $R + W > N$)	From leader with lease, or via log
Failover	External detector promotes a backup	Master service splices chain	Not needed for writes	Not needed	Built into protocol
Tolerates	$n - 1$ crashes, if detector is correct	$n - 1$ crashes	Region loss, partitions	Partitions, slow nodes	f of $2f + 1$ crashes
Typical systems	PostgreSQL, MySQL, Kafka ISR	FAWN-KV, CRAQ	Multi-region databases, offline apps	Dynamo, Cassandra, Riak	etcd, ZooKeeper, Spanner (Ch 26)
Choose when	One region, simple ops	High write throughput with strong reads	Multi-region writes or offline clients	Always-writable, latency-sensitive keys	Metadata, locks, strong consistency

Figure 27.1 — Choosing a replication strategy.



Reading the diagram. The diagram is a decision path, not a data flow. The first question splits designs that remain writable on both sides of a network partition (right branch, which must accept conflicts and resolve them, §27.14) from those that keep one ordering of writes (left branch). On the ordered side, consensus-based replication gives automatic, safe failover; chain replication gives high throughput with strong reads but relies on a separately replicated master service; primary–backup is simplest but its safety depends on the failure detector and fencing. Both availability-first branches feed into conflict resolution, the shared failure point: whichever resolver you choose decides which concurrent writes survive.

KEY CONCEPT

Concept — Replication is ordering plus acknowledgment. Every strategy answers two questions: who decides the order of writes, and how many copies must hold a write before the client hears “done”. Primary–backup, chain and consensus fix the order at one place; multi-leader and leaderless let order emerge and repair disagreements afterwards.

27.4 Primary–backup replication

27.4.1 State transfer and operation shipping

> DEFINITION
>
> **Definition — Primary-backup replication.** One replica, the **primary**, receives all requests, executes them and propagates the result to one or more **backups**. If the primary fails, a backup is **promoted** to primary. It is also called **passive replication** [Alsberg and Day 1976; Budhiraja et al. 1993].

First-principles explanation

A head chef cooks while an apprentice keeps an identical copy of each dish. The chef can photograph each finished plate (**state transfer**: send the resulting state) or read out each instruction, “add 5 g salt”, for the apprentice to perform (**operation shipping**, also called log shipping, or **active** replication when every replica executes it). Photographs are bigger but exact; instructions are small but work only if every step gives the same result on both stoves.

Why does this exist?

Primary–backup is the oldest and simplest fault-tolerance pattern. One node decides the order of operations, so there are no write conflicts and reads from the primary are linearizable while the primary is genuinely the only primary. Most relational databases (§14.3), Kafka partitions and many file systems use it.

How it works internally

1. The client sends a request to the primary.
2. The primary executes it and produces either a state delta (changed pages, rows) or an operation record (a log entry).
3. The primary sends the delta or record to the backups, in the order it executed them.
4. In **synchronous** mode the primary waits for the backups’ acknowledgments before replying; in asynchronous mode it replies at once (§14.4 compares the modes).
5. A **failure detector** (§27.10) watches the primary. When it suspects a crash, a backup is chosen, made consistent with the most up-to-date surviving copy, **fenced** off from the old primary (§26.13) and promoted.

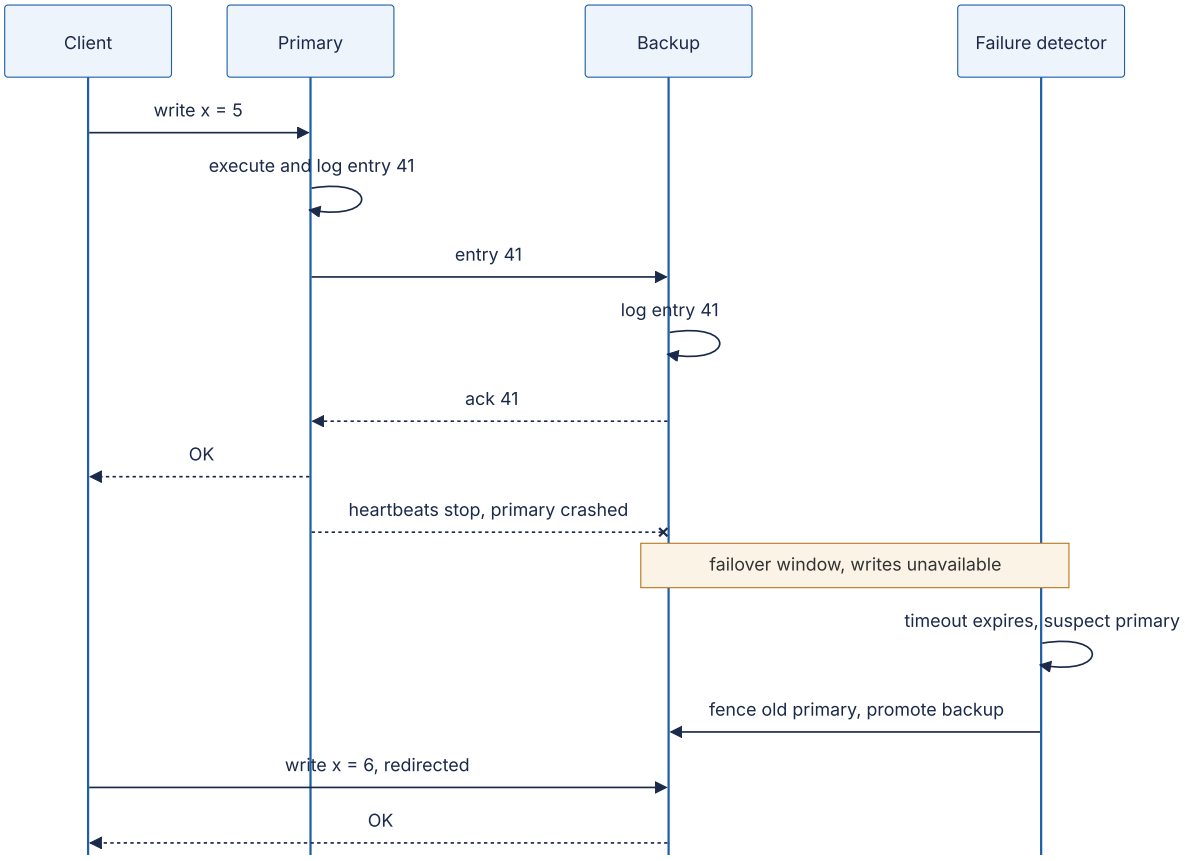
The trade-off between the two forms is concrete:

- **State transfer** is deterministic by construction, works for any computation and is the basis of physical (WAL) replication (§14.4.5). It costs bandwidth proportional to

the amount of state changed, which can be large: one `UPDATE` that touches a million rows ships a million row images.

- **Operation shipping** sends the request, so it is compact, but every replica must execute it **deterministically**. Clocks, random numbers, thread scheduling and unordered iteration break determinism. Systems either forbid non-deterministic operations, log their results (for example, the value of `NOW()`), or replay at a very low level, as VMware Fault Tolerance does.

Figure 27.2 — Primary-backup with a synchronous backup and the failover window.



Reading the diagram. Solid arrows are synchronous messages; the client waits until the backup has logged entry 41, so a primary crash after the reply loses nothing. The crossed arrow marks the crash. From then until the detector's timeout expires and the backup is promoted, no write can succeed: that interval is the **failover window**, and it is dominated by detection time (§27.11). The storage boundaries are the two logs. The failure points are the detector (too slow lengthens the window; too eager causes needless failovers and possible split brain) and the backup itself (if it is down, synchronous commits stall). Scaling adds backups, which adds acknowledgments to wait for and copies for the primary to send.

Mathematical foundations

With asynchronous shipping, everything the primary acknowledged but had not yet shipped is lost when a backup is promoted.

FORMULA

Writes lost in an asynchronous failover

$$L = r_w \times \ell$$

Symbol	Meaning	Units
L	Acknowledged writes lost when the most up-to-date backup is promoted	writes
r_w	Write rate on the primary just before the crash	writes/s
ℓ	Replication lag of the promoted backup at the moment of the crash	s

WORKED EXAMPLE

Worked example — Sizing the loss. An order service commits $r_w = 2,000$ writes/s. Its asynchronous backup normally lags by 50 ms, but under a burst the lag reaches 500 ms.

1. Normal lag: $L = 2,000 \times 0.05 = 100$ acknowledged orders lost.
2. During the burst: $L = 2,000 \times 0.5 = 1,000$ orders lost.
3. With one synchronous backup in the same region: $\ell = 0$ for acknowledged writes, so $L = 0$, at a cost of one intra-region round trip per commit (about 0.5–1 ms, §14.4.1).

Interpretation. Asynchronous loss scales with load *and* lag, and lag grows exactly when the system is busiest. **Engineering implication.** If any loss is unacceptable, make at least one backup synchronous, or make failover choose only a backup known to hold every acknowledged write, and alert on lag in seconds as well as bytes.

There is also a bandwidth cost. With n replicas the primary sends every update $n-1$ times, so its outbound network link limits write throughput: $X_{\max} = B_{\text{out}}/((n-1)\cdot s)$ for updates of size s. That bottleneck is what chain replication removes (§27.5).

Real-world industry applications

INDUSTRY EXAMPLE

VMware vSphere Fault Tolerance. VMware FT replicates an entire virtual machine by operation shipping at the instruction level. The primary's hypervisor logs every non-deterministic event (interrupts, network packets, timer reads) and sends it over a logging channel; the backup replays the same execution. The **output rule** makes the primary delay any externally visible output until the backup has acknowledged the log entry that produced it, so a failover never contradicts what the outside world has already seen. Failure detection uses heartbeats plus an atomic test-and-set on shared storage to prevent both copies from going live. *Evidence: Primary* — [Scales et al. 2010]

INDUSTRY EXAMPLE

Apache Kafka in-sync replicas. Each Kafka partition has a leader and followers that fetch from it. Followers that keep up form the **in-sync replica set (ISR)**. A producer with `acks=all` is acknowledged once every current ISR member has the record, and `min.insync.replicas` sets how small the ISR may shrink before such writes are refused. A replica outside the ISR may become leader only if unclean leader election is enabled, which trades data loss for availability. *Evidence: Primary* — [Apache Kafka Docs: Replication]

Failure scenarios

Table 27.2 — Failure scenarios in primary-backup replication.

What goes wrong	Why	Detection	Recovery	Prevention
Acknowledged writes vanish after failover	Async backup promoted while lagging	Gap in log positions; user reports	Replay old primary's unshipped log if disk survives	Sync backup or lossless semi-sync; promote most-advanced replica
Two primaries accept writes	Old primary was slow, not dead; detector misfired	Two nodes report primary role	Fence old primary; reconcile divergent writes	Leases and fencing tokens (§26.11–§26.13)
Replicas diverge silently	Non-deterministic operation shipped	Checksums differ between replicas	Rebuild backup by state transfer (§27.12)	Row-based or physical logs; log non-deterministic values
All commits stall	Sole synchronous backup is down	Commit latency spikes	Drop to async or add a backup	Quorum acks over ≥ 2 backups

COMMON MISTAKE

Mistake — "A backup is a backup, so failover is safe." A backup is only as current as its last acknowledged entry, and failover is only safe if the old primary is stopped. Without fencing, a primary paused for 20 s by garbage collection can wake up and accept writes alongside the new one.

27.5 Chain replication

27.5.1 Writes at the head, reads at the tail

DEFINITION

Definition — Chain replication. Replicas are arranged in a linear **chain**. Every update enters at the **head** and is forwarded node by node to the **tail**; the tail replies to the client. Every query is answered by the tail. A separate, fault-tolerant **master** service detects failures and reconfigures the chain [van Renesse and Schneider 2004].

First-principles explanation

Think of a bucket brigade. Buckets pass along the line, and only when the last person pours one on the fire does it count, so anyone asking "how much water has reached the fire?" asks the last person. Each person passes each bucket once, so no one is overloaded; the price is that every bucket travels the whole line.

Why does this exist?

In primary–backup the primary sends every update to every backup. Van Renesse and Schneider designed chain replication for storage needing both high throughput and strong consistency: each node forwards each update once, and because the tail holds only updates every other node already has, tail reads are linearizable without extra coordination.

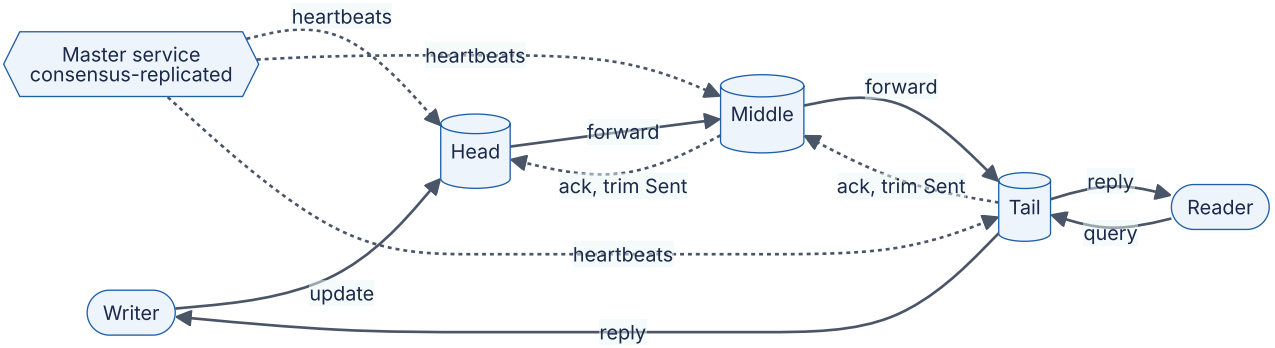
How it works internally

1. The client sends an update to the head. The head applies it and forwards it to its successor.
2. Each middle node applies the update, records it in a **Sent** list of updates forwarded but not yet confirmed, and forwards it.
3. The tail applies the update, replies to the client and sends an acknowledgment back up the chain, so predecessors can trim their Sent lists.
4. Queries go only to the tail, which reflects exactly the set of fully replicated updates.

5. The master (itself replicated with consensus, Chapter 26) detects crashes and repairs the chain:
    - **Head fails:** its successor becomes the head. Updates the old head received but had not forwarded are lost, but none had been acknowledged.
    - **Tail fails:** its predecessor becomes the tail. That node already holds everything the old tail held, and possibly more.
    - **Middle node fails:** the master links its predecessor to its successor, and the predecessor resends everything in its Sent list that the successor may have missed.
6. A new node is added at the tail end: it copies the current tail's state, then takes over as tail.

A chain of n nodes tolerates $n - 1$ crashes, because any surviving node holds every acknowledged update.

Figure 27.3 — Chain replication with an external master.



Reading the diagram. Updates flow synchronously left to right over TCP; the writer's reply comes from the tail, so the write's latency spans every hop. Readers talk only to the tail. Dotted arrows are asynchronous: acknowledgments flowing back up the chain to trim each node's Sent list, and the master's failure detection. Each node stores a full copy. Failure points are any chain node (repaired by the master as listed above) and the master itself, which is why the master must be consensus-replicated. Scaling: a longer chain adds fault tolerance and latency but no read capacity, since only the tail serves reads; systems scale out by running many chains, each owning a range of keys.

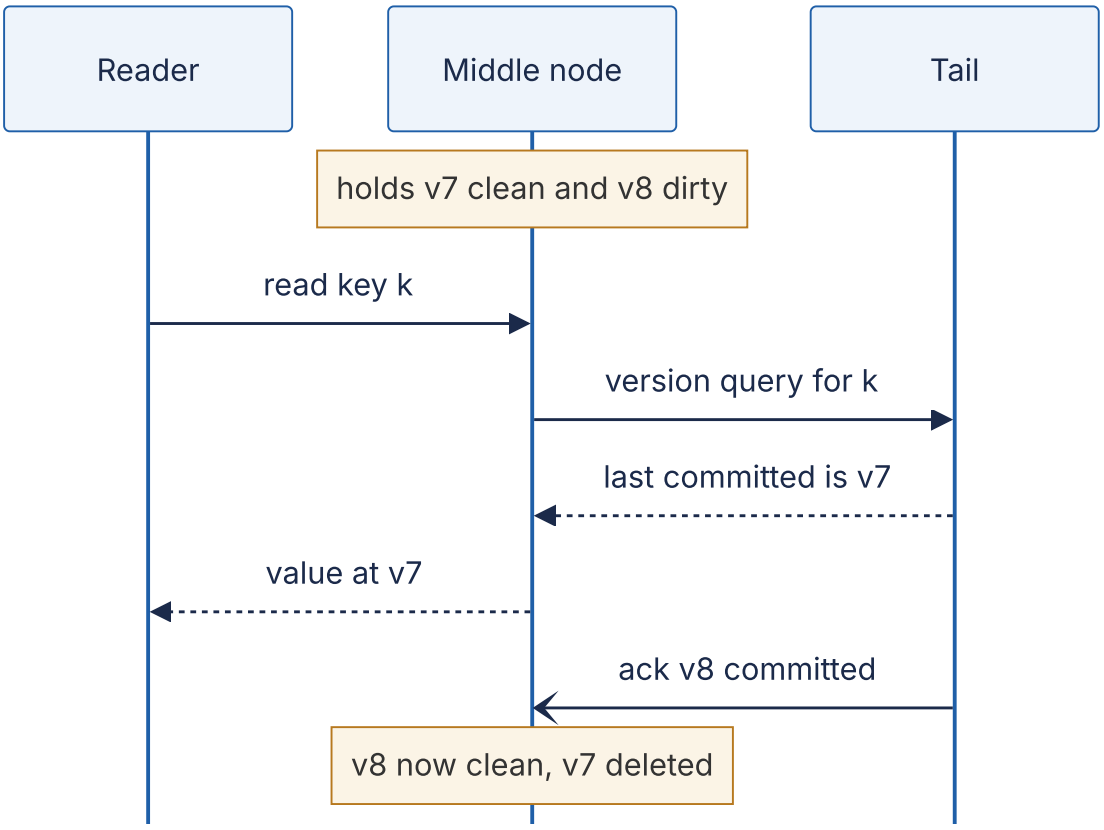
27.5.2 CRAQ: reading from every node

Chain replication has an obvious waste: $n - 1$ nodes hold the data but only the tail can answer queries. **CRAQ** (Chain Replication with Apportioned Queries) lets any node answer reads while keeping strong consistency [Terrace and Freedman 2009].

1. Each node may store several versions of an object. A version is **clean** once the node knows the tail has it, and **dirty** before that.

2. On an update, each node appends a new dirty version and forwards it. When the tail applies it, the version is committed; acknowledgments flow back, each node marks that version clean and deletes older ones.
3. On a read at any node: if the latest local version is clean, return it. If it is dirty, send a small **version query** to the tail, which returns its latest committed version number, and return that version (which the node has, because the chain delivers versions in order).

Figure 27.4 — A CRAQ read that hits a dirty object.



Reading the diagram. The reader contacts a middle node synchronously. Because the newest local version (v8) is dirty, that node asks the tail which version is committed, a message carrying only a version number, and returns v7, the value every other reader would also see. The later asynchronous acknowledgment marks v8 clean, after which the node answers locally. Storage holds several versions per key during an update. The failure point is the tail: dirty reads depend on it, so a write-heavy hot key concentrates version queries there. Read capacity scales with chain length when most objects are clean.

Mathematical foundations

FORMULA

Chain write latency and read capacity

$$T_{\text{write}} \approx (n+1)\,d + n\,s \qquad X_{\text{read}}^{\text{CR}} = c \qquad X_{\text{read}}^{\text{CRAQ}} \approx n\,c \text{ (clean reads)}$$

Symbol	Meaning	Units
n	Number of nodes in the chain	nodes
d	One-way network delay per hop	ms
s	Processing time per node for an update	ms
c	Read capacity of one node	reads/s
T_{write}	Client-observed write latency (client → head → … → tail → client)	ms
X_{read}	Read capacity of one chain	reads/s

WORKED EXAMPLE

Worked example — Chain versus primary-backup in one datacenter. Take $d = 0.25$ ms, $s = 0.05$ ms, $c = 50,000$ reads/s, 4 KiB updates and 10 Gb/s network interfaces (1.25 GB/s each way).

1. Chain of 3: $T_{\text{write}} = 4 \times 0.25 + 3 \times 0.05 = 1.15$ ms. Chain of 5: $6 \times 0.25 + 5 \times 0.05 = 1.75$ ms.
2. Primary–backup with parallel fan-out: client → primary → backups → primary → client is 4 one-way hops regardless of n, so $4 \times 0.25 + 2 \times 0.05 = 1.1$ ms.
3. Write throughput limit from the busiest outbound link, $n = 5$: the primary sends 4×4 KiB $= 16$ KiB per write, so $1.25 \times 10^9 / 16,384 \approx 76,000$ writes/s. In a chain each node sends each update once: $1.25 \times 10^9 / 4,096 \approx 305,000$ writes/s.
4. Reads with $n = 3$: chain replication serves 50,000 reads/s at the tail; CRAQ serves up to about $3 \times 50,000 = 150,000$ reads/s if most reads find clean objects.

Interpretation. Chains trade latency that grows linearly with length for throughput that does not depend on length. **Engineering implication.** Keep chains short (3 is typical) and inside one datacenter; use CRAQ or many independent chains when reads dominate.

Real-world industry applications

INDUSTRY EXAMPLE

FAWN-KV. FAWN-KV, a key-value store built on clusters of low-power nodes, places nodes on a consistent-hash ring and replicates each key range with chain replication along the ring, with a front-end that routes puts to the head and gets to the tail. *Evidence: Primary* — [Andersen et al. 2009]

INDUSTRY EXAMPLE

CRAQ across datacenters. The CRAQ paper describes chains that span datacenters, with chain membership kept in ZooKeeper, and offers eventual-consistency and bounded-staleness read modes in addition to strong reads, so applications can trade freshness for local reads. *Evidence: Primary* — [Terrace and Freedman 2009]

Advantages and disadvantages

Chain replication gives linearizable reads and writes, balanced network load and simple recovery. Its costs are write latency proportional to chain length, every write waiting for the slowest node, and dependence on an external master for reconfiguration.

27.6 Multi-leader replication

27.6.1 Use cases and topologies

Chapter 14 introduced multi-primary replication for databases (§14.5). Here we generalize: **multi-leader replication** lets each of several leaders accept writes and asynchronously exchange them, and it reappears wherever writers cannot wait for a single authority.

DEFINITION

Definition — Replication topology. The graph along which leaders forward writes to each other: a **circular** ring, a **star** with a hub, or **all-to-all**.

Why does this exist?

Three use cases recur:

1. **Multi-datacenter operation.** Each region has a leader, so writes take a local round trip (about 1 ms) instead of a cross-region one (70–150 ms), and a region keeps writing when cut off.

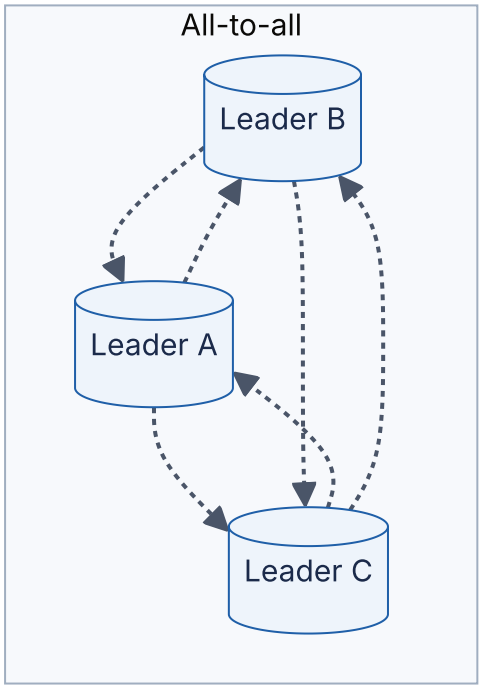
2. **Offline clients.** A calendar or notes app on a phone is a leader with a local database; it syncs when the network returns, possibly days later.
3. **Collaborative editing.** Every participant's editor applies its own keystrokes immediately and exchanges changes, so typing never waits for a server round trip.

All three accept the same consequence: two leaders can change the same item concurrently, and nobody finds out until the changes meet.

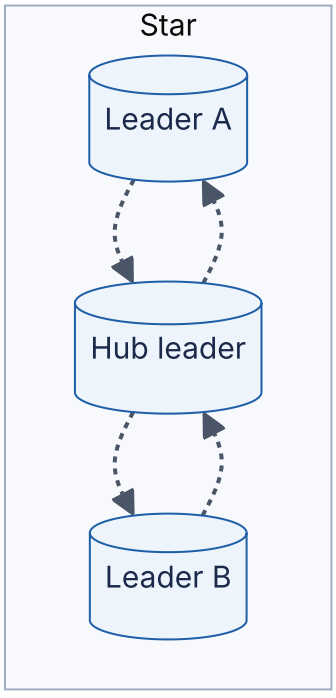
How it works internally

1. Each leader commits a write locally and tags it with its origin (a leader ID) and a version (a log position, timestamp or version vector).
2. The write is forwarded along the topology. A node that receives a write it has already seen, recognized by origin and version, drops it, which prevents infinite loops in rings.
3. A receiving leader **detects a conflict** if the incoming write and a local write touched the same item and neither causally precedes the other. Version vectors detect this exactly (§27.14); timestamps cannot.
4. The conflict is resolved by a policy (§27.14) or recorded for the application.

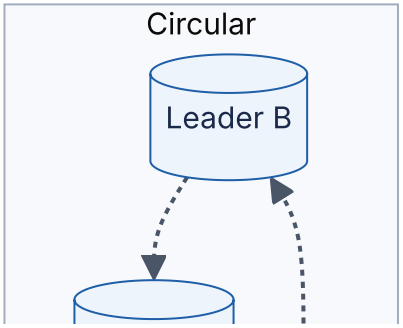
Figure 27.5 — Multi-leader topologies.



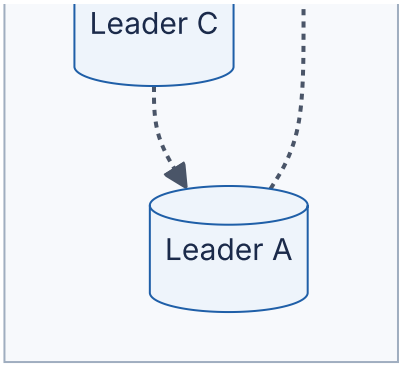
All-to-all
Leader B
Leader A
Leader C



Star
Leader A
Hub leader
Leader B



Circular
Leader B



Reading the diagram. Every arrow is asynchronous replication of committed writes, typically a log stream over TCP. In the circular topology each write travels through every other leader in turn, so one failed or slow leader stops propagation for everyone downstream until the ring is reconfigured. In the star, the hub is a single point of failure for replication (though not for local writes). All-to-all has no single point of failure but sends every write along $m(m-1)$ links for m leaders and allows writes to overtake each other on different paths. Each leader stores a full copy. Scaling beyond a handful of leaders multiplies both links and potential conflicts.

Mathematical foundations

How often do conflicts happen? Two writes to the same item conflict if they are made at different leaders within one replication delay of each other.

FORMULA

Conflict rate for one item written at two leaders

$$\kappa \approx 2\,\lambda_A\,\lambda_B\,\Delta \qquad (\lambda_A\Delta \ll 1,\ \lambda_B\Delta \ll 1)$$

Symbol	Meaning	Units
κ	Expected conflicts per second for the item	conflicts/s
λ_A, λ_B	Write rate to the item at leaders A and B	writes/s
Δ	Replication delay between the leaders	s

Derivation. Each write at A conflicts if B wrote the same item within Δ before or after it, a window of length 2Δ, which happens with probability about $2\Delta\lambda_B$ when that is small. Multiply by A's write rate.

WORKED EXAMPLE

Worked example — Rare per key, common in aggregate. Two regions replicate with $\Delta = 0.2$ s.

1. A busy shared document written 0.1 times per second in each region: $\kappa = 2 \times 0.1 \times 0.1 \times 0.2 = 0.004$ conflicts/s, about 14 per hour.
2. One million ordinary keys, each written 0.001 times per second in each region: per key $2 \times 10^{-6} \times 0.2 = 4 \times 10^{-7}$ conflicts/s; over all keys 0.4 conflicts/s, about 34,600 per day.
3. Partitioned ownership, where each key is written in only one region: $\lambda_B = 0$, so $\kappa = 0$.

Interpretation. Conflicts grow with the product of the two write rates and with the delay; a partition that makes Δ last for minutes multiplies them. **Engineering implication.** Conflict resolution cannot be an afterthought you hope never runs. Either give each item a home leader, or make the resolution rule correct and tested (§27.14).

Real-world industry applications

INDUSTRY EXAMPLE

Amazon DynamoDB global tables. Global tables replicate a table across Regions with every replica writable. For the multi-Region eventually consistent mode, AWS documents that concurrent updates to the same item are reconciled by last-writer-wins, so applications needing different semantics must avoid concurrent cross-Region writes to an item (as of 2026; AWS has since added a multi-Region strongly consistent option). *Evidence: Primary* — [AWS Docs: DynamoDB Global Tables]

INDUSTRY EXAMPLE

CouchDB. CouchDB replicates between any pair of databases, including offline devices. Each document has a revision tree; when replicas diverge, every node deterministically picks the same winning revision so readers agree, while the losing revisions are kept as conflicts that the application can read and merge. *Evidence: Primary* — [Apache CouchDB Docs: Replication and Conflict Model]

Failure scenarios

Table 27.3 — Failure scenarios in multi-leader replication.

What goes wrong	Why	Detection	Recovery	Prevention
Replication stops for a subset of leaders	Ring or hub node failed	Replication lag grows on downstream leaders	Reconfigure ring or hub	All-to-all, or redundant hubs
Update applied before its insert	Messages overtook on different links	Apply errors, missing parents	Buffer and retry	Version vectors; causal delivery
Uniqueness violated	Two leaders accept same username	Duplicate detected after sync	Rename or merge manually	Route uniqueness checks to one home leader

27.7 Leaderless replication

27.7.1 Dynamo-style coordination

DEFINITION

Definition — Leaderless replication. Any replica of a key may accept reads and writes; the client, or a **coordinator** node acting for it, sends each request to several replicas in parallel and treats it as successful once enough of them respond. There is no failover because there is no leader [DeCandia et al. 2007].

First-principles explanation

A club keeps its membership list on three noticeboards. The secretary pins each notice on at least two boards; a reader checks any two and believes the newer notice. Any two boards share one with the secretary's two, so the reader always sees the latest notice, and losing one board stops nothing.

Why does this exist?

Amazon built Dynamo for the shopping cart, where refusing an "add to cart" during a failure costs money. A leader is a single point that must be detected dead and replaced; during that window writes stop. Leaderless replication keeps writing as long as *enough* replicas answer, and it masks slow replicas by not waiting for the slowest ones [DeCandia et al. 2007].

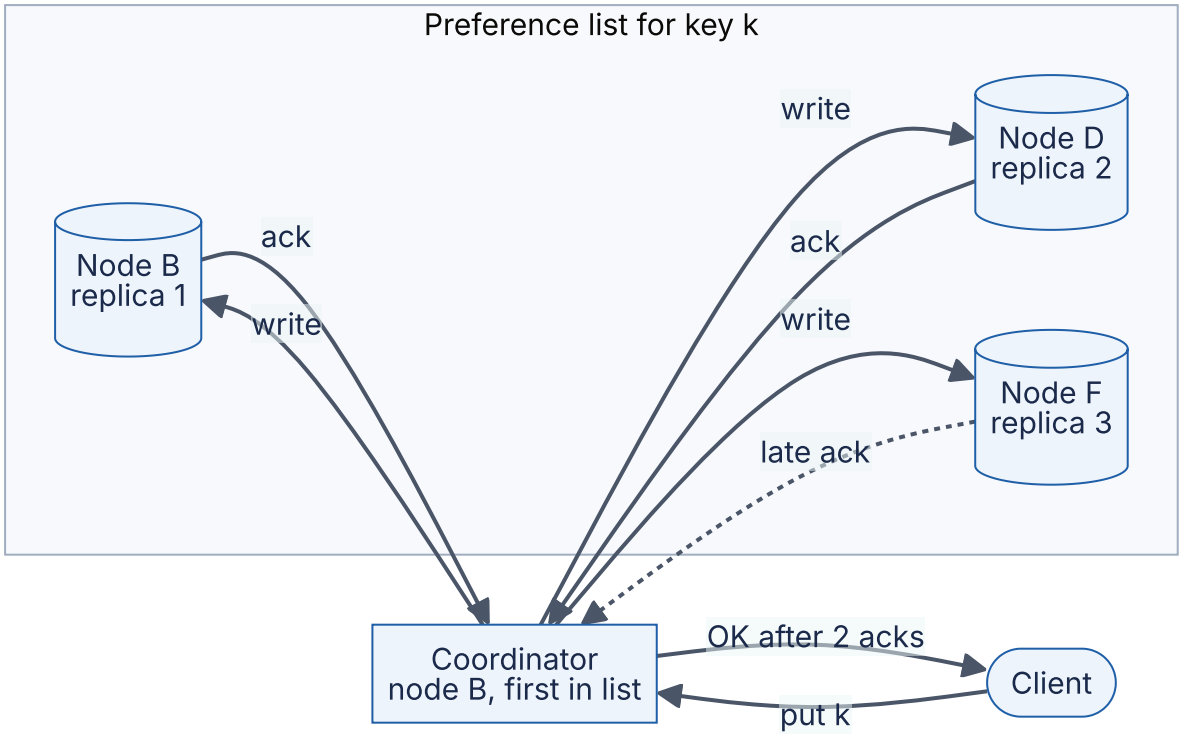
How it works internally

1. **Placement.** Keys are hashed onto a consistent-hash ring (§14.8). The **preference list** for a key is the first N distinct physical nodes clockwise from its position; the list kept is longer than N so that substitutes are known when nodes fail.
2. **Coordinator.** A request arrives at a partition-aware client library or at any node, which forwards it to a coordinator, typically the first healthy node in the key's pref-

erence list.

3. **Write.** The coordinator attaches a new version (a vector clock in Dynamo, a timestamp in Cassandra), writes locally and sends the write to the other replicas in parallel. It reports success once *W* replicas, counting itself, acknowledge.
4. **Read.** The coordinator asks the replicas and waits for *R* responses. If the versions differ, it returns the newest, or all causally concurrent versions for the client to reconcile (§27.14), and it may repair stale replicas (§27.13).
5. **Background repair.** Hinted handoff (§27.9) and Merkle-tree anti-entropy (§27.13) bring replicas that missed writes back into agreement.

Figure 27.6 — A Dynamo-style write with N = 3 and W = 2.



Reading the diagram. The client sends the write to a coordinator, here node B, which owns the first position in the key's preference list. The coordinator sends the write to all three replicas in parallel over the internal RPC protocol and replies once two acknowledgments arrive; the third (dotted) arrives later and is not waited for. Each replica stores the key in its local storage engine. Failure points: a replica that never receives the write (repaired later), and the coordinator crashing after some but not all replicas applied the write, leaving partial state (§27.8). Scaling adds nodes to the ring; each key still has exactly *N* replicas.

INDUSTRY EXAMPLE

Apache Cassandra. Cassandra adopted Dynamo's ring, replication and repair mechanisms with a Bigtable-style data model [Lakshman and Malik 2010]. Any node can coordinate; a replication strategy chooses replicas per datacenter; each request carries a **consistency level** such as `ONE`, `QUORUM`, `LOCAL_QUORUM` or `ALL` that sets how many replica responses the coordinator waits for. Concurrent writes to a cell are resolved by timestamp (§27.14). *Evidence: Primary* — [Lakshman and Malik 2010; Apache Cassandra Docs]

27.8 Read and write quorums: R + W > N

27.8.1 The overlap argument

DEFINITION

Definition — Quorum. With N replicas per key, a write is acknowledged after W replicas confirm and a read returns after R replicas respond. The configuration is a **strict quorum** when $R + W > N$, so every read set intersects every write set.

FORMULA

Quorum overlap and fault tolerance

$$|S_R \cap S_W| \geq R + W - N \qquad f_{\text{read}} = N - R \qquad f_{\text{write}} = N - W$$

Symbol	Meaning	Units
N	Replicas per key (replication factor)	replicas
R	Responses a read waits for	replicas
W	Acknowledgments a write waits for	replicas
S_R, S_W	The sets of replicas that answered a read and acknowledged a write	sets
$f_{\text{read}}, f_{\text{write}}$	Unavailable replicas a read or write can tolerate	replicas

Derivation. Both sets are drawn from N replicas, so $|S_R \cup S_W| \leq N$. Since $|S_R \cap S_W| = |S_R| + |S_W| - |S_R \cup S_W|$, the overlap is at least $R + W - N$, which is at least 1 exactly when $R + W > N$.

WORKED EXAMPLE

Worked example — The N = 3 configurations.

1. $R = 2, W = 2$: overlap ≥ 1. Reads and writes each survive one unavailable replica. This is Dynamo's common configuration and Cassandra's `QUORUM` with RF = 3.
2. $R = 1, W = 3$: overlap ≥ 1. Reads are fastest and survive two failures, but a single unavailable replica blocks every write.
3. $R = 3, W = 1$: overlap ≥ 1. Writes survive two failures; a single unavailable replica blocks strong reads.
4. $R = 1, W = 1$: overlap ≥ -1, meaning none is guaranteed. A read can miss the latest write entirely. This is `ONE` / `ONE`: fast and available, eventually consistent.
5. $R = 2, W = 1$ or $R = 1, W = 2$: $R + W = 3 = N$, no guaranteed overlap.

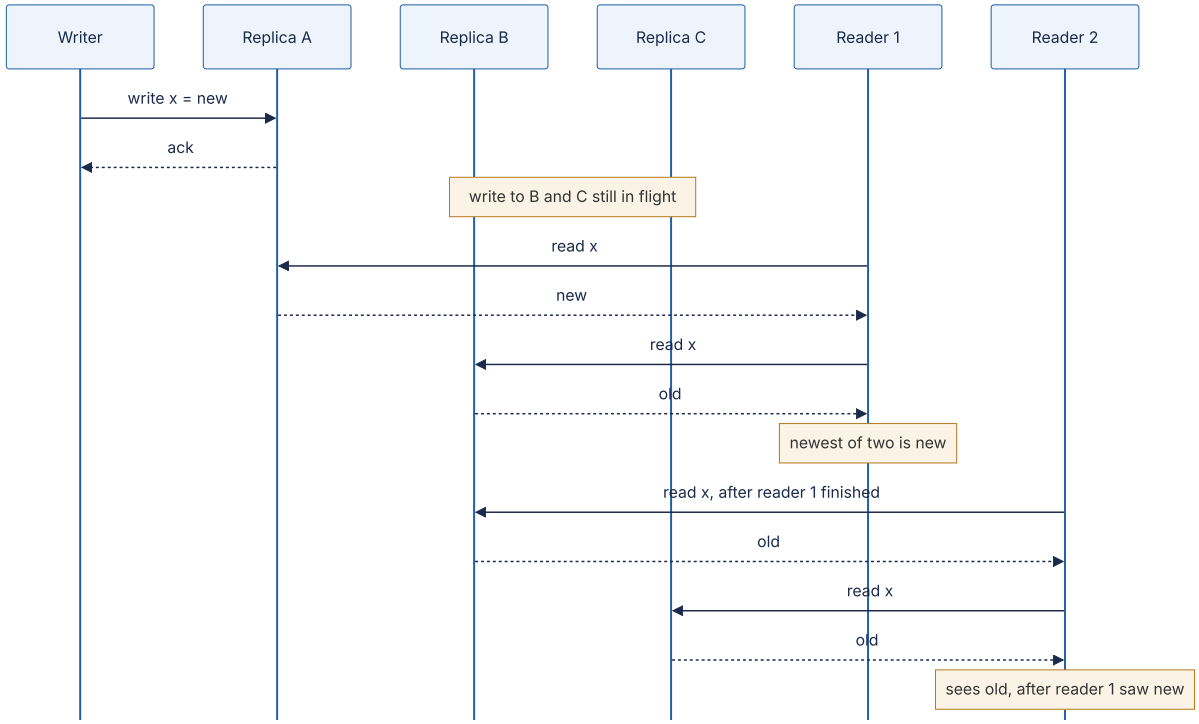
Interpretation. $R + W > N$ trades read cost against write cost along a line; it does not change total fault tolerance much. **Engineering implication.** Choose W by how many failures writes must survive and how slow a write may be, then set $R = N - W + 1$, the cheapest read that still overlaps.

27.8.2 What R + W > N does not guarantee

The overlap argument says that *some* replica in every read set holds the latest *completed* write. It is tempting to conclude that quorum reads are linearizable (§25.3). They are not, for five reasons [Kleppmann 2017, ch. 5]:

1. **Concurrent writes.** Two clients write the same key at the same time and their writes reach replicas in different orders. Overlap guarantees you see both, not that there is an agreed winner. With timestamps (last-writer-wins), one write is silently dropped (§27.14).
2. **A write concurrent with a read.** If a write has reached only some replicas when a read arrives, the read may or may not see it.
3. **Failed writes leave partial state.** If a write reaches one replica but fewer than W, the client is told it failed, but the one replica is not rolled back. Later reads may return the "failed" value, and may later stop returning it.
4. **Sloppy quorums.** If writes may go to substitute nodes outside the key's N home replicas (§27.9), the read and write sets need not intersect at all.
5. **Lost replicas.** If a replica holding the new value fails and is rebuilt from a replica with the old value, the number of copies of the new value can fall below W.

Figure 27.7 — R = W = 2, N = 3, and a read that goes back in time.



Reading the diagram. All calls are synchronous RPCs. The writer's update has reached only replica A. Reader 1 happens to include A in its quorum and returns `new`. Reader 2 starts strictly after Reader 1 finished but picks B and C, both still `old`. Each read overlapped every *completed* write (none has completed yet), so $R + W > N$ is not violated, yet the history is not linearizable: a later read observed an earlier state. The fix is for Reader 1 to write `new` back to a quorum before returning (**blocking read repair**, §27.13), which ABD-style register protocols do and which Cassandra performs for `QUORUM` reads that find a mismatch. Even then, operations that need compare-and-set require consensus (Chapter 26).

27.8.3 Latency: waiting for the k-th fastest replica

A quorum operation sends to all N replicas and waits for the first k replies, where $k = W$ for writes and $k = R$ for reads. Its latency is the **k-th order statistic** of the replica latencies: waiting for fewer replies hides the slow ones.

FORMULA

Latency of the k-th fastest of N replicas (independent, identically distributed)

$$P(T_{(k)} > t) = \sum_{j=0}^{k-1} \binom{N}{j} F(t)^j \, (1 - F(t))^{N-j} \qquad \mathbb{E}[T_{(k)}] = \mu \sum_{i=N-k+1}^{N} \frac{1}{i} \ \text{(exponential)}$$

Symbol	Meaning	Units
$T_{(k)}$	Time until the k-th reply arrives	ms
$F(t)$	Probability that one replica replies within t	dimensionless
N, k	Replicas contacted; replies required	count
j	Number of replicas that replied within t (summation index)	count
μ	Mean latency of one replica, if exponentially distributed	ms

Derivation. The k-th reply is later than t exactly when fewer than k replicas have replied by t; the number that have is binomial with success probability $F(t)$. For exponential latencies, the gap before the first of N replies has mean μ/N, the next gap $\mu/(N-1)$, and so on, by memorylessness.

WORKED EXAMPLE

Worked example — How much does W cost? $N = 3$.

1. *Tail model.* Each replica is independently "slow" (a garbage-collection pause, say 50 ms) with probability $p = 0.01$, so $F(t) = 0.99$ for t below 50 ms. The operation is slow when fewer than k replicas are fast:
   - $k = 1$: $p^3 = 10^{-6}$.
   - $k = 2$: $p^3 + 3p^2(1-p) = 10^{-6} + 2.97 \times 10^{-4} = 2.98 \times 10^{-4}$.
   - $k = 3$: $1 - 0.99^3 = 0.0297$.
2. *Mean model.* Exponential replica latency with $\mu = 2$ ms: $k = 1$: $2 \times \frac{1}{3} = 0.67$ ms; $k = 2$: $2 \times (\frac{1}{3} + \frac{1}{2}) = 1.67$ ms; $k = 3$: $2 \times (\frac{1}{3} + \frac{1}{2} + 1) = 3.67$ ms.

Interpretation. Waiting for all three replicas exposes about 3% of operations, so the p99, to the 50 ms pause; waiting for two exposes 0.03%, beyond even the p99.9. **Engineering implication.** Quorums of two out of three keep the slowest replica off the tail. This is why Dynamo-style systems contact all N replicas even when they need only R or W answers, and why "read from one replica, retry on timeout" is slower in the tail than a parallel quorum.

The program below verifies the overlap table and both latency models.

```
        """Quorum overlap and the latency of waiting for the k-th fastest of N repli-
cas."""
        from itertools import combinations
        from math import comb
        import random

        def min_overlap(n, r, w):
            """Smallest possible intersection of any read set and any write set."""
            replicas = range(n)
            return min(len(set(rs) & set(ws))
                       for rs in combinations(replicas, r)
                       for ws in combinations(replicas, w))

        def p_kth_slow(n, k, p_slow):
            """P(the k-th fastest reply is slow) = P(fewer than k replicas are fast)."""
            q = 1 - p_slow
            return sum(comb(n, j) * q**j * p_slow**(n - j) for j in range(k))

        def mean_kth_exponential(n, k, mean):
            """E[k-th smallest of n i.i.d. exponential latencies with the given
mean]."""
            return mean * sum(1 / i for i in range(n - k + 1, n + 1))

        if __name__ == "__main__":
            n = 3
            print("R W  R+W>N  min overlap  read faults ok  write faults ok")
            for r in range(1, n + 1):
                for w in range(1, n + 1):
                    print(f"{r} {w}  {str(r + w > n):5}  {min_overlap(n, r, w):^11}  "
                          f"{n - r:^14}  {n - w:^15}")

            print("\nP(k-th reply is slow), each replica slow with p = 0.01")
            for k in (1, 2, 3):
                print(f"  k = {k}: {p_kth_slow(n, k, 0.01):.3e}")

            random.seed(1)
            trials = 200_000
            print("\nk-th fastest of 3 exponential replies, mean 2 ms")
            for k in (1, 2, 3):
                sim = sum(sorted(random.expovariate(1 / 2.0) for _ in range(n))[k - 1]
                          for _ in range(trials)) / trials
                print(f"  k = {k}: formula {mean_kth_exponential(n, k, 2.0):.3f} ms, "
                      f"simulated {sim:.3f} ms")
```

Output (abridged to the $R = W$ rows and the latency results):

```
R W  R+W>N  min overlap  read faults ok  write faults ok
1 1  False       0             2               2
2 2  True        1             1               1
3 3  True        3             0               0

P(k-th reply is slow), each replica slow with p = 0.01
  k = 1: 1.000e-06
  k = 2: 2.980e-04
  k = 3: 2.970e-02

k-th fastest of 3 exponential replies, mean 2 ms
  k = 1: formula 0.667 ms, simulated 0.667 ms
  k = 2: formula 1.667 ms, simulated 1.666 ms
  k = 3: formula 3.667 ms, simulated 3.663 ms
```

What to notice:

- `min_overlap` checks every pair of read and write sets by brute force, confirming that the overlap is positive exactly when $R + W > N$.
- The simulated means match the harmonic-sum formula to three digits.

COMMON MISTAKE

Mistake — "QUORUM reads and writes make Cassandra linearizable." They give overlap, not linearizability: concurrent writes are resolved by timestamp, failed writes are not rolled back, and only blocking read repair prevents the read anomaly of Figure 27.7. Compare-and-set needs Cassandra's Paxos-based lightweight transactions.

27.9 Sloppy quorums and hinted handoff

27.9.1 Writing to a stand-in

DEFINITION

Definition — Sloppy quorum and hinted handoff. In a **sloppy quorum**, a write that cannot reach W of a key's N home replicas is accepted by the next healthy nodes on the ring instead, and still counts toward W. Each stand-in stores the write with a **hint** naming the intended home replica and **hands it off** when that replica recovers [DeCandia et al. 2007].

First-principles explanation

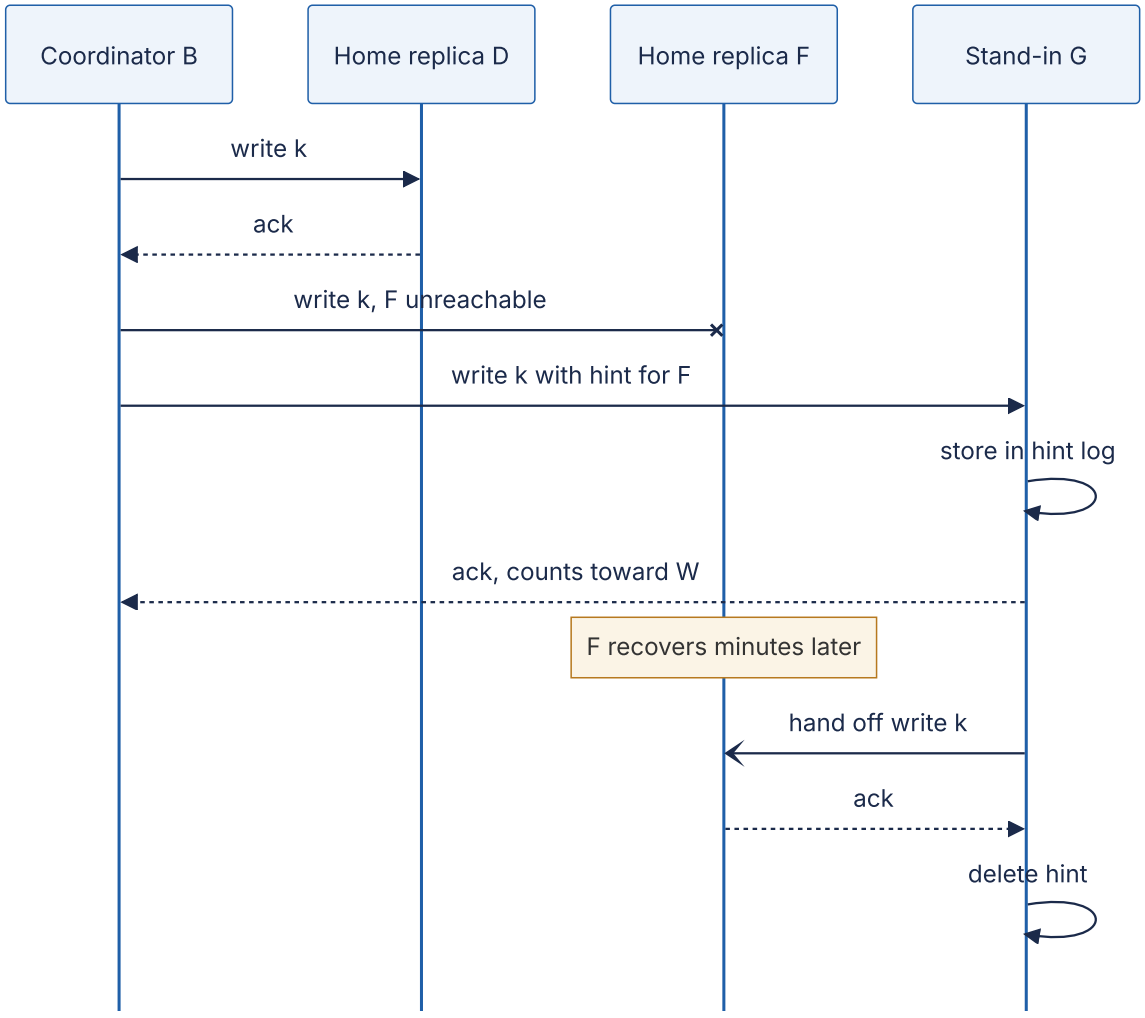
A courier leaves a parcel next door with a note, "for number 12", and the neighbor hands it over when number 12 returns. Nothing is lost, but anyone asking at number 12 in the

meantime will not find it.

How it works internally

1. The coordinator walks the preference list beyond the first *N* nodes when home replicas are unreachable, choosing the first *N* *healthy* nodes.
2. A stand-in stores the write in a separate local hint store, tagged with the intended owner.
3. The stand-in periodically checks whether the owner is reachable again and, when it is, replays the hint and deletes it.
4. If the owner stays down longer than a configured **hint window**, the stand-in stops collecting hints, and Merkle-tree repair (§27.13) must restore the replica.

Figure 27.8 — A sloppy quorum write and later handoff.



Reading the diagram. The coordinator's writes are synchronous RPCs. Home replica F is unreachable (crossed arrow), so stand-in G, the next node on the ring, accepts the write into a separate hint log, and its acknowledgment counts toward *W*. When F returns, G replays the write asynchronously (open arrowhead) and deletes the hint. Storage

boundaries are the hint log on G and the main store on F. Failure points: G failing before handoff (the hint is lost, so anti-entropy must repair F), and reads in the meantime that go to the home replicas and miss the write, because G is not in their read set.

Mathematical foundations

FORMULA

Hint volume during an outage

$$V_h = \frac{r_w \cdot N}{n} \cdot T_{\text{down}} \cdot s$$

Symbol	Meaning	Units
V_h	Total hints accumulated for the failed node across the cluster	bytes
r_w	Cluster-wide client write rate	writes/s
N	Replication factor	replicas
n	Nodes in the cluster	nodes
T_{down}	Time the node is down (capped by the hint window)	s
s	Size of one write including overhead	bytes

WORKED EXAMPLE

Worked example — A one-hour outage. A 12-node cluster takes $r_w = 60,000$ writes/s with $N = 3$ and 1 KB writes.

1. Replica writes per node: $60,000 \times 3/12 = 15,000$ writes/s.
2. Hints for a one-hour outage: $15,000 \times 3,600 = 5.4 \times 10^7$ writes, $5.4 \times 10^7 \times 1$ KB $= 54$ GB.
3. Spread over the 11 survivors: about 4.9 GB each.
4. Replay into the recovered node at 100 MB/s total: $54 \times 10^9 / 10^8 = 540$ s, about 9 minutes, during which that node still serves stale reads.

Interpretation. Hints are cheap for short outages and grow linearly with downtime. **Engineering implication.** Cap the hint window (Cassandra's default is 3 hours, as of Cassandra 4) so stand-ins do not fill their disks, alert when a node exceeds it, and run a full repair before the node rejoins the read path.

Real-world industry applications

INDUSTRY EXAMPLE

Dynamo versus Cassandra. Dynamo used sloppy quorums: hinted writes count toward W, maximizing write availability at the cost of quorum overlap [DeCandia et al. 2007]. Cassandra stores hints too, but by default they do not count toward the consistency level; only `ANY` accepts a write stored solely as a hint. Cassandra's quorums are therefore strict, and hints are a best-effort repair mechanism [Apache Cassandra Docs: Hints]. *Evidence: Primary* — [DeCandia et al. 2007; Apache Cassandra Docs: Hints]

WARNING / TRADE-OFF

Warning — Sloppy quorums break the overlap guarantee. A write acknowledged by stand-ins G and H and a later read from home replicas D and F can share no node, even though $R + W > N$. Treat a sloppy quorum as a durability promise ("W nodes hold this write"), not a consistency promise.

27.10 Failure detection

27.10.1 Heartbeats and timeouts

DEFINITION

Definition — Failure detector. A component that outputs, for each monitored process, whether it currently **suspects** that process has crashed. It is **complete** if every crashed process is eventually suspected and **accurate** if live processes are not suspected. In an asynchronous network no detector can be both perfectly complete and perfectly accurate, because a slow process is indistinguishable from a dead one [Chandra and Toueg 1996].

First-principles explanation

You phone a friend every evening. One evening there is no call. Did the friend's phone die, are they busy, or is the network down? If you raise the alarm after five minutes, you will often worry about nothing; if you wait a week, you will be late when something really happened. Every failure detector picks a point on this curve between **detection time** and **false-suspicion rate**.

How it works internally

1. Each node sends a **heartbeat** every h seconds (push), or a monitor sends **pings** and expects replies (pull).
2. The monitor records the arrival time of the last heartbeat.
3. If nothing arrives within a **timeout** T_{out}, the node is suspected.

A crash happens at a random point in the heartbeat cycle, so the crash-to-suspicion time is between $T_{\text{out}} - h$ and T_{out}, about $T_{\text{out}} - h/2$ on average. A fixed timeout must exceed the worst normal gap from jitter, garbage-collection pauses and CPU starvation; three to five heartbeat intervals is a common rule. But one number cannot suit both a quiet LAN and a congested cross-region link.

27.10.2 The phi-accrual detector

Hayashibara et al. replaced the binary verdict with a continuous **suspicion level** φ that adapts to the observed heartbeat history; each application then picks its own threshold [Hayashibara et al. 2004].

FORMULA

Phi-accrual suspicion level (normal model)

$$\varphi(t_{\text{now}}) = -\log_{10}\left(1 - F(t_{\text{now}} - t_{\text{last}})\right), \qquad F(\delta) = \Phi\left(\frac{\delta - \mu}{\sigma}\right)$$

Symbol	Meaning	Units
φ	Suspicion level; the detector's false-suspicion probability is about $10^{-\varphi}$	dimensionless
$t_{\text{now}} - t_{\text{last}}$	Time since the last heartbeat arrived, δ	ms
μ, σ	Mean and standard deviation of recent inter-arrival times (sliding window)	ms
F	Estimated cumulative distribution of inter-arrival times	dimensionless
Φ	Standard normal cumulative distribution function	dimensionless

$1 - F(\delta)$ is the probability that a live node's next heartbeat would arrive even later than δ. If you suspect the node now, that is roughly the probability you are wrong. So $\varphi = 1$ means a 10% chance of a mistake, $\varphi = 2$ means 1%, and $\varphi = 8$ means 10^{-8}.

WORKED EXAMPLE

Worked example — When does phi reach 8? Heartbeats arrive every $\mu = 1,000$ ms with $\sigma = 100$ ms.

1. After 1,200 ms of silence: $z = (1,200 - 1,000)/100 = 2$; $1 - \Phi(2) = 0.0228$; $\varphi = -\log_{10} 0.0228 = 1.64$.
2. After 1,400 ms: $z = 4$; $1 - \Phi(4) = 3.17 \times 10^{-5}$; $\varphi = 4.50$.
3. After 1,500 ms: $z = 5$; 2.87×10^{-7}; $\varphi = 6.54$.
4. After 1,600 ms: $z = 6$; 9.87×10^{-10}; $\varphi = 9.01$.
5. Threshold 8 means $1 - \Phi(z) = 10^{-8}$, so $z = 5.61$: suspicion after $1,000 + 5.61 \times 100 = 1,561$ ms.
6. On a jittery link with $\sigma = 400$ ms, the same threshold waits $1,000 + 5.61 \times 400 = 3,245$ ms.

Interpretation. The same threshold produces a short timeout on a steady link and a long one on a noisy link, because it is a statement about error probability, not about time. **Engineering implication.** Set a floor on σ (otherwise a very regular sender makes the detector hair-trigger) and an allowance for expected pauses, then tune one threshold for the whole fleet.

```
        """A phi-accrual failure detector (Hayashibara et al. 2004) with a normal
model."""
        from collections import deque
        from math import erfc, log10, sqrt
        import random
        import statistics

        class PhiAccrualDetector:
            def __init__(self, window=1000, min_std_ms=50.0):
                self.intervals = deque(maxlen=window)   # recent heartbeat inter-arrival
times
                self.last = None
                self.min_std = min_std_ms              # floor so a very regular sender
is not hair-trigger

            def heartbeat(self, now_ms):
                if self.last is not None:
                    self.intervals.append(now_ms - self.last)
                self.last = now_ms

            def phi(self, now_ms):
                if len(self.intervals) < 2:
                    return 0.0
                mu = statistics.fmean(self.intervals)
                sigma = max(statistics.stdev(self.intervals), self.min_std)
                z = (now_ms - self.last - mu) / sigma
                p_later = 0.5 * erfc(z / sqrt(2))       # P(next heartbeat arrives even
later)
                return -log10(max(p_later, 1e-300))

        if __name__ == "__main__":
            random.seed(42)
            d = PhiAccrualDetector()
            t = 0.0
            for _ in range(1000):                       # heartbeats every ~1,000 ms, sd
~100 ms
                t += random.gauss(1000, 100)
                d.heartbeat(t)
            mu = statistics.fmean(d.intervals)
            sd = statistics.stdev(d.intervals)
            print(f"learned mean {mu:.0f} ms, std {sd:.0f} ms")
            for silence in (1000, 1200, 1400, 1500, 1600, 2000):
                print(f"silent for {silence:>4} ms -> phi = {d.phi(t + silence):6.2f}")
            s = 1000
            while d.phi(t + s) < 8:                     # when does phi cross the
threshold of 8?
                s += 1
            print(f"phi reaches 8 after {s} ms of silence")
```

Output:

```
learned mean 998 ms, std 102 ms
silent for 1000 ms -> phi =   0.31
silent for 1200 ms -> phi =   1.62
silent for 1400 ms -> phi =   4.39
silent for 1500 ms -> phi =   6.36
silent for 1600 ms -> phi =   8.74
silent for 2000 ms -> phi =  22.34
phi reaches 8 after 1571 ms of silence
```

What to notice: the detector learns μ and σ from a sliding window of 1,000 intervals; `erfc` computes the normal tail without losing precision; and the learned values (998 ms, 102 ms) give a crossing at 1,571 ms, close to the 1,561 ms of the worked example.

INDUSTRY EXAMPLE

Cassandra and Akka. Cassandra marks a node down when its phi value exceeds `phi_convict_threshold`, default 8. Its implementation models gossip inter-arrival times with an exponential rather than a normal distribution, so φ grows linearly with silence [Apache Cassandra Docs; Cassandra source, `FailureDetector`]. Akka Cluster uses the normal model with a configurable threshold, a minimum standard deviation and an "acceptable heartbeat pause" [Akka Docs: Phi Accrual Failure Detector]. *Evidence: Primary* — [Apache Cassandra Docs; Akka Docs]

27.10.3 Gossip and SWIM

All-to-all heartbeating costs $n(n-1)/h$ messages per second: 999,000 per second for 1,000 nodes at one per second. Large clusters instead spread information **epidemically**: each node periodically contacts a few random peers and exchanges what it knows, as an infection spreads [Demers et al. 1987].

DEFINITION

Definition — Gossip protocol. A protocol in which, every round, each node exchanges state with f randomly chosen peers (the **fanout**). In **push** gossip informed nodes send updates; in **pull** gossip nodes ask peers for news; **push–pull** does both. **Anti-entropy** gossip exchanges full state; **rumor mongering** spreads only recent updates and stops after a while [Demers et al. 1987].

FORMULA

Rounds for push gossip to reach every node

$$T_{\text{rounds}} \approx \log_{1+f} n + \frac{\ln n}{f} \qquad (\text{for } f = 1:\ \log_2 n + \ln n + O(1))$$

Symbol	Meaning	Units
T_{rounds}	Rounds until every node is informed	rounds
n	Number of nodes	nodes
f	Peers contacted per node per round	peers/round

Derivation. Early on almost every target is uninformed, so the informed set grows by a factor of about $1 + f$ per round: $\log_{1+f} n$ rounds to reach most nodes. At the end, each uninformed node escapes all f pushes from nearly n informed nodes with probability about e^{-f} per round, so the uninformed count shrinks by e^{-f} per round and the last one is reached after about $\ln n/f$ more rounds. Pittel proved the $f = 1$ case [Pittel 1987]. Pull shrinks the uninformed fraction from p to about p^2 per round at the end, so push–pull finishes in $\log_3 n + O(\log \log n)$ rounds [Karp et al. 2000].

WORKED EXAMPLE

Worked example — Spreading a membership change to 1,000 nodes.

1. Push, $f = 1$: $\log_2 1,000 + \ln 1,000 = 9.97 + 6.91 = 16.9$ rounds.
2. Push, $f = 3$: $\log_4 1,000 + 6.91/3 = 4.98 + 2.30 = 7.3$ rounds.
3. Growth with size, $f = 1$: going to 10,000 nodes adds $\log_2 10 + \ln 10 = 3.32 + 2.30 = 5.6$ rounds.

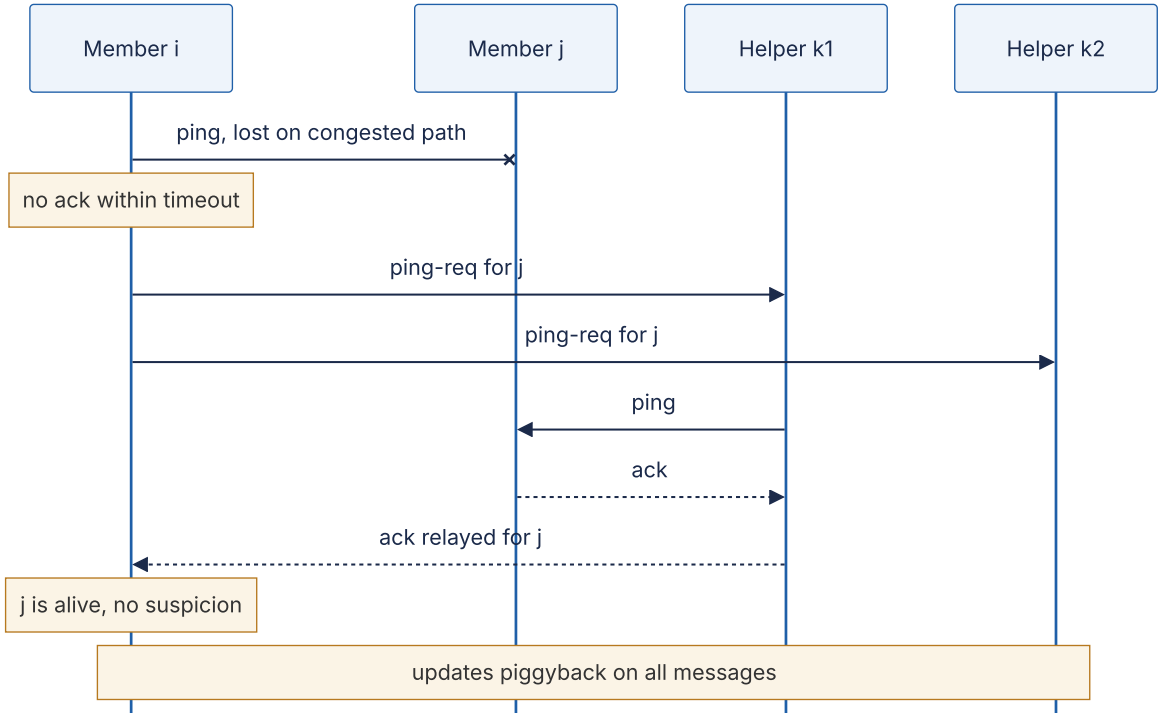
Interpretation. Dissemination time grows with $\log n$, and each node's message load is constant (f per round) regardless of cluster size. **Engineering implication.** Gossip scales membership and failure news to thousands of nodes, but a full spread takes tens of rounds; anything that must take effect everywhere *at once* belongs in a consensus-backed store (Chapter 26).

SWIM combines a randomized failure detector with gossip dissemination [Das et al. 2002]. In each **protocol period** T', every member:

1. Picks a random member M_j and sends it a `ping`.
2. If no `ack` arrives within a short timeout, sends `ping-req` to k other random members, asking them to ping M_j and relay any ack. This indirect probe avoids blaming M_j for a congested link between two particular nodes.

3. If still no ack, marks M_j **suspect**, rather than dead, and spreads the suspicion. M_j can refute it by gossiping an “alive” message with a higher **incarnation number**; if nobody refutes it within a suspicion timeout, M_j is declared failed.
4. Membership updates (joins, suspicions, failures) are **piggybacked** on ping and ack messages, so dissemination costs no extra messages.

Figure 27.9 — A SWIM protocol period with an indirect probe.



Reading the diagram. All messages are small UDP datagrams in typical implementations. Member *i*’s direct ping is lost, so it asks two helpers to probe *j* for it; one helper’s ping succeeds and its ack is relayed back, so *j* is not suspected. Had both indirect probes failed, *i* would gossip “*j* suspect”, and *j* would have a suspicion timeout to refute it. No member stores more than the membership list. Failure points: a member that is itself overloaded may miss acks and wrongly suspect others, which the Lifeguard extensions address by lengthening its own timeouts [Dadgar et al. 2017]. Message load per member is constant as the group grows.

FORMULA

SWIM expected time to first detection

$$\mathbb{E}[T_{\text{detect}}] = \frac{T'}{1 - (1 - \frac{1}{n-1})^{n-1}} \quad \overset{n \to \infty}{\to} \quad T' \cdot \frac{e}{e-1} \approx 1.58\,T'$$

Symbol	Meaning	Units
T'	Protocol period	s
n	Group size	members
$\mathbb{E}[T_{\text{detect}}]$	Expected time until some member first probes the failed member	s

Derivation. Each of the $n-1$ live members picks the failed member with probability $1/(n-1)$, so the chance that none does in a period is $(1 - \frac{1}{n-1})^{n-1} \approx e^{-1}$. The number of periods until someone does is geometric with success probability $1 - e^{-1}$, giving a mean of $1/(1 - e^{-1}) = e/(e-1)$.

WORKED EXAMPLE

Worked example — Detection budget for 1,000 members. $T' = 1$ s, $n = 1,000$.

1. $(1 - 1/999)^{999} = 0.3677$, so $\mathbb{E}[T_{\text{detect}}] = 1/(1 - 0.3677) = 1.58$ s.
2. Add a suspicion timeout of, say, 5 s for refutation: about 6.6 s from crash to declaration.
3. Spreading the verdict by piggybacking takes $O(\log n)$ further periods, about 10–17 at this size.
4. Message load: about 2 messages (ping and ack) per member per period, about 2,000 per second cluster-wide, versus 999,000 for all-to-all heartbeats.

Interpretation. Detection time is independent of group size; only dissemination grows, logarithmically. **Engineering implication.** SWIM-style membership is the standard choice for clusters of hundreds to thousands of nodes; tune the suspicion timeout, not the probe rate, to trade false positives for speed.

The simulation below measures push, pull and push–pull dissemination and SWIM’s first-detection time.

```
        """Rounds for a rumor to reach every node: push, pull and push-pull gossip,
        plus SWIM's expected time to first detection of a crashed member."""
        import math
        import random
        import statistics

        def spread(n, mode, fanout=1, rng=random):
            """Synchronous rounds: every node contacts `fanout` random peers per
round."""
            informed = [False] * n
            informed[0] = True
            count, rounds = 1, 0
            while count < n:
                rounds += 1
                new = informed[:]                       # updates take effect next
round
                for node in range(n):
                    for _ in range(fanout):
                        peer = rng.randrange(n - 1)
                        peer += peer >= node            # a random peer other than it-
self
                        if mode in ("push", "push-pull") and informed[node]:
                            new[peer] = True            # push: informed node tells
peer
                        if mode in ("pull", "push-pull") and informed[peer]:
                            new[node] = True            # pull: node asks peer for news
                informed = new
                count = sum(informed)
            return rounds

        def swim_first_detection(n, rng=random):
            """Protocol periods until some live member pings the one crashed member."""
            periods = 0
            while True:
                periods += 1
                # each of the n-1 live members pings one random other member
                if any(rng.randrange(n - 1) == 0 for _ in range(n - 1)):
                    return periods

        if __name__ == "__main__":
            rng = random.Random(2026)
            n, trials = 1000, 100
            print(f"n = {n}, fanout 1, {trials} trials each")
            for mode in ("push", "pull", "push-pull"):
                r = [spread(n, mode, 1, rng) for _ in range(trials)]
                print(f"  {mode:9s}: mean {statistics.fmean(r):5.2f} rounds, max
{max(r)}")
            print(f"  model log2(n) + ln(n) = {math.log2(n) + math.log(n):.2f} rounds
(push)")
            for f in (2, 3):
                r = [spread(n, "push", f, rng) for _ in range(trials)]
                model = math.log(n, 1 + f) + math.log(n) / f
                print(f"  push, fanout {f}: mean {statistics.fmean(r):5.2f}, model
{model:5.2f}")
            for size in (100, 1000, 10000):
                print(f"  push, n = {size:>5}: mean "
```

```
                      f"{statistics.fmean(spread(size, 'push', 1, rng) for _ in
range(30)):5.2f} rounds")

            d = [swim_first_detection(n, rng) for _ in range(5000)]
            print(f"SWIM first detection: mean {statistics.fmean(d):.3f} periods, "
                  f"e/(e-1) = {math.e / (math.e - 1):.3f}")
```

Output:

```
n = 1000, fanout 1, 100 trials each
  push     : mean 17.99 rounds, max 22
  pull     : mean 13.66 rounds, max 19
  push-pull: mean  9.13 rounds, max 10
  model log2(n) + ln(n) = 16.87 rounds (push)
  push, fanout 2: mean 10.62, model  9.74
  push, fanout 3: mean  8.28, model  7.29
  push, n =   100: mean 12.23 rounds
  push, n =  1000: mean 18.33 rounds
  push, n = 10000: mean 23.70 rounds
SWIM first detection: mean 1.597 periods, e/(e-1) = 1.582
```

What to notice:

- Push gossip takes about one round more than the model, the $O(1)$ term; each tenfold increase in n adds about 5.6 rounds, as predicted.
- Push–pull halves the rounds because pull mops up the last uninformed nodes quadratically fast.
- SWIM's simulated detection time matches $e/(e-1)$ periods.

COMMON MISTAKE

Mistake — "A failure detector tells you a node is dead." It tells you a node is *suspected*. A suspected primary may still be running and writing. Every action taken on suspicion, such as promoting a replica, must fence the suspect (§26.13).

27.11 Failover

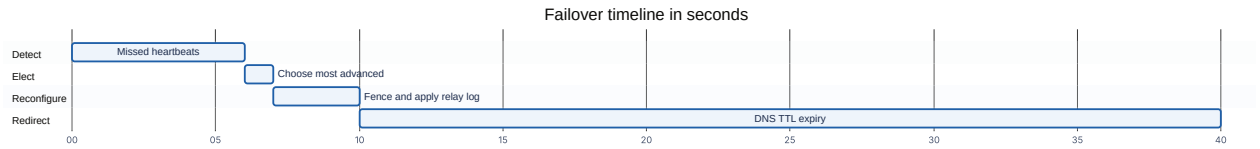
27.11.1 From detection to redirection

DEFINITION

Definition — Failover. The sequence that replaces a failed node in a role: **detection**, **election** of a replacement, **reconfiguration** (making the replacement consistent and fencing the old node) and **client redirection**.

Leaderless systems need no failover for writes; primary–backup, chain and consensus systems do. Each step consumes part of the availability budget.

Figure 27.10 — A failover time budget with DNS redirection.



Reading the diagram. Time runs left to right from the crash; each bar must finish before the next starts, so the steps are sequential. Detection waits for the timeout; election picks the replica holding the most acknowledged log (or runs a consensus election, §26.5); reconfiguration fences the old primary, applies any unapplied log and switches the replica to read–write mode; redirection waits for clients to learn the new address. The DNS bar dominates. The failure points are a premature detection (split brain if fencing fails) and redirection that never completes for clients that cache addresses beyond the TTL.

FORMULA

Failover time budget

$$T_{\text{fo}} = T_{\text{detect}} + T_{\text{elect}} + T_{\text{reconfig}} + T_{\text{redirect}} \qquad D_{\text{yr}} = v \cdot T_{\text{fo}}$$

Symbol	Meaning	Units
T_{fo}	Time from crash until clients write successfully again	s
T_{detect}	Time to suspect the failure	s
T_{elect}	Time to choose a replacement	s
T_{reconfig}	Time to fence, catch up and promote	s
T_{redirect}	Time until clients reach the replacement	s
v	Failovers per year	1/year
D_{yr}	Write downtime per year from failovers	s/year

WORKED EXAMPLE

Worked example — DNS versus a proxy. Heartbeats every 2 s with a 6 s timeout; election 1 s; reconfiguration 3 s.

1. DNS redirection with a 30 s TTL: $T_{\text{fo}} = 6 + 1 + 3 + 30 = 40$ s.
2. Proxy or virtual IP that switches in 1 s: $T_{\text{fo}} = 6 + 1 + 3 + 1 = 11$ s.
3. With $v = 6$ failovers a year (crashes, kernel patches, zone events): $6 \times 40 = 240$ s versus $6 \times 11 = 66$ s.
4. Against a 99.99% target (52.6 min = 3,156 s per year, §4.14): DNS failovers use 7.6% of the budget, the proxy 2.1%. Against a monthly budget of 4.32 min, one DNS failover uses 15%.

Interpretation. Redirection, not detection, is often the largest term. Consensus-replicated systems shrink detection and election together to about 0.16–1.2 s (§26.7.2), which leaves redirection even more dominant. **Engineering implication.** Put a proxy, a virtual IP or a topology-aware client in front of a replicated primary, and measure each term in game days rather than assuming it.

Dangers

- **Split brain.** If the old primary is merely slow or partitioned, it may still accept writes. Both "primaries" then diverge (§26.12). Only fencing, by lease expiry, a fencing token checked by storage, or cutting power, makes promotion safe.
- **Data loss with asynchronous replication.** The promoted replica lacks the last $r_w \ell$ writes (§27.4). Worse, when the old primary returns, its unreplicated writes conflict with new writes that reused the same keys or IDs.

INDUSTRY EXAMPLE

GitHub, October 2018. A 43-second loss of connectivity between GitHub's US East Coast network hub and its primary East Coast datacenter led its MySQL failover tooling (Orchestrator) to promote replicas in the US West Coast. When connectivity returned, the East Coast databases held writes not present in the West and vice versa, so GitHub could not simply fail back. It chose data integrity over speed and ran degraded for 24 hours and 11 minutes while reconciling; its follow-ups included preventing automatic cross-region promotion. *Evidence: Primary* — [GitHub 2018]

27.12 Recovery

27.12.1 Catching up, snapshotting and rebuilding

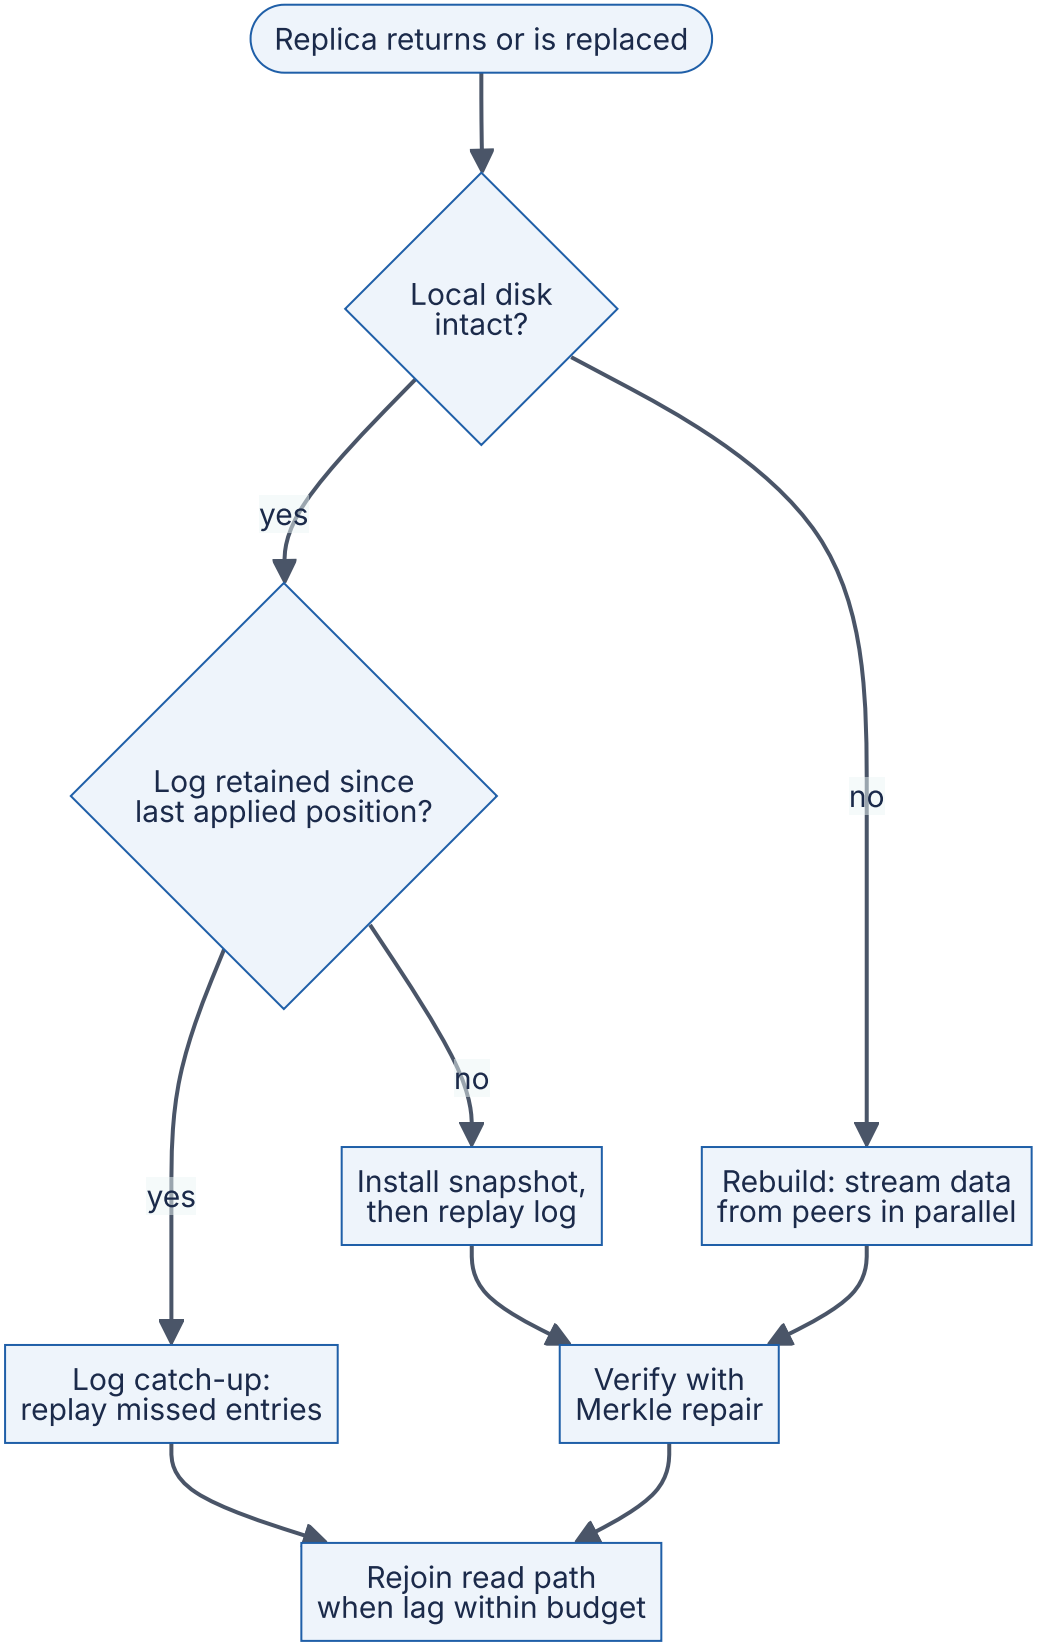
DEFINITION

Definition — Replica recovery. Returning a replica to full membership after a crash or replacement, by **log catch-up** (replaying missed log entries), **snapshot plus log** (installing a copy of the state, then replaying from the snapshot's position) or **rebuild** (copying all data from peers).

How it works internally

1. **Log catch-up.** If the node's disk survived and the primary still retains every log entry since the node's last applied position, the node replays them (§14.4.2). PostgreSQL retains WAL for a replica through `wal_keep_size` or a **replication slot**; MySQL keeps binlogs for `binlog_expire_logs_seconds`.
2. **Snapshot plus log.** If the log has been truncated past the node's position, it installs a snapshot taken at a known log position and replays from there. PostgreSQL's `pg_basebackup` and Raft's `InstallSnapshot` (§26.7) work this way.
3. **Rebuild.** A replacement node in a leaderless store streams its token ranges from the surviving replicas; with virtual nodes (§14.8), many peers send in parallel. New writes for those ranges go to the joining node while it streams.

Figure 27.11 — Choosing a recovery path.



Reading the diagram. Decisions run top to bottom. Every path ends at the same gate: the replica rejoins the read path only once its lag is within the staleness budget. Snapshot and rebuild paths transfer bulk data over the network and are throttled to protect the sources; log catch-up streams only missed entries. Storage boundaries are the source’s

log retention (which decides the middle branch) and the new node’s disk. Failure points: a second failure during a long rebuild, which leaves the data with fewer copies (§4.16), and a source overwhelmed by streaming.

FORMULA

Recovery time for snapshot plus log

$$T_{\text{rec}} = \frac{D}{B_{\text{eff}}} + \frac{r_{\text{in}} \cdot D/B_{\text{eff}}}{r_{\text{apply}} - r_{\text{in}}}, \qquad B_{\text{eff}} = \min\left(\sum_i B_{\text{src},i},\ B_{\text{dst}}\right)$$

Symbol	Meaning	Units
T_{rec}	Time until the replica is current	s
D	Size of the snapshot or data to copy	bytes
B_{eff}	Effective copy bandwidth	bytes/s
$B_{\text{src},i}$	Throttled send rate of source i	bytes/s
B_{dst}	Receiver limit: NIC or disk write rate	bytes/s
r_{in}	Rate of new log entries during the copy	entries/s
r_{apply}	Rate at which the replica replays entries	entries/s

The second term is the catch-up time of §14.4.2 applied to the backlog accumulated during the copy.

WORKED EXAMPLE

Worked example — Rebuilding a 2 TB replica. New writes arrive at $r_{\text{in}} = 5,000$ entries/s and the replica applies $r_{\text{apply}} = 8,000$ entries/s.

1. One source throttled to 250 MB/s: copy $= 2 \times 10^{12} / 2.5 \times 10^{8} = 8,000$ s (2.2 h). Backlog $= 5,000 \times 8,000 = 4 \times 10^{7}$ entries; catch-up $= 4 \times 10^{7} / 3,000 = 13,333$ s (3.7 h). Total about 5.9 h.
2. Twenty sources at 100 MB/s each (2 GB/s) into a 10 Gb/s NIC (1.25 GB/s): $B_{\text{eff}} = 1.25$ GB/s; copy $= 1,600$ s (27 min). Backlog 8×10^{6}; catch-up 2,667 s (44 min). Total about 71 min.
3. Durability during recovery: from §4.16, the chance of losing a three-way replicated item grows with the square of repair time, so cutting 21,333 s to 4,267 s improves it by about $(21,333/4,267)^2 = 5^2 = 25$ times.

Interpretation. Recovery time is dominated by copy bandwidth and by apply headroom, and parallel sources help only until the receiver saturates. **Engineering implication.** Spread replicas with virtual nodes, keep apply headroom, and retain enough log that short outages never need a full copy.

WARNING / TRADE-OFF

Warning — A rejoining replica can resurrect deleted data. Leaderless stores record deletes as **tombstones** and purge them after a grace period (Cassandra's `gc_grace_seconds`, 10 days by default). A replica that was down longer than that, or never repaired within it, still holds the deleted rows and will spread them back. Repair every replica within the grace period, and never return a long-dead node without a full repair.

27.13 Anti-entropy and read repair

27.13.1 Repairing on the read path and in the background

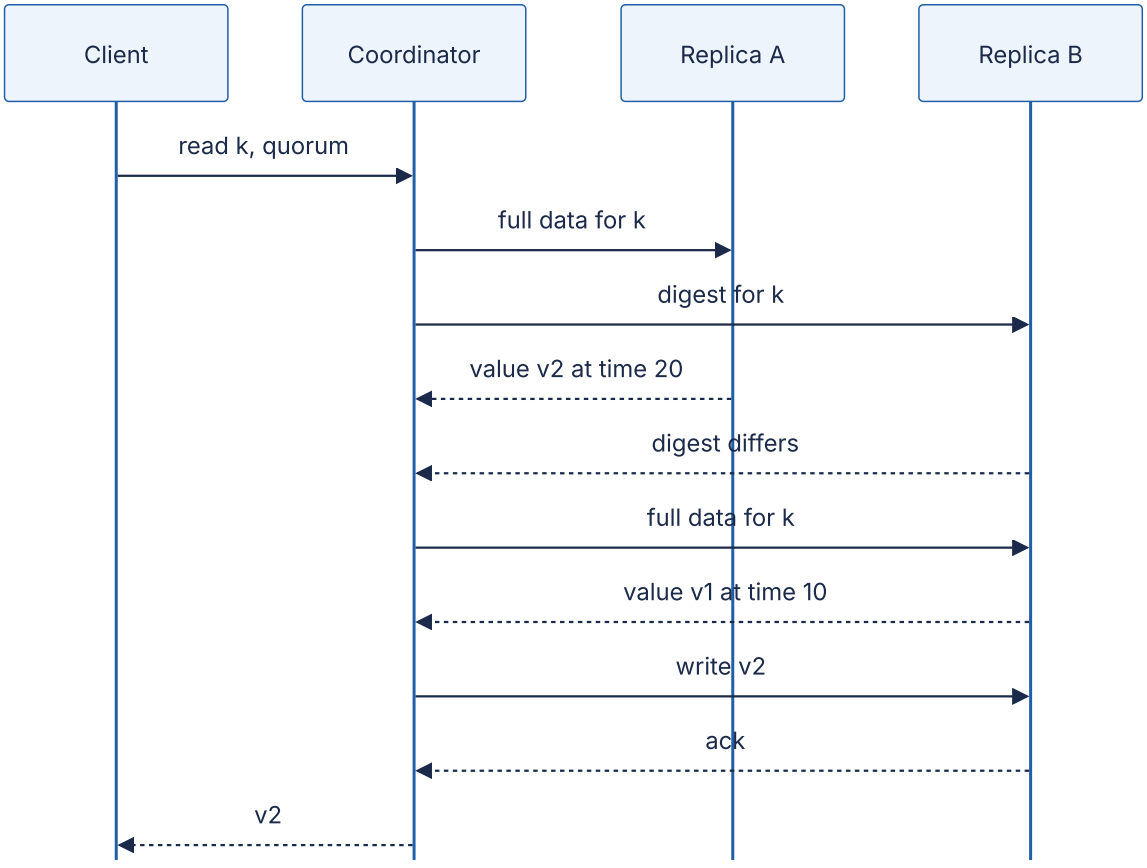
DEFINITION

Definition — Read repair and anti-entropy. Read repair fixes stale replicas discovered while serving a read: the coordinator writes the newest version back to replicas that returned older ones. **Anti-entropy** is a background process that compares whole replicas, typically with Merkle trees, and copies the differences [DeCandia et al. 2007; Demers et al. 1987].

Hints can be lost and cover only short outages. Two further mechanisms close the gaps:

1. **Read repair.** On a read the coordinator compares versions, usually by requesting full data from one replica and digests (hashes) from the others. On a mismatch it fetches full data, computes the newest version, returns it and writes it back to the stale replicas. **Blocking** read repair finishes the write-back before replying, which is what prevents the anomaly of Figure 27.7; **asynchronous** read repair replies first. Read repair only fixes keys that are read, so rarely read keys can stay divergent indefinitely.
2. **Merkle-tree anti-entropy.** Each replica builds a hash tree over each key range (§17.8). Two replicas compare roots, descend only into differing subtrees and stream only the divergent leaf ranges. For two replicas of a million-leaf tree that differ in two leaves, this compares about 80 hashes instead of the whole data set (§17.8).

Figure 27.12 — Blocking read repair with R = 2.



Reading the diagram. All calls are synchronous. Asking one replica for data and others for digests saves bandwidth when replicas agree, the common case. On a mismatch the coordinator fetches B's value, picks the newer one by timestamp (or by version vector), writes it to B and only then replies, so any later quorum read must meet a replica holding v2. The storage boundary is each replica's local store. Failure points: the extra round trips on mismatches inflate read tail latency, and a write-back racing a newer concurrent write must not overwrite it, which version comparison prevents.

INDUSTRY EXAMPLE

Cassandra repair. Cassandra's `nodetool repair` builds Merkle trees per token range on each replica, compares them and streams mismatched ranges; incremental repair limits the work to data written since the last repair. Operators are told to repair every node within `gc_grace_seconds` so that tombstones reach every replica before they are purged. *Evidence: Primary* — [Apache Cassandra Docs: Repair]

27.14 Conflict resolution: LWW, version vectors and CRDTs

27.14.1 Last-writer-wins

DEFINITION

Definition — Last-writer-wins (LWW). Each write carries a timestamp, and when replicas hold different values for an item, the one with the greatest timestamp is kept and the others are discarded.

LWW is simple, needs no application code and always converges, which is why Cassandra and DynamoDB global tables use it. Its cost is **silent data loss**: of two concurrent writes, one is discarded even though both were acknowledged. Worse, "last" is decided by clocks that can disagree by milliseconds or more (§24.9; §24.9.6 derives the danger window), so a write that happened *later* in real time can lose to one whose node's clock runs fast.

WORKED EXAMPLE

Worked example — Losing a later write to clock skew. Node A's clock runs 5 ms fast. At real time 98 ms a client removes "milk" from a list through A, stamped 103. At real time 100 ms another client re-adds "milk" through B, stamped 100.

1. Real-time order: remove (98), then add (100). The user expects milk on the list.
2. LWW order: add (100) < remove (103), so the remove wins on every replica.
3. Any two writes closer together than the skew bound ε can be misordered; with $\varepsilon = 5$ ms and a key written 10 times per second, about $10 \times 0.005 = 5\%$ of consecutive write pairs fall inside the window.

Interpretation. LWW is correct only when concurrent writes to the same item are rare or interchangeable. **Engineering implication.** Use LWW for immutable values or keys written by one client (insert-only events, cache entries), and something else for shared mutable state.

27.14.2 Version vectors and siblings

Instead of picking a winner, a store can **detect** concurrency and keep every concurrent value as a **sibling**, letting the application merge. Detection uses **version vectors** (§24.11.2; the runnable example of §24.11.3 also shows the same-replica flaw that dotted version vectors, §24.11.5, fix): a map from replica ID to a counter of writes coordinated by that replica.

FORMULA

Comparing version vectors

$$V \le V' \iff \forall i:\ V[i] \le V'[i] \qquad V \parallel V' \iff V \not\le V' \ \wedge\ V' \not\le V \qquad \text{merge: } (V \sqcup V')[i] = \max(V[i], V'[i])$$

Symbol	Meaning	Units
V, V'	Version vectors of two versions of the same item	counters per replica
$V[i]$	Number of writes to the item coordinated by replica i that this version has seen	count
$V \le V'$	V' descends from V, so V can be discarded	—
$V \parallel V'$	The versions are concurrent: keep both as siblings	—
$\sqcup$	Element-wise maximum, the vector of a merged version	—

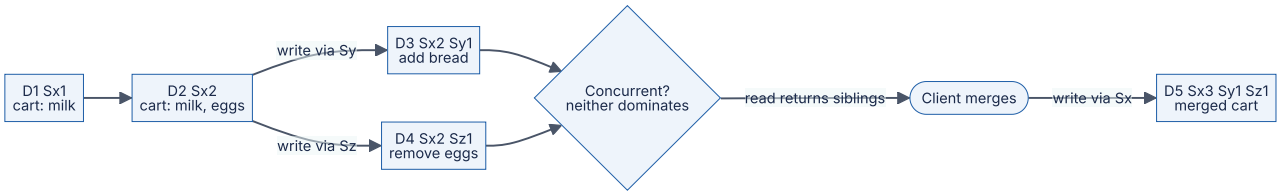
WORKED EXAMPLE

Worked example — The Dynamo shopping cart. Following the Dynamo paper's example, with servers S_x, S_y, S_z:

1. A write coordinated by S_x creates D1 with $\{S_x:1\}$; an update through S_x creates D2, $\{S_x:2\}$. Since $\{S_x:1\} \le \{S_x:2\}$, D1 is discarded.
2. Two clients read D2 and write concurrently: through S_y, D3 $= \{S_x:2, S_y:1\}$; through S_z, D4 $= \{S_x:2, S_z:1\}$.
3. Compare D3 and D4: S_y is 1 vs 0 and S_z is 0 vs 1, so neither dominates. A read returns both siblings.
4. The client merges them (for a cart, the union of items) and writes back through S_x with the merged context: D5 $= \{S_x:3, S_y:1, S_z:1\}$, which dominates both [DeCandia et al. 2007].

Interpretation. No write was lost, but the application had to merge, and a union merge re-adds an item that one sibling had deleted. **Engineering implication.** Siblings move conflict resolution into application code; give that code a deterministic, tested merge, or use a CRDT.

Figure 27.13 — Version vectors creating and resolving siblings.



Reading the diagram. Boxes are versions of one key, labeled with their version vectors; arrows mean "descends from". D3 and D4 are written through different coordinators from the same parent, so their vectors are incomparable and the store keeps both. A read returns both siblings with their combined context; the client's merged write dominates both and replaces them. Storage holds every sibling until a merge, so a key with many unmerged concurrent writers grows. The failure point is the merge function: a union resurrects "eggs". Dynamo truncated vectors beyond a threshold of about 10 entries, which can cause false conflicts.

INDUSTRY EXAMPLE

Riak siblings. With `allow_mult` enabled, Riak keeps concurrent writes as siblings and returns them with a causal context that the client sends back with its resolved write; Riak 2.0 added dotted version vectors (§24.11.5) to avoid sibling explosion and lost updates when many clients write through the same node, and built-in CRDT data types (counters, sets, maps, registers, flags) that merge automatically. *Evidence: Primary* — [Riak KV Docs: Conflict Resolution; Riak KV Docs: Data Types; Preguiça et al. 2010]

In production Dynamo, siblings were rare: the paper reports that 99.94% of requests saw exactly one version over a 24-hour period of the shopping cart service [DeCandia et al. 2007].

27.14.3 CRDTs

DEFINITION

Definition — Conflict-free replicated data type (CRDT). A data type whose replicas can be updated independently and concurrently without coordination and are guaranteed to converge to the same state once they have received the same updates, a property called **strong eventual consistency** [Shapiro et al. 2011a].

First-principles explanation

Two scorekeepers each keep a sheet with one column per scorekeeper, and each only ever increases its own column. Whenever they compare sheets, they take the larger number in each column and agree, however often and in whatever order they compare. A CRDT is a data structure designed so that "compare and combine" cannot go wrong.

How it works internally

There are two styles, and each can emulate the other [Shapiro et al. 2011b]:

- **State-based CRDTs (CvRDTs)** ship whole states and combine them with a **merge** function. Convergence requires the states to form a **join semilattice**: merge must be **commutative** ($a \sqcup b = b \sqcup a$), **associative** ($(a \sqcup b) \sqcup c = a \sqcup (b \sqcup c)$) and **idempotent** ($a \sqcup a = a$), and every update must move the state upward. Then gossip may deliver states in any order, any number of times. **Delta-state** CRDTs ship only recent changes to cut bandwidth [Almeida et al. 2018].
- **Operation-based CRDTs (CmRDTs)** ship operations. Concurrent operations must commute, and the delivery layer must deliver every operation exactly once and in causal order.

The four classic designs are:

1. **G-Counter** (grow-only counter): one slot per replica; a replica increments only its own slot; value is the sum; merge takes the per-slot maximum.
2. **PN-Counter:** two G-Counters, one for increments and one for decrements; value is the difference.
3. **LWW-Register:** a value with a (timestamp, replica ID) stamp; merge keeps the larger stamp. It is LWW, packaged so that merge is a lattice join.
4. **OR-Set** (observed-remove set): each add creates a unique tag; a remove deletes only the tags it has observed. A concurrent add's new tag survives, so **add wins**. Removed tags must be remembered as tombstones, unless an optimized design summarizes them with version vectors [Bieniusa et al. 2012].

The program implements all four and checks the three merge laws, plus convergence under every merge order, on random histories.

```
        """State-based CRDTs: G-Counter, PN-Counter, LWW-Register and OR-Set,
        with randomized tests that merge is commutative, associative and idempotent."""
        import copy
        import itertools
        import random

        class GCounter:
            """Grow-only counter: one slot per replica; merge takes the per-slot max."""
            def __init__(self, replica):
                self.replica, self.slots = replica, {}
            def increment(self, n=1):
                assert n >= 0, "a G-Counter only grows"
                self.slots[self.replica] = self.slots.get(self.replica, 0) + n
            def value(self):
                return sum(self.slots.values())
            def merge(self, other):
                for r, v in other.slots.items():
                    self.slots[r] = max(self.slots.get(r, 0), v)
            def state(self):
                return dict(sorted(self.slots.items()))

        class PNCounter:
            """Counter with decrements: one G-Counter for increments, one for decre-
ments."""
            def __init__(self, replica):
                self.p, self.n = GCounter(replica), GCounter(replica)
            def increment(self, k=1):
                self.p.increment(k)
            def decrement(self, k=1):
                self.n.increment(k)
            def value(self):
                return self.p.value() - self.n.value()
            def merge(self, other):
                self.p.merge(other.p)
                self.n.merge(other.n)
            def state(self):
                return (self.p.state(), self.n.state())

        class LWWRegister:
            """Last-writer-wins register; ties on timestamp broken by replica ID."""
            def __init__(self, replica):
                self.replica, self.value_, self.stamp = replica, None, (0, "")
            def assign(self, value, timestamp):
                stamp = (timestamp, self.replica)
                if stamp > self.stamp:
                    self.value_, self.stamp = value, stamp
            def value(self):
                return self.value_
            def merge(self, other):
                if other.stamp > self.stamp:
                    self.value_, self.stamp = other.value_, other.stamp
            def state(self):
                return (self.value_, self.stamp)

            bad = SumCounter("A"); bad.increment(5)
            print("SumCounter: value 5, after merging a duplicate delivery:",
merged(bad, bad).value())

            # Add-wins: A removes "milk" while B concurrently re-adds it.
            a, b = ORSet("A"), ORSet("B")
            a.add("milk"); b.merge(a)                    # both replicas see milk
            a.remove("milk")                             # A removes the tag it observed
            b.add("milk")                                # B adds again with a fresh tag
            a.merge(b); b.merge(a)
            print("OR-Set after concurrent remove and add:", a.value(), b.value())

            # The same story with LWW on timestamps loses B's add if A's clock is ahead.
            ra, rb = LWWRegister("A"), LWWRegister("B")
            ra.assign("<removed>", timestamp=103)        # A removes at real time 98;
its clock is 5 ms fast
            rb.assign("milk", timestamp=100)             # B re-adds later, at real time
100
            ra.merge(rb); rb.merge(ra)
            print("LWW register after the same history:", ra.value(), rb.value())
```

Output:

```
GCounter   : 200 random histories, all laws hold
PNCounter  : 200 random histories, all laws hold
LWWRegister: 200 random histories, all laws hold
ORSet      : 200 random histories, all laws hold
SumCounter: value 5, after merging a duplicate delivery: 10
OR-Set after concurrent remove and add: {'milk'} {'milk'}
LWW register after the same history: <removed> <removed>
```

What to notice:

- Each `merge` is a lattice join: per-slot `max`, set union, or the larger stamp. That is why all three laws hold on every random history, including histories with partial gossip between replicas.
- `SumCounter` looks plausible but is not idempotent: a duplicated gossip message doubles the count. Idempotence is what lets state-based CRDTs ride on unreliable, repeating gossip.
- The OR-Set keeps “milk” after a concurrent remove and re-add, matching user intent; the LWW register replays the clock-skew example of §27.14.1 and drops the later add.

Real-world industry applications

INDUSTRY EXAMPLE

Redis active-active databases and collaborative editors. Redis Enterprise's Active-Active databases replicate across regions with every replica writable and resolve concurrent updates with CRDT-based data types, such as counters that sum concurrent increments and sets with add-wins semantics [Redis Docs: Active-Active]. Libraries such as Automerge and Yjs apply sequence CRDTs to collaborative text and JSON documents. *Evidence: Primary* — [Redis Docs: Active-Active; Automerge and Yjs project documentation]

Alternatives and trade-offs

Table 27.4 — Conflict-resolution strategies.

	Last-writer-wins	Version vectors + siblings	CRDTs
What it is	Keep greatest timestamp	Keep all concurrent values	Types whose merge always converges
Data loss	Silent, on concurrent writes	None	None, within the type's semantics
Application work	None	Write a merge for every type	Choose a type that fits
Metadata	One timestamp	One counter per coordinating replica	Per-replica slots or tags; tombstones
Clock dependence	Yes	No	Only for LWW-based types
Choose when	Immutable or single-writer data	Domain-specific merges	Counters, sets, maps, collaborative documents

Failure scenarios

Table 27.5 — Failure scenarios in conflict resolution.

What goes wrong	Why	Detection	Recovery	Prevention
Acknowledged update disappears	LWW discarded a concurrent write	Audit log shows the write; final value lacks it	Replay from audit log	Siblings or CRDTs for shared mutable data
Deleted item reappears	Union merge of siblings, or tombstone purged before repair	User reports	Delete again	OR-Set semantics; repair within grace period
Sibling explosion	Many clients write without causal context	Value size and sibling count metrics	Merge and write back	Always read before write; dotted version vectors
CRDT state grows without bound	Tombstones and per-replica entries never collected	State size metrics	Compaction at causal stability	Optimized OR-Set; retire replica IDs

COMMON MISTAKE

Mistake — “CRDTs make every invariant safe.” CRDTs guarantee convergence, not application invariants. A PN-Counter for stock can converge to −3 because two regions each sold the last two items. Invariants such as “never below zero” or “unique username” still need coordination (Chapter 26) or escrow-style partitioning of the allowance.

27.15 Summary and revision notes

SUMMARY

- Replication decides who orders writes and how many copies hold a write before acknowledgment; multi-leader and leaderless designs diverge and repair afterwards.
- Primary–backup ships state or operations; asynchronous failover loses $r_w \ell$ writes, and safe promotion needs fencing.
- Chain replication: writes at the head, strong reads at the tail, $T_{\text{write}} \approx (n+1)d + ns$; CRAQ serves clean reads from any node.
- Multi-leader serves multi-region, offline and collaborative writers; ring and star have single points of failure, all-to-all reorders messages; conflicts per item $\approx 2\lambda_A \lambda_B \Delta$.
- $R + W > N$ guarantees overlap with completed writes, not linearizability. Quorum latency is the k-th order statistic: 2-of-3 hides the slowest replica.
- Sloppy quorums and hinted handoff trade overlap for write availability; hints grow linearly with downtime.
- Phi-accrual turns silence into an error probability; SWIM detects in about $1.58\,T'$ with constant load per member; gossip spreads in $\approx \log_{1+f} n + \ln n/f$ rounds.
- Failover time is detection + election + reconfiguration + redirection; redirection often dominates. Recovery time is copy time plus catch-up of the backlog.
- Read repair fixes keys that are read; Merkle anti-entropy fixes everything, and must run within the tombstone grace period.
- LWW loses concurrent writes silently; version vectors keep siblings; CRDTs converge because merge is commutative, associative and idempotent, but do not protect invariants.

27.16 Knowledge checkpoint

1. What is the difference between state transfer and operation shipping, and which needs determinism?
2. An asynchronous backup lags by 300 ms when the primary, taking 4,000 writes/s, crashes. How many acknowledged writes are lost?
3. Why are reads at the tail of a chain linearizable?
4. For $N = 5$, what is the smallest R that overlaps $W = 3$, and how many failures can each tolerate?
5. Give two reasons why $R + W > N$ does not give linearizability.
6. With $N = 3$ and each replica independently slow with probability 0.02, what fraction of $W = 2$ writes are slow?
7. Heartbeats have $\mu = 500$ ms and $\sigma = 50$ ms. What is φ after 600 ms of silence?

8. Estimate push-gossip rounds with fanout 1 for 4,096 nodes.
9. Detection 4 s, election 2 s, reconfiguration 2 s, DNS TTL 60 s: what is the failover time, and what is the biggest lever?
10. Why must a state-based CRDT merge be idempotent?

Answers

1. State transfer sends resulting state; operation shipping sends the operation, which every replica must execute deterministically.
2. $4,000 \times 0.3 = 1,200$ writes.
3. The tail holds only updates every other chain node already has, and it is the only node that replies to writes and reads.
4. $R = 3$ ($3 + 3 > 5$); reads and writes each tolerate 2 unavailable replicas.
5. Any two of: concurrent writes resolved by timestamp; writes concurrent with reads; failed writes not rolled back; sloppy quorums; replicas restored from stale copies.
6. $p^3 + 3p^2(1-p) = 8 \times 10^{-6} + 3 \times 0.0004 \times 0.98 = 0.001184$, about 0.12%.
7. $z = 2$, $1 - \Phi(2) = 0.0228$, $\varphi = 1.64$.
8. $\log_2 4,096 + \ln 4,096 = 12 + 8.3 \approx 20$ rounds, plus about one.
9. $4 + 2 + 2 + 60 = 68$ s; replace DNS redirection with a proxy, virtual IP or topology-aware client.
10. Gossip may deliver the same state many times; a non-idempotent merge (such as summing) would count it repeatedly.

27.17 Interview questions

Basic

Q1. What does R + W > N give you? Answer. Every read set intersects every completed write's set, so a read sees at least one replica with that write. It does not order concurrent writes, roll back failed ones or prevent a later read seeing an older value without blocking read repair.

Q2. How do you detect a failed node? Answer. Heartbeats or pings with a timeout, ideally adaptive (phi-accrual) and, in large clusters, SWIM-style probing with indirect pings, suspicion and gossip. A detector only suspects; actions taken on suspicion must fence.

Intermediate

Q3. Walk through a database failover and its time budget. Answer. Detection (timeout), election (most advanced replica or consensus), reconfiguration (fence, apply remaining log, promote), redirection (proxy, VIP or DNS). Quantify each term; fence against split brain; expect $r_w \ell$ loss if replication is asynchronous.

Q4. Chain replication or primary-backup? Answer. Chain spreads network load and gives strong tail reads, but write latency grows with length and one slow node slows every write. Primary–backup has constant hops but the primary sends $n-1$ copies. Choose chain or CRAQ for high-throughput storage with a reliable master.

Advanced

Q5. Design an inventory counter replicated in three regions with local writes. Answer. A PN-Counter converges but cannot enforce "stock ≥ 0". Partition the stock into per-region allowances (escrow), sell locally within the allowance, and rebalance allowances with a coordinated transfer when one runs low; strong checks only at the boundary.

Q6. A Cassandra cluster shows deleted rows reappearing after a node replacement. Explain and fix. Answer. A replica missed deletes and was not repaired within `gc_grace_seconds`; others purged their tombstones, so repair copied the old rows back. Repair every node within the grace period and alert on repair age.

Q7. Compare gossip dissemination and a consensus-backed store for cluster membership. Answer. Gossip spreads changes in $O(\log n)$ rounds with constant per-node load, but views differ briefly. Consensus gives one agreed view and fencing at the cost of quorum round trips. Many systems use gossip for liveness and consensus for authoritative ownership.

27.18 Practical exercises

1. Extend the quorum program to estimate p99 read and write latency for $N = 5$ from a measured latency sample, for every (R, W) with $R + W > N$.
2. Add a suspicion timeout and incarnation numbers to the SWIM simulation and measure false positives with 5% packet loss.
3. Implement a delta-state G-Counter that ships only changed slots and measure bytes sent against the full-state version.

27.19 Design challenges

1. **Global shopping cart.** Three regions, writes always accepted, no lost additions. Choose replication, conflict resolution and repair, and explain deleted-item behavior.
2. **Metadata store failover.** A primary–backup metadata service must fail over in under 10 s with zero acknowledged-write loss. Produce the time budget and fencing design.
3. **Membership for 5,000 nodes.** Choose protocol parameters so a crash is declared within 10 s with a false-positive rate below one per day.

Chapter 28 — Distributed Transactions

> **Level:** 4 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

On one database server a transaction is a solved problem: the write-ahead log, locks and MVCC of Chapter 11 make a transfer between two accounts all-or-nothing, isolated and durable. Partition the accounts across two servers (Chapter 14) and the guarantee disappears. Each server can still commit or abort *its own* half, but nothing forces the two halves to agree, and either server, or the network between them, can fail at any moment.

This chapter is about getting the guarantee back. It starts with the **atomic commitment problem** and the classic answer, two-phase commit, including exactly what must be logged and why it can block. It then follows the ideas that made distributed transactions practical at scale: running 2PC over replicated consensus groups, Percolator's timestamp oracle and primary lock, Spanner's TrueTime and commit wait, Calvin's deterministic ordering, and the commit protocols inside CockroachDB, YugabyteDB and TiDB. It ends with a decision procedure, because the cheapest distributed transaction is the one your data model avoids. Consensus itself is Chapter 26's subject, hybrid logical clocks are introduced in §24.12, and sagas and the transactional outbox are treated in depth in Chapter 32.

28.1 Learning objectives

After this chapter you should be able to:

- State the atomic commitment problem and explain why partial failure makes it harder than local commit.
- Walk through two-phase commit, naming every forced log write, and show where and why it blocks when the coordinator fails.
- Compute 2PC latency, the availability of a transaction spanning k partitions (A^k) and the expected number of in-doubt transactions per coordinator crash.
- Explain presumed abort, XA and PostgreSQL prepared transactions, and recover an in-doubt transaction by hand.
- Explain why three-phase commit is non-blocking only under synchrony assumptions and why it is rarely deployed.
- Describe Percolator's write and read paths, Spanner's commit wait and external-consistency argument, and Calvin's deterministic execution, and compute their latencies.

- Compare CockroachDB, YugabyteDB, TiDB and Spanner, and choose a transaction strategy for a given workload.

28.2 Prerequisites

- Transactions, ACID, isolation anomalies (especially write skew), MVCC and two-phase locking — §11.11–§11.15 (this chapter distributes those mechanisms).
- Write-ahead logging and `fsync` — §13.5 and §6.14 (every protocol here is defined by what it forces to the log).
- Partitioning and the cross-shard transaction preview — §14.6–§14.7 and §14.12.
- Partial failure, clock skew and hybrid logical clocks — §24.8, §24.9 and §24.12.
- Consensus and leases — §26.3, §26.7 and §26.11 (2PC is made highly available by running it over consensus groups).
- Idempotency keys — §22.15 (commit and abort messages are retried and must be harmless when duplicated).

28.3 Why distributed transactions are hard

28.3.1 The atomic commitment problem

DEFINITION

Definition — Atomic commitment. A protocol by which a set of **participants** (nodes that each executed part of a transaction) reach a single outcome, commit or abort, such that: (1) all participants that decide reach the same decision; (2) a participant cannot reverse a decision once made; (3) commit is decided only if every participant voted yes; (4) if there are no failures and every participant voted yes, the decision is commit; and (5) once failures are repaired and no new ones occur for long enough, every participant eventually decides [Bernstein et al. 1987].

First-principles explanation

Picture a wedding ceremony. The officiant asks each partner “Do you?” Each partner, before answering, must be *certain* they can follow through, because after saying “I do” they may not back out on their own. Only when both have said yes does the officiant pronounce the marriage, and from that moment it is binding on both. If the officiant faints after hearing two yeses but before pronouncing, the couple stands at the altar unable to leave and unable to celebrate. That picture, used by Gray, is two-phase commit, weakness included [Gray 1978].

The single-server version is easy because there is one log and one decision. One `fsync` of a commit record is the instant at which the whole transaction becomes durable. Across servers there is no shared instant. Each server can promise only things about its own log, and it learns about the others solely through messages that may be delayed, lost or never sent because the sender died.

Why does this exist?

Partitioning scales writes (Chapter 14), but business operations ignore partition boundaries: a transfer touches two accounts, an order touches stock and orders, a global index entry lives apart from its row (§14.11). Each needs all-or-nothing behavior across nodes.

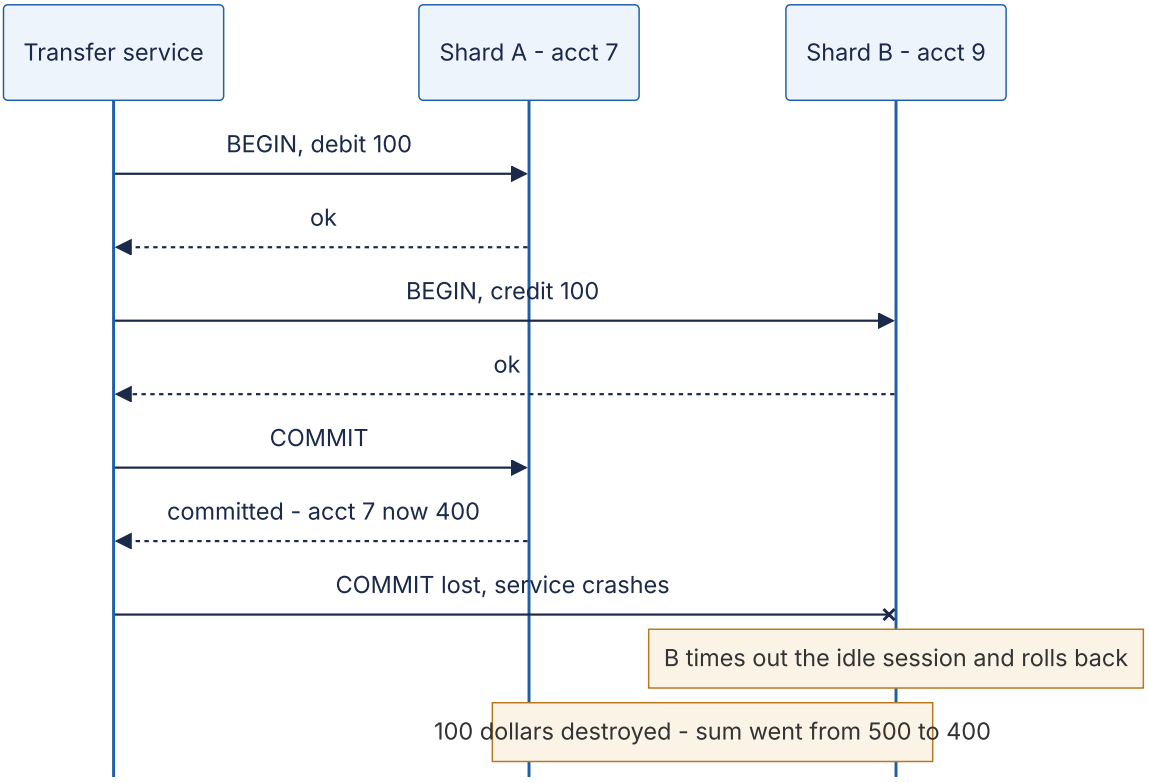
28.3.2 Partial failure: a money transfer across two shards

DEFINITION

Definition — Partial failure. A failure in which some components of a distributed system fail, or become unreachable, while others keep running, and the running components cannot reliably tell which (§24.8).

Take two PostgreSQL shards. Account 7 (balance $500) lives on shard A and account 9 (balance $0) on shard B. A service transfers $100 by running an ordinary local transaction on each shard, one after the other.

Figure 28.1 — A naive cross-shard transfer that loses money.



Reading the diagram. The transfer service talks to each shard over its own synchronous SQL connection; each shard has its own write-ahead log, so there are two independent storage boundaries. Shard A's commit is durable before the service even sends B's commit. The service crashes (the crossed arrow), B's session times out and B rolls back its half. Committing B first fails symmetrically, creating money. No ordering of two independent commits is safe, and scaling changes nothing: the flaw is in the protocol.

Three facts make the problem hard:

1. **No participant may commit until it knows every other participant can.** Shard B might fail a `CHECK` constraint, run out of disk or deadlock. A must not make its half permanent until that is ruled out.
2. **A participant that has promised cannot change its mind.** Once B has said "I can commit", it must keep that promise through crashes, so the promise itself must be durable.
3. **Silence is ambiguous.** A coordinator that hears nothing from B cannot distinguish "B crashed", "B is slow" and "the network dropped B's reply" (§24.7). Any protocol must be safe in all three cases.

KEY CONCEPT

Concept — Atomic commitment is a consensus problem with veto. Every participant must agree on one value (commit or abort), and any single participant can force abort. The FLP result (§24.13) says no deterministic protocol can guarantee that agreement terminates in an asynchronous system with even one crash. Every protocol in this chapter therefore gives up something: two-phase commit gives up termination while the coordinator is down; three-phase commit assumes bounded delays; consensus-based commit needs a majority of replicas to be up.

28.3.3 Isolation across partitions: snapshot isolation versus serializability

Atomicity is half the job. A distributed transaction must also be isolated (§11.13), which needs two things a single server gets for free:

1. **A consistent snapshot across partitions.** A reader must see either both halves of the transfer or neither. On one server a snapshot is a list of committed transaction IDs (§11.14). Across servers you need a common notion of "before" and "after": a central **timestamp oracle** (Percolator, TiDB), tightly bounded physical clocks (Spanner) or hybrid logical clocks with uncertainty handling (CockroachDB, YugabyteDB).
2. **Conflict detection across partitions.** Write-write conflicts are easy, because both writers touch the same key on the same partition. Read-write conflicts, the ones that cause **write skew**, are not: transaction T1 reads key *x* on partition 1 and writes

y on partition 2, while T2 reads *y* and writes *x*. Neither partition sees both edges of the dependency cycle.

That second point explains a pattern you will see throughout this chapter. **Snapshot isolation** (SI) needs only per-key write-write checks, so it distributes cheaply, and Percolator and TiDB offer it [Peng and Dabek 2010; Huang et al. 2020]. SI permits write skew: two transfers that each check "sum of a customer's two accounts ≥ 0" and each debit a *different* account can both commit and overdraw the customer, exactly the doctors-on-call anomaly of Figure 11.8 with the rows on different machines (§28.7.4 reproduces it). **Serializable** isolation needs either read locks held to commit (Spanner's two-phase locking for read-write transactions [Corbett et al. 2012]) or validation of reads at commit time (CockroachDB's timestamp ordering with read refresh [Taft et al. 2020]). Serializable snapshot isolation (SSI), which PostgreSQL implements on one node by tracking read-write dependencies [Cahill et al. 2008], is hard to distribute because the dependency graph spans partitions.

RECOMMENDATION

Recommendation — Know which isolation your distributed database gives by default. Spanner and CockroachDB default to serializable; TiDB defaults to snapshot isolation (exposed as `REPEATABLE READ`); YugabyteDB's YSQL defaults to snapshot isolation in recent versions (as of 2026). Under SI, protect cross-row invariants with `SELECT ... FOR UPDATE` or a materialized conflict row (§11.13).

COMMON MISTAKE

Common misconception — "Distributed transactions are just slow local transactions." The extra latency is the visible cost. The deeper costs are new failure modes (a transaction stuck between commit and abort), new availability arithmetic (a transaction needs *every* participant), and anomalies that local snapshot isolation never had to handle across machines.

28.4 Two-phase commit

28.4.1 The protocol

DEFINITION

Definition — Two-phase commit (2PC). An atomic commitment protocol in which one node, the **coordinator** (also called the transaction manager), first asks every participant (resource manager) to **prepare**, that is, to make its part of the transaction durable while keeping it invisible and to promise to commit on request; and then, only if every participant voted yes, durably records a **commit** decision and tells all participants to commit. Any no vote or timeout leads to abort [Gray 1978; Bernstein et al. 1987].

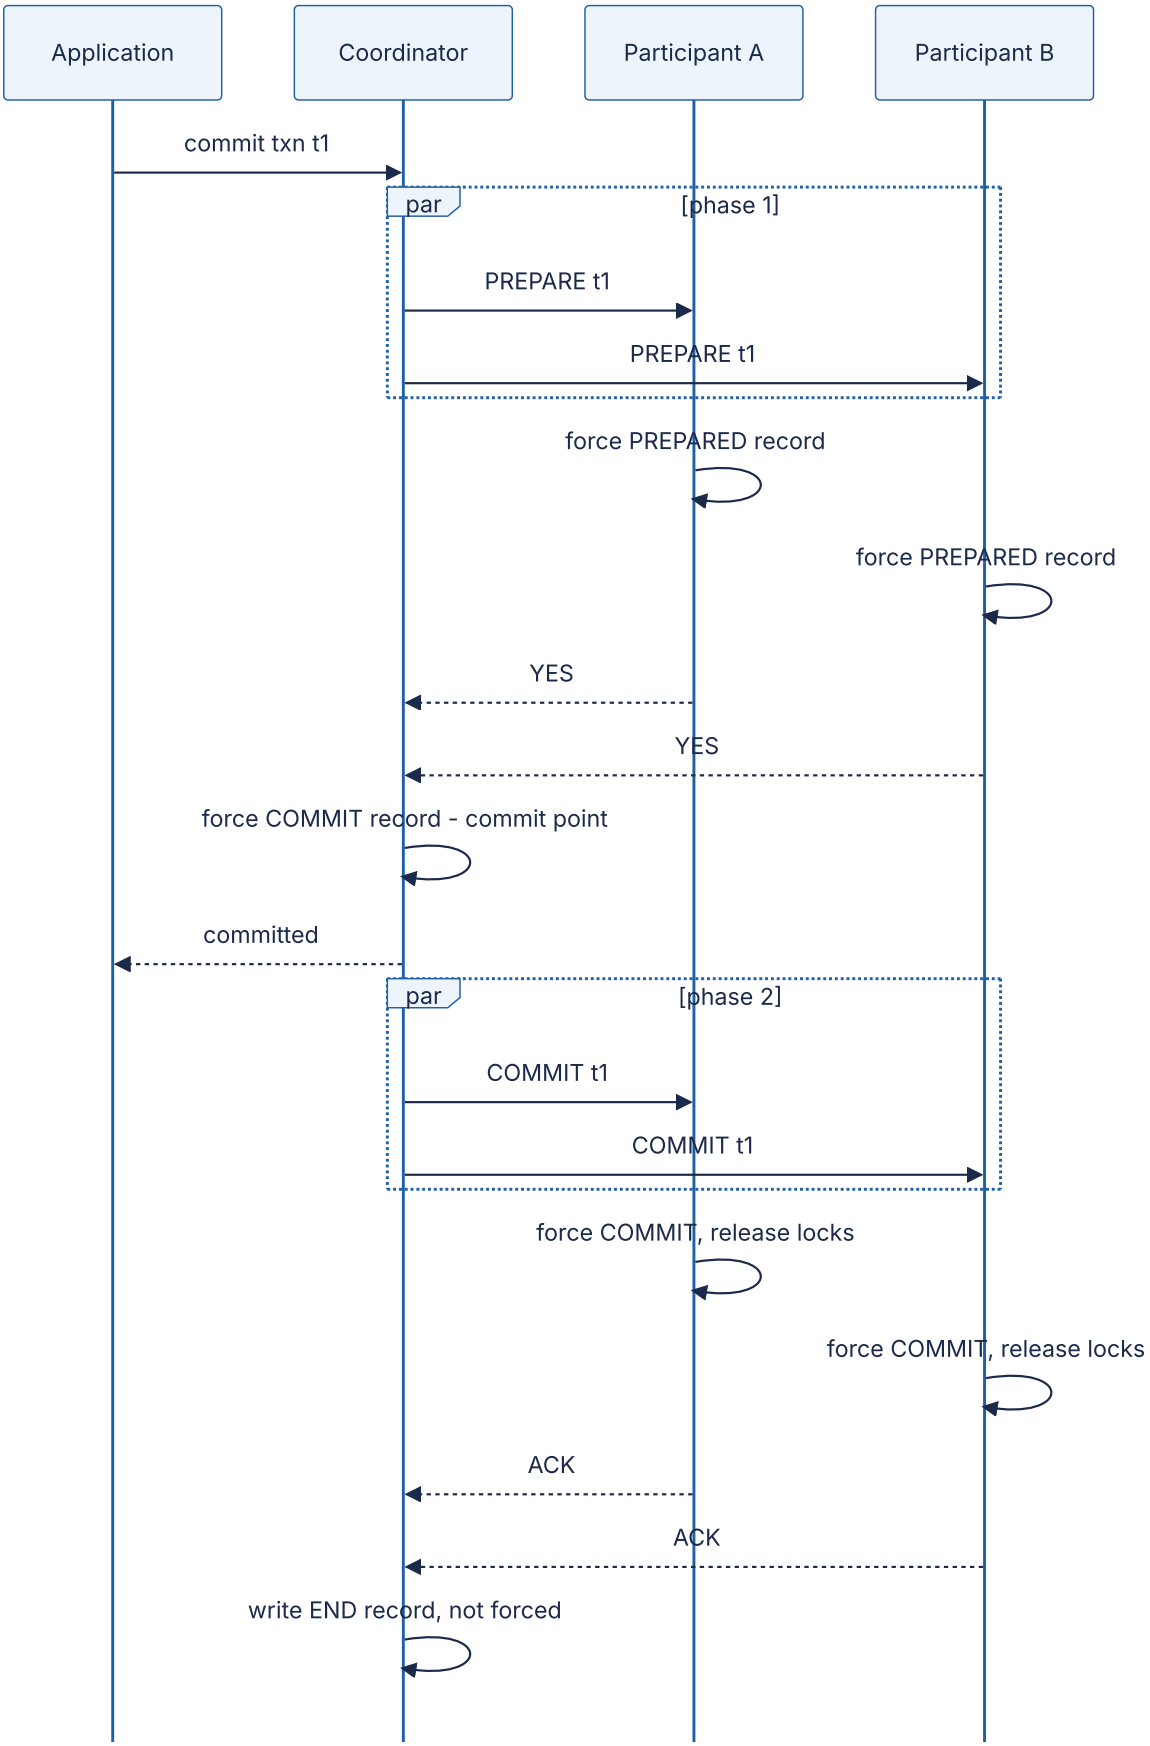
Why does this exist?

Figure 28.1 failed because each shard decided alone. 2PC separates the *ability* to commit from the *decision* to commit. Phase 1 collects durable promises; phase 2 distributes one decision, made in one place and recorded in one log. The coordinator's log record is the distributed equivalent of the single-server commit record.

How it works internally

1. **Execution.** The application runs the transaction's reads and writes on each participant as usual; participants take locks (or write MVCC intents) and keep undo and redo information.
2. **Prepare.** When the application says commit, the coordinator sends `PREPARE` to every participant.
3. **Vote.** Each participant checks it can commit (constraints satisfied, no deadlock victim, resources available). If yes, it **forces a prepared record** to its log, containing enough to redo or undo its writes and to re-acquire its locks after a crash, then replies `YES`. From this moment it is **in doubt**: it may not commit or abort on its own. If it cannot commit, it aborts locally and replies `NO`.
4. **Decision.** If every vote is `YES`, the coordinator **forces a commit record** to its log. This write is the **commit point** of the whole distributed transaction. Any `NO` or a timeout leads to abort.
5. **Completion.** The coordinator sends `COMMIT` (or `ABORT`) to each participant, retrying until it is acknowledged. Each participant logs the outcome, releases its locks and sends `ACK`.
6. **Forget.** When all acknowledgments are in, the coordinator writes a non-forced end record and may discard its memory of the transaction.

Figure 28.2 — Two-phase commit, happy path.



Reading the diagram. Three logs are involved: the coordinator's and each participant's, and every self-arrow is a write to one of them. Prepare messages go out in parallel, so

phase 1 costs one round trip plus the slowest participant's forced write, not the sum. The coordinator may answer the application as soon as its commit record is durable: the outcome is now decided, and phase 2 only propagates it. Phase 2 messages are retried until acknowledged, so participants must treat duplicate `COMMIT`s as no-ops. The failure point is the interval between a participant's `YES` and its receipt of the decision (Figure 28.4). Messages grow as $4k$ for k participants; latency stays two round trips.

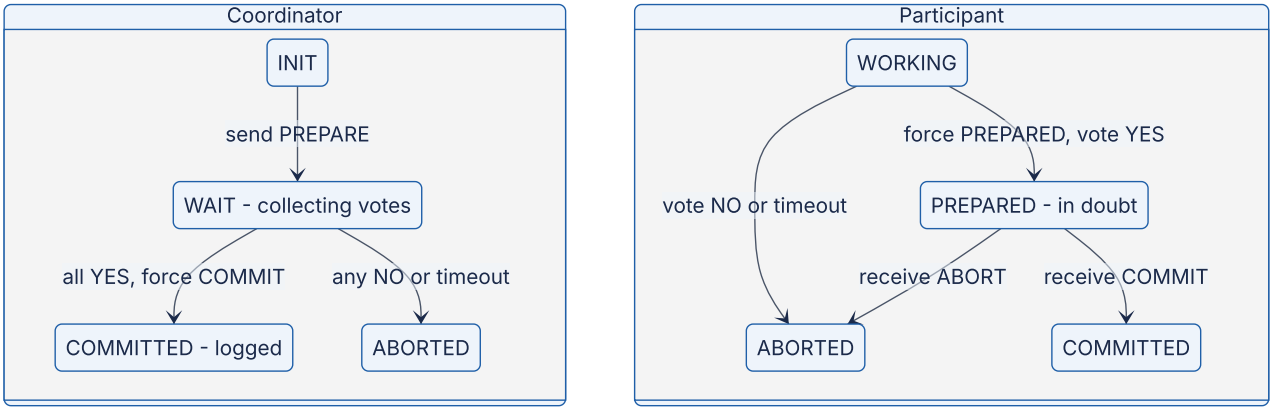
28.4.2 What must be logged, and when

2PC is defined as much by its log writes as by its messages. A **forced** write is one the node `fsync`s (§6.14) before sending the next message, because the message makes a promise the node must keep after a crash.

Table 28.1 — Log records in two-phase commit (basic protocol).

Who	Record	Forced?	When	Why it must be durable
Participant	PREPARED (redo/undo, lock list, coordinator ID)	Yes	Before sending `YES`	After a crash it must still be able to commit, and must keep others from seeing or changing the rows
Coordinator	COMMIT (transaction ID, participant list)	Yes	After all `YES`, before sending any `COMMIT`	The decision must survive a crash, or a recovered coordinator could abort a transaction some participant already committed
Participant	COMMIT	Yes	Before `ACK`	Once it acknowledges, the coordinator may forget, so the participant must not need to ask again
Coordinator	ABORT	Yes in basic 2PC; no under presumed abort	On any `NO` or timeout	See §28.4.5
Participant	ABORT	Yes in basic 2PC; no under presumed abort	On receiving `ABORT`	See §28.4.5
Coordinator	END	No	After all `ACK`s	Lets the coordinator garbage-collect; losing it causes only a harmless resend

Figure 28.3 — Coordinator and participant state machines.



Reading the diagram. Each box is one node's local state, recovered from its log after a crash. The participant has a free choice only in WORKING: it may abort for any reason, including the coordinator taking too long to send `PREPARE`. PREPARED is the dangerous state, because it has no outgoing transition the participant can take alone; both exits are triggered by a message from the coordinator. The coordinator, by contrast, never blocks: in WAIT it may time out and abort. This asymmetry is the root of 2PC's blocking behavior.

Recovery rules. After a restart, each node reads its log:

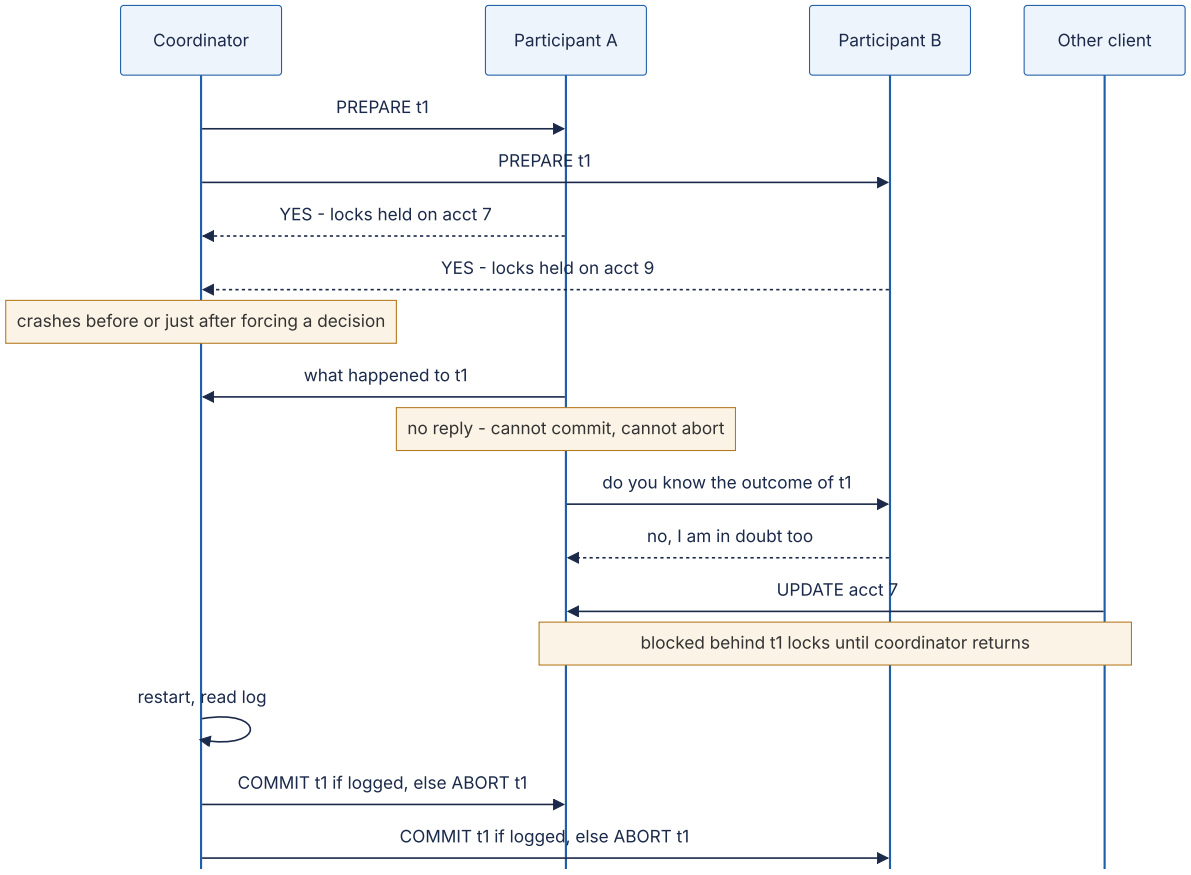
- **Participant, no PREPARED record:** abort locally; the coordinator cannot have decided commit without its vote.
- **Participant, PREPARED plus COMMIT or ABORT:** redo or undo accordingly.
- **Participant, PREPARED only:** in doubt. Re-acquire the locks listed in the record, then ask the coordinator for the outcome, repeatedly, until it answers.
- **Coordinator, COMMIT without END:** resend `COMMIT` to every listed participant until all acknowledge.
- **Coordinator, no COMMIT record:** the transaction aborted (it may have been mid-vote at the crash); answer `ABORT` to any inquiry.

28.4.3 Blocking and in-doubt transactions

DEFINITION

Definition — In-doubt (blocked) transaction. A transaction at a participant that has voted yes but has not learned the outcome. It must hold its locks and cannot decide until the coordinator, or another participant that knows the outcome, answers.

Figure 28.4 — Coordinator failure after the votes: participants block.



Reading the diagram. Both participants are in PREPARED and their locks are durable promises. A asks the coordinator (no answer), then tries the **cooperative termination protocol**: asking other participants. If any participant had not yet voted, or had already received a decision, A could decide. Here B is equally in doubt, and neither can tell whether the coordinator logged commit before dying; deciding either way could contradict a decision the coordinator already made. Unrelated client X now waits on account 7 for as long as the coordinator is down. The storage boundary that matters is the coordinator's log: only it holds the answer. Replicating that log (§28.4.8) is the fix.

How likely is this? A transaction is exposed while any participant is in doubt: from the first `YES` until every participant has the decision.

FORMULA

Exposure to in-doubt blocking

$$w \approx \mathrm{RTT} + t_{f,c} \qquad P_{\mathrm{doubt}} = 1 - e^{-\lambda w} \approx \lambda w \qquad N_{\mathrm{doubt}} = X w$$

Symbol	Meaning	Units
w	Window from the first YES vote reaching the coordinator's path until all participants hold the decision: half an RTT for votes, the coordinator's forced write, half an RTT for decisions	seconds
RTT	Network round-trip time between coordinator and participants	seconds
$t_{f,c}$	Time of the coordinator's forced log write	seconds
λ	Coordinator crash rate	crashes/second
P_{doubt}	Probability a given transaction is caught in doubt by a coordinator crash	dimensionless
X	Rate of distributed transactions through this coordinator	transactions/second
N_{doubt}	Expected number of transactions left in doubt by one crash (Little's Law, §4.11)	transactions

WORKED EXAMPLE

Worked example — How many transactions does a coordinator crash strand? A payments service coordinates $X = 2,000$ cross-shard transfers per second. RTT $= 0.5$ ms, coordinator forced write $t_{f,c} = 1$ ms, and the coordinator process crashes about once a month ($\lambda = 1/2,592,000$ s $= 3.86 \times 10^{-7}$ /s). Restarting it with its log takes 10 minutes when an operator must intervene.

1. Window: $w = 0.5 + 1 = 1.5$ ms $= 0.0015$ s.
2. Per-transaction probability: $P_{\text{doubt}} \approx 3.86 \times 10^{-7} \times 0.0015 = 5.8 \times 10^{-10}$, about one in 1.7 billion.
3. Stranded per crash: $N_{\text{doubt}} = 2,000 \times 0.0015 = 3$ transactions.
4. Each holds its row locks for the 10-minute outage. If one of those rows is a merchant's settlement account receiving 50 transfers/s, $50 \times 600 = 30,000$ transfers queue behind the lock or time out.

Interpretation. The probability per transaction is negligible; the *consequence* is not, because a few in-doubt transactions can freeze hot rows for the whole recovery time. **Engineering implication.** Minimize coordinator recovery time (automatic restart, a replicated coordinator log), keep hot rows out of distributed transactions, and alert on prepared transactions older than a few seconds.

28.4.4 Latency and availability

FORMULA

Two-phase commit latency and participant lock hold time

$$T_{2PC} \approx 2\,\mathrm{RTT} + t_{f,p} + t_{f,c} \qquad T_{hold} \approx t_{f,p} + \mathrm{RTT} + t_{f,c}$$

Symbol	Meaning	Units
T_{2PC}	Commit latency until every participant has received the decision	seconds
RTT	Round trip between coordinator and the slowest participant	seconds
$t_{f,p}$	Slowest participant's forced write of its PREPARED record (writes happen in parallel)	seconds
$t_{f,c}$	Coordinator's forced write of the COMMIT record	seconds
T_{hold}	Extra time a participant holds locks during commit, from forcing PREPARED until the decision arrives	seconds

The commit phase adds two sequential round trips and two sequential forced writes. Replying right after the coordinator's commit record (Figure 28.2) hides the second round trip from the client, but not from participants' lock hold time.

WORKED EXAMPLE

Worked example — 2PC inside a datacenter and across regions. Forced writes take $t_f = 1$ ms on cloud block storage; a local commit therefore costs about 1 ms.

1. Same datacenter, RTT $= 0.5$ ms: $T_{2PC} = 2(0.5) + 1 + 1 = 3$ ms, three times a local commit. Lock hold: $1 + 0.5 + 1 = 2.5$ ms.
2. Participants in two regions, RTT $= 70$ ms: $T_{2PC} = 140 + 2 = 142$ ms; lock hold $= 72$ ms.
3. A hot row protected by row locks can commit at most $1/T_{hold}$ transactions per second (§11.15.3): about 400/s in one datacenter, about 14/s across regions.

Interpretation. Inside a datacenter, 2PC's latency is tolerable; its lock hold time, not its latency, is what limits contended rows. Across regions both explode.
Engineering implication. Keep coordinators near participants, avoid multi-region 2PC on hot rows, and use group commit so that many transactions share each forced write.

The availability arithmetic is harsher still. A distributed transaction commits only if the coordinator and *every* participant are reachable for its duration.

FORMULA

Availability of a transaction spanning k partitions

$$A_{\text{txn}} = A_c \prod_{i=1}^{k} A_i \approx A^k \quad \text{(equal partitions, coordinator co-located with one of them)}$$

Symbol	Meaning	Units
A_{txn}	Probability that the transaction can commit at a random moment	dimensionless
A_c	Availability of the coordinator and its log	dimensionless
A_i	Availability of partition i	dimensionless
k	Number of partitions the transaction touches	count

WORKED EXAMPLE

Worked example — Ten shards at three nines versus ten consensus groups at five nines. Assume independent failures and a 30-day month (43,200 minutes).

1. One unreplicated shard at $A = 0.999$: unavailable $0.001 \times 43,200 = 43.2$ min/month.
2. A transaction over $k = 10$ such shards: $0.999^{10} = 0.990045$, unavailable $0.009955 \times 43,200 \approx 430$ min, more than 7 hours a month.
3. If each partition is a consensus group (§26.7) with $A = 0.99999$: $0.99999^{10} = 0.99990$, unavailable about 4.3 min/month.

Interpretation. Fan-out multiplies unavailability almost linearly ($1 - A^k \approx k(1 - A)$ for small $1 - A$). **Engineering implication.** Never run 2PC over unreplicated nodes for anything that must stay up; make each participant a replicated group, and keep k small by co-locating data that is written together (§14.7).

28.4.5 Presumed abort and other optimizations

Basic 2PC forces records and collects acknowledgments for aborts as well as commits. Mohan, Lindsay and Obermarck, building IBM's R* distributed database, observed that the coordinator can make one outcome the *default* for transactions it has no record of, and then skip logging for that outcome [Mohan et al. 1986].

DEFINITION

Definition — Presumed abort (PA). A 2PC variant in which a coordinator that has no information about a transaction answers inquiries with “abort”. Aborts therefore need no forced coordinator record, no forced participant record and no acknowledgments.

The argument is short. Under PA the coordinator forgets an aborted transaction immediately. If a participant later asks, the coordinator finds nothing and says “abort”, which is correct. Commits are unchanged: the coordinator must force its commit record, and keep it until every participant has acknowledged, because forgetting a committed transaction would turn it into a presumed abort.

Table 28.2 — Cost of commit protocol variants for one coordinator and n participants.

Variant	Commit: forced writes	Commit: messages	Abort: forced writes	Abort: messages	Notes
Basic 2PC	$1 + 2n$	$4n$	$1 + 2n$	$4n$	Every outcome logged and acknowledged
Presumed abort	$1 + 2n$	$4n$	n prepares only, nothing for the outcome	$3n$ (no ACK)	No information means abort; the usual choice in commercial systems
Presumed commit	$2 + n$	$3n$ (no ACK)	$2 + 2n$	$4n$	Coordinator forces a “collecting” record listing participants before prepare
Read-only participant	0 for that participant	2 for that participant	—	—	Votes READ in phase 1 and drops out of phase 2
One participant	1 local commit	2	—	—	Skip 2PC entirely (“one-phase commit”)

Three other optimizations matter in practice:

1. **Read-only participants.** A participant that only read data has nothing to commit; it releases its read locks and votes READ, and the coordinator omits it from phase 2. If every participant is read-only, nothing is logged at all.
2. **One-phase commit.** A transaction that touched one participant needs no vote: the coordinator just commits it locally. Transaction managers do this automatically,

which is why designing for single-partition transactions (§28.11) eliminates 2PC rather than merely shortening it.

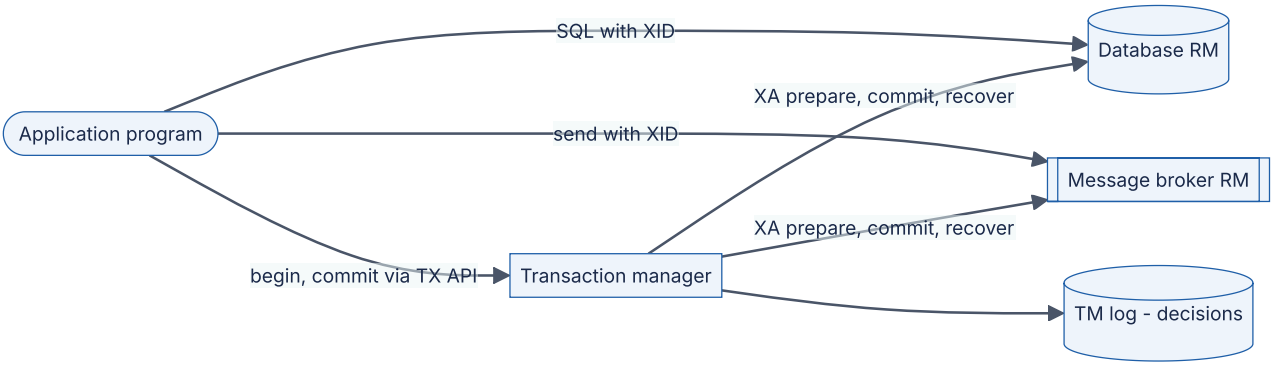
3. **Coordinator co-located with a participant** (sometimes called the last-agent optimization). The coordinator's log is the same as one participant's, saving one round trip and one forced write; Spanner, CockroachDB and TiDB all place the coordinator's state in one of the participating partitions.

28.4.6 XA and prepared transactions in practice

DEFINITION

Definition — XA. The X/Open Distributed Transaction Processing standard interface between a **transaction manager** (TM, the coordinator) and **resource managers** (RMs: databases, message brokers), with an **application program** (AP) demarcating transactions. Its main calls are `xa_start` and `xa_end` (associate work with a global transaction ID, the XID), `xa_prepare`, `xa_commit`, `xa_rollback` and `xa_recover` (list in-doubt XIDs after a crash) [X/Open 1991].

Figure 28.5 — The X/Open DTP model.



Reading the diagram. The application sends ordinary work directly to each resource manager, tagged with a global transaction ID; the transaction manager never sees the data. At commit, the TM runs 2PC over the XA interface and keeps its decisions in its own durable log, a separate storage boundary from every RM. All arrows are synchronous calls. Failure points: the TM log (lose it and in-doubt XIDs must be resolved by hand) and any RM that cannot answer `xa_recover`. Java's JTA is the best-known binding of this model.

PostgreSQL exposes the participant side directly. `PREPARE TRANSACTION 'gid'` performs phase 1, writing the transaction's state durably and dissociating it from the session; `COMMIT PREPARED` or `ROLLBACK PREPARED` performs phase 2, from any session; the view `pg_prepared_xacts` lists in-doubt transactions. The feature is disabled by default (`max_prepared_transactions = 0`) because orphaned prepared transactions are dangerous

[PostgreSQL Docs: PREPARE TRANSACTION]. MySQL offers `XA START`, `XA END`, `XA PREPARE`, `XA COMMIT` and `XA RECOVER` [MySQL Docs: XA Transactions].

The following session ran against two PostgreSQL 16 servers (shard A on port 5433, shard B on 5434, both with `max_prepared_transactions = 10`), with the human operator acting as coordinator:

```
        -- On shard A (acct 7 = 50000 cents) and shard B (acct 9 = 0): phase 1
        BEGIN;                                              -- shard A
        UPDATE accounts SET balance_cents = balance_cents - 10000 WHERE account_id = 7;
        PREPARE TRANSACTION 'xfer-42';
        BEGIN;                                              -- shard B
        UPDATE accounts SET balance_cents = balance_cents + 10000 WHERE account_id = 9;
        PREPARE TRANSACTION 'xfer-42';

        -- The "coordinator" disappears. On shard A:
        SELECT gid, prepared FROM pg_prepared_xacts;
        SET lock_timeout = '1s';
        UPDATE accounts SET balance_cents = balance_cents - 1 WHERE account_id = 7;

        -- Restart shard A (pg_ctl restart), then:
        SELECT gid FROM pg_prepared_xacts;
        SELECT * FROM accounts;

        -- The coordinator's log says COMMIT: phase 2 on both shards
        COMMIT PREPARED 'xfer-42';                          -- shard A, then shard B
```

Output (shard A unless noted):

```
   gid   |          prepared
---------+---------------------------
 xfer-42 | 2026-10-30 11:08:33.859+00

ERROR:  canceling statement due to lock timeout
CONTEXT:  while updating tuple (0,1) in relation "accounts"

   gid          <- after restart: the prepared transaction survived
---------
 xfer-42

 account_id | balance_cents      <- still invisible before COMMIT PREPARED
------------+---------------
          7 |         50000

 account_id | balance_cents      <- after COMMIT PREPARED on both shards
------------+---------------
          7 |         40000      (shard B: account 9 = 10000)
```

What to notice:

- The prepared transaction outlives its session *and a server restart*: that is the durable promise of phase 1, taken from the PREPARED record in the WAL.
- An unrelated update to account 7 blocks and times out: in-doubt transactions hold row locks indefinitely. PostgreSQL will never resolve them on its own, and they also hold back VACUUM (§11.14.2).

WARNING / TRADE-OFF

Warning — Heuristic decisions break atomicity. When an in-doubt transaction blocks production for too long, operators (or XA resource managers configured to do so) may force a **heuristic commit** or **heuristic abort** without the coordinator. If the guess contradicts the coordinator's logged decision, the transaction is no longer atomic and the damage must be repaired by hand. XA reports this as a *heuristic hazard* or *heuristic mixed* outcome. Treat a heuristic decision as an incident, and record which XIDs were forced.

28.4.7 A 2PC simulation with coordinator crash and recovery

The program below implements presumed-abort 2PC with durable logs that survive crashes and volatile lock tables that do not. Crash points can be injected into the coordinator, and the tests check that recovery from the logs alone always restores atomicity.

```
        """Two-phase commit with presumed abort: coordinator crash and recovery from its
log.

        Each node has a durable log (a list that survives crash()) and volatile state
        (locks, pending writes) that is lost on a crash and rebuilt from the log.
        Run it directly with python3 to execute the scenario tests.
        """
        import unittest

        class Crash(Exception):
            """Raised when a node is killed at an injected crash point."""

        class Participant:
            def __init__(self, name, balances):
                self.name, self.up = name, True
                self.data = dict(balances)        # committed state (durable)
                self.log = []                     # durable log: (record, txid, payload)
                self.locks, self.pending = {}, {}  # volatile: key -> txid, txid -> new
values

            def prepare(self, txid, deltas):
                if not self.up:
                    raise Crash(self.name)        # the coordinator sees a timeout
                new = {}
                for key, delta in deltas.items():
                    if self.locks.get(key, txid) != txid:
                        return "NO"               # row locked by an in-doubt or active
txn
                    new[key] = self.data[key] + delta
                    if new[key] < 0:
                        return "NO"               # invariant: no overdraft
                for key in new:
                    self.locks[key] = txid
                self.pending[txid] = new
                self.log.append(("PREPARED", txid, new))   # forced before voting YES
                return "YES"

            def finish(self, txid, decision):
                """Apply COMMIT or ABORT. Idempotent: duplicates are harmless."""
                if not self.up:
                    raise Crash(self.name)
                new = self.pending.pop(txid, None)
                if new is None:
                    return "ACK"                  # already finished, or never prepared
                if decision == "COMMIT":
                    self.data.update(new)
                    self.log.append(("COMMIT", txid, None))   # forced, then ACK
                else:
                    self.log.append(("ABORT", txid, None))    # not forced under pre-
sumed abort
                for key in new:
                    del self.locks[key]
                return "ACK"
```

```
            def crash(self):
                self.up, self.locks, self.pending = False, {}, {}

            def recover(self):
                """Redo from the log: a PREPARED txn with no outcome is in doubt and re-
locked."""
                self.up = True
                done = {txid for rec, txid, _ in self.log if rec in ("COMMIT", "ABORT")}
                for rec, txid, new in self.log:
                    if rec == "PREPARED" and txid not in done:
                        self.pending[txid] = new
                        for key in new:
                            self.locks[key] = txid

            def in_doubt(self):
                return sorted(self.pending)

            def resolve(self, coordinator):
                """Termination protocol: ask the coordinator about each in-doubt txn."""
                for txid in self.in_doubt():
                    if not coordinator.up:
                        return False              # blocked: cannot decide alone
                    self.finish(txid, coordinator.outcome(txid))
                return True

        class Coordinator:
            def __init__(self, participants):
                self.parts = {p.name: p for p in participants}
                self.log = []                     # durable

        if __name__ == "__main__":
            unittest.main(verbosity=1)
```

Output (Python 3.13; the timing varies):

```
........
----------------------------------------------------------------------
Ran 8 tests in 0.000s

OK
```

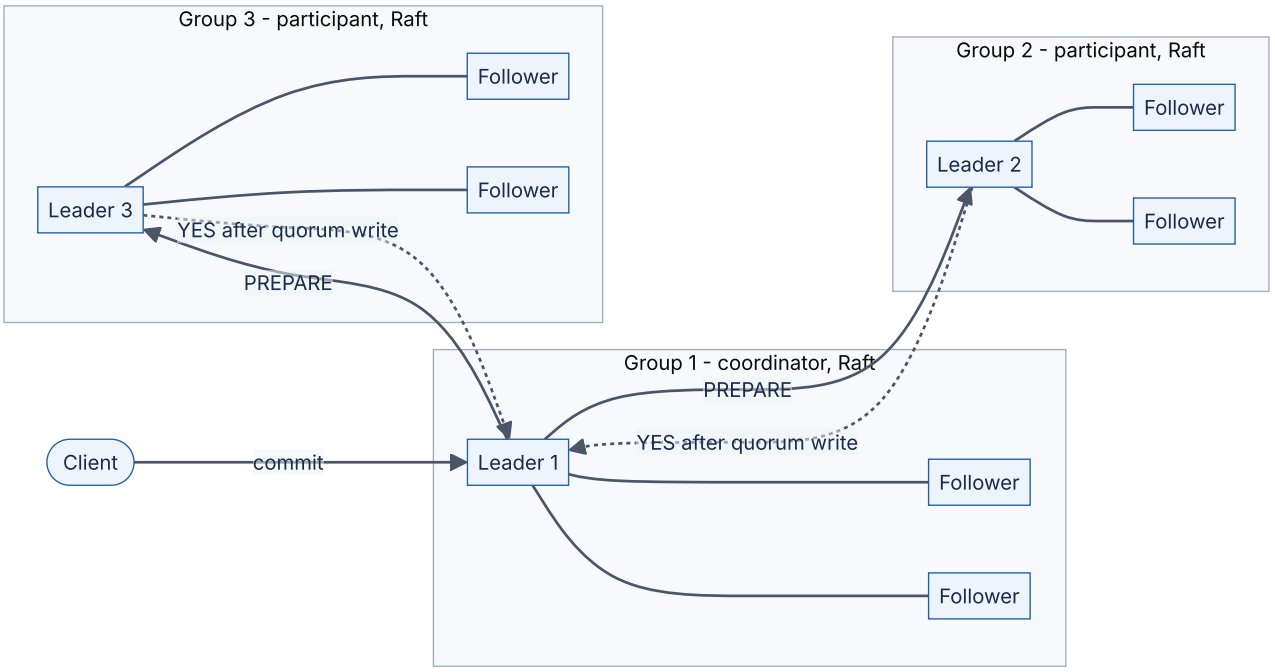
What to notice:

- The only thing that survives a coordinator crash is `self.log`, and recovery reads nothing else. A `COMMIT` without `END` is re-driven; any other transaction is aborted by presumption, which is why `test_no_vote_aborts_without_coordinator_log` can assert an empty log.
- `test_crash_before_decision_blocks_then_aborts` reproduces Figure 28.4: while the coordinator is down, `resolve` returns `False` and a competing transaction on account 7 is refused because the in-doubt transaction still holds the lock.
- `test_crash_mid_phase2_is_completed` shows a moment where A has committed and B has not. This is not an atomicity violation: the outcome was fixed at the commit record and recovery converges B to it.
- `outcome` is valid only for transactions the coordinator is no longer running; a real coordinator answers “ask later” for active ones.
- `finish` is idempotent because phase 2 messages are retried (§22.15).

28.4.8 Two-phase commit over consensus groups

Every blocking scenario above has the same cause: the decision lives in one node’s log. Replace that log with a **replicated log** (Raft or Multi-Paxos, §26.6–§26.7) and the coordinator’s crash is no longer a long outage, because a new leader of the coordinator’s group takes over within an election timeout, reads the decision from the replicated log and finishes phase 2. Do the same for each participant, and a participant’s prepared record survives the loss of any minority of its replicas.

Figure 28.6 — Two-phase commit across consensus groups.



Reading the diagram. Each subgraph is a consensus group of three replicas, typically in three availability zones; "forcing a log record" now means replicating it to a quorum (two of three) of the group. The coordinator is the leader of one group, often a group that is also a participant. Solid arrows are synchronous requests; the dotted votes are replies that arrive only after the participant's prepared record is replicated. Failure points move from nodes to groups: losing one replica of any group is invisible to the transaction; losing a majority of one group blocks the transactions that touch it, as for any consensus system. Each transaction pays its slowest group's quorum write, twice.

Gray and Lamport generalized the idea as **Paxos Commit**, which runs one Paxos instance per participant's vote and tolerates F failures of the acceptors with $2F + 1$ acceptors; with $F = 0$ it reduces to 2PC [Gray and Lamport 2006]. Most production systems use the simpler structure of Figure 28.6, and so does nearly every system in the rest of this chapter.

INDUSTRY EXAMPLE

Apache Kafka — 2PC with a replicated coordinator log. Kafka transactions let a producer write atomically to several partitions and commit consumer offsets. A *transaction coordinator* records each transaction's state in the internal, replicated `__transaction_state` topic: it writes a prepare-commit entry (the commit point), then writes commit markers into every partition involved, then a completion entry. If the coordinator broker fails, a new leader for that `__transaction_state` partition reads the log and finishes the markers. Consumers in `read_committed` mode skip data whose markers are not yet written. See §31.11. *Evidence: Primary* — [Kafka KIP-98 2017]

28.4.9 Advantages, disadvantages and failure scenarios

Advantages. 2PC gives true atomicity and, combined with locking, serializability across independent resource managers. It is standardized (XA), supported by most relational databases and several brokers, and its logic is simple enough to verify.

Disadvantages. It blocks when the coordinator fails after votes; it holds locks across at least one round trip plus two forced writes; its availability is the product of its participants'; and it couples otherwise independent services in time, which is why microservice architectures avoid it (§28.6, Chapter 34).

Table 28.3 — Two-phase commit failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Rows locked for minutes	Coordinator down while participants are in doubt	Age of `pg_prepared_xacts` / `XA RECOVER` entries	Restart coordinator from its log; resolve by GID	Replicated coordinator log; fast automatic restart
Orphaned prepared transaction	Coordinator's log lost or GID never recorded	Prepared transactions with unknown GID	Manual heuristic decision, then audit	Log GID and participant list before phase 2; never lose the TM log
Inconsistent outcome	Heuristic commit/abort contradicting the coordinator	Heuristic-mixed report; reconciliation	Manual compensation	Forbid heuristics without the coordinator's log
Transaction aborts under load	Participant times out waiting for `PREPARE` and aborts unilaterally	Abort rate and reason codes	Retry the transaction	Tune timeouts; avoid slow work between execution and commit
Duplicate commit applied twice	Retried phase 2 message not deduplicated	Balance reconciliation	Repair data	Idempotent `finish` keyed by transaction ID
VACUUM or purge stalls	Long-lived prepared transaction pins old versions	Table bloat, `age(datfrozenxid)`	Resolve the prepared transaction	Alert on prepared transactions older than seconds

COMMON MISTAKE

Common misconception — "If the coordinator dies, participants can just time out and abort." Before voting yes, they can. After voting yes, they cannot: the coordinator may have logged commit and told another participant, which has already made its half visible. A timeout-driven abort at that point violates atomicity.

COMMON MISTAKE

Common misconception — "2PC guarantees all participants commit at the same instant." It guarantees they reach the same *decision*. Participants apply it at different times, so a reader can see A's half before B's unless the system also provides consistent snapshots, which is what Percolator's timestamps and Spanner's commit wait add.

28.5 Three-phase commit

28.5.1 How 3PC removes blocking

DEFINITION

Definition — Three-phase commit (3PC). A commit protocol that inserts a **pre-commit** phase between voting and committing, so that no participant can commit until every operational participant knows that all voted yes. Under a synchronous system model with reliable failure detection and no network partitions, it lets the surviving participants always reach a decision without the failed coordinator [Skeen 1981].

Why does this exist?

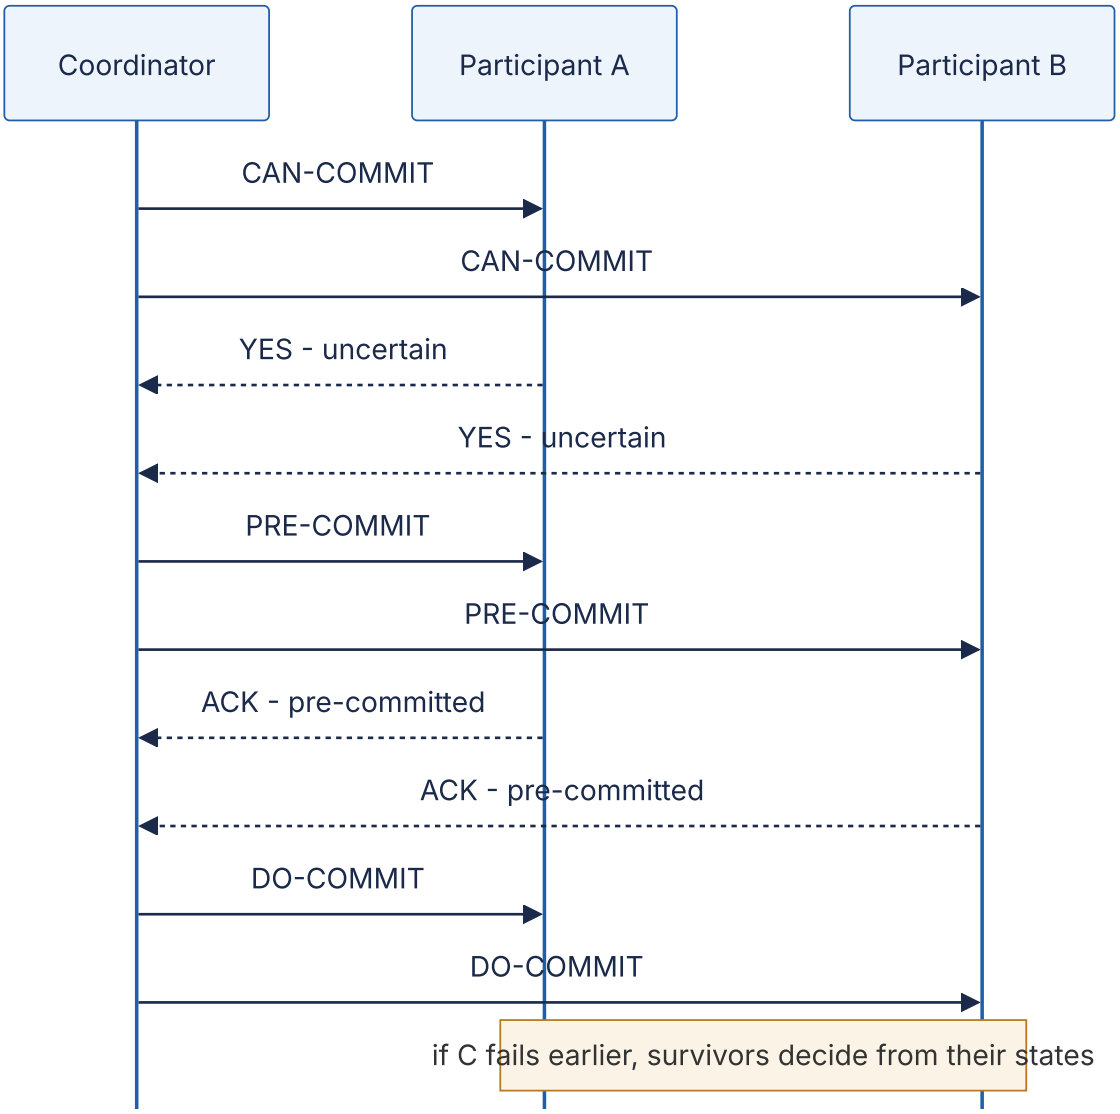
2PC blocks because a prepared participant cannot tell whether some other node has already committed. Skeen proved that a commit protocol is non-blocking (for crash failures, in a synchronous system) only if no participant can be in a state from which *both* commit and abort are reachable in one step, and no non-committable state is adjacent to commit [Skeen 1981]. 2PC's PREPARED state violates the first rule. 3PC adds a buffer state so that "someone may have committed" implies "everyone already knows the vote was unanimous".

How it works internally

1. **CanCommit.** The coordinator asks each participant whether it can commit; each replies yes (and becomes *uncertain*, as in 2PC's PREPARED) or no.
2. **PreCommit.** If all said yes, the coordinator sends `PRE-COMMIT`; each participant logs it, enters the *pre-committed* state and acknowledges. Pre-committed means "everyone voted yes; I will commit unless I fail".
3. **DoCommit.** After all acknowledgments, the coordinator sends `COMMIT`.
4. **Termination when the coordinator fails.** The survivors elect a new coordinator, which collects their states. If any has committed, or any is pre-committed, it drives everyone to commit (sending `PRE-COMMIT` first to those still uncertain). If any has

aborted, or *all* are merely uncertain, it aborts. Aborting is safe in the last case because nobody can have committed without first being pre-committed.

Figure 28.7 — Three-phase commit.



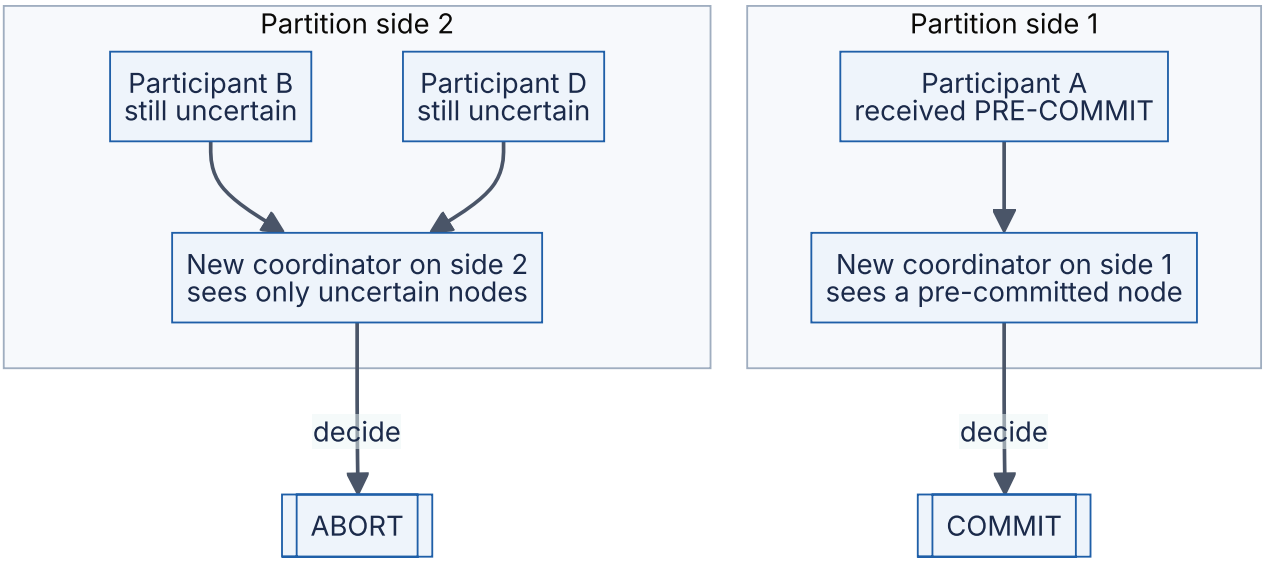
Reading the diagram. Each phase is a synchronous parallel fan-out, so 3PC costs three round trips instead of two; in a datacenter with RTT $= 0.5$ ms and 1 ms forced writes, about $3(0.5) + 2(1) = 3.5$ ms before the decision is known everywhere, versus 3 ms for 2PC. The extra round trip buys the invariant shown in the note: whenever any node may have committed, every live node is at least pre-committed, so the survivors can always decide among themselves. Failure points are the timeouts used to declare the coordinator dead, which must be accurate for the protocol to be safe.

28.5.2 Why 3PC fails under network partitions

The termination rule “all uncertain means abort” assumes that a node which cannot be reached has *crashed*. In an asynchronous network it may simply be on the other side of a

partition (§24.7).

Figure 28.8 — A partition makes 3PC decide both ways.



Reading the diagram. The original coordinator sent `PRE-COMMIT` to A and then lost connectivity; the network splits A from B and D. Each side runs the termination protocol with the nodes it can see. Side 1 contains a pre-committed node, so it commits; side 2 sees only uncertain nodes, so it aborts. Both decisions are durable, and the transaction is no longer atomic. The failure point is the timeout-based failure detector, which cannot distinguish crashed from partitioned. No amount of scaling fixes it; only a majority-based decision does.

3PC is rarely deployed for three reasons: real networks partition and timeouts misfire under GC pauses and overload (§23.9); it adds a round trip and a forced write to every commit; and running 2PC over consensus groups (§28.4.8) tolerates crashes *and* partitions, staying safe even when timeouts are wrong.

Table 28.4 — Commit protocols compared.

Property	2PC	3PC	2PC over consensus groups
Message rounds to decide	2	3	2 (each a quorum write)
Blocks if coordinator crashes	Yes, until it recovers	No (synchronous model)	Only until a new leader is elected
Safe under network partition	Yes (blocks, never inconsistent)	No	Yes (minority side blocks)
Failure assumption	Crash-recovery	Crash-stop, bounded delays	Crash-recovery, majority up
Used in practice	XA, databases, brokers	Rarely	Spanner, CockroachDB, TiDB, YugabyteDB, Kafka

COMMON MISTAKE

Common misconception — "3PC is 2PC without blocking." It removes blocking only by assuming perfect failure detection. In an asynchronous network it trades 2PC's *blocking* for the far worse possibility of *inconsistency*.

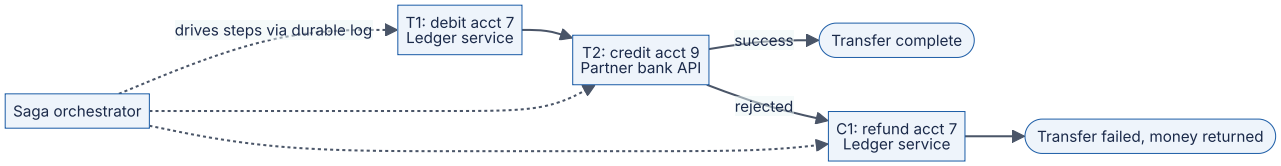
28.6 Sagas: a preview

DEFINITION

Definition — Saga. A long-lived transaction written as a sequence of local transactions $T_1, T_2, \ldots, T_n$, each committed independently, where each T_i has a **compensating transaction** C_i that semantically undoes it. Either $T_1 \ldots T_n$ all complete, or $T_1 \ldots T_j, C_j \ldots C_1$ run [Garcia-Molina and Salem 1987].

A saga replaces atomicity with **semantic atomicity**: the system ends in a state equivalent to "all happened" or "none happened" as the *business* defines it, not byte for byte. Refunding a charge does not erase the charge; it adds a refund. Because each step commits locally, a saga holds no locks across services and never blocks on a coordinator, which is why it suits long-running business processes and microservices.

Figure 28.9 — A transfer saga with compensation.



Reading the diagram. Each box is a local transaction in a different service with its own database; between steps, other transactions can see the intermediate state (account 7 debited, account 9 not yet credited). The orchestrator persists its progress and drives steps asynchronously (dotted arrows), retrying each step until it succeeds, so steps and compensations must be idempotent (§22.15). The failure point is the gap between steps: a saga provides no isolation, so another transaction might read the debited balance and refuse a payment it should have allowed.

The price is isolation, plus a compensation for every step, even steps that cannot truly be undone (an email sent). Chapter 32 covers sagas in depth (§32.7–§32.8) and the **transactional outbox** (§32.5), which makes "commit locally *and* publish a message" atomic without 2PC.

28.7 Percolator-style transactions

28.7.1 The problem Percolator solved

DEFINITION

Definition — Percolator transaction. A snapshot-isolated, multi-row, multi-table transaction built entirely by a client library on top of a store that offers only single-row atomic updates and multiple timestamped versions per cell. Ordering comes from a central **timestamp oracle**; atomicity comes from making one row's lock, the **primary lock**, the commit point for the whole transaction [Peng and Dabek 2010].

First-principles explanation

Think of a team editing many pages of a shared binder. Before editing, each writer clips a sticky note to every page they will change, and every note says "see page 1". Page 1's note is special: whoever removes it and stamps page 1 "done at 14:02" has committed the whole edit, even if they collapse before unclipping the other notes. A reader who finds a stale note on page 37 just turns to page 1 to learn whether that edit happened.

Why does this exist?

Google's web index was rebuilt in large MapReduce batches, so a newly crawled page could take days to appear in search. Updating the index *incrementally* meant many concurrent workers changing billions of Bigtable rows (§14.6), each document touching many rows, with no stale or half-applied results. Bigtable offered only single-row transactions. Percolator added cross-row snapshot-isolated transactions and notifications on top, and Google reported that moving indexing to it cut the average age of documents in search results by 50% [Peng and Dabek 2010].

28.7.2 How it works internally

Every logical column is stored as several Bigtable columns, each holding timestamped versions.

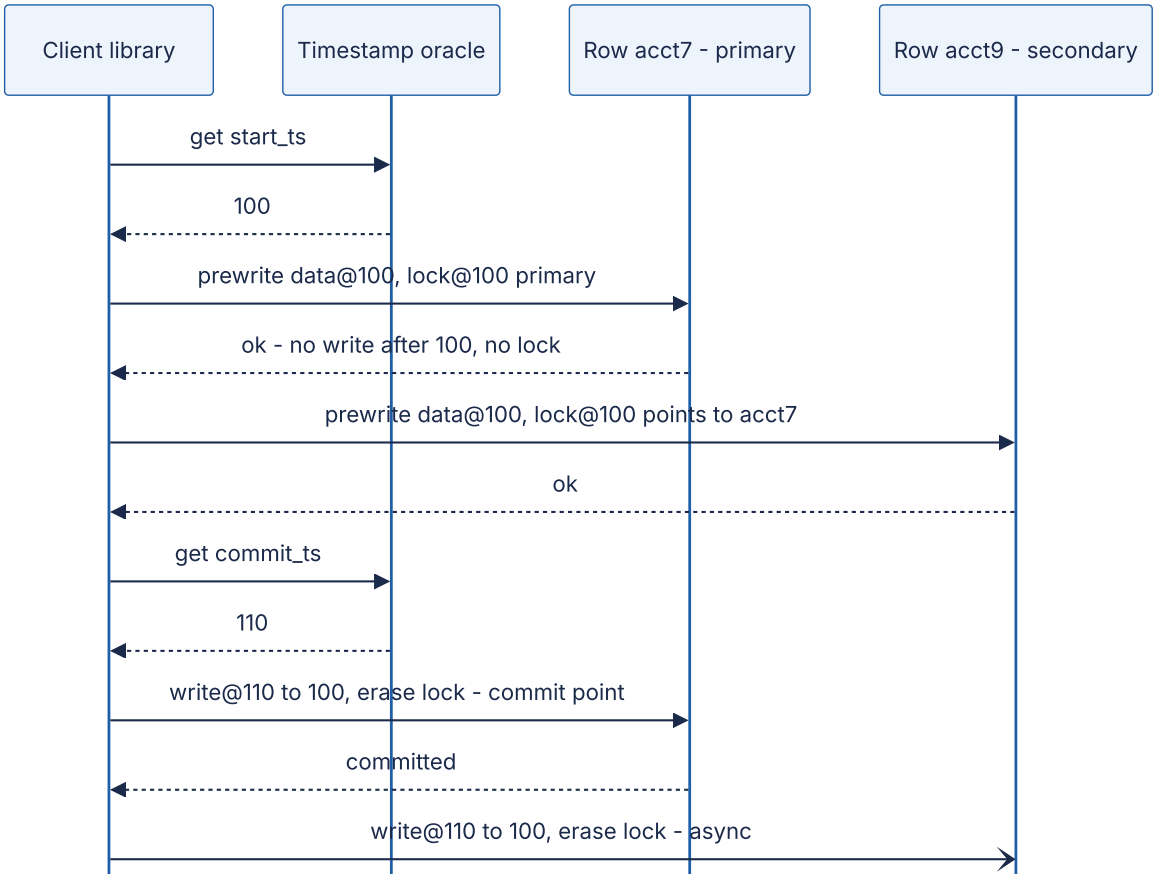
Table 28.5 — Percolator's columns for one logical cell.

Column	Version timestamp	Contents	Meaning
`data`	transaction start timestamp	The value	Written during prewrite, invisible until a `write` record points to it
`lock`	transaction start timestamp	Location of the primary lock (or "primary")	An uncommitted transaction holds this cell
`write`	transaction commit timestamp	Start timestamp of the committed `data` version	Makes `data@start_ts` visible to snapshots at or after `commit_ts`

Write path.

1. **Start.** Get `start_ts` from the timestamp oracle. Buffer writes at the client.
2. **Prewrite (phase 1).** Pick one written cell as the **primary**; the rest are secondaries. For each cell, primary first, run a Bigtable single-row transaction that aborts if there is a `write` record with timestamp $\geq$ `start_ts` (a write-write conflict with a transaction that committed after our snapshot) or *any* `lock` (a concurrent writer); otherwise it writes `data@start_ts` and `lock@start_ts` pointing at the primary.
3. **Commit (phase 2).** Get `commit_ts` from the oracle. In one single-row transaction on the primary, check that our lock is still there, write `write@commit_ts` $\rightarrow$ `start_ts` and erase the lock. **This is the commit point.**
4. **Secondaries.** Write `write@commit_ts` and erase the lock on each secondary. This step can happen lazily, after replying to the client, because the outcome is already fixed.

Figure 28.10 — A Percolator write of two cells.



Reading the diagram. All coordination lives in the client library; there is no coordinator process and no coordinator log, because the primary row's lock *is* the coordinator's state, stored durably in replicated Bigtable. The oracle is a single logical service on every transaction's path, twice. Phase 1 messages to different rows can run in parallel after the primary's. The final secondary update is asynchronous (open arrowhead). Failure points: the client can die anywhere; after the primary's `write` record exists the transaction is committed and readers will roll the secondaries forward, before it they will roll everything back. Scaling: the oracle batches requests, and Peng and Dabek report a single oracle machine serving about two million timestamps per second.

Read path and lazy cleanup. A reader with snapshot `start_ts` checks for a `lock` with timestamp $\leq$ `start_ts` on the cell. If one exists, a writer that may commit *before* our snapshot is in flight, so the reader waits. If the lock looks abandoned (Percolator checks writer liveness through Chubby, §26.14, and lock age), the reader cleans up by looking at the primary: if the primary's lock is still there, it erases it, rolling the transaction back; if the primary has a `write` record for that `start_ts`, it rolls this secondary forward by writing the same `write` record. Otherwise the reader returns the newest `data` version referenced by a `write` record with timestamp $\leq$ `start_ts`.

KEY CONCEPT

Concept — Why a single-row atomic operation is enough. 2PC needs a coordinator log so that one durable record decides the outcome. Percolator makes that record the primary cell's `write` entry, written by a single-row transaction in a replicated store. Every participant (every secondary lock) names the primary, so anyone can find the decision. There is no blocking on a coordinator: the decision is always readable, and an abandoned transaction can be resolved by whichever reader trips over it.

28.7.3 TiKV and TiDB

TiDB is a MySQL-compatible distributed SQL database. Its storage layer, TiKV, implements Percolator's protocol over **Regions**, contiguous key ranges each replicated by Raft, and its **Placement Driver** (PD) acts as the timestamp oracle, handing out hybrid timestamps (physical milliseconds plus a logical counter) in batches [Huang et al. 2020]. Since v3.0.8, new clusters default to **pessimistic transactions**, which acquire Percolator-style locks during statement execution, as MySQL users expect, rather than discovering conflicts only at commit [TiDB Docs: Transactions]. Two later optimizations shorten the protocol: **async commit** returns to the client once all prewrites succeed, computing the commit timestamp from the participants' prewrite responses instead of a second oracle call; and **one-phase commit** writes a transaction confined to one Region in a single step.

FORMULA

Percolator commit latency

$$T_{\text{perc}} \approx 2\,\text{RTT}_{\text{TSO}} + 2\,(\text{RTT} + t_w) \qquad T_{\text{async}} \approx \text{RTT}_{\text{TSO}} + \text{RTT} + t_w$$

Symbol	Meaning	Units
T_{perc}	Timestamp and commit overhead of a classic Percolator transaction (start and commit timestamps, prewrite, primary commit)	ms
T_{async}	The same with async commit (no commit timestamp fetch, no wait for the primary commit)	ms
RTT_{TSO}	Round trip to the timestamp oracle	ms
RTT	Round trip from the client to the storage node	ms
t_w	Durable, replicated write on the storage node (Raft quorum plus `fsync`)	ms

WORKED EXAMPLE

Worked example — TiDB in one region. Take $\text{RTT}_{\text{TSO}} = 0.5$ ms, RTT = 0.5 ms and $t_w = 2$ ms for a Raft write across three availability zones.

1. Classic: $2(0.5) + 2(0.5 + 2) = 1 + 5 = 6$ ms.
2. Async commit: $0.5 + 0.5 + 2 = 3$ ms, half the overhead.
3. If the PD leader is in another region with $\text{RTT}_{\text{TSO}} = 60$ ms, classic costs $120 + 5 = 125$ ms.

Interpretation. Percolator's latency is dominated by replicated writes inside a region, and by the oracle as soon as it is far away. **Engineering implication.** Keep the timestamp oracle in the region where transactions run, and treat a single global oracle as the scaling and geo-distribution limit of this design; Spanner (§28.8) removes it with clocks.

28.7.4 A Percolator model you can run

```
        """A Percolator-style transaction on a multi-version key-value store.

        Each row has three columns, each a map timestamp -> value (as in Bigtable):
          data[ts]  = value written by the txn that started at ts
          lock[ts]  = name of the primary row, while the txn that started at ts is in
flight
          write[cts] = start ts of the txn whose data became visible at commit ts cts
        Assumes the holder of any lock a reader finds is dead (Percolator checks live-
ness first).
        """
        import itertools

        class Store:
            def __init__(self):
                self.rows = {}

            def row(self, key):
                return self.rows.setdefault(key, {"data": {}, "lock": {}, "write": {}})

        class Oracle:                                   # the timestamp oracle
            def __init__(self):
                self._next = itertools.count(1)

            def ts(self):
                return next(self._next)

        class Txn:
            def __init__(self, store, oracle):
                self.s, self.o = store, oracle
                self.start = oracle.ts()                # snapshot timestamp
                self.writes = {}

            def get(self, key):
                r = self.s.row(key)
                for lts in [t for t in r["lock"] if t <= self.start]:
                    self._cleanup(key, lts)             # stale lock below our snap-
shot

                elif not committed:
                    r["data"].pop(lts, None)
                r["lock"].pop(lts, None)

        def setup():
            s, o = Store(), Oracle()
            t = Txn(s, o)
            t.set("acct7", 500)
            t.set("acct9", 0)
```

```
            assert t.commit()
            return s, o

        def transfer(s, o, amount, crash=None):
            t = Txn(s, o)
            t.set("acct7", t.get("acct7") - amount)
            t.set("acct9", t.get("acct9") + amount)
            return t.commit(crash)

        def balances(s, o):
            t = Txn(s, o)
            return t.get("acct7"), t.get("acct9")

        if __name__ == "__main__":
            # 1. Snapshot isolation: a reader that started earlier keeps its snapshot.
            s, o = setup()
            old_reader = Txn(s, o)
            assert transfer(s, o, 100)
            assert (old_reader.get("acct7"), old_reader.get("acct9")) == (500, 0)
            assert balances(s, o) == (400, 100)

            # 2. Write-write conflict: the second concurrent writer aborts.
            s, o = setup()
            t1, t2 = Txn(s, o), Txn(s, o)
            t1.set("acct7", 1)
            t2.set("acct7", 2)
            assert t1.commit() and not t2.commit()

            # 3. Client dies after committing the primary: a reader rolls the secondary
forward.
            s, o = setup()
            assert transfer(s, o, 100, crash="after_primary")
            assert balances(s, o) == (400, 100)

            # 4. Client dies before the commit point: a reader rolls everything back.
            s, o = setup()
            transfer(s, o, 100, crash="before_primary")
            assert balances(s, o) == (500, 0)

            # 5. Write skew is allowed: invariant acct7 + acct9 >= 0 is violated.
            s, o = setup()
            a, b = Txn(s, o), Txn(s, o)
            if a.get("acct7") + a.get("acct9") >= 400:
                a.set("acct7", a.get("acct7") - 400)      # writes acct7 only
            if b.get("acct7") + b.get("acct9") >= 400:
                b.set("acct9", b.get("acct9") - 400)      # writes acct9 only
            assert a.commit() and b.commit()
            print("after write skew:", balances(s, o), "sum =", sum(balances(s, o)))
            print("all Percolator scenarios passed")
```

Output:

```
after write skew: (100, -400) sum = -300
all Percolator scenarios passed
```

What to notice:

- Scenario 3 is the heart of the protocol: the client "dies" right after deleting the primary lock, yet the next reader returns (400, 100) because `_cleanup` finds the primary's `write` record and rolls `acct9` forward.
- Scenario 4 is the mirror image: with the primary lock still present, the reader rolls the whole transaction back. No coordinator was needed in either case.
- Scenario 5 is write skew (§28.3.3). The two transactions write disjoint rows, so no write-write check fires, and the customer ends $300 overdrawn. TiDB users avoid this with `SELECT ... FOR UPDATE` on both rows.

INDUSTRY EXAMPLE

Google Percolator — incremental web indexing. Google replaced batch MapReduce index builds with Percolator-based incremental processing for its Caffeine indexing system. Transactions spanning many Bigtable rows and tables update the index as each document is crawled, with observers triggered by notifications. The trade-off was explicit: per-document processing used substantially more resources than batch processing, in exchange for much fresher results. *Evidence: Primary* — [Peng and Dabek 2010]

COMMON MISTAKE

Common misconception — "A leftover lock means data loss." A Percolator lock left by a dead client is an unresolved, not a lost, transaction. Its fate is already fixed by the primary row; the first reader that needs the cell resolves it. What it costs is latency: readers wait, then pay for the cleanup.

28.8 Spanner and TrueTime

28.8.1 The TrueTime API

DEFINITION

Definition — TrueTime. Google's clock API that returns time as an interval with a guaranteed error bound instead of a single value. `TT.now()` returns $[earliest, latest]$, guaranteed to contain the absolute time at which it was called; `TT.after(t)` is true if t has definitely passed, and `TT.before(t)` is true if t has definitely not arrived. The half-width of the interval is the **uncertainty** ε [Corbett et al. 2012].

First-principles explanation

Ordinary clocks lie with confidence: a server says 12:00:00.000 when the true time might be 11:59:59.950 (§24.9). TrueTime is a clock that admits its error: "it is between 11:59:59.996 and 12:00:00.004". To be sure an event happens after time s everywhere, wait until your clock's *earliest* possible reading has passed s.

How it works internally

Each datacenter has **time masters** with GPS receivers and some with atomic clocks, which fail in different ways. A daemon on every machine polls several masters, rejects outliers and derives ε from the masters' uncertainty, communication delay and a conservatively assumed local drift between polls (the paper uses 200 µs/s). In the 2012 paper, ε followed a sawtooth from about 1 to 7 ms over each 30-second polling interval, averaging about 4 ms [Corbett et al. 2012]. If a machine's clock drifts or loses contact with masters, ε grows; it never silently becomes wrong.

28.8.2 Read-write transactions and commit wait

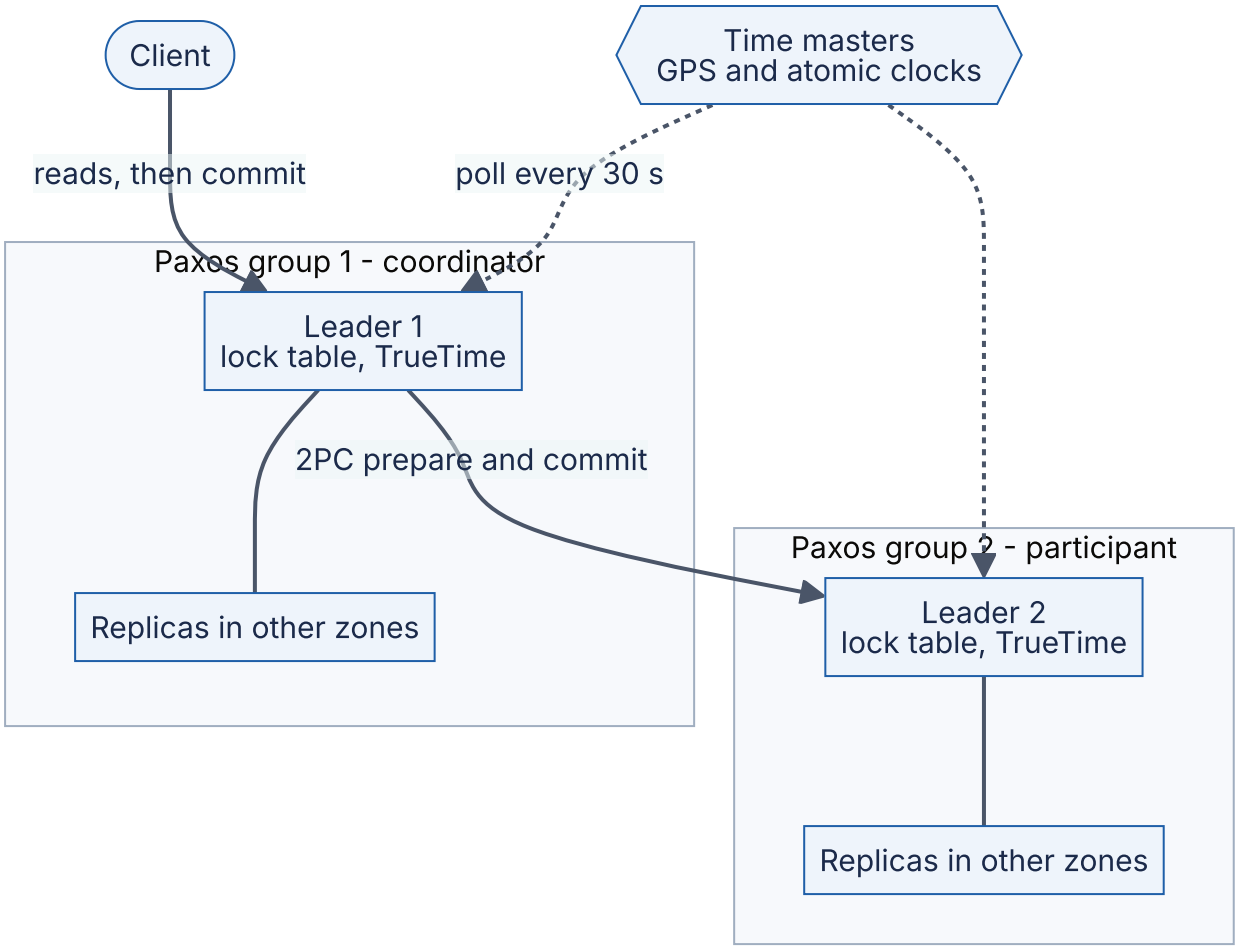
Spanner shards data into **splits** replicated by Multi-Paxos groups spread over zones; each group's leader holds a time-based leader lease (§26.11) and a lock table, and runs two-phase locking for read-write transactions. A transaction that touches several groups runs 2PC across them (§28.4.8), with one group's leader as coordinator.

1. The client buffers writes and acquires read locks at participant leaders as it reads.
2. At commit, each participant leader acquires write locks, chooses a **prepare timestamp** larger than any timestamp it has assigned, and logs a prepare record through Paxos.
3. The coordinator leader, after receiving all prepare timestamps, chooses the **commit timestamp** s: at least every prepare timestamp, greater than `TT.now().latest` at

the moment it received the commit request, and greater than any timestamp it has assigned.

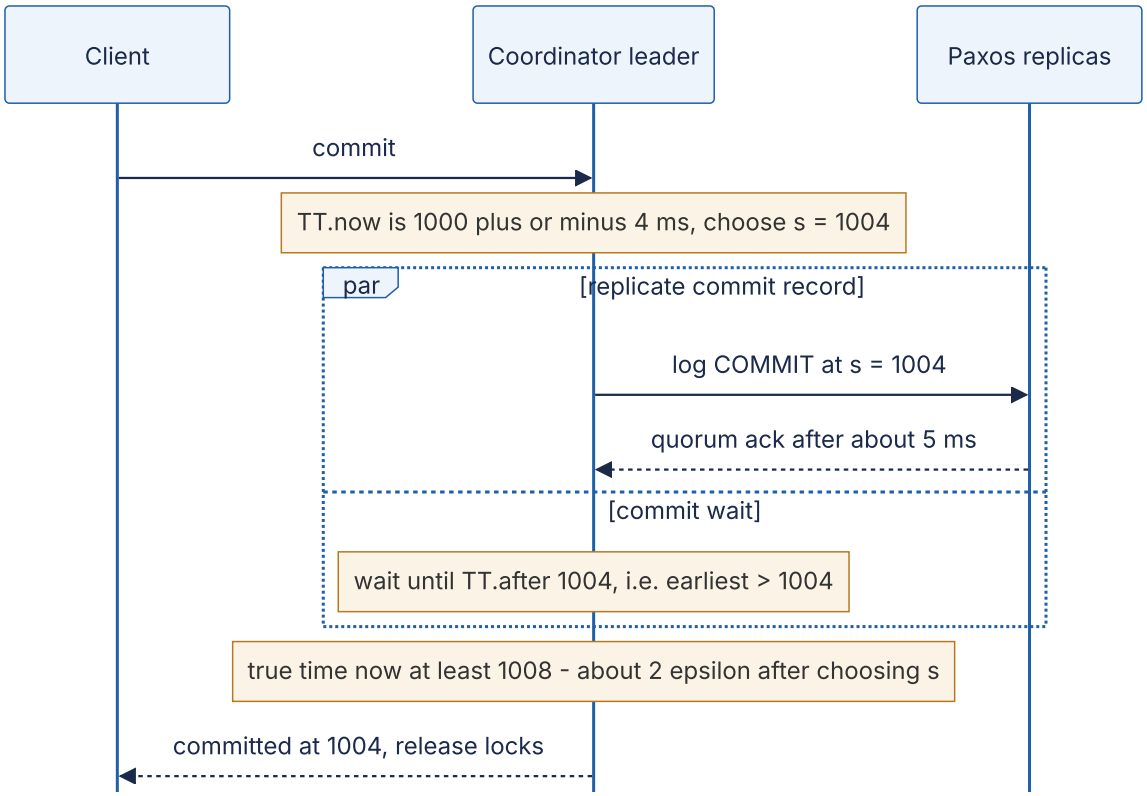
4. It logs the commit record through Paxos and, *in parallel*, performs **commit wait**: it does not let anyone see the commit until `TT.after(s)` is true.
5. It then tells the client and the participants, which apply the writes at timestamp s and release locks.

Figure 28.11 — Spanner: transactions across Paxos groups.



Reading the diagram. Each subgraph is a Paxos group whose leader serves locks and timestamps; replicas live in other zones or regions, so every “log” step is a Paxos round. 2PC runs only between leaders, synchronously. The time masters are an external dependency polled asynchronously (dotted); they bound ε but sit on no transaction’s critical path. Failure points: a leader failure costs a lease expiry and election; time master failures or network trouble widen ε, which slows commits but never breaks correctness. Scaling comes from adding splits and groups.

Figure 28.12 — Commit wait timeline at the coordinator leader.



Reading the diagram. All times are milliseconds on an illustrative scale. When the request arrives, true time is somewhere in [996, 1004], so the leader picks $s = 1004$, the latest possible “now”. It then waits until even the earliest possible reading exceeds 1004, which takes about $2\varepsilon = 8$ ms if ε stays at 4 ms. Paxos replication runs in parallel, so the client sees roughly the larger of the two delays. The storage boundary is the Paxos log; locks are held until the end of commit wait, so wait time directly adds to contention on hot rows.

FORMULA

Commit wait

$$T_{\text{wait}} \approx 2\bar{\varepsilon} \qquad T_{\text{commit}} \approx \max(T_{\text{Paxos}}, 2\bar{\varepsilon})$$

Symbol	Meaning	Units
T_{wait}	Time from choosing s = `TT.now().latest` until `TT.after(s)` holds	ms
$\bar{\varepsilon}$	Average TrueTime uncertainty (half-width) during the wait	ms
T_{Paxos}	Time to replicate the commit record to a quorum	ms
T_{commit}	Commit latency at the coordinator leader, ignoring 2PC phase 1	ms

WORKED EXAMPLE

Worked example — When does commit wait hurt?

1. Regional configuration, replicas 1 ms apart, $T_{\text{Paxos}} \approx 2$ ms; with $\bar{\varepsilon} = 4$ ms, $T_{\text{wait}} = 8$ ms. $T_{\text{commit}} = \max(2, 8) = 8$ ms: commit wait dominates.
2. Multi-region configuration, quorum RTT 50 ms: $T_{\text{commit}} = \max(50, 8) = 50$ ms: commit wait is hidden entirely.
3. Clock trouble widens $\bar{\varepsilon}$ to 100 ms: $T_{\text{wait}} = 200$ ms in both configurations, and hot-row throughput under locking falls to at most $1/0.2 = 5$ commits/s.

Interpretation. Spanner converts clock uncertainty directly into commit latency, so the quality of the time infrastructure is a performance parameter. **Engineering implication.** Commodity NTP is usually accurate to milliseconds but gives no guaranteed bound (§24.9), so a safe configured bound must be hundreds of milliseconds (CockroachDB's default maximum offset is 500 ms, §28.10.1), which would make commit wait unacceptable; this is why systems without TrueTime-class clocks use HLCs and uncertainty intervals instead (§28.10).

28.8.3 External consistency: a proof sketch

DEFINITION

Definition — External consistency. If transaction T_1 commits before T_2 starts, in absolute (wall-clock) time, then T_1's commit timestamp is smaller than T_2's. Combined with serializability, this is **strict serializability**: the serial order respects real-time order, as linearizability does for single objects (§25.3).

Let e_i^{start}, e_i^{server} and e_i^{commit} be the events where T_i's commit request reaches the coordinator, where it is assigned timestamp s_i, and where it becomes visible; let $t_{\text{abs}}(e)$ be absolute time. Suppose $t_{\text{abs}}(e_1^{\text{commit}}) < t_{\text{abs}}(e_2^{\text{start}})$. Then [Corbett et al. 2012]:

1. $s_1 < t_{\text{abs}}(e_1^{\text{commit}})$, by **commit wait**: T_1 is not visible until `TT.after(s_1)`.
2. $t_{\text{abs}}(e_1^{\text{commit}}) < t_{\text{abs}}(e_2^{\text{start}})$, the assumption.
3. $t_{\text{abs}}(e_2^{\text{start}}) \le t_{\text{abs}}(e_2^{\text{server}})$, by causality.
4. $t_{\text{abs}}(e_2^{\text{server}}) \le s_2$, by the **start rule**: $s_2 \ge$ `TT.now().latest` at that moment, which is at least the absolute time.

Chaining the inequalities gives $s_1 < s_2$. Both rules are needed: without commit wait, s_1 could be in the future of T_2's start; without the start rule, s_2 could lag real time.

28.8.4 Read-only transactions and snapshot reads

A read-only transaction takes $s_{\text{read}} =$ `TT.now().latest` and reads at that timestamp, without locks, from *any* replica that is sufficiently up to date. A replica can serve a read at t once $t \le t_{\text{safe}} = \min(t_{\text{safe}}^{\text{Paxos}}, t_{\text{safe}}^{\text{TM}})$: it has applied every Paxos write up to t, and no prepared-but-undecided transaction could still commit at or below t. Because commit timestamps are externally consistent, such a read sees every transaction that committed before it started. Reads at a timestamp in the past (**stale reads**, for example 10 s old) are cheaper still: any replica can serve them immediately. Read-only transactions are therefore never blocked by, and never block, read-write transactions.

28.8.5 Spanner and the CAP theorem

CAP (§25.8) says that during a network partition a system must give up either consistency or availability. Spanner chooses consistency: a minority side of a partition cannot commit. Brewer argues that Spanner is nevertheless "effectively CA": partitions are rare on Google's private network, and Spanner's measured availability exceeds five nines, so users experience a system that is both consistent and available. In the incident data he reports, network problems were a small minority of Spanner's outages, below user error, overload and bugs [Brewer 2017]. The lesson: availability is an engineering number, and

a consistent system on a well-run network can beat a weakly consistent one on a poor network.

INDUSTRY EXAMPLE

Google F1 on Spanner — the AdWords backend. Google migrated its advertising backend from a sharded MySQL deployment to F1, a distributed SQL system built on Spanner, to get cross-shard transactions, consistent secondary indexes and resharding without application changes. The authors describe higher commit latency than MySQL, offset by hierarchical schemas that cluster related rows and by batching and parallelism. *Evidence: Primary* — [Shute et al. 2013]

COMMON MISTAKE

Common misconception — "Spanner works because Google's clocks are perfectly synchronized." Its clocks are not perfect; they are *honest*. Correctness requires only that the true time lie inside TrueTime's interval. Tight intervals determine performance, not correctness.

28.9 Calvin and deterministic databases

28.9.1 Agree on the order first, then execute

DEFINITION

Definition — Deterministic database. A database in which replicas and partitions first agree on a global order of transaction *inputs*, then execute transactions so that the outcome depends only on that order and the initial state. Every node that executes the same log reaches the same state, so no node needs to ask another whether to commit [Thomson et al. 2012].

First-principles explanation

2PC is a meeting held *after* the work: "did everyone manage to do their part?" Calvin holds the meeting *before*: everyone agrees on the list of jobs and their order, then works through the list independently. If every worker follows the same list with the same rules, they cannot disagree about the outcome, so there is nothing to vote on.

Why does this exist?

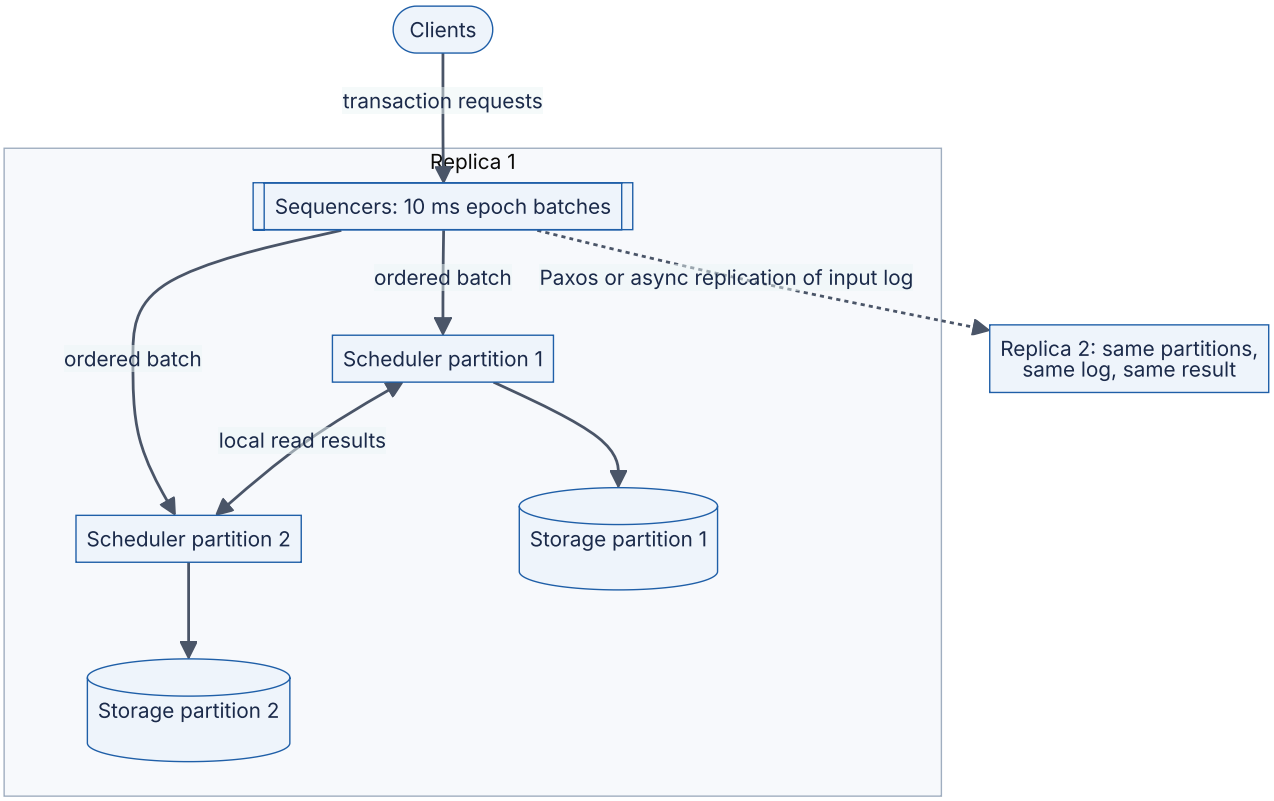
In 2PC a participant can abort for *nondeterministic* reasons: a deadlock victim, a node crash, a timeout. The vote exists to catch those. Thomson and colleagues observed that if

the system removes nondeterministic aborts, the vote becomes unnecessary, and locks no longer need to be held across a commit protocol. Contended transactions then hold locks only for their execution time, which is where Calvin's throughput advantage under contention comes from.

How it works internally

1. **Sequencing.** Clients send transaction requests to a sequencer on any node. Sequencers collect requests into **epochs** of 10 ms, replicate each batch (with Paxos, or asynchronously for lower latency and weaker durability) and send it to the schedulers of every partition the transactions touch. The merged batches form the global input log.
2. **Scheduling.** Each partition's scheduler acquires locks in global log order, deterministically: if T5 precedes T9 in the log and both want key *x*, T5 always gets it first. This rules out deadlocks.
3. **Execution.** Each participating partition performs its local reads and sends the results to the partitions that have writes; each of those runs the transaction logic and applies its own writes. A transaction that fails a constraint aborts on every partition alike, because every partition computes the same result.
4. **Failures.** A crashed node does not cause aborts; a replica, or the node after restart, replays the input log from a checkpoint and reaches the same state.

Figure 28.13 — Calvin's architecture.



Reading the diagram. The sequencing layer is the only place where nodes coordinate synchronously, and what it replicates is the *input* (subroutine shape: a log), not the resulting data. Schedulers within a replica exchange read results directly (two-way arrow) and never exchange votes. Replica 2 receives the same log asynchronously or through Paxos and computes the same state independently, so storage on each replica is a pure function of the log. Failure points: an unreplicated batch lost with its sequencer, and a slow transaction stalling later conflicting ones. Scaling: add partitions; throughput grew nearly linearly in the paper's experiments on up to 100 machines.

FORMULA

Calvin transaction latency

$$T_{\text{Calvin}} \approx \frac{e}{2} + T_{\text{rep}} + T_{\text{exec}}$$

Symbol	Meaning	Units
e	Epoch length; a request waits on average half an epoch to be batched	ms
T_{rep}	Time to replicate the batch (Paxos round, or 0 for asynchronous)	ms
T_{exec}	Lock wait, read forwarding and execution	ms
T_{Calvin}	Expected time from request to result	ms

WORKED EXAMPLE

Worked example — Calvin versus 2PC across regions. Epoch $e = 10$ ms; three replicas in three regions with quorum RTT 70 ms; $T_{\text{exec}} = 2$ ms.

1. Calvin: $5 + 70 + 2 = 77$ ms, and locks are held for only about 2 ms.
2. 2PC over geo-replicated consensus groups: two quorum rounds, ≈ 140 ms, with locks held across the second round of 70 ms or more.
3. In one region with $T_{\text{rep}} = 2$ ms: Calvin needs $5 + 2 + 2 = 9$ ms, slower than about 5 ms for 2PC over consensus groups.

Interpretation. Calvin wins across regions and under contention, because one agreement round replaces two and locks are not held during it; in a single region, batching delay can make it slower. **Engineering implication.** Calvin's lock hold time, not its latency, is what makes it attractive for high-contention workloads such as inventory or ticketing.

28.9.2 Trade-offs and lineage

Advantages. No 2PC and no distributed deadlocks; cheap active replication of inputs instead of data; high throughput on contended keys; easy recovery by replay.

Disadvantages. Transactions must declare their read and write sets before execution. A transaction whose keys depend on data it reads (look up an index, then update the row it points to) needs a **reconnaissance** read first and must restart if the prediction proves wrong; the paper calls this optimistic lock location prediction. Interactive SQL sessions (`BEGIN`, think, `UPDATE`, think, `COMMIT`) do not fit at all. Every request pays half an epoch of batching. One slow or stalled transaction delays every later transaction that conflicts with it, because the order is fixed.

Calvin influenced commercial systems most visibly through **FaunaDB**, whose transaction engine was publicly described as Calvin-inspired; Fauna's hosted service shut down on 30 May 2025 [Fauna Docs: End of Life FAQ]. Later research, such as SLOG, extends deterministic ordering to geo-distributed data with region-local "home" data, so that single-home transactions avoid cross-region ordering [Ren et al. 2019].

> COMMON MISTAKE
>
> **Common misconception — "Deterministic databases have no coordination."** They move all coordination to one place, before execution. The global sequencer is still a consensus problem; it is simply solved once per batch rather than once per transaction.

28.10 Distributed SQL: CockroachDB, YugabyteDB and TiDB

28.10.1 CockroachDB

CockroachDB is a PostgreSQL-wire-compatible distributed SQL database that runs serializable transactions without specialized clocks [Taft et al. 2020].

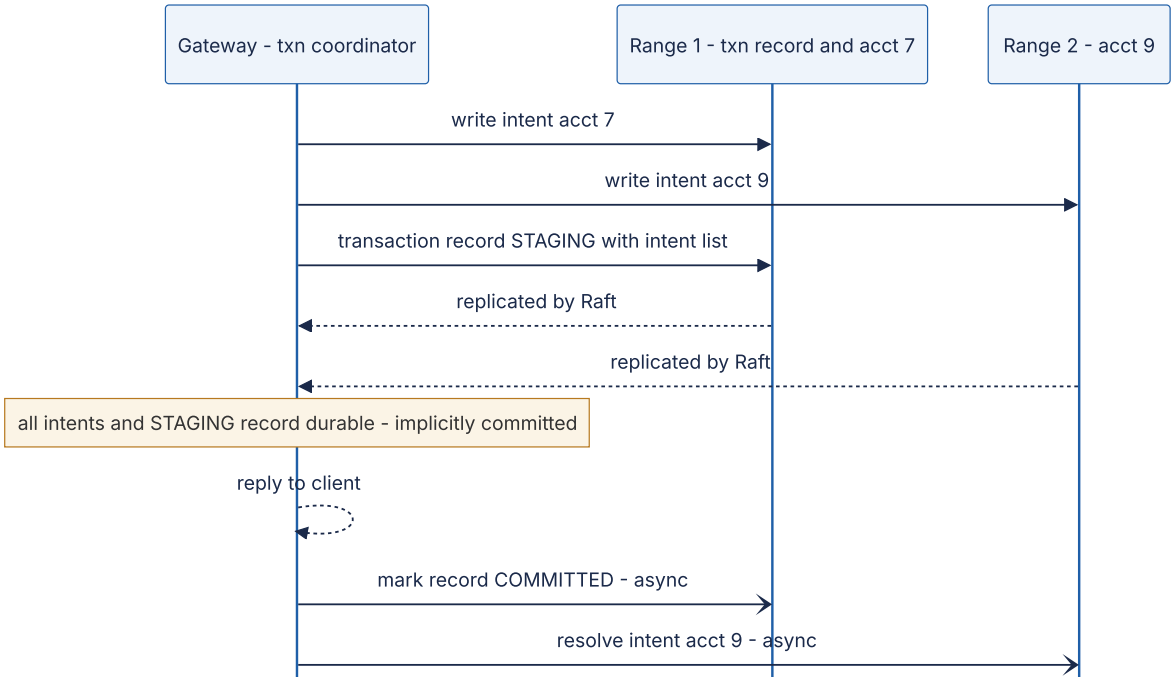
How it works internally

1. **Ranges and leaseholders.** Data is a sorted key space split into **ranges** (512 MiB maximum by default in recent versions) each replicated with Raft. One replica holds a lease and serves reads and coordinates writes for the range.
2. **HLC timestamps.** Every transaction gets a timestamp from the gateway node's **hybrid logical clock** (§24.12), and MVCC versions are tagged with HLC timestamps.
3. **Transaction record and write intents.** A transaction writes provisional values called **write intents**, each pointing to a **transaction record** stored in the range of the transaction's first key. The record's status (`PENDING`, `STAGING`, `COMMITTED`,

`ABORTED`) is the single source of truth, playing the role of Percolator's primary lock. Readers that meet an intent consult the record and may push or wait for the writer.

4. **Serializability by timestamp ordering.** Each leaseholder remembers the latest timestamp at which each key was read (the timestamp cache). A write below that timestamp is pushed to a higher one; before committing at the higher timestamp the transaction must **refresh** its reads, checking they are unchanged in between, or else retry.
5. **Uncertainty intervals.** Clocks may differ by up to a configured maximum offset (500 ms by default). A read at timestamp t that finds a value with timestamp in $(t, t + \text{max offset}]$ cannot know whether that write happened before it in real time, so it restarts at a higher timestamp. Nodes whose clocks drift too far from their peers shut themselves down rather than risk anomalies.
6. **Parallel commits.** Instead of writing intents and *then* a committed record (two sequential consensus rounds), the coordinator writes the intents and a `STAGING` record listing them in parallel. A transaction is **implicitly committed** once the staging record and all its intents are replicated; the client is answered then, and the record is marked `COMMITTED` asynchronously [Cockroach Labs 2019].

Figure 28.14 — CockroachDB parallel commits.



Reading the diagram. The three writes are independent Raft proposals in different ranges, issued concurrently, so the client waits for one consensus round, not two. "Implicitly committed" is a property any node can verify: a reader that finds a `STAGING` record checks whether every listed intent exists at the staged timestamp, and if so treats the transaction as committed. The asynchronous arrows clean up afterwards. If the gate-

way dies, a recovering transaction completes it if all intents exist, or prevents the missing intent from being written and aborts it.

FORMULA

Commit latency in consensus rounds

$$T_{\text{serial}} \approx 2\,T_{\text{c}} \qquad T_{\text{parallel}} \approx T_{\text{c}}$$

Symbol	Meaning	Units
T_{c}	One consensus (Raft) round for the slowest range	ms
T_{serial}	Commit with intents then a committed record	ms
T_{parallel}	Commit with parallel commits	ms

WORKED EXAMPLE

Worked example — A multi-region cluster. Ranges have voters in three regions and $T_{\text{c}} = 40$ ms. Serial commit: $2 \times 40 = 80$ ms. Parallel commit: 40 ms, halving commit latency. In one region with $T_{\text{c}} = 2$ ms the saving is 2 ms, worth having but not decisive. **Engineering implication.** Commit protocols matter most where consensus rounds are expensive, which is exactly where geo-distributed SQL is deployed.

28.10.2 YugabyteDB

YugabyteDB reuses PostgreSQL's query layer code above a distributed storage engine, **DocDB**, which splits tables into **tablets** replicated by Raft. Multi-tablet transactions write **provisional records** (intents) to each tablet and keep their state in a **transaction status tablet**, again a replicated record that decides the outcome. Timestamps come from **hybrid time**, an HLC, with a bounded maximum clock skew used for read uncertainty, as in CockroachDB. Single-row and single-tablet operations take a fast path without a status record. It supports snapshot, serializable and read committed isolation [YugabyteDB Docs: Distributed Transactions].

28.10.3 TiDB

TiDB, described in §28.7.3, runs Percolator over Raft Regions with a central timestamp oracle in PD, defaulting to snapshot isolation with pessimistic locking, with async commit and one-phase commit as optimizations [Huang et al. 2020].

Table 28.6 — Distributed SQL databases compared (as of 2026).

Row	Spanner	CockroachDB	YugabyteDB	TiDB
What it is	Google's globally distributed database, managed service	PostgreSQL-wire-compatible distributed SQL	PostgreSQL-compatible distributed SQL	MySQL-compatible distributed SQL with HTAP
How it works	Paxos groups, 2PL, 2PC across groups, TrueTime commit wait	Raft ranges, HLC, intents, transaction record, parallel commits	Raft tablets, hybrid time, intents, status tablet	Raft Regions, PD timestamp oracle, Percolator 2PC
Default isolation	Serializable, externally consistent	Serializable	Snapshot (YSQL)	Snapshot (`REPEATABLE READ`), pessimistic locking
Advantages	Strongest guarantee; lock-free snapshot reads anywhere	No special clocks; geo-partitioning; serializable default	PostgreSQL feature compatibility; flexible isolation	MySQL compatibility; columnar replicas for analytics
Disadvantages	Google Cloud only; commit wait	Retries under contention; uncertainty restarts	Clock-skew bound; younger ecosystem	Central oracle limits geo-distribution
Performance	Bounded by Paxos RTT and $2\bar{\varepsilon}$	One consensus round per commit with parallel commits	One consensus round for single-tablet writes	Oracle RTTs plus prewrite and commit; async commit saves one
Operational complexity	Low (managed)	Moderate; clock sync must be monitored	Moderate	Moderate to high: TiDB, TiKV, PD, TiFlash
Cost	Managed pricing per node or processing unit	Open-source core and commercial licenses; managed cloud	Open source; managed cloud	Open source; managed cloud
Use cases	Global financial, advertising, inventory systems	Multi-region OLTP with data residency	Migrating PostgreSQL apps that outgrew one node	Migrating sharded MySQL; real-time analytics on OLTP data
Choose when	You are on Google Cloud and need strict serializability globally	You need serializable SQL across regions on any cloud	You need PostgreSQL semantics at scale	You run MySQL and want to drop manual sharding

INDUSTRY EXAMPLE

CockroachDB — geo-distributed OLTP. Taft and colleagues give the goals as surviving zone and region failures automatically while keeping serializable SQL, with per-table or per-row placement for latency and residency; parallel commits and pipelined writes help most in multi-region deployments. *Evidence: Primary* — [Taft et al. 2020]

COMMON MISTAKE

Common misconception — "A distributed SQL database makes cross-region transactions fast." It makes them *correct*. Physics still sets the cost: any transaction whose data has voters in several regions pays at least one cross-region consensus round. Fast systems place data so that most transactions are regional.

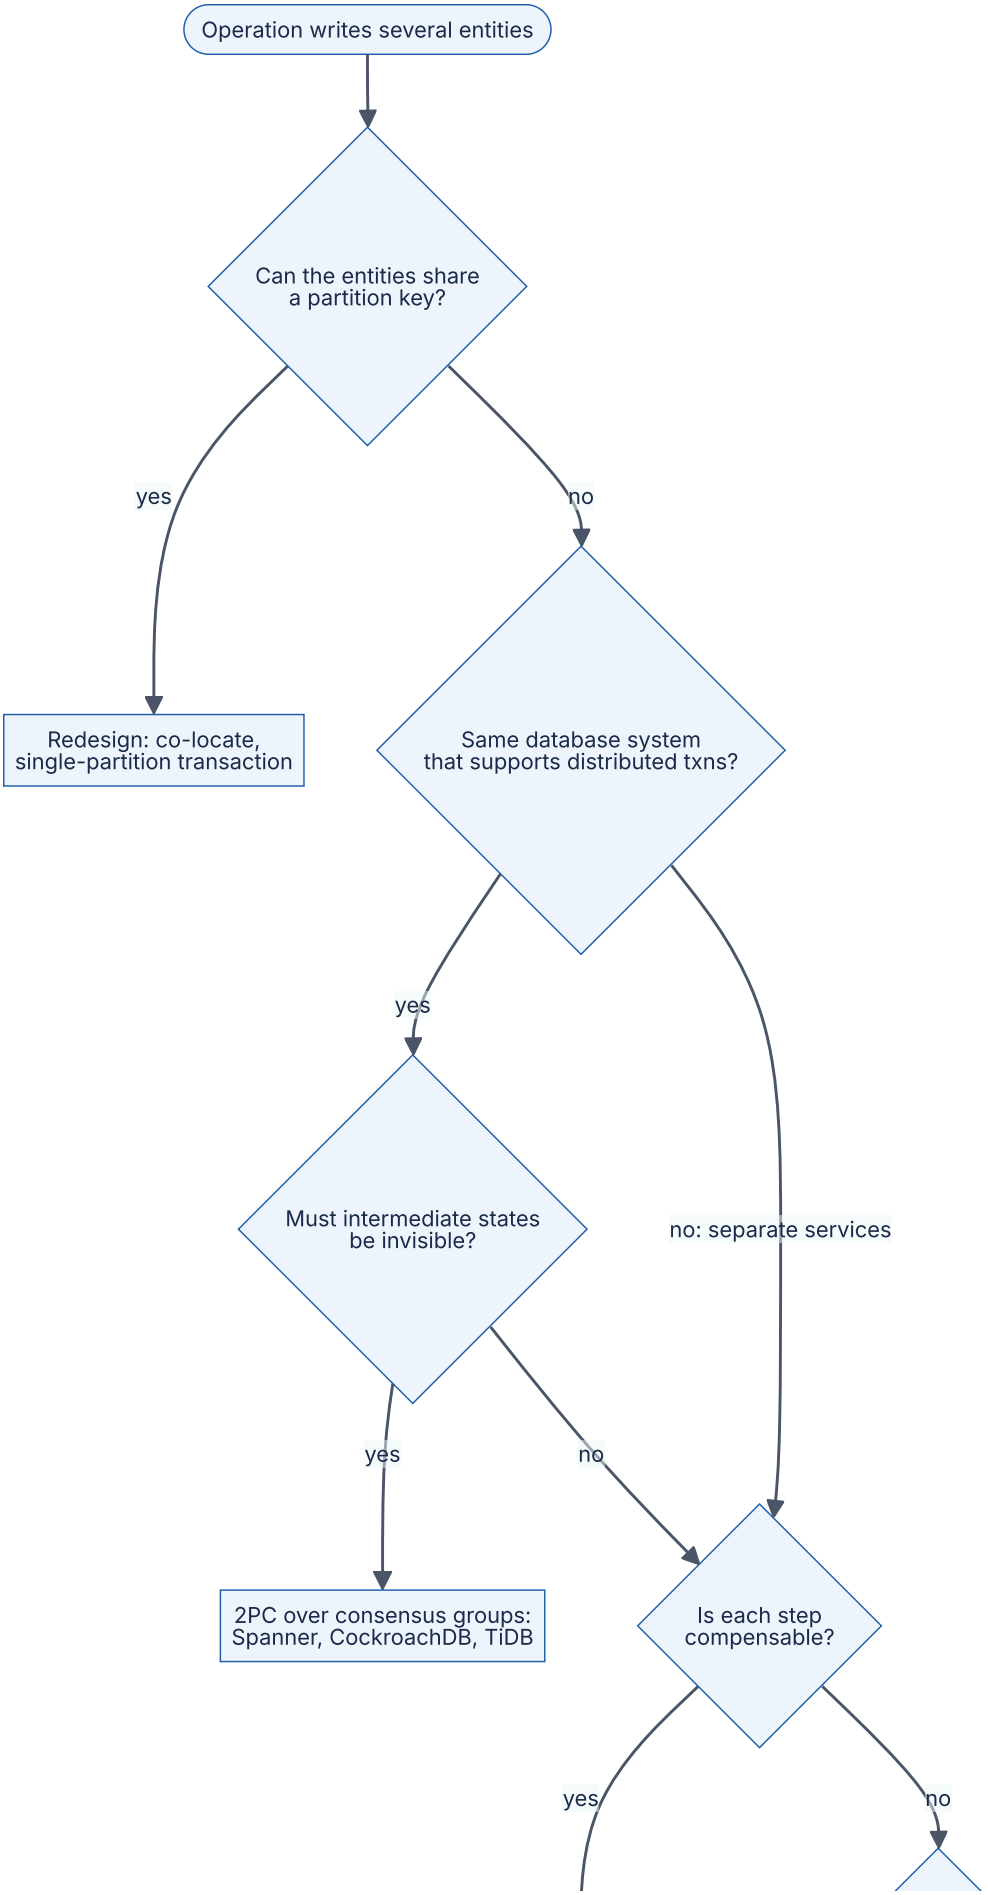
Failure scenarios in distributed SQL

What goes wrong	Why	Detection	Recovery	Prevention
Spike in transaction retry errors	Contention, timestamp pushes failing read refresh	Retry and restart metrics by statement	Client retry loop with backoff	Shorter transactions; avoid hot keys; `SELECT ... FOR UPDATE`
Clock offset alarms, nodes exiting	NTP failure or VM pause beyond max offset	Clock-offset metrics	Fix time sync; restart nodes	Reliable time sync (PTP or cloud time service); alert early
Long-held locks after client crash	Abandoned intents or Percolator locks	Lock wait time	Lock resolution by readers, TTL expiry	Heartbeating transaction records; short TTLs

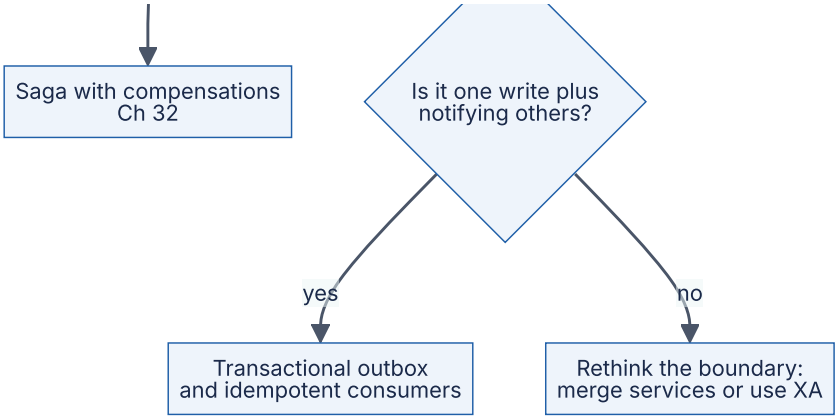
28.11 Choosing a transaction strategy

Every mechanism in this chapter costs latency, availability or isolation. The best strategy therefore starts by *not needing* a distributed transaction, and climbs the ladder only as far as the requirements force it.

Figure 28.15 — Choosing a transaction strategy.



Operation writes several entities
Can the entities share a partition key?
yes
no
Redesign: co-locate, single-partition transaction
Same database system that supports distributed txns?
yes
Must intermediate states be invisible?
no: separate services
yes
no
2PC over consensus groups: Spanner, CockroachDB, TiDB
Is each step compensable?
yes
no



Reading the diagram. Decision nodes are questions about the data and the business, not the technology. The first question removes most distributed transactions: if a customer's orders and order lines share `customer_id` as partition key (§14.7), the transaction is local. Inside one distributed database, its own 2PC over consensus groups is the right tool when intermediate states must stay invisible; if they may be visible, the cheaper cross-service patterns also apply. Across services with separate databases, sagas (asynchronous, compensating) and the outbox (atomic local write plus at-least-once publication) replace atomic commitment with eventual, semantic consistency. Explicit XA across heterogeneous systems is the last resort.

Table 28.7 — Transaction strategies compared.

Strategy	Atomicity	Isolation	Latency	Availability	Choose when
Single-partition transaction	Full	Full (local)	One local or quorum write	One partition's	You can choose the partition key
2PC over consensus groups	Full	Serializable or SI	2 quorum rounds (1 with parallel commits)	Product over groups, each highly available	Data is in one distributed database
Explicit 2PC / XA	Full	Depends on RMs	2 RTT + 2 forced writes	Product over unreplicated RMs; blocks	Heterogeneous resources, short transactions, no alternative
Saga	Semantic	None between steps	Sum of local steps, asynchronous	High; steps retry independently	Long-running cross-service processes
Transactional outbox	Local write plus guaranteed publish	Local only	One local commit	One service's	One owner of the write, others react

RECOMMENDATION

Recommendation — A default order of preference. (1) Model data so that transactions are single-partition. (2) If not possible and the data lives in one system, use a distributed SQL database's native transactions and keep them short and regional. (3) Across service boundaries, use sagas and the outbox (Chapter 32), with idempotent consumers. (4) Use XA only for short transactions between a few resources you control, and operate its recovery deliberately: monitor in-doubt transactions, protect the transaction manager's log, forbid heuristic decisions without its records.

WORKED EXAMPLE

Worked example — A wallet service. Each user's wallet and transaction history share partition key `user_id`, so a purchase is single-partition (step 1). Peer-to-peer transfers touch two users. At 500 transfers/s in one region on CockroachDB, a parallel commit adds one consensus round, about 2 ms, which is acceptable, so native transactions are chosen (step 2). Paying out to an external bank cannot join any transaction, so the payout is a saga: debit the wallet, call the bank, and refund on rejection; the debit and the "payout requested" event are written together with an outbox (step 3).

28.12 Summary and revision notes

SUMMARY

- **Atomic commitment** needs every participant to reach the same irreversible decision, with any one able to veto. Partial failure and ambiguous silence make independent local commits unsafe (Figure 28.1).
- **2PC**: participants force a PREPARED record and vote; the coordinator forces the COMMIT record (the commit point) and propagates it. A prepared participant cannot decide alone, so a coordinator crash **blocks** in-doubt transactions and their locks.
- Exposure per crash is $N_{\text{doubt}} = Xw$ with $w \approx \text{RTT} + t_{f,c}$; latency is about $2\,\text{RTT} + 2t_f$; availability is A^k.
- **Presumed abort** removes forced writes and acknowledgments for aborts; read-only and one-phase optimizations remove 2PC for many transactions. XA and PostgreSQL `PREPARE TRANSACTION` expose 2PC; heuristic decisions break atomicity.
- **3PC** avoids blocking only with perfect failure detection; partitions make it inconsistent. Production systems run **2PC over consensus groups** instead.
- **Sagas** trade isolation for availability with compensations (Chapter 32).
- **Percolator** builds SI transactions from single-row atomicity: a timestamp oracle, prewrite locks pointing to a primary, and the primary's `write` record as commit point; readers roll abandoned transactions forward or back. TiDB uses it over Raft.
- **Spanner** assigns commit timestamps from TrueTime and waits about 2ε before exposing a commit, yielding external consistency and lock-free snapshot reads.
- **Calvin** agrees on input order first and executes deterministically, eliminating 2PC at the cost of declared read/write sets and batching delay.
- **CockroachDB** uses HLCs, uncertainty intervals, transaction records and parallel commits (one consensus round); YugabyteDB uses hybrid time and a status tablet.
- Snapshot isolation distributes cheaply but permits **write skew**; serializability needs read locks or read validation.
- Prefer single-partition design, then native distributed transactions, then sagas and the outbox; use XA last.

28.13 Knowledge checkpoint

1. Why can a participant abort unilaterally before voting yes but not after?
2. Which two log writes must be forced in 2PC's commit path, and what goes wrong if each is not?

3. What does a recovering coordinator do with a COMMIT record that has no END record?
4. Under presumed abort, why may the coordinator forget an aborted transaction immediately?
5. A coordinator handles 5,000 distributed transactions/s with RTT 1 ms and a 2 ms forced write. How many are left in doubt by a crash?
6. What is the availability of a transaction spanning 4 partitions at 99.9 % each?
7. Why does 3PC become unsafe under a network partition?
8. What is Percolator's commit point, and how does a reader resolve a lock left by a dead client?
9. Why must Spanner's coordinator perform commit wait?
10. With $\bar{\varepsilon} = 3$ ms and regional Paxos latency 4 ms, what is Spanner's approximate commit latency?
11. How does Calvin avoid 2PC, and what does it require from transactions?
12. What makes a CockroachDB transaction "implicitly committed"?
13. Why does snapshot isolation allow write skew across partitions?
14. Give the first strategy to try before any distributed transaction.

Answers

1. Before voting, no decision can include its yes vote, so abort is safe. After voting yes, the coordinator may already have logged commit.
2. The participant's PREPARED record (else a crash loses the promise and the participant might later be unable to commit) and the coordinator's COMMIT record (else a recovered coordinator could presume abort while some participant has committed).
3. Resends COMMIT to every listed participant until all acknowledge, then writes END.
4. Inquiries about a transaction it has no record of are answered "abort", which is correct for aborted transactions.
5. $w = 1 + 2 = 3$ ms; $N = 5,000 \times 0.003 = 15$.
6. $0.999^4 \approx 0.996$, about 173 minutes of unavailability per 30 days.
7. Each side runs the termination protocol; one side may see a pre-committed node and commit while the other sees only uncertain nodes and aborts.
8. Writing the primary cell's `write` record and erasing its lock. A reader checks the primary: lock still present means roll back; a `write` record for that start timestamp means roll the secondary forward.
9. To guarantee that its timestamp s is in the past everywhere before anyone sees the commit, so any later transaction gets a larger timestamp (external consistency).
10. $\max(4, 2 \times 3) = 6$ ms.
11. It fixes a global input order before execution and executes deterministically, so there are no nondeterministic aborts to vote on. Transactions must declare read and write sets in advance.

12. A STAGING transaction record and all intents it lists are durably written at the staged timestamp.
13. SI checks only write-write conflicts; the two transactions write different keys, and the read-write dependencies span partitions that never compare notes.
14. Choose partition keys so the entities written together share a partition, making the transaction local.

28.14 Interview questions

Basic

Q1. Explain two-phase commit and its main weakness. Answer. A coordinator sends prepare; each participant forces a prepared record and votes; if all vote yes, the coordinator forces a commit record and tells everyone to commit, otherwise abort. The weakness is blocking: participants that voted yes cannot decide if the coordinator fails, and hold locks until it recovers. Also mention two round trips, two forced writes and A^k availability.

Q2. When would you use a saga instead of 2PC? Answer. When the steps cross service or organizational boundaries, run for seconds to days, involve external APIs that cannot participate in 2PC, or must stay available when one service is down. Each step must have a compensation and be idempotent, and the business must tolerate visible intermediate states.

Intermediate

Q3. How does Percolator achieve atomicity without a coordinator process? Answer. The primary lock stores the coordinator's state. Prewrite locks every cell, each secondary lock pointing to the primary. Committing writes the primary's `write` record at the commit timestamp in one single-row transaction; that is the commit point. Any reader finding a stale secondary lock looks at the primary to roll forward or back. Timestamps from the oracle give snapshot isolation; costs are two oracle calls and SI's write skew.

Q4. Your XA-based order system has rows locked for 20 minutes after a deploy. Diagnose. Answer. Likely in-doubt prepared transactions: the deploy killed the transaction manager after participants voted yes. Check `pg_prepared_xacts` or `XA RECOVER` for old XIDs; bring the transaction manager back with its log so it re-drives outcomes; if the log is lost, resolve manually by auditing each XID. Prevent with graceful shutdown that drains transactions, a durable replicated TM log, and alerts on prepared-transaction age.

Advanced

Q5. Explain why Spanner's commit wait gives external consistency, and its cost. Answer. The coordinator picks $s \geq$ `TT.now().latest` and does not expose the commit until `TT.after(s)`, so s is in the past when anyone can observe it. A transaction starting later gets a timestamp at least its own `TT.now().latest`, which exceeds true time and therefore s. Cost: about $2\bar{\varepsilon}$ per commit with locks held, overlapped with Paxos replication; it grows if clock uncertainty grows.

Q6. Design transfers between accounts in a multi-region bank where most accounts are regional. Answer. Partition by home region and customer so most transfers are regional single- or multi-range transactions in a distributed SQL database with serializable isolation and parallel commits. Cross-region transfers either pay one cross-region consensus round, or become a saga through a regional clearing account with idempotent steps and an outbox. Quantify: regional commit about 2–5 ms, cross-region 70+ ms. Discuss write skew on overdraft checks and hot merchant accounts.

28.15 Practical exercises

1. Extend the simulation in §28.4.7 with a cooperative termination protocol: an in-doubt participant asks the others, and decides if any knows the outcome or has not voted. Add a test where it succeeds.
2. Convert the simulation to presumed commit and count forced writes and messages in both outcomes; compare with Table 28.2.
3. Repeat the PostgreSQL session of §28.4.6 and measure how long an unrelated `UPDATE` waits; then watch `age(datfrozenxid)` while a prepared transaction stays open.
4. Modify the Percolator model to prevent write skew in scenario 5 by having each transaction also lock the row it only read.
5. Compute Spanner commit latency for $\bar{\varepsilon} \in \{1, 4, 10\}$ ms against Paxos latencies of 2, 20 and 80 ms, and identify where commit wait matters.

28.16 Design challenges

1. **Ticketing flash sale.** 100,000 buyers compete for 5,000 seats in one stadium. Compare Calvin-style deterministic ordering, a single-partition design and 2PC across seat partitions on contention and latency.
2. **Cross-service checkout.** Order, inventory, payment and shipping services each own a database. Design checkout using sagas and an outbox; list each compensation and the isolation anomalies you accept.

3. **Global ledger.** A ledger must be strictly serializable across three continents with p99 commit below 200 ms. Choose a database, data placement and transaction pattern, and estimate latency.

28.18 Open verification items

- Table 28.2 forced-write and message counts for presumed abort and presumed commit, against Mohan et al. 1986.
- Percolator oracle throughput (~2 million timestamps/s) and the 50 % document-age reduction.
- Brewer 2017: exact share of Spanner incidents attributed to the network (a secondary source says under 8 %).
- Calvin’s near-linear scaling to 100 machines; FaunaDB’s description as Calvin-inspired.
- Defaults as of 2026: CockroachDB range size (512 MiB), max offset (500 ms); YugabyteDB YSQL default isolation; TiDB async commit and 1PC status.

Chapter 29 — Distributed Data Processing

> **Level:** 3 · **Track:** Shared (A Traditional and B ML/AI) · **Estimated reading time:** 3 h

Chapters 11–15 stored data; Chapters 24–28 kept copies of it consistent. This chapter is about *computing over* data too large for one machine: counting a month of click logs, joining two billion orders with their customers, or keeping a live per-minute fraud score for every card. The same few ideas recur in every engine: split the input, run the same function on each piece, move records with the same key to the same place (the **shuffle**), and recover from failures by recomputing rather than replicating. You will meet them in MapReduce, where every step is visible; in Apache Spark, which keeps data in memory and plans jobs as graphs; and in stream processing and Apache Flink, where the input never ends. Chapter 61 (ML data pipelines) builds directly on this chapter.

29.1 Learning objectives

After this chapter you should be able to:

- Explain immutable inputs and throughput-first design, and estimate a job’s scan time.
- Trace a MapReduce job from splits to reduce, estimate its run time, and quantify what a combiner saves.
- Explain recovery by re-execution and lineage, and how backup tasks cut straggler delay.
- Choose between a sort-merge join and a broadcast join by cost.
- Describe RDDs, narrow and wide dependencies, stages, caching, DataFrames, Catalyst and Adaptive Query Execution, and write a correct PySpark job.
- Calculate shuffle time on a rack-structured cluster, the slowdown from key skew, and the effect of salting.
- Explain data locality and why disaggregated storage changed its importance.
- Define event time, windows, watermarks, triggers and allowed lateness, and compute the late fraction for a watermark delay.
- Explain Flink’s state, barrier snapshots and savepoints, and size a checkpoint interval.
- Compare Lambda and Kappa, batch and stream, and Spark and Flink, and place Apache Beam.

29.2 Prerequisites

- Object storage and GFS/HDFS — §15.4–§15.5 (where batch inputs live).
- Columnar storage and Parquet — §13.13.
- Partitioning, hash and range — §14.6 and hot partitions §14.10 (the shuffle is partitioning on the fly).
- Datacenter networking and oversubscription — §7.17 (shuffle time is a network problem).
- Probability and Amdahl's Law — §4.6 and §4.12 (stragglers and the serial parts of a job).
- Clocks and logical time — §24.9–§24.10 (event time; the happens-before reasoning behind the Chandy–Lamport snapshots of §29.9.2).
- Backpressure and idempotency — §22.10 and §22.15 (streaming operators slow their sources; sinks must tolerate replays).
- Units: **MB/GB/TB** are powers of ten; network speeds are in bits per second (Gb/s), so 25 Gb/s = 3.125 GB/s.

29.3 Batch processing concepts

29.3.1 Bounded, immutable inputs and throughput-first design

> DEFINITION
>
> **Definition — Batch processing.** Running a computation over a **bounded** dataset (one whose size is known when the job starts, such as "yesterday's logs") that reads immutable input files, writes new output files, and is judged mainly by **throughput** (bytes or records processed per second) and total completion time rather than by the latency of individual records.

First-principles explanation

Imagine counting every word in a library. You could ask one person to read every book: correct, but it takes years. Or you could give each of 1,000 volunteers a shelf, have each write a tally sheet, then have a second group add the tally sheets together letter by letter: one person totals words beginning with "a", another "b", and so on. Nobody edits a book; the books are only read. If a volunteer goes home sick, someone else redoes the same shelf. That is batch processing: **split, process in parallel, regroup by key, combine**, over inputs that do not change.

The Unix shell already works this way on one machine. To find the five most common URLs in a web server log you can write:

```
cat access.log | awk '{print $7}' | sort | uniq -c | sort -rn | head -5
```

Each program reads a stream, does one job, and writes a stream; the input file is never modified; and `sort` is the step that brings equal keys together so `uniq -c` can count them. MapReduce and its successors are this pipeline spread over thousands of machines, with the distributed file system playing the role of the pipe [Kleppmann 2017, ch. 10].

Why does this exist?

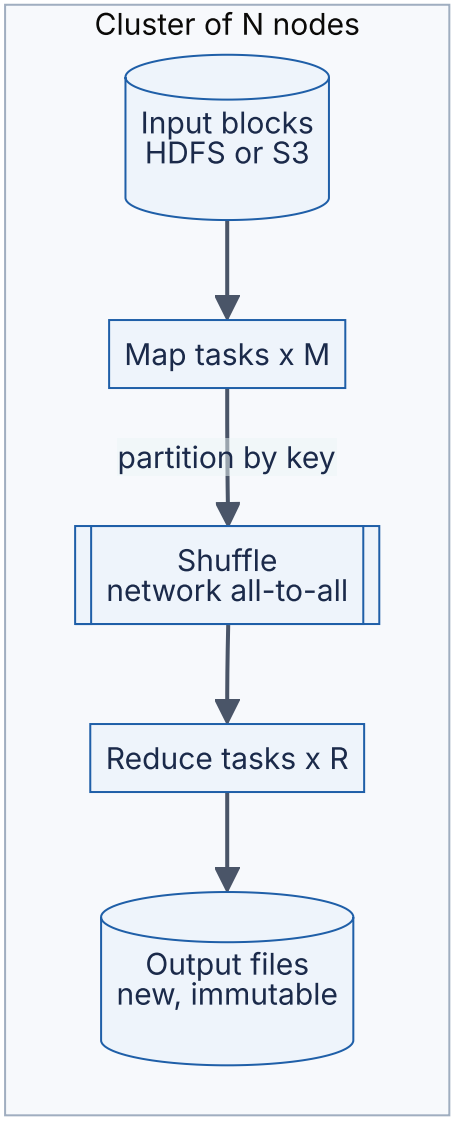
Three properties make large computations tractable:

1. **Immutable inputs.** If inputs are never modified, any piece of work can be rerun and will produce the same output. Fault tolerance becomes "do it again" rather than distributed transactions (Chapter 28). A buggy job can simply be fixed and rerun.
2. **Bounded datasets.** Knowing the whole input exists lets the system sort it, count it, plan the work in waves, and decide when the job is finished.
3. **Throughput over latency.** Nobody waits on one record, so the system can use large sequential I/O, keep every disk and core busy, and accept tens of seconds of scheduling overhead.

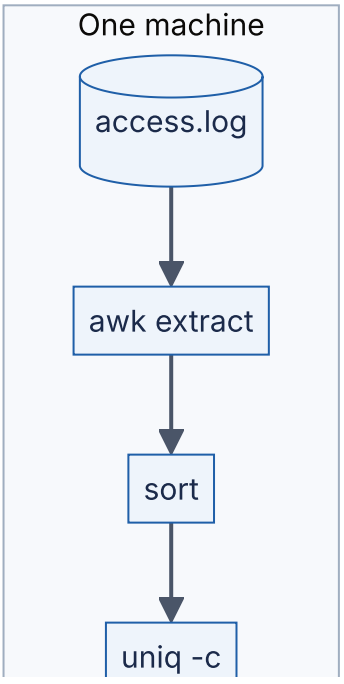
How it works internally

1. Store the input as large files split into blocks (128 MB in HDFS, §15.5.2) or objects.
2. Divide the input into **splits**, usually one per block, and run one **task** per split.
3. Run tasks in parallel on many nodes, each writing intermediate output locally.
4. Regroup intermediate records by key across the network.
5. Write the final output as new immutable files; a job "commits" by atomically renaming or registering its output directory.

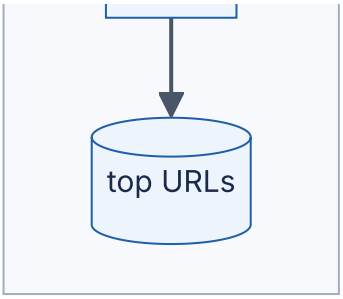
Figure 29.1 — A Unix pipeline and the distributed batch job that generalizes it.



Cluster of N nodes
Input blocks
HDFS or S3
Map tasks x M
partition by key
Shuffle
network all-to-all
Reduce tasks x R
Output files
new, immutable



One machine
access.log
awk extract
sort
uniq -c



Reading the diagram. The top row is a single-machine pipeline: `awk` extracts the URL, `sort` brings equal URLs together, `uniq -c` counts them, and the input file is only read. The bottom row is the cluster equivalent: *input blocks* feed *M map tasks* in parallel; the *shuffle* (asynchronous, all-to-all) plays the role of `sort`, delivering every record with one key to one of *R reduce tasks*, which write *new output files*. Storage: inputs and outputs are durable and replicated; intermediate output sits on local disks. Failure points: a dead node loses running tasks and local files, recovered by rerunning tasks. Scaling: add nodes to raise M and R.

Mathematical foundations

The first estimate for any batch job is how long it takes just to read the input.

FORMULA

Scan time of a bounded dataset

$$T_{\text{scan}} = \frac{D}{N \cdot b}$$

Symbol	Meaning	Units
T_{scan}	Time to read the whole input once, ignoring stragglers	s
D	Input size	bytes
N	Number of nodes reading in parallel	count
b	Sustained read-and-process rate per node	bytes/s

WORKED EXAMPLE

Worked example — Why a 10 TB log needs a cluster. A day of clickstream logs is $D = 10$ TB $= 10^{13}$ B. One node can read and parse at $b = 500$ MB/s.

1. One node: $10^{13}/(5 \times 10^{8}) = 20,000$ s ≈ 5.6 hours.
2. 100 nodes: $10^{13}/(100 \times 5 \times 10^{8}) = 200$ s ≈ 3.3 minutes.
3. Reading only 3 of 30 columns from Parquet (§13.13) cuts effective D to about 1 TB: 20 s on 100 nodes.

Interpretation. Parallelism turns hours into minutes, but start-up, the slowest task and serial steps do not shrink (Amdahl's Law, §4.12). **Engineering implication.** Reduce D first (columnar formats, date pruning), then raise N; later sections add shuffle and straggler terms.

COMMON MISTAKE

"Batch means old-fashioned or slow." Batch is a contract about bounded inputs and throughput, not about hardware. A modern Spark job over Parquet can finish in seconds; a streaming job can lag hours behind. Choose by whether the input is bounded and how fresh the output must be (§29.11).

29.4 MapReduce

29.4.1 The programming model and word count

DEFINITION

Definition — MapReduce. A programming model and execution system in which the user writes two functions: **map**, which turns one input record into zero or more intermediate key–value pairs, and **reduce**, which receives one intermediate key with *all* values emitted for it and produces output. The system handles splitting, scheduling, regrouping by key, and failures [Dean and Ghemawat 2004].

First-principles explanation

The model works because many computations have the same shape: *look at each record independently* (map), then *combine everything that shares a key* (reduce). Counting words, building an inverted index (word → documents), computing per-user totals and joining two tables by ID all fit. The user writes only the two functions; the framework supplies the parallelism. The signatures are:

```
map:    (k1, v1)        -> list of (k2, v2)
reduce: (k2, list of v2) -> list of v3
```

For word count, map receives one line of text and emits `(word, 1)` for each word; reduce receives `("the", [1, 1, 1, …])` and emits `("the", count)`.

Why does this exist?

Google in the early 2000s ran hundreds of special-purpose programs over crawled documents and request logs. Each reimplemented parallelization, data distribution and failure handling. MapReduce moved that plumbing into a library so engineers without distributed-systems experience could use thousands of machines, and Google rewrote its production indexing system on it [Dean and Ghemawat 2004]. Hadoop MapReduce, the open-source reimplementation on HDFS, brought the same model to the rest of the industry.

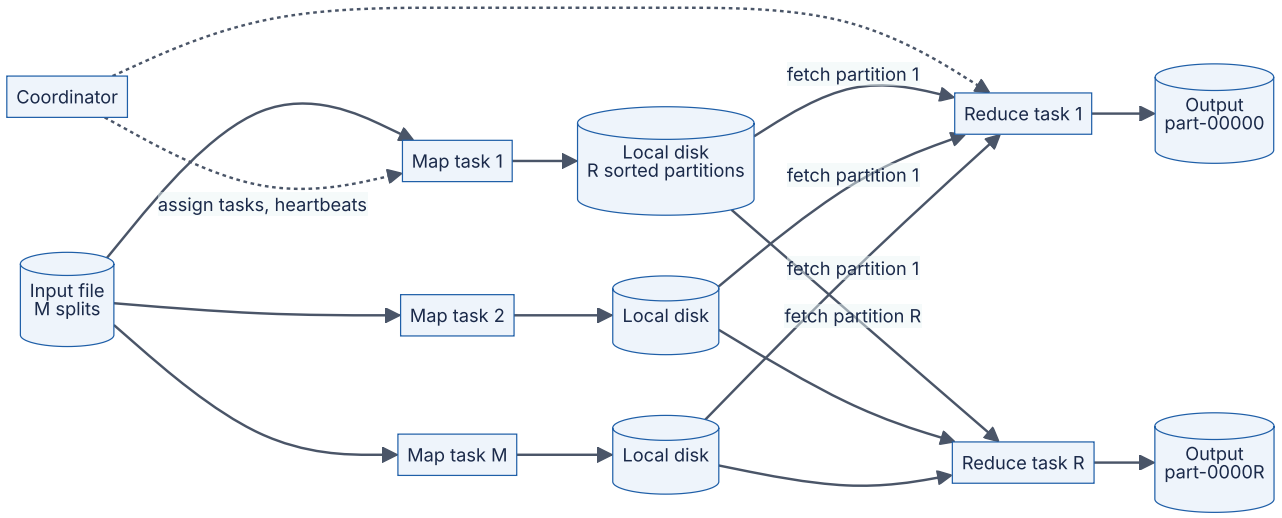
29.4.2 Execution: splits, map, partition, sort and spill, shuffle, reduce

How it works internally

1. **Split.** The input is divided into M splits, typically one per 64–128 MB block. A single **coordinator** (Google's "master"; on YARN an ApplicationMaster) assigns map tasks to idle workers, preferring a worker that stores the split locally (§29.7).
2. **Map.** The worker parses records from its split and calls `map` on each one.
3. **Partition.** Each intermediate pair is assigned to one of R reduce partitions, by default $\text{hash}(k) \bmod R$, so every pair with the same key goes to the same reducer no matter which mapper emitted it.
4. **Buffer, sort and spill.** Pairs accumulate in a memory buffer (100 MB by default in Hadoop). When it fills, the worker sorts the buffer by (partition, key), optionally runs the **combiner**, and **spills** a sorted run to local disk. At task end, spills are merged into one partitioned, indexed file.
5. **Shuffle.** Each reduce task fetches its partition from *every* map task's output over the network, usually starting while maps are still finishing. This all-to-all copy is the shuffle.
6. **Merge.** The reducer merge-sorts the M sorted runs it fetched, spilling to disk if they do not fit in memory, so that all values for a key are adjacent.
7. **Reduce.** The reducer calls `reduce` once per key, streaming the sorted values, and writes one output file per reduce task (`part-00000`, …), made visible by an atomic rename on commit.

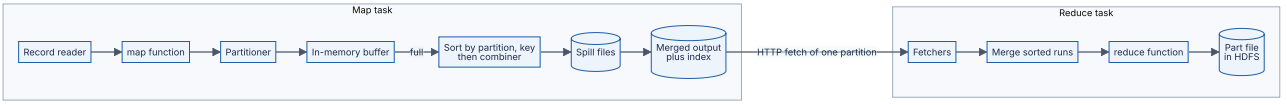
A **combiner** is a reduce function run on the map side, on one mapper's output, before the shuffle. It is legal only for associative and commutative operations (sum, count, max).

Figure 29.2 — MapReduce job execution.



Reading the diagram. The *coordinator* (dotted arrows) assigns tasks and receives heartbeats; it never touches data. Each *map task* reads one split of the replicated *input* and writes R sorted partitions to *local disk*. Each *reduce task* fetches its partition from every map output (synchronous HTTP fetches), merges, reduces and writes one *output* file to the distributed file system. Storage: input and output are replicated; intermediate data is not, so a lost node forces its map tasks to rerun. Scaling: M follows input size, R is chosen by the user, and the shuffle is $M \times R$ transfers.

Figure 29.3 — Inside a map task and a reduce task.



Reading the diagram. Within a map task, records flow from the *record reader* through the user's *map function* and the *partitioner* into a memory *buffer*. Each time the buffer fills, it is sorted by (partition, key), the *combiner* runs, and a *spill file* is written; at the end all spills are merged into one partitioned file with an index giving each partition's byte range. The reduce task's *fetchers* pull its partition from every map output, the *merge* step produces one sorted stream, and the *reduce function* writes a part file to HDFS. Failure points: a full disk fails the task; a fetch failure reruns the map. Scaling: larger buffers mean fewer spills.

Code example

The program below is a complete MapReduce engine in about 70 lines: map tasks with partitioning, per-partition sorting and an optional combiner; a shuffle that gives reducer *r* run *r* from every mapper; a k-way merge; and reduce. Map tasks that "crash" are re-executed. It runs word count with and without a combiner and a reduce-side join, and checks every answer against plain Python.

```
        """A mini MapReduce engine: splits -> map -> (combine) -> partition -> sort ->
shuffle -> reduce.
        Map tasks are pure functions of their split, so a failed task is simply re-exe-
cuted."""
        import heapq
        import itertools
        import zlib
        from collections import Counter, defaultdict

        def hash_partition(key, num_reducers):
            # Deterministic across processes (Python's built-in hash() is salted per
process).
            return zlib.crc32(repr(key).encode()) % num_reducers

        class TaskFailure(Exception):
            pass

        class MiniMapReduce:
            def __init__(self, mapper, reducer, num_reducers=4, combiner=None,
                         partitioner=hash_partition, max_attempts=4):
                self.mapper, self.reducer, self.combiner = mapper, reducer, combiner
                self.R, self.partitioner, self.max_attempts = num_reducers, partitioner,
max_attempts
                self.stats = Counter()

            def _map_task(self, split, crash):
                if crash:                               # simulate a worker dying mid-
task
                    raise TaskFailure("worker lost")
                buckets = [defaultdict(list) for _ in range(self.R)]
                for record in split:
                    for key, value in self.mapper(record):

        def join_reduce(user_id, tagged):
            country, orders = None, []
            for tag, payload in tagged:
                if tag == "U":
                    country = payload
                else:
                    orders.append(payload)
            yield sorted((oid, amt, country) for oid, amt in orders)   # orders en-
riched; None = no profile

        if __name__ == "__main__":
            text = ["the quick brown fox", "jumps over the lazy dog", "the dog barks",
                    "The fox runs. The dog sleeps!", "a quick test of the engine"] * 200
            splits = [text[i:i + 100] for i in range(0, len(text), 100)]        # 10 in-
```

```
put splits
            expected = Counter(w.strip(".,;:!?\"'") for line in text for w in
line.lower().split())

            plain = MiniMapReduce(wc_map, wc_sum, num_reducers=4)
            out_plain = plain.run(splits)
            combined = MiniMapReduce(wc_map, wc_sum, num_reducers=4, combiner=wc_sum)
            out_comb = combined.run(splits, crash_first_attempt={2, 7})
            assert out_plain == dict(expected) == out_comb
            print("distinct words:", len(out_comb), " 'the' =", out_comb["the"])
            print("map output records:", plain.stats["map_output_records"])
            print("shuffled without combiner:", plain.stats["shuffled_records"])
            print("shuffled with combiner:   ", combined.stats["shuffled_records"])
            print("re-executed map tasks:", combined.stats["map_reexecutions"])

            users = [("users", (u, c)) for u, c in [(1, "IN"), (2, "US"), (3, "DE")]]
            orders = [("orders", (100 + i, 1 + i % 4, 10 * i)) for i in range(8)]   #
user 4 has no profile
            joined = MiniMapReduce(join_map, join_reduce, num_reducers=2).run([users,
orders[:4], orders[4:]])
            assert joined[1] == [(100, 0, "IN"), (104, 40, "IN")]
            assert joined[4] == [(103, 30, None), (107, 70, None)]   # orphan orders
keep country None
            print("join, user 2:", joined[2])
            print("all tests passed")
```

Output:

```
distinct words: 15  'the' = 1200
map output records: 4800
shuffled without combiner: 4800
shuffled with combiner:    150
re-executed map tasks: 2
join, user 2: [(101, 10, 'US'), (105, 50, 'US')]
all tests passed
```

What to notice:

- `hash_partition` uses CRC32, not Python's `hash()`, because every mapper must send a key to the *same* reducer; a per-process salted hash would scatter a key across reducers and give wrong counts.
- The combiner cut shuffled records from 4,800 to 150 (10 splits × 15 distinct words) without changing the answer, because addition is associative and commutative.
- Two map tasks crashed and were rerun; the output is identical, because a map task depends only on its immutable split.
- `heapq.merge` is the reduce-side merge of sorted runs: it never loads all values for all keys at once, which is how real reducers handle partitions larger than memory.

Mathematical foundations

FORMULA

MapReduce job time (first-order estimate)

$$T_{\text{job}} \approx T_0 + \left\lceil \frac{M}{Ns_m} \right\rceil \frac{C}{r_m} + \frac{\sigma D}{NB} + \left\lceil \frac{R}{Ns_r} \right\rceil \frac{\sigma D/R}{r_r}, \qquad M = \left\lceil \frac{D}{C} \right\rceil$$

Symbol	Meaning	Units
T_0	Job start-up and commit overhead	s
D	Input size	bytes
C	Split size	bytes
M, R	Number of map and reduce tasks	count
N	Worker nodes	count
s_m, s_r	Map and reduce slots (concurrent tasks) per node	count
r_m, r_r	Per-task processing rate of map and reduce	bytes/s
σ	Shuffle ratio: map output bytes ÷ input bytes, after any combiner	dimensionless
B	Effective per-node shuffle network bandwidth	bytes/s

WORKED EXAMPLE

Worked example — A 1 TB log aggregation on 50 nodes. $D = 10^{12}$ B, $C = 128$ MB, $N = 50$ nodes with $s_m = 16$ map slots and $s_r = 8$ reduce slots, $r_m = 10$ MB/s (parsing-heavy), $\sigma = 0.3$, $B = 1$ GB/s, $R = 400$, $r_r = 20$ MB/s, $T_0 = 20$ s.

1. Map tasks: $M = \lceil 10^{12} / 1.28 \times 10^{8} \rceil = 7,813$. Slots: $50 \times 16 = 800$. Waves: $\lceil 7,813/800 \rceil = 10$.
2. One map task: $128/10 = 12.8$ s, so the map phase takes $10 \times 12.8 = 128$ s.
3. Shuffle: $\sigma D = 300$ GB; per node $300/50 = 6$ GB at 1 GB/s $= 6$ s (much of it overlaps the map phase).
4. Reduce: $50 \times 8 = 400$ slots, so one wave. Each reducer gets 300 GB$/400 = 750$ MB, taking $750/20 = 37.5$ s.
5. Total: $20 + 128 + 6 + 37.5 \approx 192$ s, about 3.2 minutes.

Interpretation. The map phase dominates, and since $7,813/800 = 9.77$, the last wave runs 77% full. **Engineering implication.** Keep tasks to tens of seconds so the last wave is short, and treat the estimate as a *lower bound*: one slow last-wave task adds its whole delay (§29.4.3).

FORMULA

Shuffle volume with and without a combiner

$$V_{\text{no comb}} = n_{\text{pairs}} \cdot b_{\text{pair}}, \qquad V_{\text{comb}} \approx M \cdot u \cdot b_{\text{pair}}$$

Symbol	Meaning	Units
V	Bytes moved across the network in the shuffle	bytes
n_{pairs}	Total intermediate pairs emitted by all mappers	count
b_{pair}	Average serialized size of one key–value pair	bytes
M	Map tasks	count
u	Distinct keys per map task after combining ($u \leq$ pairs per task)	count

WORKED EXAMPLE

Worked example — Word count over 1 TB of text. Assume 6 bytes per word on average (including the space), so a 128 MB split holds about $1.28 \times 10^8 / 6 \approx 2.1 \times 10^7$ words; $M = 7,813$; $b_{\text{pair}} = 12$ B; about $u = 200,000$ distinct words per split.

1. Without a combiner: $n_{\text{pairs}} = 10^{12}/6 = 1.67 \times 10^{11}$ pairs; $V = 1.67 \times 10^{11} \times 12 = 2.0 \times 10^{12}$ B $= 2$ TB, twice the input.
2. With a combiner: $V = 7,813 \times 2 \times 10^5 \times 12 = 1.9 \times 10^{10}$ B ≈ 19 GB.
3. Reduction: $2,000/19 \approx 105\times$.

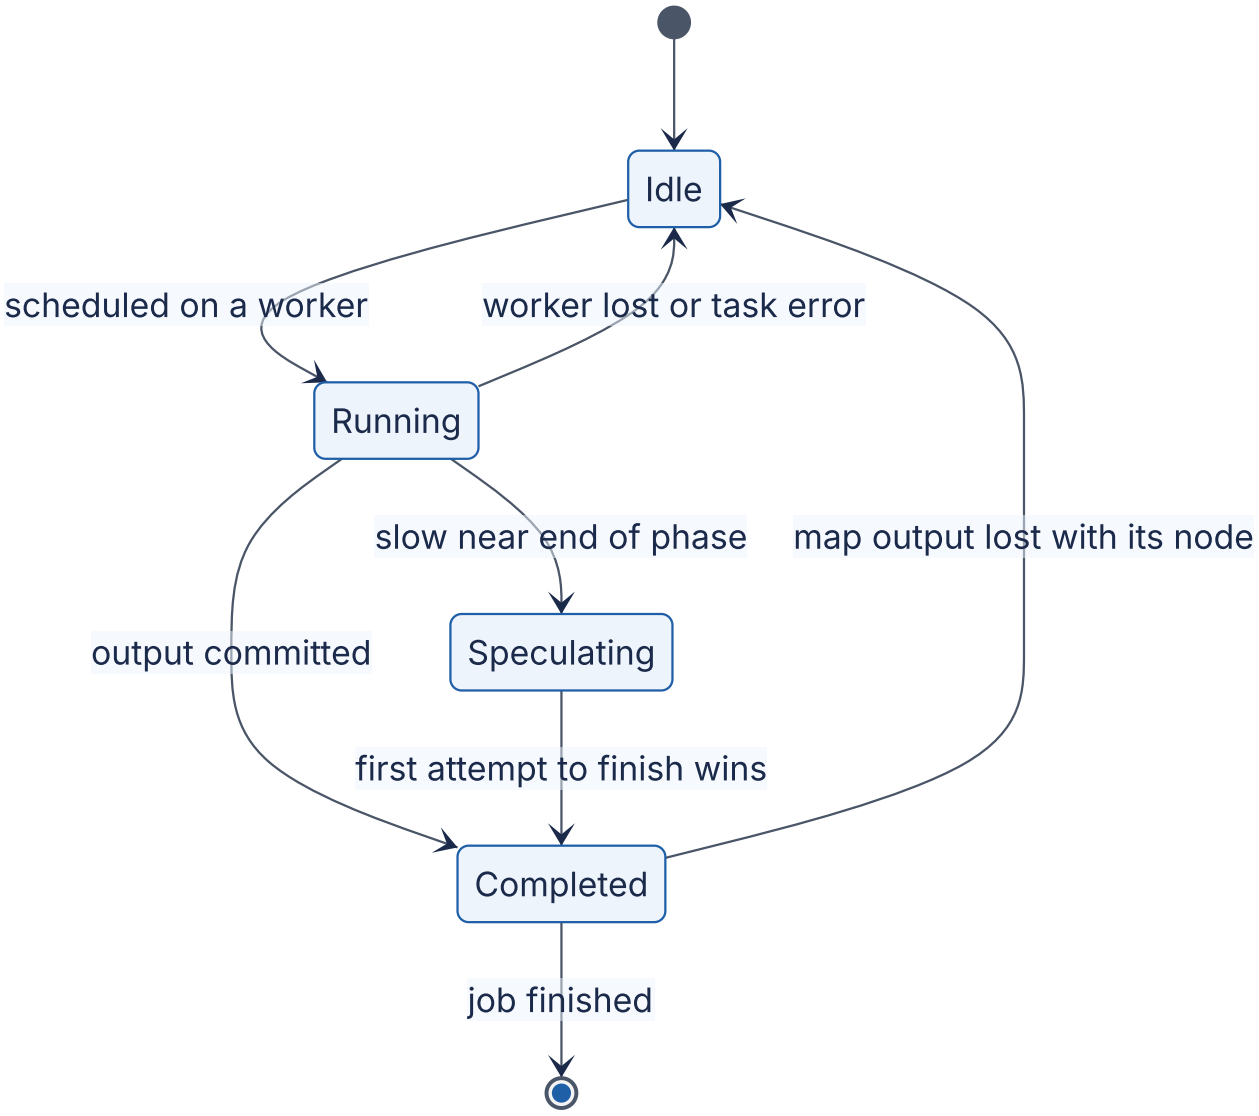
Interpretation. A 12-byte pair replaces a 6-byte word, so naive map output doubles the data; words repeat heavily within a split, so local aggregation removes almost all of it. **Engineering implication.** Always pre-aggregate before a shuffle when the operation allows it; Spark's `reduceByKey` and DataFrame `groupBy().agg()` do this automatically (the `partial_count` step in the Spark plan of §29.5.4), while `groupByKey` does not.

29.4.3 Fault tolerance: re-execution, stragglers and backup tasks

How it works internally

1. **Worker failure.** The coordinator pings workers. If one stops responding, every map task it *completed* is reset to idle and rescheduled, because its output lived on that worker's local disk and is now unreachable; its in-progress map and reduce tasks are rescheduled too. Completed reduce tasks are not rerun, because their output is already in the replicated file system. Reducers that had not yet fetched from the dead worker are told to fetch from the new attempt.
2. **Deterministic re-execution.** Because tasks are functions of immutable inputs, a rerun produces the same output; atomic commit keeps only one attempt's output.
3. **Stragglers and backup tasks.** A **straggler** is a task that runs far slower than its peers because of a bad disk, a noisy neighbor, or a misconfigured machine. Near the end of a phase the coordinator launches **backup** (speculative) copies of the remaining in-progress tasks on other workers and takes whichever finishes first. Google reported that a sort of 1 TB took 44% longer with backup tasks disabled [Dean and Ghemawat 2004].
4. **Bad records** that crash user code deterministically can be skipped after repeated failures.

Figure 29.4 — Lifecycle of a task under re-execution and speculation.



Reading the diagram. Each *task* starts *Idle*, is *Running* once a worker accepts it, and becomes *Completed* when its output is committed. A lost worker or task error sends it back to *Idle* for another attempt (up to a retry limit, four by default in Hadoop). A slow task near the end of a phase enters *Speculating*: a second attempt runs elsewhere, the first to commit wins and the other is killed. The unusual edge is *Completed* → *Idle*: a completed map task's output sits on unreplicated local disk, so losing the node invalidates it. Storage boundary: only committed reduce output is durable. Scaling: speculation costs a few percent extra work and removes most of the tail.

Mathematical foundations

FORMULA

Probability that a phase contains at least one straggler

$$P(\text{at least one straggler}) = 1 - (1-p)^n \approx 1 - e^{-np}$$

Symbol	Meaning	Units
p	Probability that any one task is a straggler	probability
n	Number of tasks in the phase (or in its last wave)	count

WORKED EXAMPLE

Worked example — Why big jobs always have a straggler. Suppose $p = 0.001$: one task in a thousand lands on a machine that runs it 5× slower.

1. Whole map phase of the previous example: $n = 7,813$; $np = 7.8$; $P = 1 - e^{-7.8} = 0.9996$.
2. Only the last wave matters for completion time, because earlier slow tasks are hidden by later waves: $n = 613$ (the tasks in wave 10); $np = 0.613$; $P = 1 - e^{-0.613} = 0.46$.
3. Cost of that straggler: $5 \times 12.8 = 64$ s instead of 12.8 s, adding about 51 s to a 192 s job (+27%).
4. With a backup task launched when the phase is about 95% done, the copy finishes about 13 s after launch, so the delay drops to roughly one task duration.

Interpretation. At scale, “rare” slow machines are present in almost every job, and the slowest task, not the average, sets the finish time (the same tail effect as in §23.6). **Engineering implication.** Enable speculative execution for idempotent tasks, keep tasks short, and do not speculate tasks with side effects (writes to external databases) unless the writes are idempotent (§22.15).

INDUSTRY EXAMPLE

Google MapReduce (2004). The paper describes commodity PCs with 2–4 GB of RAM, 100 Mb/s or 1 Gb/s networking and local disks, with GFS storing input and output. In its sort benchmark (10^{10} 100-byte records, about 1 TB, on roughly 1,800 machines), normal execution took 891 s; with backup tasks disabled it took 1,283 s, 44% longer; and deliberately killing 200 worker processes mid-job increased the time by only about 5%, because the lost tasks were simply re-executed. *Evidence: Primary* — [Dean and Ghemawat 2004]

29.4.4 Joins in MapReduce: sort-merge and broadcast

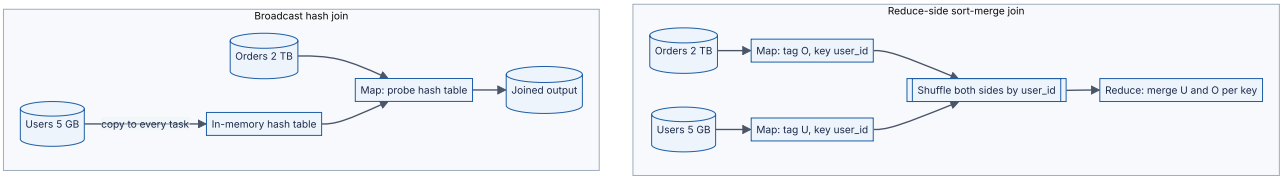
DEFINITION

Definition — Reduce-side (sort-merge) join and broadcast (map-side) join. In a **reduce-side join**, both inputs are mapped to `(join key, tagged record)`, shuffled so that all records with the same key meet at one reducer, sorted, and combined there. In a **broadcast join**, the smaller input is copied in full to every map task, loaded into an in-memory hash table, and each record of the larger input is joined locally by lookup, with no shuffle of the larger input.

How it works internally

1. **Reduce-side join.** Mappers tag each record with its source (`U` or `O` in the code above) and both tables are partitioned by key. A **secondary sort** can put the user record before its orders, so the reducer streams orders past one buffered user. It works for any sizes but shuffles *both* tables.
2. **Broadcast hash join.** The small table (say 5 GB of user profiles) is shipped to every task. Each mapper streams the large table and probes the hash table. Nothing large crosses the network, and no sort is needed. It fails if the small side does not fit in a task's memory.
3. **Bucketed map-side join.** If both inputs were *already* written sorted into the same number of buckets by the join key, task *i* merges bucket *i* of each without a shuffle.

Figure 29.5 — Reduce-side join versus broadcast join.



Reading the diagram. In the *reduce-side join*, mappers key both tables by `user_id` and the *shuffle* (asynchronous, all-to-all) brings matching records to one *reducer*. In the *broadcast join*, *users* are copied to every task as a *hash table* and *orders* are streamed and joined in place. Storage: inputs and outputs are durable; the hash table lives in task memory. Failure points: a broadcast side larger than memory causes out-of-memory failures; a skewed key overloads one reducer (§29.6.3). Scaling: broadcast cost grows with the number of tasks, shuffle cost with both inputs.

Mathematical foundations

FORMULA

Network cost of a shuffle join versus a broadcast join

$$V_{\text{shuffle}} \approx (|L| + |S|) \cdot \frac{N-1}{N}, \qquad V_{\text{broadcast}} \approx |S| \cdot (N-1)$$

Broadcast is cheaper when $|S| \cdot N < |L| + |S|$, roughly $|S| < |L|/(N-1)$, and $|S|$ fits in each executor's memory.

Symbol	Meaning	Units
$\|L\|, \|S\|$	Size of the large and small input	bytes
N	Number of executors or nodes receiving data	count
V	Bytes sent over the network	bytes

WORKED EXAMPLE

Worked example — Orders and users on 100 executors. $|L| = 2$ TB of orders, $N = 100$.

1. $|S| = 5$ GB. Shuffle: $2.005\ \text{TB} \times 0.99 = 1.985$ TB. Broadcast: $5\ \text{GB} \times 99 = 495$ GB. Broadcast moves 4× less and skips sorting 2 TB.
2. $|S| = 50$ GB. Broadcast: $50 \times 99 = 4.95$ TB versus a shuffle of $2.05 \times 0.99 = 2.03$ TB. Shuffle wins, and 50 GB would not fit in most executors anyway.
3. Break-even: $|S| \approx 2\ \text{TB}/99 \approx 20$ GB.

Interpretation. Broadcasting trades a copy per executor for avoiding a shuffle of the big side, which pays only while the small side is really small. **Engineering implication.** Spark broadcasts automatically below `spark.sql.autoBroadcastJoinThreshold` (10 MB by default, deliberately conservative), and Adaptive Query Execution can switch to a broadcast at run time when the actual size after filtering turns out small (§29.5.4). Raise the threshold cautiously and only with memory headroom.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Job never finishes; one reducer at 99%	Hot key or straggler	Task duration histogram; one task 10–100× median	Kill and resubmit with salting or speculation	Sample key frequencies; salting (§29.6.3); speculation
Map phase restarts late in the job	Node holding completed map output died	Fetch-failure counters in reducers	Coordinator reruns those maps	External shuffle service or replicated shuffle storage
Executors die with out-of-memory errors in a join	Broadcast side bigger than estimated	OOM logs; broadcast size in plan	Fall back to sort-merge join	Fresh table statistics; AQE
Duplicate rows in output	Two attempts both wrote output without atomic commit	Row counts exceed input-derived bound	Rerun with commit protocol	Commit by rename or table-format transaction

COMMON MISTAKE

"A combiner is just the reducer run early, so any reducer can be a combiner." Only associative and commutative operations qualify, and the combiner may run zero, one or many times. An average computed in the combiner and then averaged again in the reducer is wrong; emit `(sum, count)` pairs and divide only in the reducer.

29.5 Apache Spark

29.5.1 Resilient Distributed Datasets and lineage

DEFINITION

Definition — Resilient Distributed Dataset (RDD). A read-only, partitioned collection of records that can be created only by deterministic operations (**transformations** such as `map`, `filter`, `join`) on stable storage or on other RDDs. Each RDD records its **lineage**, the graph of transformations that produced it, so a lost partition can be recomputed from its parents instead of being restored from a replica [Zaharia et al. 2012].

First-principles explanation

A recipe card is cheaper to keep than a fridge full of prepared dishes. If someone drops the sauce, you do not need a backup sauce; you need the recipe and the raw ingredients, and you redo only the sauce. An RDD is a recipe plus a pointer to ingredients in durable

storage. Spark keeps the dishes (partitions) in memory when it can, and if a node dies it reruns the recipe only for the partitions that node held.

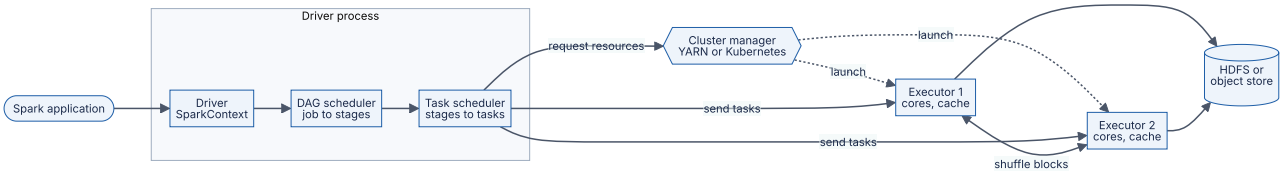
Why does this exist?

MapReduce writes every job's output to the replicated distributed file system, and multi-step pipelines are chains of jobs. That is wasteful for **iterative** algorithms (logistic regression, k-means, PageRank) that reread the same data many times, and for **interactive** analysis. Replicating in-memory data instead would cost network bandwidth comparable to the writes it saved. Lineage gives fault tolerance by logging the *coarse-grained* transformation once per dataset rather than every record [Zaharia et al. 2012].

How it works internally

1. **Transformations are lazy.** `rdd.map(f)` returns a new RDD object describing the computation; nothing runs.
2. **Actions trigger jobs.** `count()`, `collect()` or `saveAsTextFile()` submit a **job** for the final RDD's lineage graph.
3. **The driver plans, executors run.** The **driver** program holds the `SparkContext`, the **DAG scheduler** and the **task scheduler**. A **cluster manager** (YARN, Kubernetes or Spark's standalone manager) grants **executors**, long-lived JVM processes on worker nodes, each with a number of cores and a memory region for cached partitions and shuffle buffers.
4. **Recovery.** When an executor dies, the driver identifies which partitions it held, walks the lineage back to the nearest available ancestors (cached partitions, surviving shuffle files, or the input), and reruns only the needed tasks.
5. **Checkpointing** (`rdd.checkpoint()`) writes an RDD to reliable storage and truncates very long lineages.

Figure 29.6 — Spark runtime: driver, cluster manager and executors.



Reading the diagram. The *driver* turns each action into a job; the *DAG scheduler* splits it into stages and the *task scheduler* places tasks, preferring executors that hold the data. The *cluster manager* starts *executors* asynchronously (dotted). Tasks are sent synchronously; executors read and write *durable storage* and exchange *shuffle blocks*. Storage: cached partitions and shuffle files are unreplicated, on executors. Failure points: a dead executor's partitions are recomputed from lineage; a dead driver loses the application unless restarted in cluster mode. Scaling: add executors, statically or by dynamic allocation.

29.5.2 Narrow and wide dependencies, stages and tasks

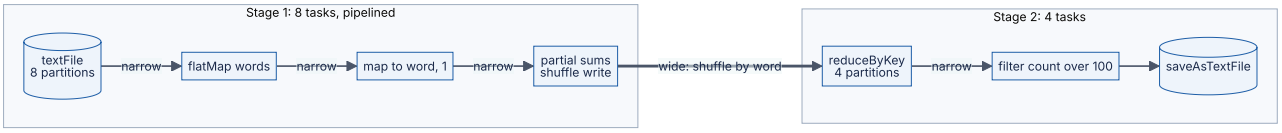
DEFINITION

Definition — Narrow and wide dependencies. A **narrow dependency** exists when each partition of the parent RDD is used by at most one partition of the child (`map` , `filter` , `union` , a join of co-partitioned inputs). A **wide (shuffle) dependency** exists when a child partition may depend on many or all parent partitions (`groupByKey` , `reduceByKey` , a join of unpartitioned inputs), which requires a shuffle.

The distinction drives both performance and recovery. Narrow transformations are **pipelined**: one task applies `map` , `filter` and `map` to each record in a single pass, and recovering a child partition needs one parent partition. A wide dependency is a barrier: all parent partitions must write shuffle files before any child starts, and losing a child may require recomputing many parents.

The DAG scheduler therefore cuts the lineage graph at every wide dependency. Each piece is a **stage**: a chain of narrow transformations ending in a shuffle write (a *shuffle map stage*) or in the action's result (a *result stage*). Each stage runs as one **task** per partition. Stages whose shuffle output already exists are skipped.

Figure 29.7 — Lineage of a word-count job cut into stages at the wide dependency.



Reading the diagram. Each of Stage 1's 8 tasks pipelines `flatMap` , `map` and the partial sum (all narrow) record by record and ends by writing shuffle files partitioned by word. The thick arrow is the *wide* dependency: each of Stage 2's 4 tasks fetches its partition from all 8 outputs (asynchronous fetch), then reduces, filters and writes to durable storage. Shuffle files sit on executor disks between stages. Failure points: a lost Stage 2 executor reruns only its tasks if the shuffle files survive, otherwise also the Stage 1 tasks that wrote them. Scaling: Stage 2 parallelism is the shuffle partition count.

29.5.3 Caching and persistence

`rdd.persist(level)` or `df.cache()` asks Spark to keep the computed partitions after the first action so later actions reuse them. **Storage levels** choose the trade-off: `MEMORY_ONLY` recomputes partitions that do not fit; `MEMORY_AND_DISK` (the DataFrame `cache()` default) spills them to local disk; serialized and replicated (`_2`) variants trade CPU for memory or faster recovery. `cache()` is lazy (the first action fills it), and it is a hint for reuse, not durability: lost cached partitions are recomputed from lineage.

FORMULA

Speedup from caching an iterative job

$$S = \frac{k\,(T_{\text{load}} + T_{\text{iter}})}{T_{\text{load}} + k\,T_{\text{iter}}} \;\xrightarrow{k \to \infty}\; 1 + \frac{T_{\text{load}}}{T_{\text{iter}}}$$

Symbol	Meaning	Units
S	Speedup of the cached version over reloading every iteration	dimensionless
k	Number of iterations (or repeated queries)	count
T_{load}	Time to read, parse and build the working dataset from storage	s
T_{iter}	Compute time of one iteration over the in-memory data	s

WORKED EXAMPLE

Worked example — Ten iterations of a training-feature job. A logistic-regression job reads 1 TB of Parquet from object storage and parses it: $T_{\text{load}} = 60$ s on the cluster. Each gradient pass over the in-memory data takes $T_{\text{iter}} = 6$ s. $k = 10$.

1. Without caching: $10 \times (60 + 6) = 660$ s.
2. With caching: $60 + 10 \times 6 = 120$ s.
3. Speedup: $660/120 = 5.5\times$; the asymptotic limit is $1 + 60/6 = 11\times$.

Interpretation. Caching helps when loading dominates and data is reused; for one pass it only costs memory. **Engineering implication.** Cache the reused dataset after expensive parsing and filtering, check in the Spark UI that it fits (deserialized objects are often several times larger than Parquet), and `unpersist()` it when done.

INDUSTRY EXAMPLE

RDD paper and the 100 TB sort. The RDD paper reported Spark up to 20× faster than Hadoop for iterative applications and interactive queries over a 1 TB dataset in 5–7 s [Zaharia et al. 2012]. In 2014 Databricks reported sorting 100 TB with Spark in 23 minutes on 206 cloud machines, against a previous Hadoop MapReduce record of 72 minutes on 2,100 machines; the run did not rely on in-memory caching but on a new sort-based shuffle and network layer [Xin 2014]. *Evidence: Primary* — [Zaharia et al. 2012; Xin 2014]

29.5.4 DataFrames, Catalyst, Tungsten and Adaptive Query Execution

DEFINITION

Definition — DataFrame, Dataset and Catalyst. A **DataFrame** is a distributed table with a known schema (named, typed columns), manipulated with relational operators or SQL. A **Dataset** (Scala and Java) adds compile-time types to the same abstraction; in Python and R, every DataFrame is untyped at compile time. **Catalyst** is Spark SQL's extensible query optimizer, which turns DataFrame or SQL queries into an optimized physical plan using rule-based and cost-based transformations of trees [Armbrust et al. 2015].

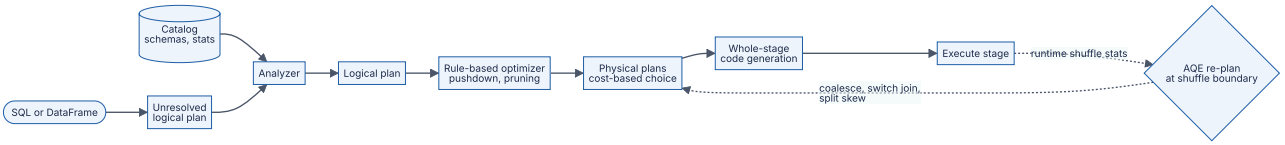
Why does this exist?

An RDD of Python or Java objects is opaque: Spark cannot see that a `lambda` only reads two fields, or that a filter could run before a join. DataFrames make the computation **declarative**: you say *what* (group by country, count), and the engine decides *how*. With a schema, Spark can read only needed columns from Parquet, push filters into the scan, choose join strategies from table sizes, and store rows in compact binary form instead of objects.

How it works internally

1. **Analysis.** The query is parsed into an unresolved logical plan; column and table names are resolved against the catalog.
2. **Logical optimization.** Rules rewrite the tree: predicate pushdown, column pruning, constant folding, combining filters and projections.
3. **Physical planning.** Candidate physical plans are generated (for example broadcast hash join versus sort-merge join) and one is chosen, using size statistics.
4. **Code generation. Tungsten**, Spark's execution layer, stores rows in a compact binary format and uses **whole-stage code generation** to fuse a chain of operators into one generated function (the `*(1)` markers in the plan below).
5. **Adaptive Query Execution (AQE).** Statistics guessed before running are often wrong. With AQE (on by default since Spark 3.2), Spark re-optimizes the remaining plan at each shuffle boundary using the *actual* sizes of completed shuffle outputs. It can (a) coalesce many small shuffle partitions into fewer, right-sized ones (target 64 MB by default); (b) switch a sort-merge join to a broadcast join when one side turned out small; and (c) split skewed partitions, those over 5× the median and over 256 MB by default, into smaller tasks [Apache Spark Docs: Performance Tuning].

Figure 29.8 — Catalyst query planning with Adaptive Query Execution.



Reading the diagram. The *analyzer* resolves names against the *catalog*; the *optimizer* applies rewrite rules; *physical planning* picks operators using statistics; *code generation* compiles each stage; stages *execute* on executors. The dotted loop is AQE: when a shuffle-producing stage finishes, real partition sizes flow back asynchronously and the remaining plan is re-optimized. Planning happens in the driver. Failure points: stale statistics cause bad initial choices, which AQE corrects only at shuffle boundaries. Scaling: planning cost is independent of data size.

Code example

The PySpark program computes page views with the RDD API and the DataFrame API, joins events with users using a broadcast hint, prints the physical plan, and checks every result against plain Python. It was executed with PySpark 4.0.1 in local mode on Java 21.

```
        """PySpark: the same aggregation with the RDD API and the DataFrame API, plus a
broadcast join.
        Tested with PySpark 4.0.1 in local mode (Java 21); results are checked against
plain Python."""
        import random
        from collections import Counter

        from pyspark.sql import SparkSession, functions as F

        spark = (SparkSession.builder.master("local[4]").appName("ch29-demo")
                 .config("spark.sql.shuffle.partitions", "8")          # default is 200
                 .config("spark.sql.adaptive.enabled", "true")          # AQE (default
on since 3.2)
                 .getOrCreate())
        spark.sparkContext.setLogLevel("ERROR")

        rng = random.Random(29)
        pages = ["/home", "/search", "/item", "/cart", "/checkout"]
        events = [(rng.randrange(1_000), rng.choice(pages)) for _ in range(50_000)]
        users = [(u, rng.choice(["IN", "US", "DE", "BR"])) for u in range(1_000)]

        # 1. RDD API: explicit functions, lineage parallelize -> map -> reduceByKey
        rdd = spark.sparkContext.parallelize(events, numSlices=8)
        views_rdd = dict(rdd.map(lambda e: (e[1], 1)).reduceByKey(lambda a, b: a +
b).collect())

        # 2. DataFrame API: declarative, optimized by Catalyst
        ev = spark.createDataFrame(events, ["user_id", "page"]).cache()      # reused
twice below
        us = spark.createDataFrame(users, ["user_id", "country"])
        views_df = {r["page"]: r["n"] for r in
ev.groupBy("page").agg(F.count("*").alias("n")).collect()}

        # 3. Join + aggregate; the small side is broadcast, so the large side is never
shuffled for the join
        by_country = (ev.join(F.broadcast(us), "user_id")
                        .groupBy("country", "page").agg(F.count("*").alias("views")))
        by_country.explain()                        # physical plan: BroadcastHashJoin,
then one Exchange
        result = {(r["country"], r["page"]): r["views"] for r in by_country.collect()}

        # Check against plain Python
        truth_pages = Counter(p for _, p in events)
        country = dict(users)
        truth_join = Counter((country[u], p) for u, p in events)
        assert views_rdd == views_df == dict(truth_pages)
        assert result == dict(truth_join)
        print("views per page:", dict(sorted(views_df.items())))
        print("country/page groups:", len(result), "- all checks passed")
        spark.stop()
```

Output (log lines removed; plan identifiers such as `#13` vary between runs):

```
== Physical Plan ==
AdaptiveSparkPlan isFinalPlan=false
+- HashAggregate(keys=[country#13, page#1], functions=[count(1)])
   +- Exchange hashpartitioning(country#13, page#1, 8), ENSURE_REQUIREMENTS,
[plan_id=90]
      +- HashAggregate(keys=[country#13, page#1], functions=[partial_count(1)])
         +- Project [page#1, country#13]
            +- BroadcastHashJoin [user_id#0L], [user_id#12L], Inner, BuildRight, false
               :- Filter isnotnull(user_id#0L)
               :  +- InMemoryTableScan [user_id#0L, page#1], [isnotnull(user_id#0L)]
               :        +- InMemoryRelation [user_id#0L, page#1], StorageLevel(disk,
memory, deserialized, 1 replicas)
               :              +- *(1) Scan ExistingRDD[user_id#0L,page#1]
               +- BroadcastExchange HashedRelationBroadcastMode(List(input[0, bigint,
false]),false), [plan_id=85]
                  +- Filter isnotnull(user_id#12L)
                     +- Scan ExistingRDD[user_id#12L,country#13]

views per page: {'/cart': 9945, '/checkout': 10053, '/home': 10073, '/item': 9954,
'/search': 9975}
country/page groups: 20 - all checks passed
```

What to notice:

- Read the plan bottom-up. The users side goes through a `BroadcastExchange`; the events side is joined in place by `BroadcastHashJoin`, so the large input is never shuffled for the join.
- There is exactly one `Exchange` (shuffle), for the `groupBy`. Before it, `partial_count` is the map-side combiner of §29.4.2; after it, the final `count` merges partial counts.
- Catalyst added `Filter isnotnull(user_id)` itself: an inner join never matches a null key.
- `AdaptiveSparkPlan isFinalPlan=false`: AQE may still rewrite the plan after the shuffle.
- The RDD version gives the same answer, but Catalyst cannot see inside its lambdas and every record crosses the JVM–Python boundary. Prefer DataFrames and built-in functions.

29.6 Partitioning and shuffle

29.6.1 Hash and range partitioning

Every shuffle must decide which partition each key goes to. The two schemes are the same ones databases use for storage (§14.6), applied on the fly:

- **Hash partitioning**, $p = \text{hash}(k) \mod P$, spreads keys evenly regardless of their values and is the default for aggregations and joins. Keys in one partition are in no useful order.

- **Range partitioning** assigns contiguous key ranges to partitions, so partition i holds keys smaller than those in partition $i+1$. Concatenating sorted partitions gives a globally sorted output (`ORDER BY`, sort benchmarks); the engine first **samples** the input to choose balanced boundaries.

Both schemes balance *keys*, not *records*: a key with 20% of the records lands entirely in one partition under either. That is the skew problem of §29.6.3.

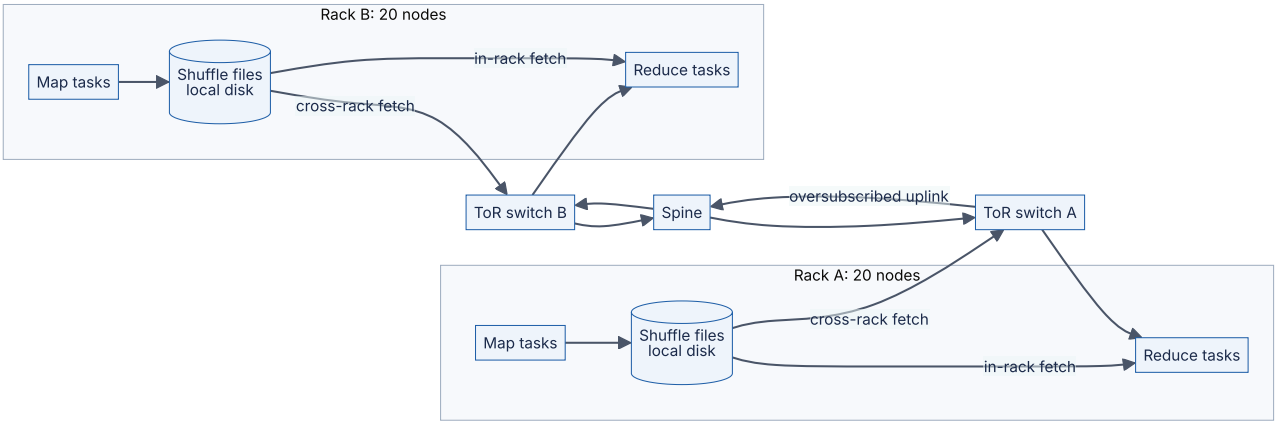
29.6.2 The cost of a shuffle

DEFINITION

Definition — Shuffle. The all-to-all redistribution of intermediate data between two stages, in which every task of the producing stage writes its output partitioned by key and every task of the consuming stage reads its partition from every producer. It costs serialization, local disk writes and reads, and network transfer, and it is a barrier between stages.

On a cluster of N nodes with keys spread evenly, a fraction $(N-1)/N$ of the shuffled data leaves its node. In a datacenter built from racks behind oversubscribed uplinks (§7.17), a fraction $(K-1)/K$ of it also leaves its rack when there are K racks, and the rack uplinks are usually the tightest pipe.

Figure 29.9 — A shuffle crossing rack uplinks.



Reading the diagram. Map tasks in each rack write partitioned *shuffle files* to local disk. Reduce tasks fetch their partition from every file: fetches within a rack go through the top-of-rack switch only, while cross-rack fetches climb through the *ToR switch*, an *oversubscribed uplink* and the *spine*. All fetches are pull-based TCP transfers that start as soon as producers finish. Shuffle files are on unreplicated local disks. Failure points: a congested uplink slows every reducer; a lost node invalidates its files. Scaling: more partitions create $M \times R$ ever-smaller blocks and random I/O.

FORMULA

Shuffle time lower bound on a rack-structured cluster

$$T_{\text{shuffle}} \approx \max\left(\frac{V(N-1)/N}{N\eta B_{\text{NIC}}},\ \frac{V(K-1)/K}{KU},\ \frac{2V}{NB_{\text{disk}}}\right)$$

Symbol	Meaning	Units
V	Shuffled data volume	bytes
N, K	Nodes and racks	count
B_{NIC}	Network interface speed per node	bytes/s
η	Achievable fraction of line rate	dimensionless
U	Uplink capacity per rack	bytes/s
B_{disk}	Local disk throughput per node (each byte written once, read once)	bytes/s

WORKED EXAMPLE

Worked example — Shuffling 10 TB on a 100-node cluster. $V = 10$ TB; $N = 100$ in $K = 5$ racks of 20; 25 Gb/s NICs ($B_{\text{NIC}} = 3.125$ GB/s) at $\eta = 0.7$; rack uplinks oversubscribed 4:1, so $U = 20 \times 3.125/4 = 15.6$ GB/s; NVMe $B_{\text{disk}} = 2$ GB/s.

1. NIC: each node sends $10\ \text{TB}/100 \times 0.99 = 99$ GB at $0.7 \times 3.125 = 2.19$ GB/s: 45 s.
2. Uplinks: cross-rack data $= 10 \times 0.8 = 8$ TB, so each rack sends 1.6 TB through 15.6 GB/s: 102 s.
3. Disk: each node writes 100 GB and reads 100 GB at 2 GB/s: 100 s.
4. Lower bound: $\max(45, 102, 100) \approx 102$ s, about 1.7 minutes; serialization, compression and stragglers typically add 2–3× in practice.
5. Block count: with 128 MB input splits from 10 TB of input, $M \approx 78{,}000$ map tasks; with $R = 2{,}000$ reducers there are 1.56×10^8 shuffle blocks averaging $10^{13}/1.56 \times 10^8 = 64$ KB each.

Interpretation. Moving 10 TB is dominated by oversubscribed uplinks and local disks, not NICs; and over a hundred million 64 KB random reads would cripple hard disks. **Engineering implication.** Shrink V first (filter and project before the shuffle, pre-aggregate, compress), then avoid it (broadcast joins, co-partitioned or bucketed inputs), and keep partitions around 100–200 MB so blocks stay large.

INDUSTRY EXAMPLE

LinkedIn Magnet: push-based shuffle. LinkedIn found that pull-based shuffle on hard disks produced huge numbers of small random reads and frequent fetch failures. In Magnet, map tasks *push* blocks to remote shuffle services that merge each reduce partition into larger files, turning random reads into sequential ones and keeping a second copy. It became Spark's push-based shuffle for YARN in Spark 3.2. *Evidence: Primary* — [Shen et al. 2020; Apache Spark Docs: Configuration]

29.6.3 Skew and salting

DEFINITION

Definition — Partition skew and salting. Skew is an uneven distribution of records across partitions, usually caused by a few very frequent keys (a celebrity user, a null or default value, a bot). **Salting** appends a random suffix from a small range to hot keys so their records spread over several partitions, then removes the suffix in a second, much smaller aggregation (or, for joins, replicates the matching rows of the other side once per salt value).

A stage finishes only when its slowest task finishes, so the largest partition, not the average, sets the stage time.

FORMULA

Slowdown from a single hot key

$$\text{skew} = \frac{\max_i L_i}{\bar{L}} \approx fP + (1 - f), \qquad \text{with salt } s\text{: skew} \approx \frac{fP}{s} + (1 - f)$$

Symbol	Meaning	Units
L_i, $\bar{L}$	Records in partition i; mean records per partition	records
f	Fraction of all records carrying the hot key	dimensionless
P	Number of shuffle partitions	count
s	Salt range (hot key spread over s partitions), $s \le P$	count

WORKED EXAMPLE

Worked example — A bot account with 20% of the events. $P = 200$, $f = 0.2$, and an average task takes 30 s.

1. Unsalted: $\text{skew} = 0.2 \times 200 + 0.8 = 40.8$. The hot partition takes $40.8 \times 30 = 1,224$ s (20 minutes) while 199 tasks finish in 30 s.
2. Salt $s = 8$: $40/8 + 0.8 = 5.8$, so 174 s.
3. Salt $s = 64$: $40/64 + 0.8 = 1.4$ in theory; the simulation below measures 2.1 because 64 salted keys hashed into 200 partitions collide.

Interpretation. Adding partitions does not help: one key goes to one partition however many there are, and fP even grows with P. **Engineering implication.** Find hot keys by sampling, salt only those, and let AQE's skew-join handling split oversized join partitions; filter out junk keys (nulls, test accounts) before the shuffle.

```
        """Partition skew and key salting: per-partition load before and after a two-
stage aggregation."""
        import random
        import zlib
        from collections import Counter

        def partition(key, n):
            return zlib.crc32(repr(key).encode()) % n

        def stage_loads(keys, n):
            loads = Counter(partition(k, n) for k in keys)
            return [loads.get(p, 0) for p in range(n)]

        def skew_ratio(loads):
            return max(loads) / (sum(loads) / len(loads))     # slowest task / average
task

        rng = random.Random(1)
        P = 200                                               # shuffle partitions
        records = [("hot" if rng.random() < 0.20 else f"user{rng.randrange(100_000)}",
1)
                   for _ in range(1_000_000)]                 # one key carries 20% of
all rows
        truth = Counter()
        for k, v in records:
            truth[k] += v

        # Plain aggregation: every row of a key goes to one partition.
        plain = stage_loads((k for k, _ in records), P)
        print(f"plain  : max={max(plain):>7,}  mean={sum(plain) / P:>7,.0f}  skew=
{skew_ratio(plain):5.1f}x")

        sample = Counter(k for k, _ in rng.sample(records, 10_000))   # find hot keys
from a 1% sample
        hot = {k for k, c in sample.items() if c > 0.01 * 10_000}
        print("hot keys found by sampling:", hot)

        for salt in (8, 64):
            # Stage 1: append a random salt to hot keys only, spreading each over `salt`
partitions.
            salted = [((k, rng.randrange(salt) if k in hot else 0), v) for k, v in
records]
            s1 = stage_loads((sk for sk, _ in salted), P)
            partial = Counter()
            for (k, s), v in salted:
                partial[(k, s)] += v                          # partial sums per (key,
salt)
            # Stage 2: strip the salt and combine at most `salt` partial sums per key.
            s2 = stage_loads((k for k, _ in partial), P)
            final = Counter()
            for (k, _), v in partial.items():
                final[k] += v
```

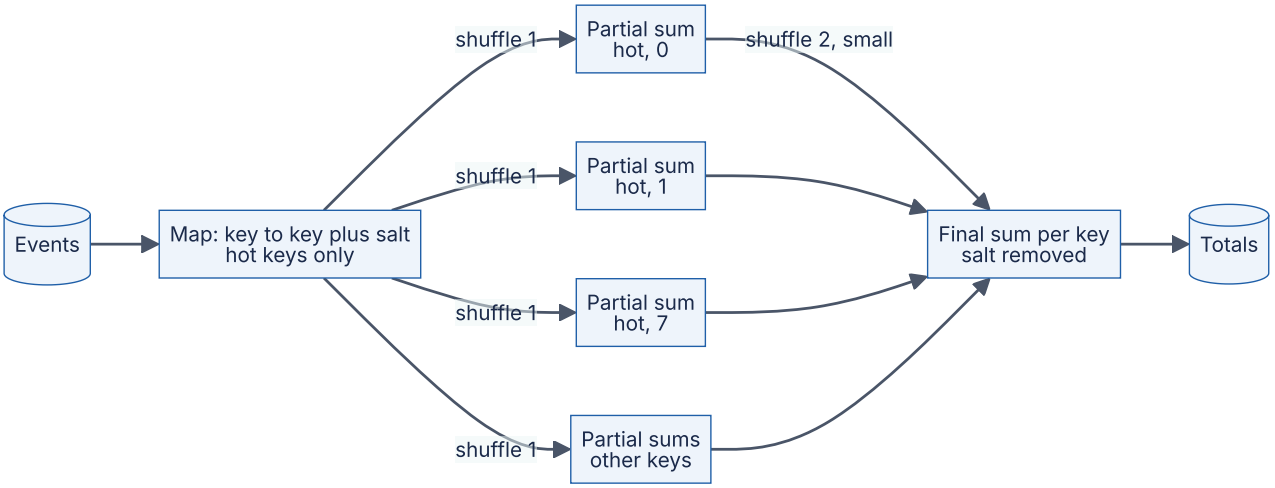
```
            assert final == truth                                  # salting never changes the
answer
            print(f"salt={salt:<3}: stage1 max={max(s1):>7,} skew={skew_ratio(s1):5.1f}x
| "
                  f"stage2 rows={len(partial):,} skew={skew_ratio(s2):4.1f}x")
```

Output:

```
plain  : max=204,210  mean=  5,000  skew= 40.8x
hot keys found by sampling: {'hot'}
salt=8  : stage1 max= 29,459 skew=  5.9x | stage2 rows=99,975 skew= 1.1x
salt=64 : stage1 max= 10,306 skew=  2.1x | stage2 rows=100,031 skew= 1.1x
```

What to notice: the measured unsalted skew (40.8×) matches the formula exactly; stage 2 handles only about 100,000 partial sums, so its cost is negligible; and the assertion proves the two-stage aggregation gives the same totals.

Figure 29.10 — Two-stage aggregation with a salted hot key.



Reading the diagram. The first map step appends a salt (0–7) to the hot key only; the first shuffle spreads `hot` over eight partitions, each computing a *partial sum*, while other keys aggregate normally. The second shuffle carries at most eight rows per hot key, so it is tiny; the final stage removes the salt and adds the partial sums. Both shuffles are asynchronous all-to-all transfers. Failure point: salting a non-associative operation (a median) gives wrong answers. Scaling: choose s so each salted piece is near the average partition size.

29.7 Data locality

DEFINITION

Definition — Data locality. Scheduling a task on or near the node that stores its input, so that the input is read from local disk or memory instead of over the network. Schedulers rank placements as **process-local** (data cached in the same executor), **node-local**, **rack-local** and **off-rack** (any).

In 2004 the network was the scarcest resource: 1 Gb/s NICs behind oversubscribed rack uplinks, while local disks delivered a few hundred MB/s per node. Moving computation to data was essential: GFS and HDFS expose block locations (§15.5), the MapReduce coordinator tried node-local then rack-local placement, and most input in large jobs was read locally [Dean and Ghemawat 2004]. Spark waits briefly for a better locality level before accepting a worse one (`spark.locality.wait`, 3 s by default), a technique called **delay scheduling** [Zaharia et al. 2010].

Two changes reduced locality's importance. Networks moved to 25–100 Gb/s NICs and fabrics with low oversubscription (§7.17), so remote reads approach local NVMe speed. And cloud deployments **disaggregated storage from compute**: data lives in object stores (§15.4) or shared file systems such as Colossus or Tectonic (§15.5.3), while stateless compute clusters scale independently, even to zero. Parquet decoding often becomes the bottleneck before the network does.

WORKED EXAMPLE

Worked example — How much locality is worth, then and now. Each node must read 100 GB of input.

1. 2004-style node: local disks 200 MB/s, effective remote rate about 25 MB/s (125 MB/s NIC behind 5:1 rack oversubscription). Fully local: $100,000/200 = 500$ s. Fully remote: $100,000/25 = 4,000$ s, 8× slower.
2. 2026-style node: local NVMe 6 GB/s; 100 Gb/s NIC delivering about 3 GB/s from an object store with parallel range reads. Local: $100/6 = 17$ s; remote: $100/3 = 33$ s, 2× slower, before columnar pruning, which applies equally to both.

Interpretation. Locality shrank from an 8× factor to 2×, which elasticity usually outweighs. **Engineering implication.** Keep columnar tables in object storage, cache hot data on local SSDs, and tune shuffle and skew instead; the shuffle remains node-to-node.

Object stores bring their own limits: per-prefix request rates (Amazon S3 documents at least 3,500 writes and 5,500 reads per second per prefix, as of 2026), slow listing, and re-

name-as-copy. Table formats such as Apache Iceberg, Delta Lake and Apache Hudi therefore track files in metadata and commit by swapping a metadata pointer (Chapter 61).

29.8 Stream processing concepts

29.8.1 Unbounded data, event time and processing time

> DEFINITION
>
> **Definition — Stream processing, event time and processing time. Stream processing** runs a long-lived computation over an **unbounded** dataset, one that grows forever, producing results incrementally. Each record has an **event time**, when the event actually happened (stamped by the device or service that produced it), and a **processing time**, when the system observes it. The difference is the record's **event-time skew**, which is variable and unbounded in the worst case.

First-principles explanation

Picture postcards from a group holiday. Each card shows the date it was written (event time), but they arrive in your mailbox days apart and out of order (processing time); one is stuck in a mailbag for a month. If you want "how many cards were written on Tuesday", you cannot answer when the first Wednesday card arrives; you have to decide how long to wait for stragglers, and what to do if a Tuesday card turns up after you announced the answer. Every streaming system makes exactly those two decisions.

Why does this exist?

Fraud scores, live dashboards and ML features over the last five minutes (Chapter 62) need answers continuously, and rerunning batch jobs every few minutes is wasteful. Grouping by processing time is easy but wrong: a phone that reconnects after a flight delivers yesterday's events today, and a consumer that restarts reprocesses old events in a burst, so processing-time counts change with operational accidents. Correct results require grouping by **event time** while data arrives out of order.

29.8.2 Windows

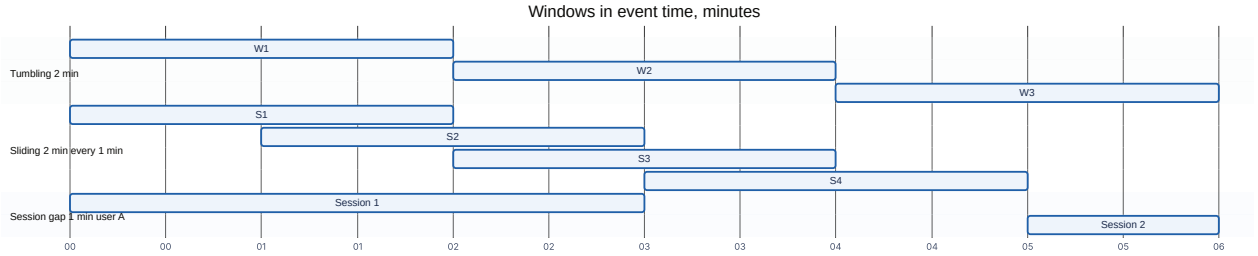
A **window** cuts an unbounded stream into finite chunks of event time so that aggregates can be computed and emitted.

- **Tumbling (fixed) windows** have size W and do not overlap: [12:00, 12:01), [12:01, 12:02). Each event belongs to exactly one.
- **Sliding (hopping) windows** have size W and slide $S < W$, so they overlap and each event belongs to W/S windows ("last 10 minutes, updated every minute" puts each

event in 10 windows, multiplying state and output).

- **Session windows** are per key and data-driven: a session continues while events arrive within a **gap** g of each other and closes after g of inactivity. Windows are merged when a new event bridges two of them.

Figure 29.11 — Tumbling, sliding and session windows over the same events.



Reading the diagram. The horizontal axis is event time in minutes. *Tumbling* windows tile the axis without overlap. *Sliding* windows of two minutes start every minute, so any instant is covered by two windows. *Session* windows belong to one key (user A): events from minute 0 to minute 3 arrived less than a minute apart and form one session, then a gap of over a minute closes it, and a new session starts at minute 5. The engine keeps state per key per open window, so sliding windows multiply state by W/S. Failure point: a bot sending every 30 s keeps a session open forever unless capped.

29.8.3 Watermarks, triggers, late data and accumulation

DEFINITION

Definition — Watermark. A watermark with value t is a statement flowing through the stream: "no more events with event time $\leq t$ are expected." It lets event-time operators decide that a window is complete. A **perfect** watermark is possible only with full knowledge of the sources; real systems use **heuristic** watermarks, such as the maximum event time seen minus a bound δ on out-of-orderness, which can be wrong. Events that arrive with event time behind the watermark are **late data**.

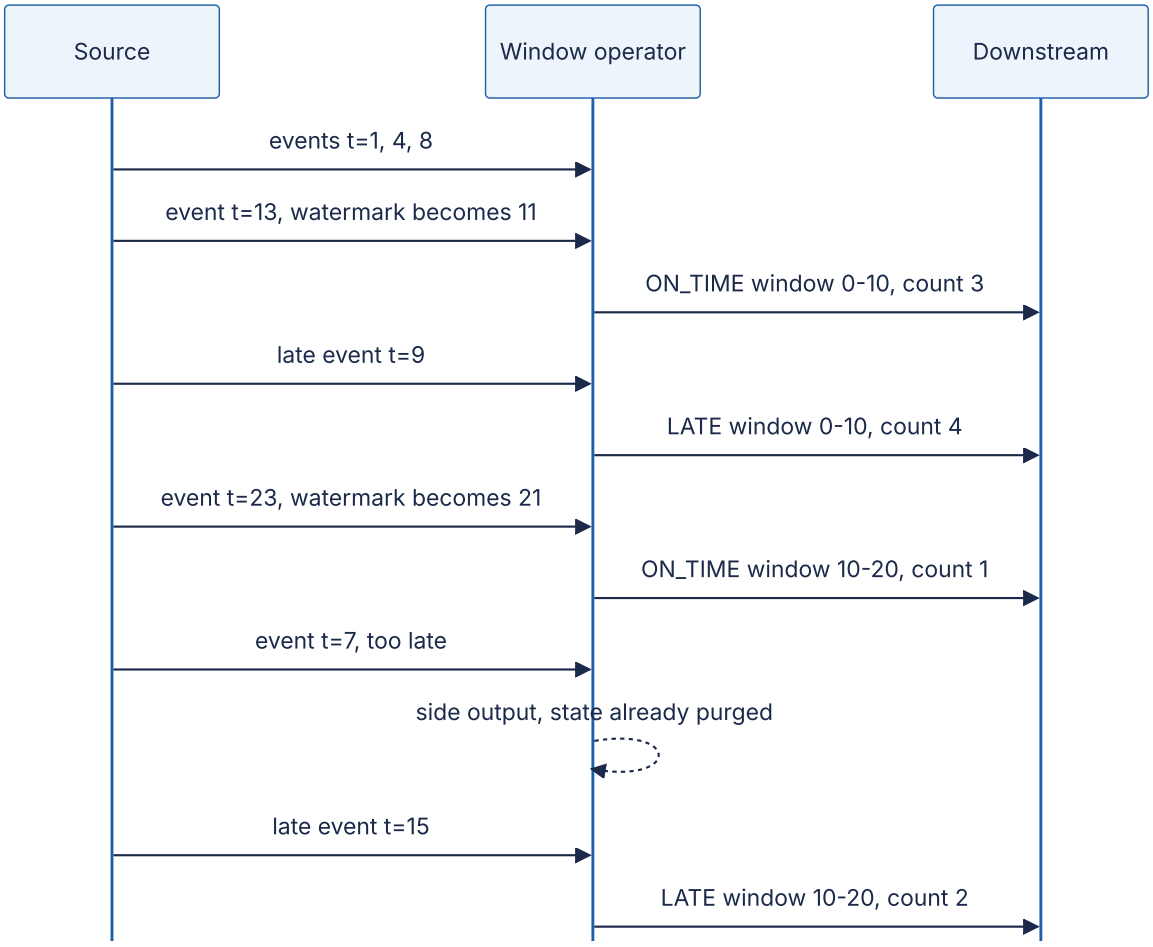
The Dataflow Model, published by Google and the basis of Google Cloud Dataflow and Apache Beam, separates four questions [Akidau et al. 2015]:

1. **What** results are computed? The transformation: sums, joins, model features.
2. **Where** in event time are they grouped? The windowing.
3. **When** in processing time are results emitted? **Triggers**: at the watermark (the on-time result), optionally early (speculative results every minute before the watermark) and late (an update for each late event).
4. **How** do successive results for one window relate? **Accumulation mode**: *discarding* (only new data), *accumulating* (the full total so far) or *accumulating and retracting*

(also withdrawing the previous value).

Allowed lateness bounds how long a window's state is kept after the watermark passes its end. Late events within it update the result; events beyond it are dropped or sent to a **side output** for separate handling. Without such a bound, state for every window ever opened would be kept forever.

Figure 29.12 — A 10 s window with a watermark, a late update and a dropped event.



Reading the diagram. This is the scenario tested by the simulator below: 10 s tumbling windows, watermark = maximum event time − 2 s, allowed lateness 5 s, accumulating mode. Event 13 moves the watermark to 11, past the end of [0, 10), so the *operator* emits its on-time count. Event 9 is late but within allowed lateness, so it triggers an update. At watermark 21 the state for [0, 10) is purged ($21 \geq 10 + 5$), so event 7 goes to the *side output*. Emissions are asynchronous. Failure point: a consumer that adds every emission would double-count; with accumulating mode it must upsert per window.

Mathematical foundations

FORMULA

Fraction of events that miss their tumbling window

$$f_{\text{late}} \approx \frac{\mu}{W} e^{-\delta/\mu}\left(1 - e^{-W/\mu}\right) \qquad \text{added output latency} \approx \delta$$

Derivation: with exponentially distributed delay d (mean μ) and the watermark close to arrival time minus δ, an event at offset u before its window's end misses the window if $d > \delta + u$; averaging $e^{-(\delta+u)/\mu}$ over u uniform on $[0, W)$ gives the formula.

Symbol	Meaning	Units
f_{late}	Fraction of events arriving after their window fired	dimensionless
μ	Mean delay between event time and arrival	s
δ	Watermark delay (bounded out-of-orderness)	s
W	Window size	s

WORKED EXAMPLE

Worked example — Choosing a watermark delay. Mobile click events have mean delay $\mu = 2$ s; windows are $W = 60$ s.

1. $\delta = 0$: $f = (2/60)(1)(1 - e^{-30}) = 0.0333$, so 3.3% of events miss their window.
2. $\delta = 5$ s: $e^{-2.5} = 0.0821$; $f = 0.0333 \times 0.0821 = 0.0027$ (0.27%), and every result is emitted 5 s later.
3. $\delta = 10$ s: $e^{-5} = 0.0067$; $f = 0.022\%$, for 10 s of extra latency.

Interpretation. Each extra μ of waiting cuts late data by $e \approx 2.7\times$, and costs that much latency on *every* result. Real delay distributions have heavy tails (phones offline for hours), so no practical δ makes f zero. **Engineering implication.** Pick δ for the latency the consumer can accept, set allowed lateness to absorb the tail (with late firings as updates), route anything later to a side output, and monitor the late fraction as a data-quality metric.

Code example

The simulator implements tumbling and sliding event-time windows with a bounded-out-of-orderness watermark, allowed lateness, on-time and late firings, state garbage collection and a side output. It checks the scenario of Figure 29.12, sliding-window member-

ship, and that no event is ever lost silently, then measures the late fraction for several watermark delays against the formula.

```
        """Event-time windowing with a bounded-out-of-orderness watermark, allowed late-
ness,
        on-time and late firings, and a side output for events that arrive too late."""
        import math
        import random

        class EventTimeWindower:
            def __init__(self, size, slide=None, max_out_of_orderness=0.0,
allowed_lateness=0.0):
                self.size, self.slide = size, slide or size        # slide == size ->
tumbling windows
                self.delta, self.lateness = max_out_of_orderness, allowed_lateness
                self.max_ts = -math.inf

all tests passed
```

What to notice:

- The late check uses the watermark *before* the event advances it, so an event cannot rescue its own window.
- Window [20, 30) fires only at `end_of_input`, which sends a final infinite watermark; Flink does the same when a bounded source finishes.
- The simulation tracks the model closely but slightly below it: the maximum event time trails the arrival clock by about 0.25 s, adding that much extra slack (the “emit delay” column), and $e^{-0.25/2} = 0.88$ explains the gap.
- With $\delta = 0$ the operator is fast but loses about 3% of events; each extra 2 s of delay divides losses by about e.

29.8.4 State and exactly-once processing

Windows, joins, deduplication and per-user features all need **state** that outlives individual events: counts per open window, the last event per user, a model's running statistics. State is partitioned by key like a shuffle. After a failure it must be recovered *consistently with the input position*: restoring counts from 12:00 but resuming input from 12:05 loses five minutes; resuming from 11:55 double-counts five.

Engines achieve **exactly-once state semantics** (effectively-once) by periodically taking a **consistent distributed snapshot** of all operator state plus source offsets and, on failure, rolling back to it and replaying input from those offsets. Events may be *processed* twice, but each affects state once. The classic algorithm is Chandy and Lamport's: a **marker** travels along every channel; a process records its state at the first marker and records in-flight messages on channels whose markers have not arrived, yielding a consistent global state without stopping the system [Chandy and Lamport 1985]. Flink's adaptation is in §29.9.2. External results are exactly-once only with idempotent or transactional sinks (§32.9; Kafka transactions in Chapter 31).

INDUSTRY EXAMPLE

Google MillWheel and Cloud Dataflow. MillWheel, Google's earlier stream processor, introduced low watermarks computed from the oldest pending work, per-key persistent state, and exactly-once delivery by deduplicating record IDs [Akidau et al. 2013]. The Dataflow Model generalized these ideas and underlies Google Cloud Dataflow; Apache Beam is its open-source SDK [Akidau et al. 2015]. *Evidence: Primary* — [Akidau et al. 2013; Akidau et al. 2015]

COMMON MISTAKE

"Exactly-once means every event is processed exactly once." It means the *effect on managed state* is as if each event were processed once. After a failure, events since the last checkpoint are reprocessed, and any non-transactional side effect (an email, an HTTP call, a write to a database without an idempotency key) happens again.

29.9 Apache Flink

29.9.1 Architecture and state

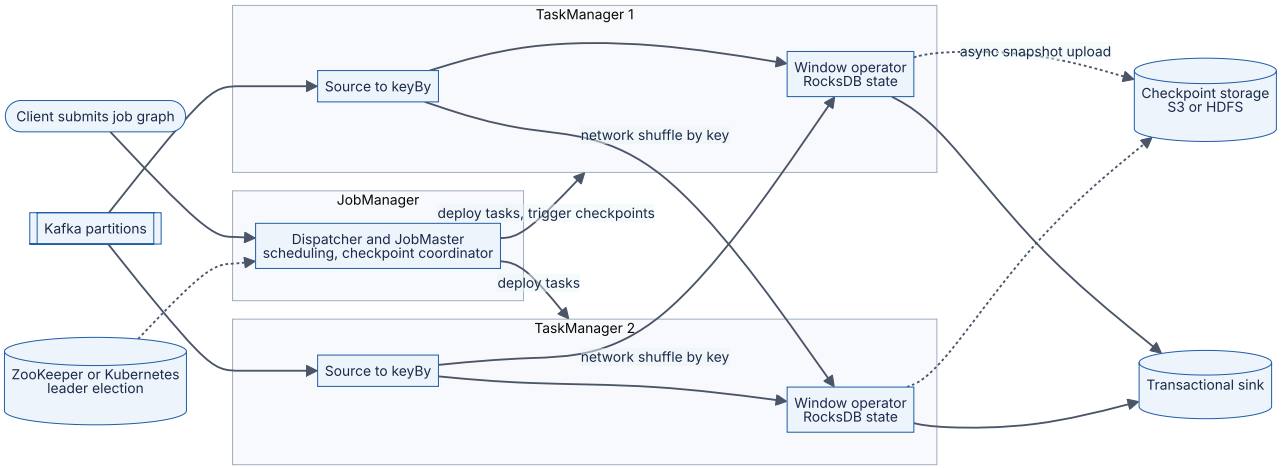
> DEFINITION
>
> **Definition — Apache Flink.** An open-source distributed engine that executes dataflow programs as a graph of long-running, pipelined operators, treating batch as a bounded special case of streaming. It provides event-time processing with watermarks, large keyed state, and exactly-once state consistency through asynchronous distributed snapshots [Carbone et al. 2015a].

A Flink cluster has a **JobManager** (a resource manager, a dispatcher, and one **JobMaster** per job that schedules tasks and coordinates checkpoints) and several **TaskManagers**, worker processes that each offer a fixed number of **task slots**. A job graph is turned into parallel subtasks; consecutive operators with the same parallelism and a one-to-one connection are **chained** into one task, so records pass between them as method calls. Unlike Spark's stage-at-a-time batch model, all stages of a streaming job run at once, and records flow continuously through network buffers between them, with **credit-based flow control** providing backpressure when a downstream task is slow (§22.10).

State comes in two kinds. **Keyed state** (value, list, map state) is scoped to the current key of a `keyBy` stream and partitioned with the stream; it is organized into **key groups**, whose number equals the job's **maximum parallelism**, so rescaling moves whole key groups between subtasks without rehashing keys. **Operator state** belongs to a parallel operator instance regardless of key; the classic example is a source's partition offsets.

State backends decide where working state lives. The **HashMapStateBackend** keeps state as heap objects: fastest, but bounded by memory and GC pressure. The **EmbeddedRocksDBStateBackend** keeps state in an embedded RocksDB LSM tree (§13.8) on local disk, serialized, so state can exceed memory by orders of magnitude at the cost of serialization on every access; it supports **incremental checkpoints** that upload only new SST files. Flink 2.0 (2025) added a disaggregated state backend, ForSt, that keeps the primary copy of state in remote storage (as of 2026). Checkpoints go to durable storage such as S3 or HDFS [Apache Flink Docs: State Backends; Carbone et al. 2017].

Figure 29.13 — Flink cluster architecture.



Reading the diagram. The *client* submits a job graph to the *JobManager*, whose JobMaster deploys tasks into *TaskManager* slots and coordinates checkpoints. Sources read *Kafka partitions* and re-partition records by key to the *window operators*, which keep state in RocksDB on local disk. Solid arrows are pipelined record streams with back-pressure; dotted arrows are asynchronous snapshot uploads and leader election for high availability. Failure points: a lost TaskManager restarts tasks from the last checkpoint; a lost JobManager fails over to a standby. Scaling: restart from a savepoint with higher parallelism.

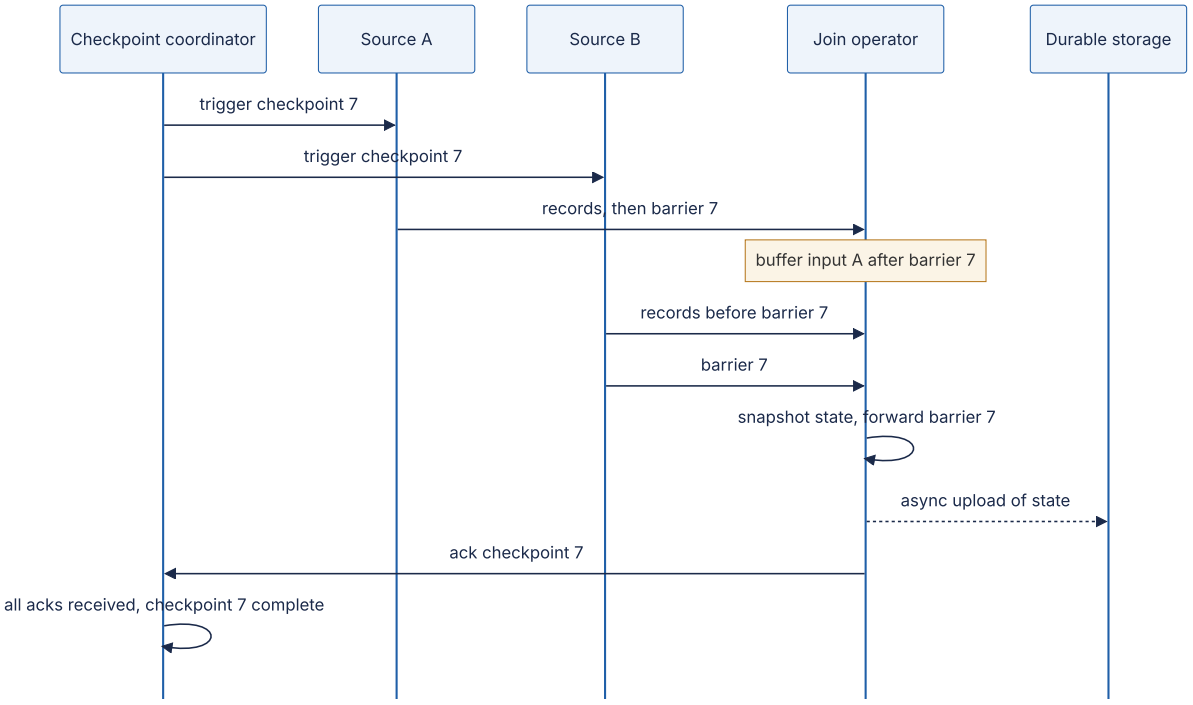
29.9.2 Asynchronous barrier snapshotting and savepoints

Flink's checkpointing is a variant of Chandy–Lamport for directed dataflow graphs, called **asynchronous barrier snapshotting** [Carbone et al. 2015b]:

1. The checkpoint coordinator tells every source to start checkpoint n. Each source records its input offset and emits a **barrier** n into its output streams, between records.
2. An operator with several inputs **aligns**: once barrier n arrives on one input, it buffers further records from that input until barrier n has arrived on all inputs. Records before the barrier belong to checkpoint n; records after it to $n+1$.
3. When aligned, the operator takes a snapshot of its state and forwards barrier n downstream. The snapshot is **asynchronous**: a quick copy-on-write or RocksDB snapshot is taken synchronously, and the upload to durable storage happens in the background while processing continues.
4. Sinks acknowledge; when every task has acknowledged, the coordinator marks checkpoint n complete. Transactional sinks then commit the output written during that checkpoint (two-phase commit), which is how Flink achieves end-to-end exactly-once with Kafka.
5. On failure, all tasks restart, load their state from checkpoint n, and sources rewind to the recorded offsets.

For acyclic graphs, alignment means in-flight channel contents need not be saved, unlike in Chandy–Lamport. Under heavy backpressure, barriers queue behind buffered data; **unaligned checkpoints** (Flink 1.11+) let barriers overtake buffered records and save those buffers in the snapshot.

Figure 29.14 — Barrier alignment in a two-input operator.



Reading the diagram. The *coordinator* triggers checkpoint 7 at both *sources*, which record their offsets and inject barriers. Barrier 7 reaches the *join operator* first from source A, so the operator pauses input A (buffering) while it keeps consuming B until B's barrier arrives. Then it snapshots state, forwards the barrier, uploads state asynchronously (dotted) to *durable storage* and acknowledges. Failure points: if any task fails before acknowledging, checkpoint 7 is abandoned and recovery uses checkpoint 6. Scaling: alignment time grows with backpressure and skew between inputs, which is what unaligned checkpoints address.

A **savepoint** is a user-triggered checkpoint in a canonical format that is never deleted automatically. To upgrade code, change parallelism or migrate clusters, stop with a savepoint, deploy the new version and resume from it; operators need stable IDs (`uid`) so state maps to the new graph.

FORMULA

Checkpoint interval: overhead versus recovery

$$T_{\text{opt}} \approx \sqrt{2CM_f}, \qquad T_{\text{catch-up}} \approx \frac{\lambda(T/2 + T_{\text{restart}} + T_{\text{restore}})}{\mu - \lambda}$$

Symbol	Meaning	Units
T, T_{opt}	Checkpoint interval; interval minimizing total lost time (Young's approximation)	s
C	Throughput-equivalent cost of one checkpoint	s
M_f	Mean time between failures of the job	s
λ	Input rate	events/s
μ	Maximum processing rate of the job	events/s
T_{restart}, T_{restore}	Time to reschedule tasks; time to download state	s
$T_{\text{catch-up}}$	Time to work off the backlog after restoring	s

WORKED EXAMPLE

Worked example — A fraud-feature job with 2 TB of state. $\lambda = 200,000$ events/s, $\mu = 500,000$ events/s; state is 2 TB over 50 TaskManagers (40 GB each), restored at 1 GB/s per node, so $T_{\text{restore}} = 40$ s; $T_{\text{restart}} = 20$ s; the job fails about once a day ($M_f = 86,400$ s); each asynchronous checkpoint costs about $C = 2$ s of throughput.

1. Young's interval: $\sqrt{2 \times 2 \times 86,400} = \sqrt{345,600} = 588$ s, about 10 minutes.
2. Catch-up at $T = 600$ s: backlog $= 200,000 \times (300 + 20 + 40) = 7.2 \times 10^7$ events; $7.2 \times 10^7 / 300,000 = 240$ s. Results are stale for $20 + 40 + 240 = 300$ s.
3. At $T = 60$ s: backlog $= 200,000 \times 90 = 1.8 \times 10^7$; catch-up 60 s; stale for 120 s. Overhead rises to $2/60 = 3.3\%$ of throughput, from 0.3%.
4. With a transactional sink, output is visible only at checkpoint completion, so $T = 600$ s adds up to 10 minutes of latency.

Interpretation. Young's formula ignores two streaming costs: catch-up, which grows with T and explodes as $\lambda \to \mu$, and sink visibility latency, which equals T.
Engineering implication. Checkpoint every 10 s to a few minutes, keep $\mu \geq 2\lambda$, use incremental checkpoints and local recovery to cut T_{restore}, and alert when checkpoint duration nears the interval.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Checkpoints time out repeatedly	Backpressure delays barriers; slow uploads	Checkpoint duration and alignment metrics	Unaligned checkpoints; scale out the slow operator	Capacity headroom; incremental checkpoints
State grows without bound	Session windows or keys never expire	State size per checkpoint rising steadily	Restart from savepoint with state TTL	State TTL, allowed-lateness bounds
Watermark stops advancing	An idle source partition emits no events	Watermark lag metric flat	Mark idle sources (`withIdleness`)	Idleness timeouts on every source
Duplicates downstream after restart	Non-transactional sink replayed	Duplicate keys in sink	Deduplicate by event ID	Transactional or idempotent sink

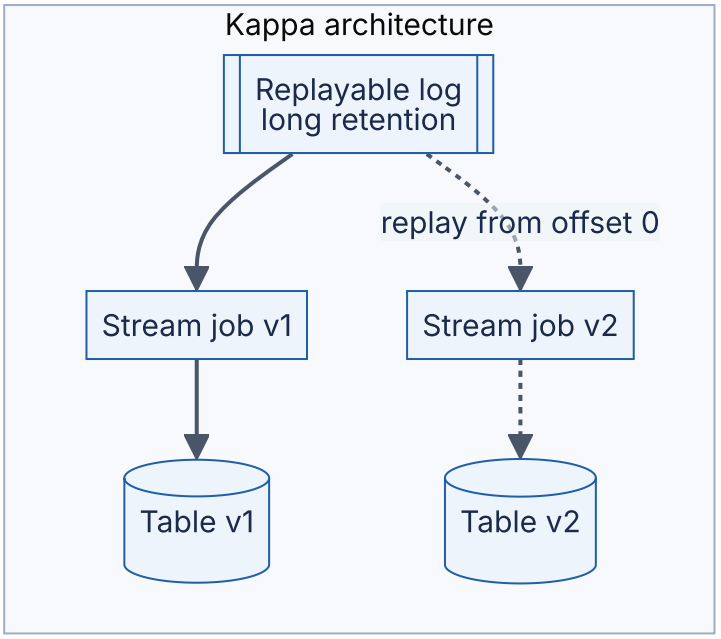
29.10 Lambda and Kappa architectures

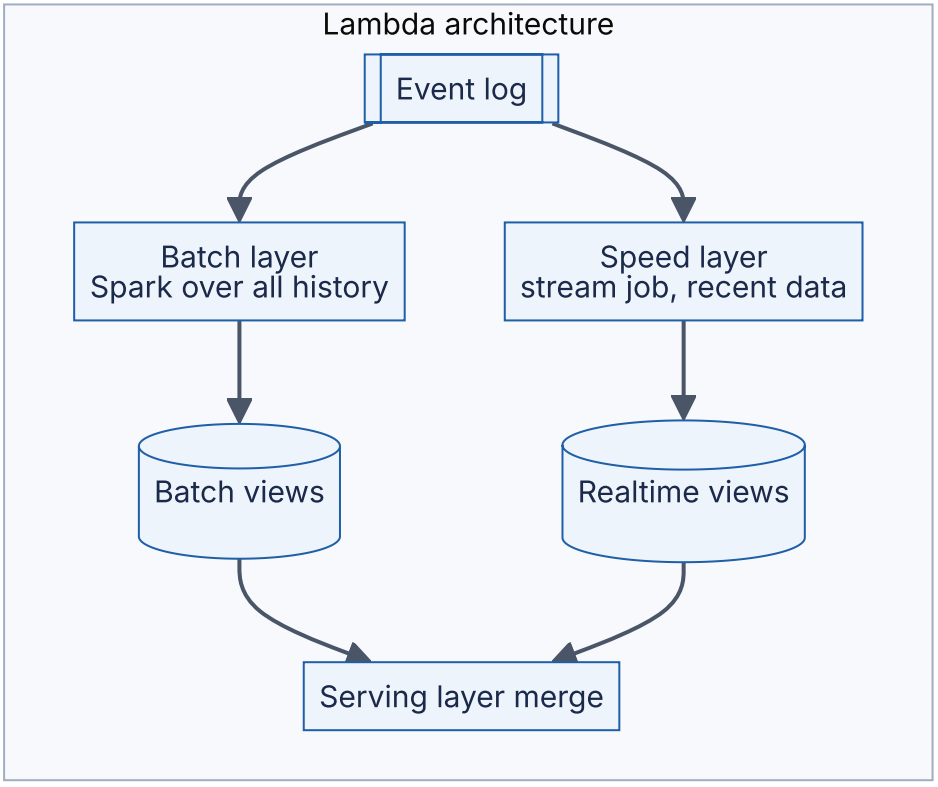
DEFINITION

Definition — Lambda and Kappa architectures. The **Lambda architecture** runs two parallel paths over the same immutable master dataset: a **batch layer** that periodically recomputes complete, accurate views from all history, and a **speed layer** that processes recent data incrementally with low latency; a **serving layer** merges the two at query time [Marz and Warren 2015]. The **Kappa architecture** uses a single stream-processing path over a replayable log; to change logic or fix a bug, it reprocesses history by replaying the log through a new version of the job [Kreps 2014].

Lambda arose when stream processors were approximate (early Storm offered at-least-once processing and no consistent state) while batch jobs were trustworthy but hours behind; batch recomputation healed the speed layer's errors. The cost, as Kreps argued, is maintaining **the same logic twice** in two frameworks and keeping them identical. Kappa removes the duplication once the stream engine is correct (exactly-once state, event time) and the log retains enough history: to deploy version 2, run a second job from the start of the log into a new table, let it catch up, switch readers, and delete version 1's output.

Figure 29.15 — Lambda versus Kappa.





Reading the diagram. In *Lambda*, one *event log* feeds a *batch layer* that recomputes *batch views* from all history every few hours and a *speed layer* that covers data since the last batch run; the *serving layer* merges both. In *Kappa*, one *stream job* consumes a *replayable log*; to change logic, *job v2* replays the log (dotted, asynchronous) into a new table and readers switch once it catches up. Storage: Lambda keeps history in files or objects; Kappa needs the log (Chapter 31) or tiered storage. Failure points: divergent logic

(Lambda); slow replay (Kappa). Scaling: replay parallelism is bounded by the log's partition count.

Replay speed decides whether Kappa is practical. Reprocessing 30 days of events at an average of 100,000 events/s means 2.6×10^{11} events; with 200 parallel tasks at 50,000 events/s each (10 million events/s), replay takes $2.6 \times 10^{11} / 10^{7} = 26,000$ s, about 7.2 hours, which is acceptable for a logic change but not for an urgent fix.

INDUSTRY EXAMPLE

Summingbird at Twitter and Kappa at LinkedIn. Twitter built Summingbird to reduce Lambda's double implementation: one Scala program is compiled to both a Hadoop batch job and a Storm streaming job, with results merged at query time [Boykin et al. 2014]. Kreps, then at LinkedIn, proposed instead reprocessing by replaying Kafka into a new job instance, which became known as the Kappa architecture [Kreps 2014]. *Evidence: Primary* — [Boykin et al. 2014; Kreps 2014]

Table 29.1 — Lambda and Kappa compared.

Aspect	Lambda	Kappa
What it is	Batch layer plus speed layer, merged at serving	One stream path; reprocess by replay
Code paths	Two, kept semantically equal	One
Correctness source	Batch recomputation heals stream errors	Exactly-once stream engine with event time
History store	Files or objects (cheap, columnar)	Log with long retention or tiered storage
Reprocessing	Rerun batch job	Replay log into a new job version
Operational complexity	High: two systems, merge logic	Medium: one system, replay capacity
Choose when	Heavy historical recomputation; stream engine cannot be trusted	Logic fits streaming; log retains enough history

In practice many teams now run a hybrid: one engine (Spark or Flink, or Beam over either) with shared code, writing streaming results into lakehouse tables that batch jobs also read and backfill (Chapters 61–62).

29.11 Batch versus stream; Spark versus Flink

Batch and streaming are two points on one spectrum: a batch job is a stream job over a bounded input whose watermark jumps to infinity at the end. The Dataflow Model and

Flink both treat them this way; Spark Structured Streaming does the reverse, running a stream as a series of small incremental batch queries [Armbrust et al. 2018].

Table 29.2 — Batch versus stream processing.

Aspect	Batch	Stream
What it is	Computation over a bounded, complete dataset	Continuous computation over an unbounded dataset
How it works	Read all input, stage by stage, write output	Long-running operators, state, watermarks, checkpoints
Advantages	Simple reasoning, easy reruns, cheap per byte	Seconds of freshness, incremental cost
Disadvantages	Hours of latency; recomputes unchanged data	Completeness is a heuristic; state and late data to manage
Performance	Throughput-optimized, minutes to hours	Latency of milliseconds to seconds
Operational complexity	Scheduler, retries, backfills	24×7 on-call, state migrations, lag monitoring
Cost	Pay per run; can use spot capacity	Always-on resources
Use cases	Reports, model training sets, backfills, index builds	Fraud, alerting, live features, dashboards
Choose when	Freshness of an hour or more is acceptable	Value decays within minutes

Table 29.3 — Apache Spark versus Apache Flink (as of 2026).

Aspect	Spark (incl. Structured Streaming)	Flink
What it is	Batch-first engine with SQL, ML and streaming	Stream-first engine; batch as bounded streams
How it works	Stages of tasks; streaming as micro-batches, plus experimental continuous mode	Pipelined long-running operators; continuous record flow
Advantages	Best-in-class batch SQL (Catalyst, AQE), huge ecosystem, Python support	Low latency, rich event-time and state APIs, large state on RocksDB
Disadvantages	Micro-batch latency floor; less flexible custom state and timers	Smaller batch and Python ecosystem; more operational tuning
Performance	Micro-batch latency of about 100 ms and up, exactly-once; continuous mode about 1 ms, at-least-once	Milliseconds, exactly-once state
Operational complexity	Lower for batch; streaming state stores simpler	Higher: checkpoints, savepoints, state backends
Cost	Efficient for large scans; can stop between runs	Always-on clusters sized for peak plus recovery headroom
Use cases	ETL, analytics, feature backfills, ML preprocessing	Fraud, CEP, real-time features, streaming ETL
Choose when	Batch dominates, latency of seconds is fine	Sub-second latency or complex event-time state

The micro-batch and continuous-mode figures are from the Spark documentation [Apache Spark Docs: Structured Streaming]. **Apache Beam** sits above both: a pipeline written once with the Dataflow Model's windowing, triggers and accumulation runs on a chosen **runner** (Google Cloud Dataflow, Flink, Spark), trading some engine-specific features for portability. Chapter 61 uses Beam and Spark for ML data pipelines.

29.12 Summary and revision notes

SUMMARY

- **Batch** processes bounded, immutable inputs for throughput; rerunning a task is safe. Scan time is $D/(Nb)$: shrink D before adding nodes.
- **MapReduce**: map → partition → sort/spill → shuffle → merge → reduce. A combiner pre-aggregates associative, commutative operations and can cut shuffle volume by 100×. Failures are handled by re-executing tasks; backup tasks tame stragglers, which appear in almost every large job ($1-(1-p)^n$).
- **Joins**: sort-merge shuffles both sides; broadcast copies the small side to every task and wins while $|S| < |L|/(N-1)$ and $|S|$ fits in memory.
- **Spark**: RDD lineage replaces replication; narrow dependencies pipeline within a stage, wide dependencies end it with a shuffle. Cache reused data. DataFrames let Catalyst prune, push down and choose joins; Tungsten generates code; AQE re-plans at shuffle boundaries (coalesce, switch to broadcast, split skew).
- **Shuffle** cost is set by the tightest of NIC, rack uplink and local disk; a 10 TB shuffle on 100 nodes needs about 100 s at best. A hot key with fraction f slows a stage by fP; salt hot keys and aggregate in two stages.
- **Locality** mattered when networks were slow; today compute and storage are disaggregated.
- **Streams**: group by event time; windows are tumbling, sliding or session; watermarks trade latency (δ) against late data ($\propto e^{-\delta/\mu}$); triggers and accumulation modes say when and how results are emitted; allowed lateness bounds state.
- **Flink**: JobManager and TaskManagers; keyed state in key groups; RocksDB for large state; asynchronous barrier snapshots give exactly-once state; savepoints enable upgrades and rescaling. Checkpoint interval trades overhead against catch-up time and sink latency.
- **Lambda** duplicates logic for freshness plus correctness; **Kappa** reprocesses by replay. Spark leads for batch, Flink for low-latency stateful streaming; Beam provides portability.

29.13 Knowledge checkpoint

1. Why do immutable inputs make batch fault tolerance simple?
2. List the steps between a map function’s output and a reduce function’s input.
3. When may the reduce function be used as a combiner?
4. A phase has 2,000 tasks and each is a straggler with probability 0.0005. What is the chance of at least one straggler?

5. Using the join-cost formula, should you broadcast a 1 GB table to 200 executors when the other side is 500 GB?
6. What is the difference between a narrow and a wide dependency, and why does it define stage boundaries?
7. What three things can Adaptive Query Execution change at run time?
8. A hot key carries 10% of rows over 400 partitions. What is the skew ratio, and what is it with a salt of 20?
9. Define event time, processing time and watermark.
10. For $\mu = 3$ s, $W = 60$ s and $\delta = 6$ s, what fraction of events misses its window?
11. What do allowed lateness and side outputs each protect against?
12. Why does a two-input Flink operator align barriers, and what do unaligned checkpoints change?
13. What is the main cost of Lambda that Kappa removes, and what does Kappa require instead?

Answers

1. A task's output depends only on its input, so rerunning it gives the same result; no undo or coordination is needed.
2. Partitioning by key, buffering, sorting by (partition, key), optional combining, spilling and merging on the map side; fetching (shuffle) and merge-sorting on the reduce side.
3. When the operation is associative and commutative and its input and output types match, so applying it zero or more times to partial groups does not change the result.
4. $1 - e^{-2,000 \times 0.0005} = 1 - e^{-1} = 0.63$.
5. Broadcast moves $1 \times 199 = 199$ GB; shuffle moves about $501 \times 0.995 = 499$ GB. Broadcast is cheaper if 1 GB fits comfortably in each executor's memory.
6. Narrow: each parent partition feeds at most one child partition, so operators pipeline in one task. Wide: a child needs many parents, requiring a shuffle and a barrier, so the scheduler starts a new stage.
7. It coalesces small shuffle partitions, converts a sort-merge join to a broadcast join, and splits skewed join partitions.
8. $0.1 \times 400 + 0.9 = 40.9$; with salt 20: $40/20 + 0.9 = 2.9$.
9. Event time: when the event happened. Processing time: when the system observes it. Watermark: an assertion that no events with earlier event time are expected.
10. $(3/60)\,e^{-2}(1 - e^{-20}) = 0.05 \times 0.135 = 0.68\%$.
11. Allowed lateness bounds state retention while still updating results for moderately late data; side outputs keep events that arrive later still from being silently lost.
12. So that the snapshot reflects exactly the records before the barrier on every input. Unaligned checkpoints let barriers overtake buffered records and save in-flight data, avoiding long alignment under backpressure.

13. Lambda maintains the same logic in two systems; Kappa needs a correct stream engine and a log retaining enough history to replay fast enough.

29.14 Interview questions

Basic

Q1. Explain MapReduce with word count. Answer. Map emits `(word, 1)` per word; a combiner sums locally; pairs are hash-partitioned by word, sorted and shuffled so every count for a word reaches one reducer, which sums them and writes the result. Failed tasks rerun because inputs are immutable.

Q2. Why is Spark faster than MapReduce for iterative jobs? Answer. MapReduce writes each job's output to replicated storage and rereads it; Spark keeps reused datasets in memory, pipelines narrow transformations within a stage, and recovers lost partitions from lineage rather than replicas. Catalyst and code generation add CPU efficiency for DataFrames.

Intermediate

Q3. A Spark job's last task runs for an hour while others take a minute. Diagnose and fix. Answer. Check the stage's task-duration and shuffle-read-size distributions. If one task reads far more data, it is key skew: find hot keys by sampling, filter junk keys, enable AQE skew-join handling, or salt and aggregate in two stages; broadcast the small side if one exists. If sizes are equal, it is a straggling node: enable speculation and check that machine.

Q4. Design per-minute click counts per page from mobile clients with delayed uploads. Answer. Key by page, one-minute tumbling event-time windows, a bounded-out-of-orderness watermark (for example 10 s from measured delay), allowed lateness of hours with accumulating late firings upserted by (page, window), a side output for later events, a nightly batch reconciliation if needed, Kafka source with checkpointed offsets, and an idempotent or transactional sink.

Advanced

Q5. How does Flink provide exactly-once results end to end with Kafka? Answer. Sources store Kafka offsets in checkpoints; barriers create consistent snapshots of all operator state; on failure, state and offsets roll back together. The Kafka sink writes inside a transaction per checkpoint, pre-commits on the barrier, and commits when the checkpoint completes; consumers read with `read_committed`. External side effects outside this protocol still need idempotency keys.

Q6. Estimate the shuffle time of a 20 TB join on 200 nodes with 25 Gb/s NICs, 10 racks and 4:1 oversubscription. Answer. NIC: about 100 GB per node at 2.19 GB/s ≈ 46 s. Uplinks (10 racks of 20): cross-rack $20 \times 0.9 = 18$ TB, 1.8 TB per rack through $20 \times 3.125/4 = 15.6$ GB/s ≈ 115 s. Disk (2 GB/s): 200 GB per node ≈ 100 s. Bound ≈ 2 minutes; expect 4–6 minutes. Then question the shuffle: can one side be broadcast or pre-bucketed?

29.15 Practical exercises

1. Extend the mini MapReduce engine with a range partitioner built from a sample, and verify that concatenating reducer outputs gives globally sorted keys.
2. Add speculative execution to the engine: give each map task a random duration with 1% stragglers at 5×, and measure job time with and without backup tasks.
3. Run the PySpark program with `spark.sql.autoBroadcastJoinThreshold=-1` and without the broadcast hint; compare the physical plans and count the `Exchange` operators.
4. Add session windows (gap g) to the windowing simulator, including merging two sessions when a late event bridges them.
5. Rerun the simulator with lognormal delays of the same mean and compare the late fraction with the exponential model.

29.16 Design challenges

1. **Daily training-set build.** 50 TB of events must be joined with a 200 GB user table and a 2 GB product table and aggregated into per-user features by 06:00 each day. Choose join strategies, partition counts and cluster size, and estimate run time and shuffle volume.
2. **Real-time fraud features.** Compute per-card counts and amounts over 1-minute, 1-hour and 24-hour sliding windows for 300,000 events/s with p99 freshness under 5 s. Choose the engine, state backend, watermark, checkpoint interval and sink, and size the state.

Part VI — Messaging and Event-Driven Systems

Chapter 30 — Messaging Fundamentals

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 2.5 h

Until now most of the services in this book have talked to each other the way people talk on the phone: one calls, the other answers, and both must be present at the same moment. This chapter introduces the alternative, the way people use a postbox. A **message broker** sits between services and holds messages until the receiver is ready, so the sender can carry on without waiting and without even knowing who will read what it sent. That single change — putting durable storage between two services — buys availability, absorbs load spikes and lets one event feed many consumers. It also brings new problems that you must design for explicitly: duplicates, reordering, messages that can never be processed, and backlogs that take hours to drain.

The running example is PhotoShare (Chapter 1). When a user uploads a photo, PhotoShare must store it, generate thumbnails, run content moderation, update the search index, notify followers and record analytics. You will see what happens when those steps are chained synchronously, then rebuild the pipeline with queues and topics, size its consumers, choose a broker, and handle the failures that messaging introduces. Kafka is introduced only briefly here; its internals are the subject of Chapter 31, and the patterns built on top of messaging (transactional outbox, sagas, CQRS, event sourcing) are the subject of Chapter 32.

30.1 Learning objectives

After this chapter you should be able to:

- Explain temporal coupling and compute the availability of a synchronous call chain versus a queue-decoupled design.
- Describe point-to-point queues, competing consumers, acknowledgments and visibility timeouts, and size a consumer fleet with Little’s Law.
- Calculate backlog drain time after an outage and choose a visibility timeout from processing-time percentiles.
- Distinguish publish/subscribe from queues, durable from ephemeral subscriptions, and estimate fan-out cost.
- Distinguish events, commands and messages, and event notification from event-carried state transfer.

- Explain the models of RabbitMQ (exchanges, bindings, quorum queues, streams), Amazon SQS and SNS (standard and FIFO, message groups), Google Cloud Pub/Sub and Apache Pulsar (brokers over BookKeeper).
- Define at-most-once, at-least-once and effectively-once delivery, and trace where duplicates come from.
- Explain per-key ordering, what breaks it, and the throughput limit it imposes.
- Design retries, poison-message handling and dead-letter queues with redrive and alerting, and implement them in a small tested queue.
- Choose between Kafka, RabbitMQ, SQS and Pulsar for a given workload.

30.2 Prerequisites

- Availability arithmetic for series and parallel components — §4.14 (the sync-versus-async comparison is a series calculation).
- Queueing and Little's Law — §4.10–§4.11 (consumer sizing and backlog latency).
- HTTP and RPC request/response — §8.6 and §8.8 (the synchronous baseline that messaging replaces).
- Timeouts, retries with backoff and jitter — §22.11–§22.12 (consumers retry too).
- Backpressure — §22.10 (what a bounded system does when consumers fall behind; owned there).
- Idempotency keys — §22.15 (the consumer-side defense against duplicates; owned there).
- Raft consensus — §26.7 (how replicated queues such as RabbitMQ quorum queues stay durable and available).
- Units: **KB/MB/GB** are powers of ten; a "30-day month" is 43,200 minutes.

30.3 Synchronous vs asynchronous communication

30.3.1 Temporal coupling

DEFINITION

Definition — Synchronous communication. An interaction in which the sender waits for the receiver to process a request and return a response before it continues; both parties must be running and reachable at the same time.

DEFINITION

Definition — Asynchronous (message-based) communication. An interaction in which the sender hands a **message** to an intermediary — a **message broker** — and continues without waiting for the receiver to process it. The broker stores the message until a receiver takes it, so sender and receiver need not be available at the same time.

First-principles explanation

A phone call needs both people on the line. If your friend is in a meeting, the call fails and you must try again later. A letter does not: you drop it in a postbox, the postal service keeps it, and your friend reads it when they get home. The postal service has removed **temporal coupling** — the requirement that both parties be available at the same moment.

Eugster et al. identify three kinds of decoupling that a messaging intermediary can provide [Eugster et al. 2003]:

1. **Time decoupling.** Sender and receiver need not be running at the same time; the broker stores messages in between.
2. **Space decoupling.** The sender need not know who, or how many, the receivers are; it addresses a queue or topic, not a host.
3. **Synchronization decoupling.** The sender is not blocked while the message is processed, and the receiver is notified (or polls) in its own thread of control.

An HTTP call provides none of these. A queue provides all three.

Why does this exist?

Three engineering problems drive services toward messaging:

1. **Availability multiplication.** A chain of synchronous calls is up only if *every* link is up, so availability falls with every hop (formula below).
2. **Load mismatch.** Producers are bursty (a celebrity posts and a million followers react); consumers have a fixed capacity. A queue is a buffer that lets consumers work at their own steady rate while the backlog absorbs the burst.
3. **Latency of slow, non-essential work.** A user uploading a photo needs to know it was stored, not that thumbnails exist in five sizes and every follower has been notified. Moving the slow work out of the request path cuts user-visible latency.

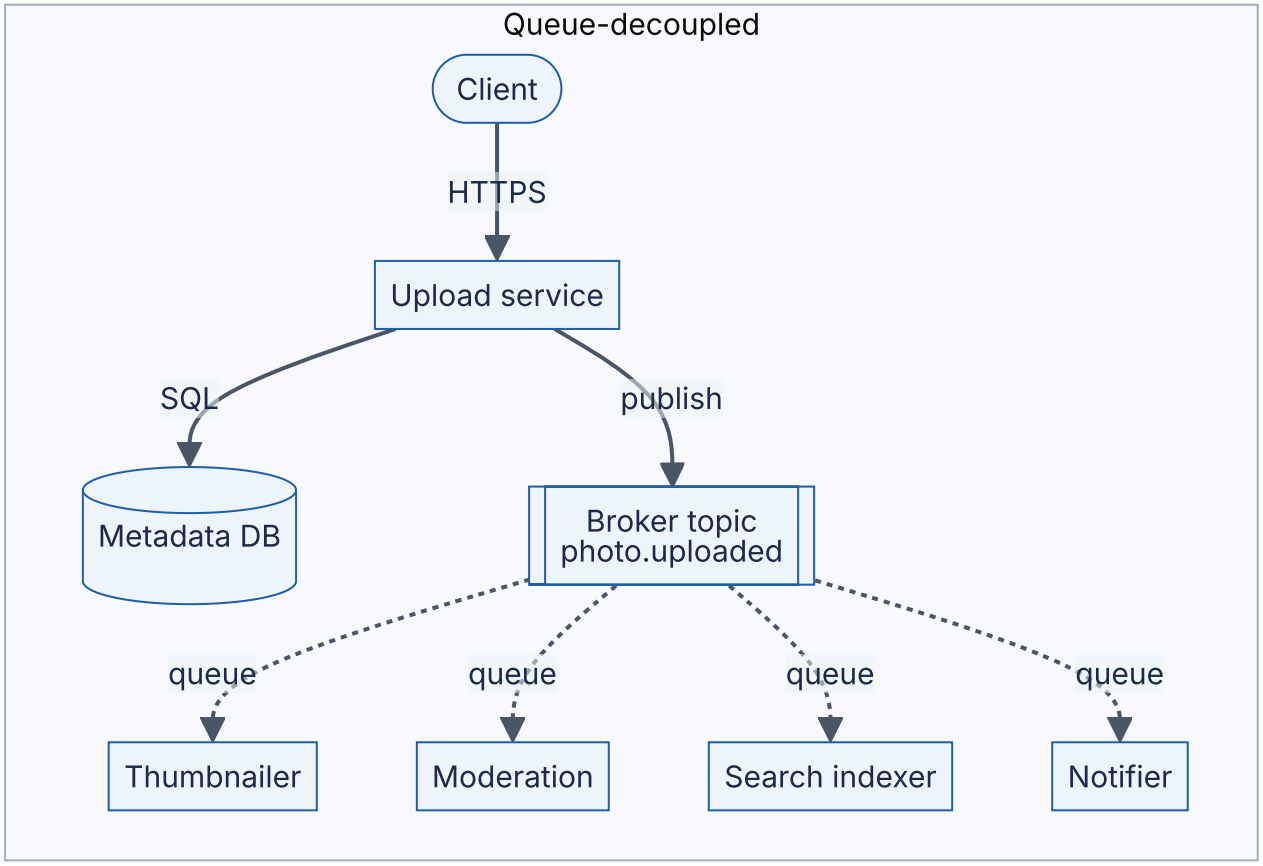
How it works internally

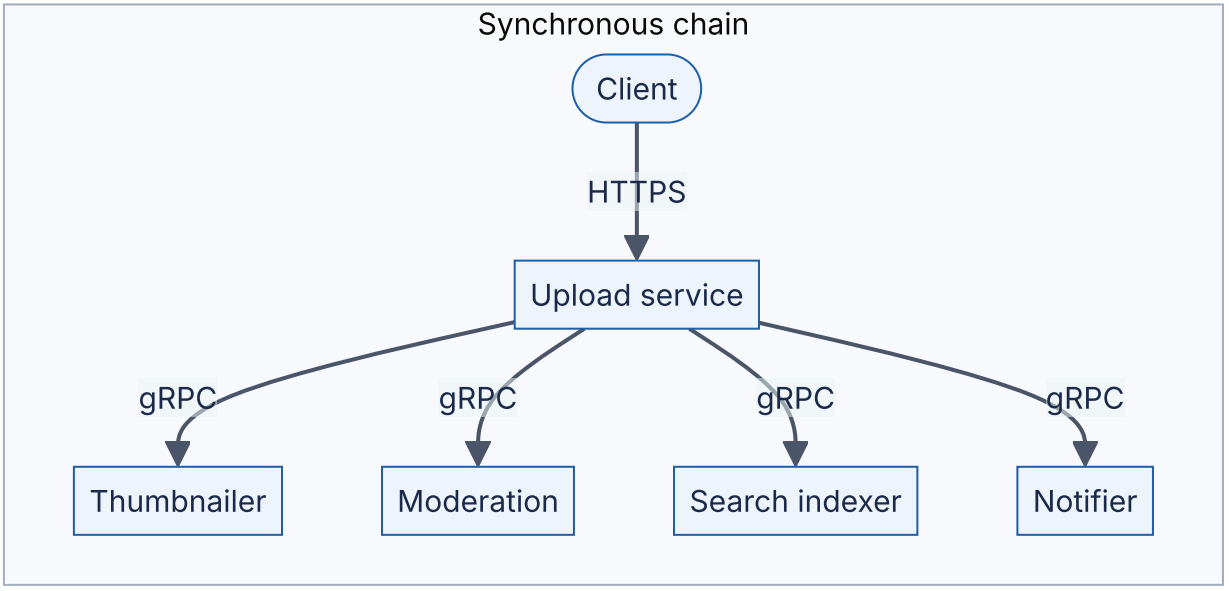
1. The producer serializes the work as a message (a payload plus headers such as an ID, type and timestamp).

2. It sends the message to the broker and waits only for the broker’s acknowledgment that the message is durably stored — typically a few milliseconds.
3. The producer returns to its own client (“upload accepted”).
4. Later — milliseconds or hours — a consumer retrieves the message, processes it and **acknowledges** it, after which the broker deletes it or marks it consumed.

Architecture diagram

Figure 30.1 — PhotoShare upload: synchronous chain versus queue-decoupled.





Reading the diagram. In the top half, the client's HTTPS request reaches the upload service, which makes four synchronous gRPC calls (solid arrows) before it can answer; the client waits for the slowest call, and a failure of any of the four services fails the upload. In the bottom half, the upload service does two synchronous things — writes the photo's metadata to its database (the storage boundary) and publishes one `photo.uploaded` message to the broker — then answers the client. Each downstream ser-

vice consumes from its own queue asynchronously (dotted arrows) at its own pace. Failure points move: a downstream outage now delays its work instead of failing uploads, while the broker becomes a new critical component that must itself be replicated. Scaling is independent: the thumbnailer can run 50 consumers while the notifier runs 5.

Mathematical foundations

FORMULA

Availability of synchronous and queue-decoupled paths (independent failures)

$$A_{\text{sync}} = \prod_{i=1}^{n} A_i \qquad A_{\text{async}} = A_{\text{front}} \times A_{\text{broker}} \times \prod_{j \in \text{sync deps}} A_j$$

Symbol	Meaning	Units
A_{sync}	Availability of a request that synchronously requires all n services	dimensionless
A_i	Availability of service i on the synchronous path	dimensionless
n	Number of services on the synchronous path, including the front service	count
A_{async}	Availability of *accepting* the request when the other work is queued	dimensionless
A_{front}	Availability of the service that receives the client request	dimensionless
A_{broker}	Availability of the broker for publishing	dimensionless
A_j	Availability of each dependency that must still be called synchronously	dimensionless

With n identical services this is simply A^n: availability decays geometrically with chain length. The asynchronous formula measures something different and weaker — that the request was *accepted* durably. The queued work completes later provided each consumer recovers before the broker's retention period expires.

WORKED EXAMPLE

Worked example — How much downtime does decoupling remove? Every PhotoShare service has $A = 0.999$; the broker has $A_{\text{broker}} = 0.9999$. Use a 30-day month of 43,200 minutes.

1. Fully synchronous (upload service plus four downstream calls, $n = 5$): $A_{\text{sync}} = 0.999^5 = 0.99501$. Unavailable fraction 0.00499, so $0.00499 \times 43,200 \approx 216$ minutes (3.6 hours) per month of failed uploads.
2. Ten services in the chain: $0.999^{10} = 0.99004$, about 430 minutes (7.2 hours) per month.
3. Hybrid: the upload service still writes synchronously to its metadata database ($A = 0.999$) and publishes to the broker: $0.999 \times 0.999 \times 0.9999 = 0.99790$, about 91 minutes per month.
4. Front service plus broker only: $0.999 \times 0.9999 = 0.99890$, about 48 minutes per month.

Interpretation. Removing four synchronous dependencies cuts failed-upload time from about 216 to about 91 minutes per month, and adding services downstream no longer costs any user-facing availability. **Engineering implication.** Keep on the synchronous path only what the client must know before it continues (here: “your photo is stored”), and make the broker more available than the services it decouples, or it becomes the new weakest link.

Advantages and disadvantages

Table 30.1 — Synchronous versus asynchronous communication.

Aspect	Synchronous (RPC, HTTP)	Asynchronous (broker)
Coupling	Time, space and synchronization	None of the three
Availability	Product of the chain	Front service × broker
User latency	Sum or max of calls	Publish time (a few ms)
Result to caller	Immediate, including errors	Later, via another message or polling
Load spikes	Must be served or rejected now	Buffered as backlog
Debugging	One trace, one stack	Distributed, needs correlation IDs
Consistency	Read-your-writes is easy	Downstream state lags (eventual consistency)
New failure modes	Timeouts, cascades	Duplicates, reordering, poison messages, backlog

Asynchrony is not free. The caller cannot get an answer, so anything the user must see immediately — a payment authorization, a login, a search result — stays synchronous. Downstream data is stale for as long as the backlog takes to drain, and the system's behavior is spread across many processes connected only by messages, which makes it harder to follow (tracing across brokers is covered in §40.6).

Failure scenarios

Table 30.2 — Failure scenarios: synchronous versus asynchronous.

What goes wrong	Why	Detection	Recovery	Prevention
Cascading timeouts in a call chain	One slow service holds every caller's threads	Rising p99, thread-pool saturation	Shed load, open circuit breakers (§22.13)	Shorter chains, deadlines, queue non-essential work
Broker outage	The new single dependency fails	Publish errors and latency	Fail over to replicas; buffer locally briefly	Replicated broker, multi-zone deployment
Silent backlog growth	Consumers slower than producers	Queue depth and age of oldest message	Scale consumers; drain	Alert on message age, autoscale on lag
User sees stale data	Work still queued	Complaints, read-after-write checks	Show "processing" state	Design the UI for eventual consistency

COMMON MISTAKE

"Asynchronous means faster." Publishing returns sooner, but the *work* takes at least as long — plus queueing time. If the user needs the result to continue, making the call asynchronous only moves the wait into polling. Use messaging for work whose result the caller does not need before it continues.

COMMON MISTAKE

"Async calls with callbacks are messaging." A non-blocking HTTP client (`async` / `await`) removes synchronization coupling inside one process, but the receiver must still be up at that moment. Only a durable intermediary removes time coupling.

30.4 Message queues

30.4.1 Point-to-point channels and competing consumers

DEFINITION

Definition — Message queue (point-to-point channel). A broker-managed, durable buffer of messages in which each message is delivered to, and processed by, exactly one of the queue's consumers; once a consumer acknowledges a message, the broker removes it [Hohpe and Woolf 2003].

DEFINITION

Definition — Competing consumers. A pattern in which several consumer processes read from the same queue concurrently, each message going to whichever consumer takes it first, so that adding consumers raises throughput [Hohpe and Woolf 2003].

First-principles explanation

Think of the ticket rail in a restaurant kitchen. Waiters clip orders to the rail; any free cook takes the next ticket; when the dish leaves the pass, the ticket is spiked and discarded. No order is cooked twice, and when the dinner rush arrives the manager adds cooks, not waiters. The rail is the queue, the cooks are competing consumers, and spiking the ticket is the acknowledgment.

The essential property is **destructive, shared consumption**: a message is work to be done once, by someone. That makes queues the right tool for *tasks* — resize this image, send this email, charge this order — and the wrong tool when several independent parties each need their own copy (§30.5).

How it works internally

1. **Send.** The producer sends a message; the broker persists it (usually replicated across nodes or availability zones) and confirms.
2. **Receive.** A consumer asks for up to *b* messages. Brokers either **push** messages to subscribed consumers up to a **prefetch** limit (RabbitMQ) or let consumers **pull** with long polling (SQS waits up to 20 seconds for a message to arrive rather than returning empty).
3. **Lease.** The broker does not delete a delivered message. It marks it **in flight** — invisible to other consumers — for a lease period: the **visibility timeout** in SQS, the **ack deadline** in Google Cloud Pub/Sub. RabbitMQ instead keeps a delivered mes-

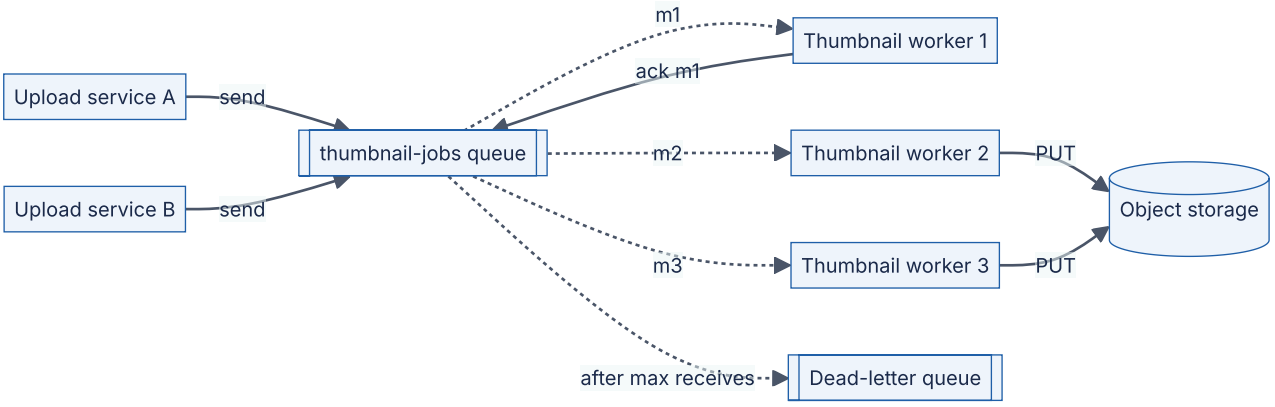
sage unacknowledged for as long as the consumer's channel stays open, and requeues it if the channel or connection closes.

4. **Process.** The consumer does the work.
5. **Acknowledge.** The consumer tells the broker it is done (SQS `DeleteMessage` with the delivery's **receipt handle**; AMQP `basic.ack`; Pub/Sub `acknowledge`). Only now is the message removed.
6. **Redeliver on failure.** If the consumer crashes, or the lease expires before the acknowledgment, the message becomes visible again and another consumer receives it. A consumer can also **negatively acknowledge** (`basic.nack`, or setting the SQS visibility timeout to zero) to release it immediately.

Acknowledging *after* processing is what makes a queue reliable: a crash at any point before step 5 leads to redelivery rather than loss. It is also why every queue that never loses messages can deliver one twice (§30.8).

Architecture diagram

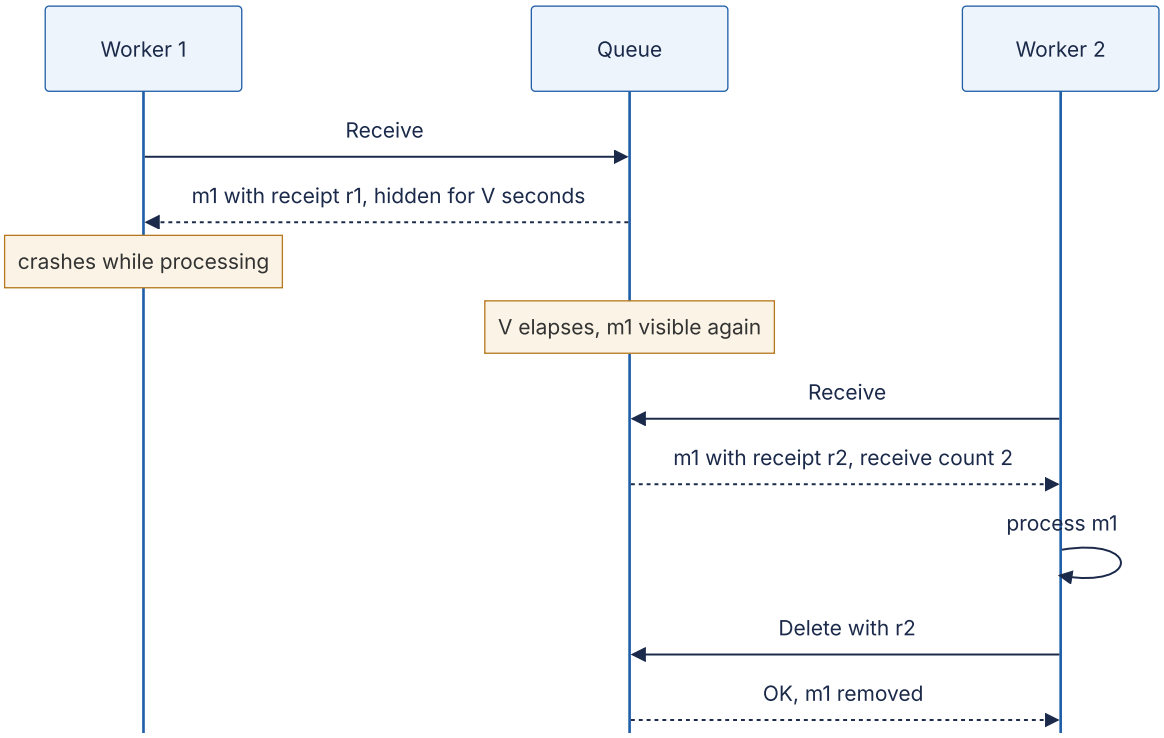
Figure 30.2 — A point-to-point queue with competing consumers.



Reading the diagram. Two upload-service instances send jobs to one queue (solid arrows: the send is a synchronous call to the broker). The queue delivers each message to exactly one of three workers (dotted: delivery is asynchronous and decoupled in time). Each worker writes thumbnails to object storage (the storage boundary outside the broker) and then acknowledges, which deletes the message; worker 1's acknowledgment is drawn as an example. A message whose processing keeps failing is moved to a dead-letter queue after a maximum number of deliveries (§30.11). Failure points: a worker crash leaves its message in flight until the lease expires; a broker-node failure is covered by replication inside the broker. Scaling: add workers until the queue's own throughput or the downstream storage becomes the limit.

30.4.2 Acknowledgments and the visibility timeout

Figure 30.3 — The visibility timeout: success, crash and redelivery.



Reading the diagram. Worker 1 receives message m1 with receipt r1, and the queue hides m1 for *V* seconds. Worker 1 crashes before acknowledging, so nothing happens until the timeout elapses; m1 then becomes visible and worker 2 receives it with a *new* receipt r2 and a receive count of 2. Worker 2 processes it and deletes it using r2. All calls are synchronous request/response between worker and queue; the redelivery itself is time-driven. The failure point to notice is the gap: m1 waited a full *V* before anyone retried it. Had worker 1 merely been slow rather than dead, both workers would have processed m1 — a duplicate.

The visibility timeout is therefore a trade-off with no free setting. Too short, and slow-but-healthy consumers lose their lease and the message is processed twice. Too long, and a crash delays the retry by the full timeout. Long-running consumers escape the dilemma with a **heartbeat**: start with a modest timeout and periodically extend it while work progresses (SQS `ChangeMessageVisibility`; Pub/Sub `modifyAckDeadline`, which its client libraries do automatically). As of 2026, SQS defaults to 30 seconds and allows 0 seconds to 12 hours [AWS Docs: SQS]; Pub/Sub defaults to 10 seconds and allows up to 600 seconds per extension [Google Cloud Docs: Pub/Sub]; RabbitMQ closes a channel whose delivery stays unacknowledged longer than its consumer timeout (30 minutes by default) and requeues its messages [RabbitMQ Docs: Confirms].

FORMULA

Visibility-timeout sizing

$$V \geq b \cdot S_{\text{tail}} + \delta$$

Symbol	Meaning	Units
V	Visibility timeout (lease length)	s
b	Messages received per batch and processed sequentially under one lease	messages
S_{tail}	High-percentile (for example p99.9) processing time per message	s
δ	Margin for acknowledgment latency, pauses and retries inside processing	s

WORKED EXAMPLE

Worked example — Sizing the thumbnail queue's timeout. Workers receive batches of $b = 10$ messages and process them one after another. Measured processing time per message: p50 0.4 s, p99.9 2.5 s. Allow $\delta = 10$ s.

1. Worst plausible batch: $10 \times 2.5 = 25$ s.
2. $V \geq 25 + 10 = 35$ s; round to 40 s.
3. The default of 30 s would expire during an unlucky batch and cause the last few messages to be processed twice.
4. Crash cost: a dead worker's 10 messages reappear only after up to 40 s.
5. Alternative: receive one message at a time ($b = 1$) with $V = 15$ s, or keep $b = 10$ with $V = 30$ s and extend the lease after each message.

Interpretation. The timeout must cover the *batch*, not the average message. **Engineering implication.** Size V from tail latency and batch size; when processing time is unbounded (video transcoding), use heartbeats rather than an hours-long timeout that would make crash recovery equally slow.

30.4.3 Sizing consumers and draining backlogs

How many consumers does a queue need? Little's Law (§4.11) answers directly: the number of messages being processed at once equals the arrival rate multiplied by the processing time.

FORMULA

Consumer count from throughput (Little's Law)

$$N = \lceil \frac{\lambda \cdot S}{k \cdot \rho} \rceil$$

Symbol	Meaning	Units
N	Number of consumer instances	instances
λ	Average arrival rate of messages	messages/s
S	Mean processing time per message, including acknowledgment	s
λS	Average messages in processing (Little's L)	messages
k	Concurrent messages per instance (threads, coroutines or prefetch)	messages
ρ	Target utilization of each processing slot	dimensionless (0–1)

WORKED EXAMPLE

Worked example — Thumbnail workers. PhotoShare receives $\lambda = 2,000$ uploads per second at peak; generating thumbnails takes $S = 150$ ms; each worker instance runs $k = 10$ concurrent jobs; target utilization $\rho = 0.7$.

1. Messages in processing: $L = \lambda S = 2,000 \times 0.15 = 300$.
2. Slots needed at 70% utilization: $300/0.7 = 428.6$.
3. Instances: $428.6/10 = 42.9$, so $N = 43$.
4. Capacity of 43 instances: $\mu = Nk/S = 43 \times 10/0.15 = 2,867$ messages/s.

Interpretation. About 43 instances keep pace with peak with 30% headroom. **Engineering implication.** Headroom is not only for spikes; it sets how quickly you recover from a backlog, as the next formula shows. Re-derive N whenever S changes — a slower downstream store raises S and silently raises N.

When consumers stop — a bad deploy, a downstream outage — producers keep sending and the backlog grows at rate λ. When consumers return, they drain it only with their *surplus* capacity.

FORMULA

Backlog drain time

$$T_{\text{drain}} = \frac{B}{\mu - \lambda}, \qquad \mu = \frac{Nk}{S}, \qquad B = \lambda \cdot T_{\text{out}}$$

Symbol	Meaning	Units
T_{drain}	Time to return to a near-empty queue	s
B	Backlog when consumers resume	messages
T_{out}	Duration of the consumer outage	s
μ	Maximum consumer throughput	messages/s
λ	Arrival rate during the drain	messages/s

WORKED EXAMPLE

Worked example — Recovering from a 30-minute outage. Thumbnail workers are down for $T_{\text{out}} = 1,800$ s while uploads continue at $\lambda = 2,000$/s.

1. Backlog: $B = 2,000 \times 1,800 = 3.6$ million messages.
2. With 43 instances, $\mu = 2,867$/s; surplus $= 867$/s; $T_{\text{drain}} = 3.6 \times 10^6 / 867 \approx 4,150$ s ≈ 69 minutes.
3. Autoscaling to 100 instances: $\mu = 100 \times 10/0.15 = 6,667$/s; surplus $4,667$/s; $T_{\text{drain}} \approx 771$ s ≈ 13 minutes — if object storage can absorb 6,667 writes per second.
4. Age of the oldest message when workers resume: 30 minutes. With Little's Law (§4.11.2), a queue depth of 3.6 million at 2,867/s means a new message waits about $3.6 \times 10^6 / 2,867 \approx 21$ minutes.

Interpretation. A 30-minute outage costs more than an hour of stale thumbnails at normal headroom. **Engineering implication.** Alert on the **age of the oldest message** (SQS exposes `ApproximateAgeOfOldestMessage`), not just depth; autoscale consumers on backlog per instance; and check that retention (4 days by default in SQS, up to 14 [AWS Docs: SQS]) comfortably exceeds the longest outage you can imagine.

INDUSTRY EXAMPLE

Slack's job queue. Slack runs much of its asynchronous work (message fan-out, link unfurling, notifications) through a job queue originally built on Redis. Slack's engineers describe an incident in which a database slowdown made jobs run slower, the backlog grew until Redis ran out of memory, and the queue could no longer accept or hand out jobs. They responded by putting Kafka in front of Redis as a durable, disk-backed buffer, so that a backlog grows on disk rather than in a memory-bound store [Slack Engineering 2020]. *Evidence: Primary* — [Slack Engineering 2020]

Failure scenarios

Table 30.3 — Failure scenarios: queues and consumers.

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate processing	Lease expired while a slow consumer still worked	Same message ID processed twice	Idempotent consumer absorbs it	Size V from tail latency; heartbeat
Messages stuck for minutes	Consumer crashed holding a large prefetch or batch	Age of oldest message jumps by V	Wait for lease expiry	Small batches; health-checked consumers
Backlog never drains	$\mu \leq \lambda$ after a slowdown	Depth rising steadily	Scale out; shed optional work	Headroom; autoscaling on age
Downstream overload during drain	Many consumers hammer the database	DB latency and errors	Cap consumer concurrency	Rate-limit consumers (§22.10)
Broker memory exhaustion	Unbounded in-memory backlog	Broker memory alarms	Block publishers, add storage	Disk-backed queues; length limits

COMMON MISTAKE

"Acknowledge as soon as you receive." Acknowledging before processing turns a reliable queue into an at-most-once one: if the consumer crashes after the acknowledgment, the work is lost. Acknowledge after the side effects are durable.

30.5 Publish/subscribe

30.5.1 Topics, subscriptions and fan-out

DEFINITION

Definition — Publish/subscribe (pub/sub). A messaging style in which a publisher sends a message to a named **topic** without knowing its receivers, and the broker delivers a copy to every **subscription** registered on that topic [Hohpe and Woolf 2003; Eugster et al. 2003].

First-principles explanation

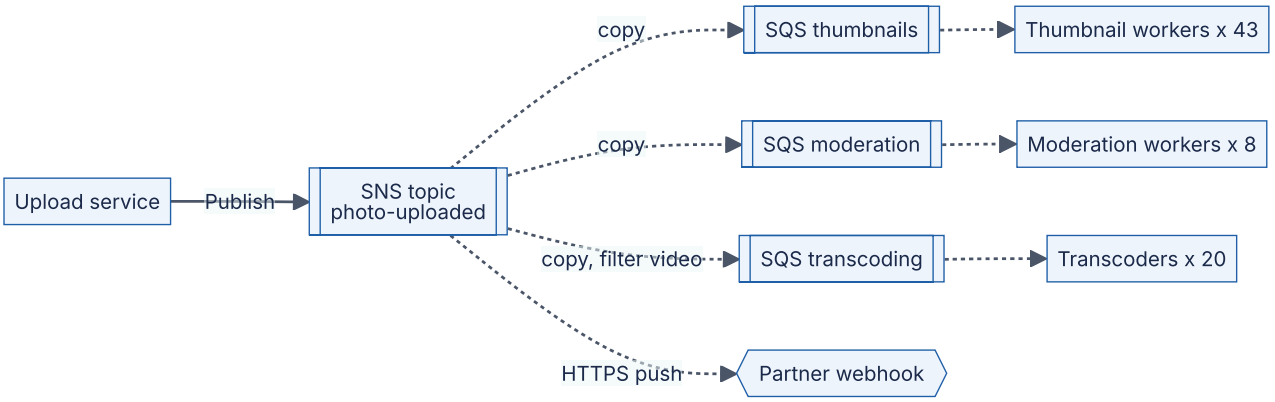
A queue is a ticket rail: each ticket is cooked once. A topic is a newspaper: every subscriber gets their own copy, and the newsroom neither knows nor cares how many there are. Adding a subscriber requires no change to the publisher — which is the point. When PhotoShare later adds a “memories” feature that needs every upload, the team creates a new subscription; the upload service is untouched. Inside a single process the same idea is the Observer pattern (§37.8), which is synchronous and keeps no messages; Table 37.1 compares the two.

The two styles compose. Each *subscription* usually behaves like a queue, with its own competing consumers, acknowledgments and backlog. Fan-out happens between subscriptions; load balancing happens within one.

How it works internally

1. Subscribers register subscriptions on the topic, optionally with a **filter** (for example, only messages whose attribute `type = "video"`).
2. The publisher sends a message to the topic; the broker stores it once or per subscription, depending on the design.
3. The broker delivers a copy to every matching subscription. Each subscription tracks its own acknowledgments, so a slow subscriber’s backlog never delays a fast one.

Figure 30.4 — Fan-out from one topic to independent subscriptions (SNS to SQS).



Reading the diagram. The upload service publishes once to an SNS topic (a synchronous API call). SNS copies the message asynchronously to three SQS queues and one external HTTPS endpoint; the transcoding subscription carries a filter, so it receives only videos. Each SQS queue is a durable storage boundary with its own pool of competing consumers. Failure points: a dead moderation fleet grows only the moderation queue; an unreachable webhook is retried by SNS under its delivery policy and can be given its own dead-letter queue. Scaling: subscriptions and their consumer pools grow independently, which is why this **topic-to-queue fan-out** is the standard AWS pattern [AWS Docs: SNS].

30.5.2 Durable and ephemeral subscriptions

DEFINITION

Definition — Durable subscription. A subscription whose messages the broker retains while the subscriber is disconnected, so the subscriber receives everything published since it subscribed, within the retention period. An **ephemeral** (non-durable) subscription exists only while the subscriber is connected; messages published while it is away are never delivered to it.

Hohpe and Woolf call the first a **Durable Subscriber**. Use durable subscriptions for business work that must not be skipped (search indexing, billing) and ephemeral ones where missed messages are worthless after a few seconds (live cursor positions, cache-invalidation hints that are also covered by TTLs, dashboards). An exclusive, auto-delete RabbitMQ queue bound to a fanout exchange, a Redis Pub/Sub channel and an SNS-to-HTTP push to a server that is down are all ephemeral in effect; an SQS queue subscribed to SNS, a Pub/Sub subscription and a Pulsar subscription cursor are durable.

Durability has a cost: a subscriber that disappears keeps accumulating messages until retention expires. Abandoned durable subscriptions are a classic source of storage alarms.

FORMULA

Fan-out delivery rate, egress and orphaned backlog

$$D = \lambda \cdot N_s, \qquad E = \lambda \cdot s \cdot N_s, \qquad B_{\text{orphan}} = \lambda \cdot s \cdot T_{\text{away}}$$

Symbol	Meaning	Units
D	Deliveries the broker performs	deliveries/s
λ	Publish rate	messages/s
N_s	Number of subscriptions (after filtering)	count
E	Broker egress	bytes/s
s	Mean message size	bytes
B_{orphan}	Storage held for one disconnected durable subscriber	bytes
T_{away}	Time the subscriber has been away	s

WORKED EXAMPLE

Worked example — PhotoShare event fan-out. The platform publishes $\lambda = 5,000$ events/s of $s = 2$ KB each to a topic with $N_s = 12$ subscriptions.

1. Deliveries: $5,000 \times 12 = 60,000$ per second, about 5.2 billion per day — and per-request pricing applies to each.
2. Egress: $5,000 \times 2,000 \times 12 = 120$ MB/s, close to 1 Gb/s.
3. One subscriber's service is turned off for 6 hours: $5,000 \times 21,600 = 108$ million messages, 216 GB retained for it alone.

Interpretation. Each subscription multiplies delivery and egress cost, and an unattended durable subscription grows by hundreds of gigabytes per day. **Engineering implication.** Filter at the broker so subscribers receive only what they need, treat subscriptions as owned resources with alarms on backlog age, and delete subscriptions whose consumers are retired.

COMMON MISTAKE

"Pub/sub replaces queues." Pub/sub decides *who* gets a copy; queues decide *how* one subscriber shares work among its instances. Nearly every production pub/sub system has a queue (or queue-like subscription) at each leaf.

30.6 Event-driven architecture

30.6.1 Events, commands and messages

DEFINITION

Definition — Message, command, event. A **message** is the transport unit a broker carries: headers plus a payload. A **command** is a message that asks one specific receiver to do something ("ResizePhoto"); it may be refused. An **event** is a message stating a fact that has already happened ("PhotoUploaded"); it cannot be refused, only reacted to, and its publisher does not know who reacts [Hohpe and Woolf 2003].

The distinction is about **direction of knowledge**. A command couples the sender to the receiver's capability: the upload service must know that a thumbnailer exists and what it needs. An event inverts that: the upload service announces what happened, and the thumbnailer decides to care. **Event-driven architecture (EDA)** is a style in which services communicate mainly by publishing and reacting to events, so that new behavior is added by adding subscribers rather than changing publishers. Its architectural treatment is in §33.8; this section covers the messaging mechanics.

Table 30.4 — Commands versus events.

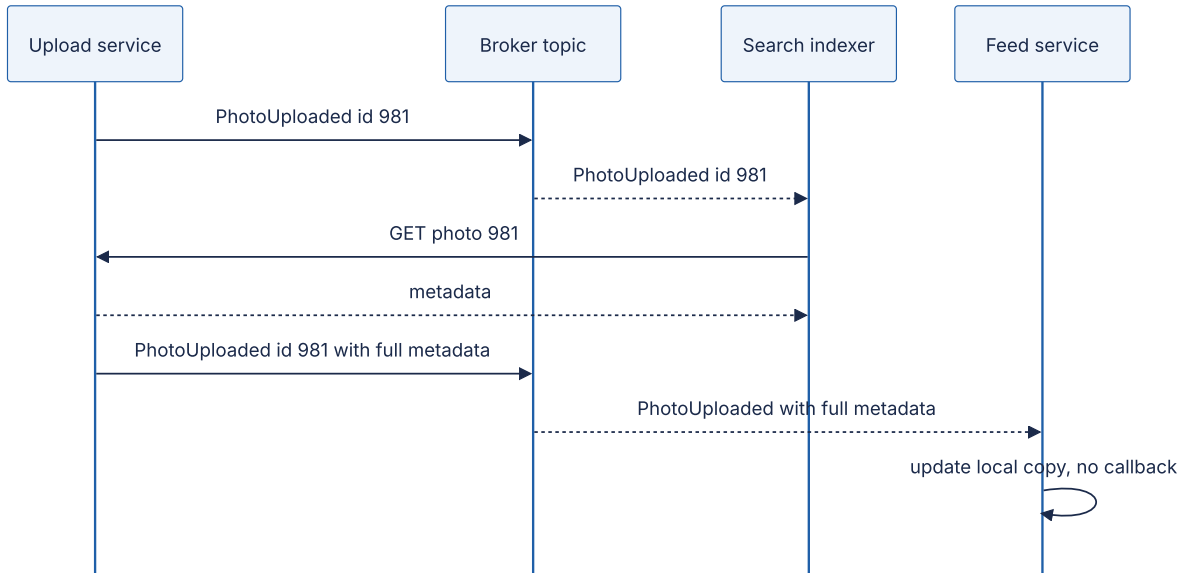
Property	Command	Event
Grammar	Imperative: `ChargeCard`	Past tense: `CardCharged`
Receivers	Exactly one logical receiver	Zero or more unknown subscribers
Channel	Queue (point-to-point)	Topic (pub/sub)
Can be rejected?	Yes, with a reply or failure	No; it already happened
Coupling	Sender knows receiver's capability	Publisher knows only its own facts
Typical use	Delegating a task	Announcing a state change

30.6.2 Event notification versus event-carried state transfer

Fowler distinguishes patterns that all get called "event-driven" [Fowler 2017]. Two concern us here (event sourcing and CQRS are in §32.3–§32.4):

- **Event notification.** The event says *that* something changed and carries little more than an identifier: `{type: "PhotoUploaded", photoId: 981}`. Subscribers that need details call back to the publisher's API.
- **Event-carried state transfer.** The event carries the state subscribers need: `{type: "PhotoUploaded", photoId: 981, ownerId: 7, url: "...", width: 4032, tags: [...]}`. Subscribers keep their own local copy and never call back.

Figure 30.5 — Event notification (with callback) versus event-carried state transfer.



Reading the diagram. In the first exchange (event notification), the upload service publishes a thin event; the broker delivers it asynchronously to the search indexer, which makes a synchronous HTTP call back to the upload service for details. The upload service is therefore still on the indexer's critical path, and a burst of events becomes a burst of callbacks. In the second exchange (event-carried state transfer), the event carries the metadata; the feed service updates its own storage without calling back. Failure points: the callback path fails when the upload service is down; the fat-event path fails when subscribers depend on fields the publisher later changes. Scaling: fat events remove callback load but enlarge every message and every subscriber's storage.

Choose event notification when payloads are large or sensitive, when subscribers need the *current* state rather than the state at event time, or when few subscribers need details. **Choose** event-carried state transfer when many subscribers need the same data, when you want subscribers to keep working while the publisher is down, and when the data is small. In both cases the event schema is a public API: version it, add fields compatibly, and validate it with a schema registry (§8.9.3 covers schema evolution and compatibility). The CNCF **CloudEvents** specification standardizes common envelope attributes (`id`, `source`, `type`, `time`, `subject`) so events can cross brokers and organizations [CNCF CloudEvents 2019].

> COMMON MISTAKE
>
> **"Events should be named after what the receiver must do."** `SendWelcomeEmail` published to a topic is a command in disguise; the publisher still knows its receiver. Name events after facts in the publisher's own domain (`AccountCreated`) and let the email service decide.

30.7 Event brokers

The ideas so far are broker-neutral. Real brokers package them differently, and the packaging decides what is easy. This section describes four widely used brokers as of 2026; Kafka, the fifth, is introduced in §30.12 and covered fully in Chapter 31. Product limits change often, so treat every number here as "as of 2026" and confirm it in current documentation before relying on it.

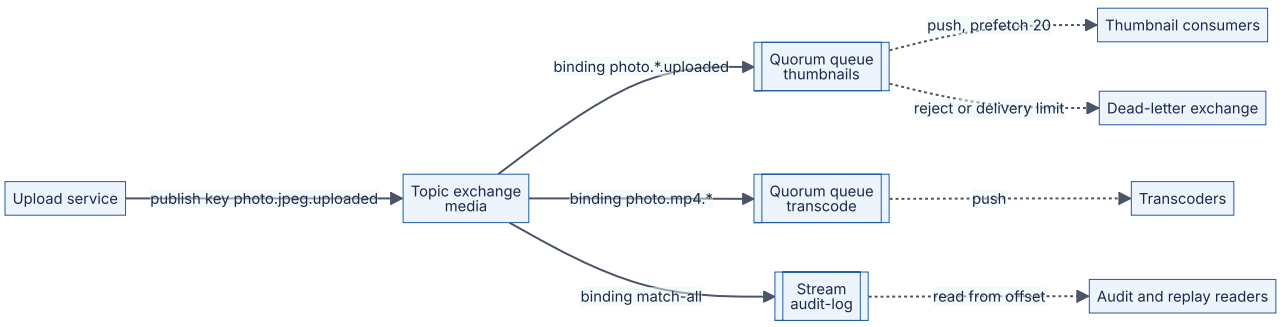
30.7.1 RabbitMQ and the AMQP 0-9-1 model

RabbitMQ is an open-source broker, written in Erlang, that implements the **AMQP 0-9-1** protocol (and, since RabbitMQ 4.0, AMQP 1.0 natively, plus MQTT and STOMP). Its central idea is that producers never write to queues directly. They publish to an **exchange** with a **routing key**; the exchange routes copies to every queue whose **binding** matches; consumers read from queues [RabbitMQ Docs: AMQP Concepts]. Routing is therefore configuration, not code.

Table 30.5 — RabbitMQ exchange types.

Exchange type	Routing rule	Typical use
Direct	Binding key equals routing key exactly	Task queues by job type; the default exchange routes to the queue named by the key
Topic	Pattern over dot-separated words: `*` matches one word, `#` matches zero or more	`photo.*.uploaded`, `audit.#`
Fanout	Ignores the key; copies to every bound queue	Broadcast to all subscribers
Headers	Matches message header values (`x-match` all or any)	Routing on several attributes

Figure 30.6 — The AMQP 0-9-1 model: exchanges, bindings and queues.



Reading the diagram. The upload service publishes over AMQP to the `media` topic exchange with routing key `photo.jpeg.uploaded`. The exchange evaluates each binding: the

key matches `photo.*.uploaded` and the match-all binding `#`, so copies go to the `thumbnails` quorum queue and the `audit-log` stream but not to `transcode`. Consumers receive from queues asynchronously; RabbitMQ pushes up to the **prefetch** count of unacknowledged messages per consumer (set with `basic.qos`). Storage lives in queues and streams, not exchanges. Messages rejected without requeue, expired, or over a delivery limit are republished to a **dead-letter exchange** (§30.11). Failure points: publishing to an exchange with no matching binding silently drops the message unless the publisher sets the `mandatory` flag or the exchange has an alternate exchange. Scaling: one queue's throughput is bounded by the node hosting its leader, so high throughput comes from many queues spread across nodes.

Reliability on both sides. Publisher confirms make the broker acknowledge each published message once it is safely stored (for quorum queues, once a majority of replicas has it); without them a publisher cannot know whether a message survived a broker crash. **Consumer acknowledgments** (`basic.ack`, `basic.nack`, `basic.reject`) work as in §30.4 [RabbitMQ Docs: Confirms].

Queue types. RabbitMQ offers three, as of 2026:

1. **Classic queues** — a single node's queue, now unreplicated: classic queue mirroring was deprecated and then removed in RabbitMQ 4.0.
2. **Quorum queues** — replicated with Raft (§26.7) across, typically, three or five nodes. A publish is confirmed when a majority stores it, and a leader failure elects a new leader without losing confirmed messages. Quorum queues track a per-message delivery count and support a **delivery limit**, after which a message is dead-lettered or dropped [RabbitMQ Docs: Quorum Queues]. They are the recommended type for data that must survive node failures.
3. **Streams** — introduced in RabbitMQ 3.9, an append-only, replicated log in which consuming does *not* remove messages. Consumers attach at an offset (first, last, next, or a timestamp), several consumers can read the same data independently, and retention is by size or age. **Super streams** partition one logical stream across several streams [RabbitMQ Docs: Streams]. Streams bring Kafka-like replay to RabbitMQ.

30.7.2 Amazon SQS and SNS

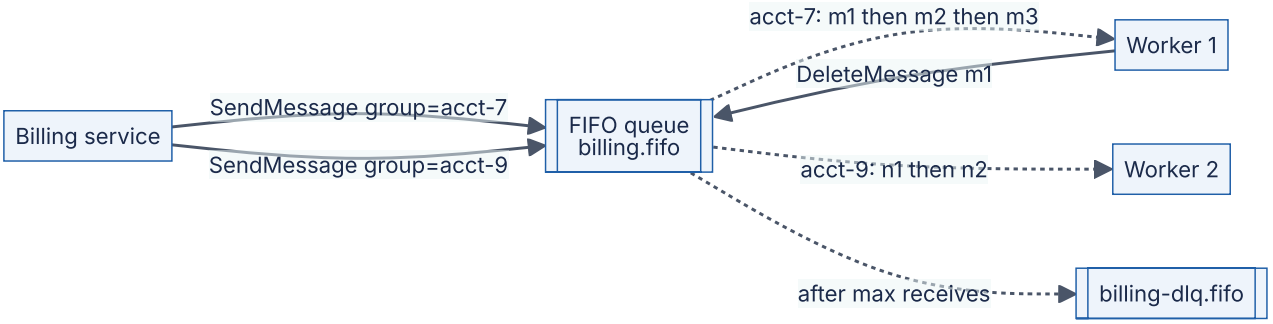
Amazon SQS is a fully managed queue service: there are no brokers to run, and you pay per request. It offers two queue types [AWS Docs: SQS]:

- **Standard queues** — at-least-once delivery, *best-effort* ordering, and a nearly unlimited number of API calls per second. Occasionally a message is delivered twice or out of order.
- **FIFO queues** — strict ordering *within a message group* and deduplication of sends: a message sent again with the same **deduplication ID** (or the same body, with con-

tent-based deduplication) within a 5-minute interval is accepted but not enqueued twice. Throughput is quota-limited (300 API calls per second per action without batching in the basic mode; much higher in high-throughput mode, varying by region).

The key FIFO concept is the **message group ID**. Messages with the same group ID are delivered in order and *one batch at a time*: while any message of a group is in flight, SQS returns no later message from that group. Different groups proceed in parallel, so the group ID is both the unit of ordering and the unit of parallelism.

Figure 30.7 — SQS FIFO message groups: ordered within a group, parallel across groups.



Reading the diagram. The billing service sends messages with a group ID per account. SQS hands account 7's messages to worker 1 strictly in order, releasing m2 only after m1 is deleted or its visibility timeout expires; account 9's messages flow to worker 2 in parallel. All calls are synchronous HTTPS API calls; delivery is pull-based. Storage is inside SQS, replicated across availability zones. Failure points: a message that keeps failing blocks *its group* (head-of-line blocking) until it moves to the FIFO dead-letter queue; a hot group is limited to one consumer's speed (§30.9). Scaling: more groups, not more workers, is what raises a FIFO queue's parallelism.

Other SQS behaviors worth knowing: long polling up to 20 s per `ReceiveMessage`; batches of up to 10 messages per call; per-message delays up to 15 minutes; retention from 60 s to 14 days; a **redrive policy** with `maxReceiveCount` that moves a message to a dead-letter queue (§30.11); and, since 2025, *fair queues*, in which standard queues use the message group ID to stop one noisy tenant's backlog from delaying the others [AWS Docs: SQS].

Amazon SNS is the managed pub/sub companion: a topic delivers to SQS queues, AWS Lambda functions, HTTP/S endpoints, email, SMS and mobile push. Subscriptions can carry **filter policies** on message attributes or payload fields, and each subscription can have its own dead-letter queue for deliveries that exhaust their retries. **SNS FIFO topics** preserve per-group order and deduplication when fanning out to SQS queues [AWS Docs: SNS]. SNS-to-SQS fan-out (Figure 30.4) is the AWS idiom for "publish once, many durable consumers".

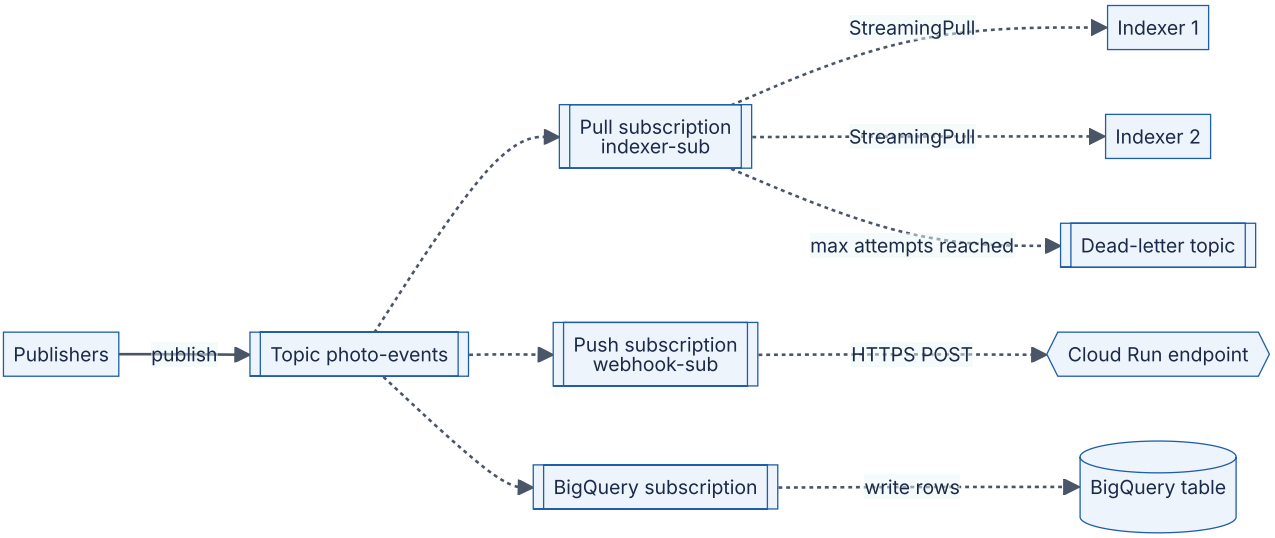
INDUSTRY EXAMPLE

Amazon SQS. SQS became generally available in 2006 and is one of the oldest AWS services. Its design choice — a standard queue that gives up strict ordering and exactly-once delivery in exchange for essentially unlimited scale — pushed a generation of engineers to write idempotent consumers, and the later FIFO type made the ordering-versus-throughput trade-off an explicit per-queue choice [AWS Docs: SQS]. *Evidence: Primary* — [AWS Docs: SQS]

30.7.3 Google Cloud Pub/Sub

Google Cloud Pub/Sub is a global, fully managed service that unifies topics and queues in one model: a **topic** fans out to any number of **subscriptions**, and each subscription is a durable queue shared by its subscribers [Google Cloud Docs: Pub/Sub].

Figure 30.8 — Google Cloud Pub/Sub: topics, subscriptions and delivery modes.



Reading the diagram. Publishers send to a topic; every message is copied to all three subscriptions (fan-out). The indexer subscription is **pull**: two indexer instances hold StreamingPull connections and share its messages (competing consumers). The webhook subscription is **push**: Pub/Sub POSTs each message over HTTPS and treats a success status as the acknowledgment. The **BigQuery subscription** writes messages directly into a table, a storage boundary with no consumer code. All delivery is asynchronous; each subscription keeps its own unacknowledged backlog. Failure points: a message that is not acknowledged within the ack deadline is redelivered; after a configured number of attempts it goes to a dead-letter topic. Scaling is automatic; the main levers are the number of subscriber instances and flow-control settings.

Features as of 2026: an ack deadline from 10 s (default) to 600 s, extended automatically by client libraries; retention of unacknowledged messages up to 7 days per subscription

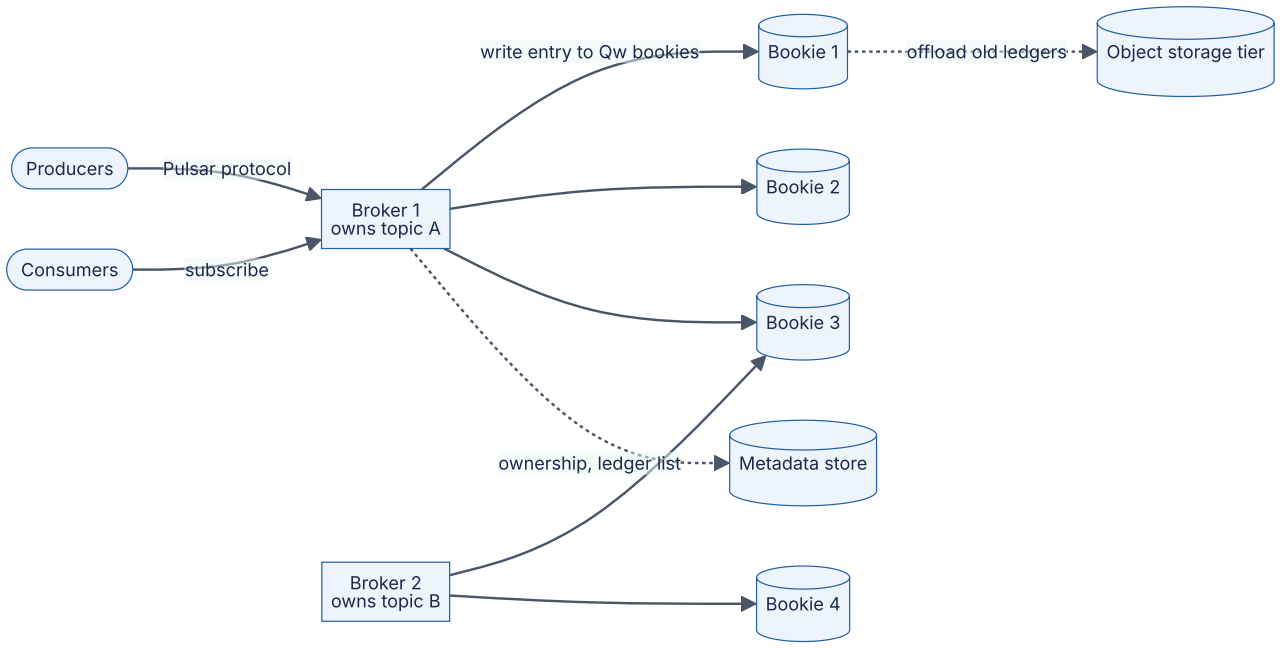
and, optionally, up to 31 days on the topic; **seek** to a timestamp or snapshot for replay; **ordering keys**, which deliver messages with the same key in publish order when the subscription enables ordering; **exactly-once delivery** for pull subscriptions within a region, which guarantees that a successfully acknowledged message is not redelivered; **dead-letter topics** with 5–100 maximum delivery attempts; and retry policies with exponential backoff [Google Cloud Docs: Pub/Sub].

30.7.4 Apache Pulsar

Apache Pulsar, created at Yahoo and an Apache top-level project since 2018, separates **serving** from **storage** [Apache Pulsar Docs]:

- **Brokers** are stateless. Each topic is owned by one broker at a time, which accepts publishes, dispatches to consumers and caches recent entries.
- **Apache BookKeeper** stores the data. A topic is a sequence of **ledgers** (segments); each ledger is written to an **ensemble** of E storage nodes called **bookies**, with each entry written to Q_w of them and acknowledged after Q_a confirm (for example $E = 3$, $Q_w = 3$, $Q_a = 2$). When a ledger closes, a new one may be placed on different bookies [Junqueira et al. 2013].
- A **metadata store** (ZooKeeper, or alternatives in newer releases) holds topic ownership and ledger lists.

Figure 30.9 — Pulsar: stateless brokers over BookKeeper segment storage.



Reading the diagram. Producers and consumers connect to the broker that owns their topic. Broker 1 writes each entry synchronously to Q_w bookies and confirms to the producer after Q_a acknowledgments; topic B's ledgers sit on a different set of bookies. Ownership and ledger metadata live in the metadata store (dotted: read and updated

asynchronously relative to the data path). Sealed ledgers can be offloaded to object storage (**tiered storage**). Failure points: if broker 1 dies, another broker takes ownership of topic A in seconds without copying data, because the data is in BookKeeper; if a bookie dies, its ledgers are re-replicated from the surviving copies. Scaling: add brokers for serving capacity and bookies for storage independently.

Pulsar supports both queueing and streaming through **subscription types**: *exclusive* and *failover* (one active consumer, ordered, stream-like), *shared* (competing consumers, queue-like) and *key_shared* (competing consumers with per-key ordering). Each subscription is a durable **cursor** over the topic, with individual acknowledgments, negative acknowledgments, a redelivery count, retry-letter and dead-letter topics in the clients, and built-in geo-replication between clusters [Apache Pulsar Docs].

INDUSTRY EXAMPLE

DistributedLog at Twitter. Twitter built DistributedLog, a replicated log service on BookKeeper, to serve as durable storage for its messaging and database replication workloads; the design segments each log into BookKeeper ledgers so that serving and storage scale separately — the same architecture Pulsar uses [Guo et al. 2017]. *Evidence: Primary* — [Guo et al. 2017]

30.8 Delivery guarantees

DEFINITION

Definition — Delivery guarantees. At-most-once: each message is processed zero or one times; failures lose messages but never duplicate them. **At-least-once**: each message is processed one or more times; failures cause duplicates but never loss. **Exactly-once** (more precisely **effectively-once**): the *observable effect* of processing is as if each message were processed exactly once, even though delivery may happen more than once.

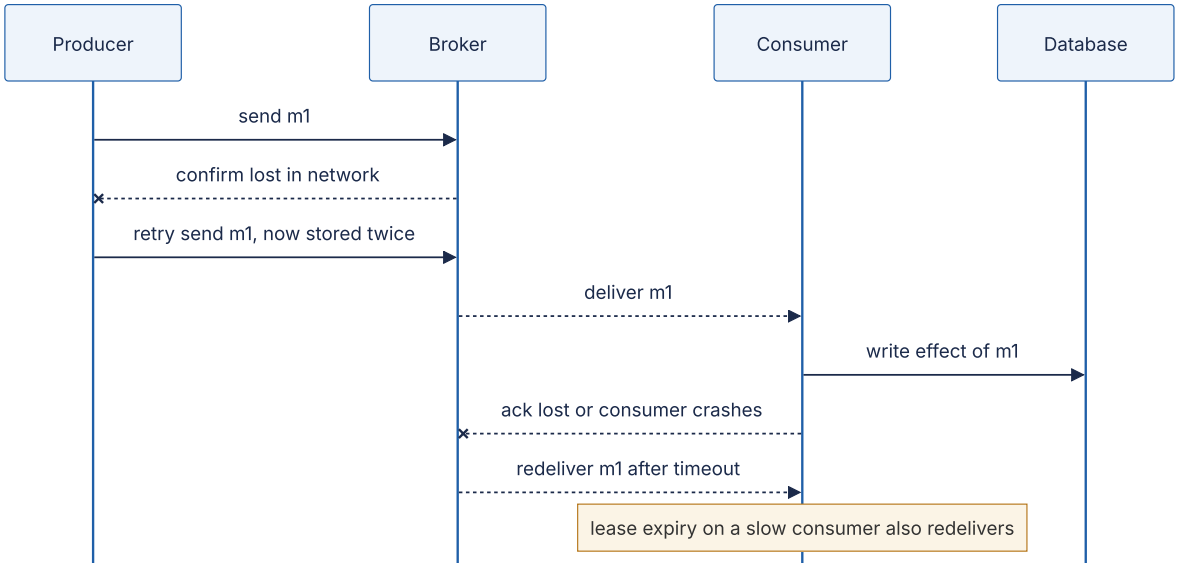
The guarantee is decided by **when the consumer acknowledges relative to its side effect**, and by whether the producer retries sends:

- Acknowledge, then process → at-most-once. A crash between the two loses the message.
- Process, then acknowledge → at-least-once. A crash between the two causes redelivery of a message whose effect already happened.
- Process idempotently, then acknowledge → effectively-once. Redeliveries happen, but the second processing changes nothing.

There is no fourth option in which the broker alone delivers each message exactly once to an arbitrary side effect: the consumer's write to its database and its acknowledgment to the broker are two different systems, and one can succeed while the other fails (the two generals problem, §24.3.3). "Exactly-once" features narrow the window rather than close it.

30.8.1 Where duplicates come from

Figure 30.10 — Three sources of duplicates.



Reading the diagram. First, the *producer* sends m1, the broker stores it, but the confirmation is lost; the producer cannot distinguish this from a lost send, retries, and the broker stores a second copy. Second, the *consumer* writes m1's effect to its database, then crashes or loses the acknowledgment; the broker redelivers m1 after the visibility timeout. Third (the note), a lease that expires while a slow consumer is still working hands the message to a second consumer (Figure 30.3). Solid arrows are synchronous calls; crossed arrows are failed messages. The storage boundary that matters is the consumer's database: it already holds m1's effect when the duplicate arrives. Rebalancing in partitioned logs is a fourth source (Chapter 31).

FORMULA

Expected duplicates under at-least-once delivery

$$E[\text{deliveries}] = \frac{1}{1-p}, \qquad r_{\text{dup}} = \lambda \cdot \frac{p}{1-p}$$

Symbol	Meaning	Units
p	Probability that a processed delivery is not successfully acknowledged (crash, lost ack, lease expiry), independent per attempt	dimensionless
$E[\text{deliveries}]$	Mean deliveries per message until one is acknowledged	deliveries
λ	Message rate	messages/s
r_{dup}	Rate of duplicate processings	duplicates/s

WORKED EXAMPLE

Worked example — How rare is rare? A notification consumer handles $\lambda = 10,000$ messages/s; one delivery in a thousand ends without an effective acknowledgment ($p = 0.001$).

1. $E[\text{deliveries}] = 1/0.999 = 1.001$.
2. $r_{\text{dup}} = 10,000 \times 0.001/0.999 \approx 10$ duplicates per second.
3. Per day: $10 \times 86,400 \approx 864,000$ duplicate notifications.

Interpretation. A 0.1% failure rate sounds negligible but produces nearly a million duplicates a day at this scale. **Engineering implication.** Every at-least-once consumer must be idempotent: record processed message IDs (or business keys) in the same transaction as the effect, or make the effect naturally idempotent (an upsert, a “set status to SHIPPED”). The full design — key scope, storage, retention and concurrency — is in §22.15; consumer patterns are in §32.10.

Table 30.6 — Delivery guarantees compared.

Guarantee	Mechanism	Loses messages?	Duplicates?	Use for
At-most-once	Ack before processing; no producer retries	Yes, on failure	No	Metrics samples, live presence
At-least-once	Ack after processing; producer retries	No	Yes, on failure	The default for business work
Effectively-once	At-least-once plus idempotent or transactional processing	No	Delivered, but without repeated effect	Payments, inventory, counters

Broker features help at specific boundaries: SQS FIFO deduplicates *sends* within 5 minutes; Pub/Sub exactly-once delivery prevents redelivery after a successful acknowledgment; Kafka's idempotent producer and transactions make read-process-write *within Kafka* atomic (§31.11). None of them can make your consumer's call to a payment provider or an email service happen once; only idempotency at that boundary can, and §32.9 discusses the limits [Kleppmann 2017, ch. 11; Helland 2007].

COMMON MISTAKE

"We use a broker with exactly-once delivery, so our consumer need not be idempotent." Broker-level guarantees stop at the broker. A consumer that sends an email and then crashes before acknowledging will send it again on redelivery, whatever the broker promised.

30.9 Ordering

DEFINITION

Definition — Message ordering. Global (total) ordering: all consumers observe all messages in one sequence. **Per-key (partial) ordering**: messages that share a key — an account, an order, a device — are processed in send order, while messages with different keys may be processed in any relative order.

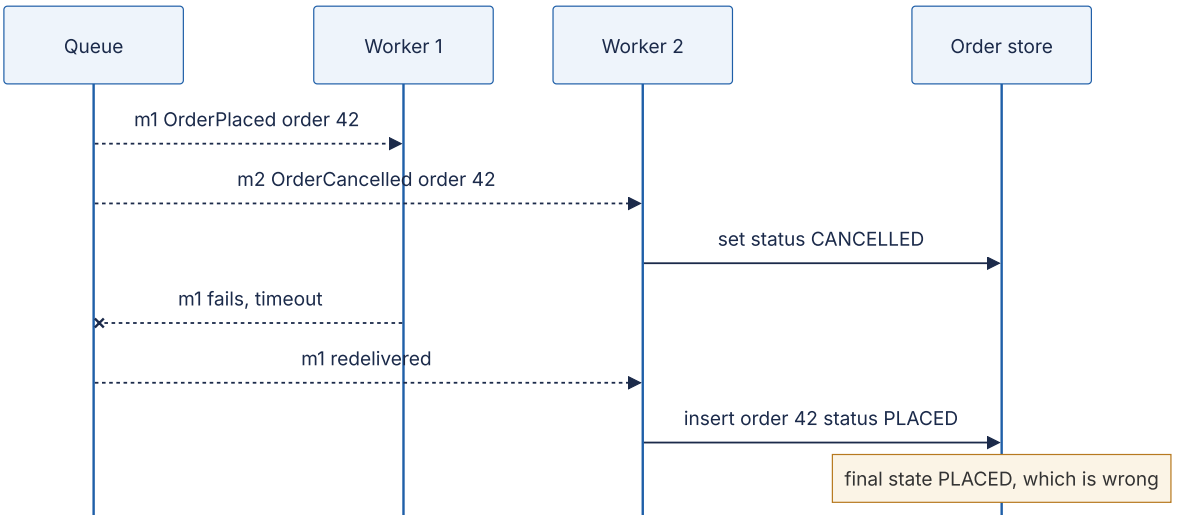
Global ordering requires a single sequence and, in effect, a single consumer at a time: its throughput is that of one consumer. Almost no business process needs it. What it needs is per-key ordering: `OrderPlaced` before `OrderCancelled` *for the same order*. Brokers express the key differently — the SQS FIFO message group ID, the Pub/Sub ordering key, the Pulsar key in a key_shared subscription, the Kafka partition key (§31.5) — but the guarantee is the same: same key, same lane, one at a time.

30.9.1 What breaks ordering

Even a broker that stores messages in order can deliver them out of order to your code:

1. **Parallel consumers.** With competing consumers, m1 goes to a slow worker and m2 to a fast one; m2's effect lands first.
2. **Retries and redelivery.** m1 fails and is redelivered after its visibility timeout, by which time m2 has been processed. Kleppmann notes that combining load balancing with redelivery inevitably reorders messages [Kleppmann 2017, ch. 11].
3. **Producer retries.** The producer sends m1, the confirmation times out, it sends m2, then retries m1: the broker now holds m2 before m1. (Kafka's idempotent producer prevents this within a partition; §31.6.)
4. **Multiple producers.** Two instances publishing events for the same key have no common clock; "send order" is undefined (§24.9).
5. **Dead-lettering.** A message moved to the DLQ and redriven later lands behind newer messages for its key.

Figure 30.11 — How parallel consumers and redelivery reorder messages for one key.



Reading the diagram. Both messages concern order 42 but go to different workers. Worker 2 applies the cancellation first; worker 1's attempt at m1 fails, and m1 is redelivered after the cancellation, so the order ends up "PLACED". Deliveries are asynchronous; writes to the order store (the storage boundary) are synchronous. Fixes: route both messages through one ordered lane (same group or partition key), or make the consumer **order-tolerant** — store a per-order version or sequence number and reject updates older than the stored one, which also defends against the other causes above.

FORMULA

Throughput limit of per-key ordering

$$X_{\text{key}} \le \frac{1}{S}, \qquad X_{\text{total}} \le \frac{\min(G, c)}{S}$$

Symbol	Meaning	Units
X_{key}	Maximum processing rate for one key (group)	messages/s
S	Mean processing time per message	s
X_{total}	Maximum processing rate for the queue	messages/s
G	Number of keys with messages waiting	count
c	Total consumer slots (instances × concurrency)	count

WORKED EXAMPLE

Worked example — A hot account in a FIFO queue. Billing events are grouped by account; $S = 50$ ms; there are $c = 200$ consumer slots and thousands of active accounts.

1. Per account: $X_{\text{key}} \le 1/0.05 = 20$ messages/s.
2. Queue: $X_{\text{total}} \le 200/0.05 = 4,000$ messages/s.
3. One large customer sends 50 messages/s. Its backlog grows by $50 - 20 = 30$ per second: after 10 minutes, 18,000 messages, which take $18,000/20 = 900$ s to process even after the burst stops.

Interpretation. Ordering turns a hot key into a single-threaded bottleneck that no amount of consumer scaling fixes. **Engineering implication.** Choose the narrowest key that preserves the invariant you need (order ID rather than customer ID), reduce S for hot keys (batch updates per key), and monitor backlog per key or group, not only per queue.

COMMON MISTAKE

"A FIFO queue guarantees the database sees updates in order." It guarantees *delivery* order per group. If your consumer hands messages to a thread pool, or performs writes asynchronously, it reintroduces the reordering the broker removed.

30.10 Retries and poison messages

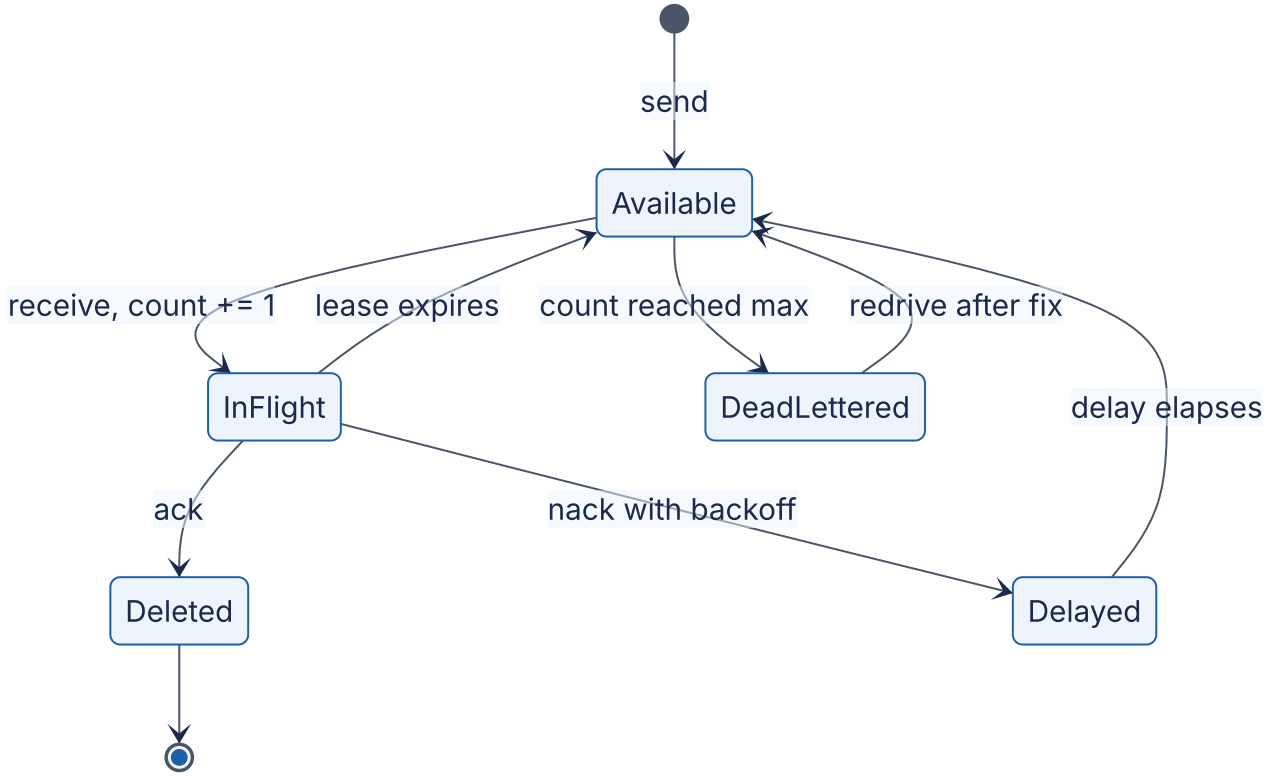
DEFINITION

Definition — Poison message. A message that fails processing every time it is delivered — because it is malformed, refers to data that does not exist, or triggers a bug — and that, if redelivered indefinitely, wastes consumer capacity and (in ordered lanes) blocks every message behind it.

Consumer failures come in two kinds, and they need opposite treatment. **Transient** failures — a downstream timeout, a throttled API, a database failover — succeed if you wait and retry. **Permanent** failures — a corrupt JPEG, a schema violation, a reference to a deleted user — fail identically on every attempt. A good consumer retries the first kind with backoff and stops retrying the second kind quickly.

1. **Classify the error.** Treat validation and parsing errors as permanent: send the message to the dead-letter queue (or an "invalid message channel" [Hohpe and Woolf 2003]) on the first attempt. Treat timeouts, 429s and 5xx responses as transient.
2. **Back off.** Retrying a transient failure immediately just repeats it, and a fleet of consumers retrying together hammers the recovering dependency. Use exponential backoff with jitter (§22.12). Brokers provide the delay in different ways: change the message's visibility timeout to the backoff delay (SQS), negatively acknowledge with a retry policy (Pub/Sub, Pulsar), or republish to delay or retry topics (the common Kafka pattern, below).
3. **Cap attempts.** A **maximum receive count** (SQS `maxReceiveCount`, the quorum-queue delivery limit, Pub/Sub maximum delivery attempts, Pulsar `maxRedeliverCount`) bounds the damage. After it, the broker moves the message to a dead-letter queue (§30.11).

Figure 30.12 — Lifecycle of a message with retries and a delivery limit.



Reading the diagram. A sent message is *Available*. Each receive makes it *InFlight* and increments its receive count. An acknowledgment deletes it. A negative acknowledgment with a backoff, or a visibility change, makes it *Delayed*; a lease that expires without an ack makes it *Available* again immediately. When an available message has already been received the maximum number of times, the broker moves it to the dead-letter queue instead of delivering it. A redrive returns it to *Available*, usually with a reset count. All transitions occur inside the broker's storage; the failure points are the two paths back to *Available*, which are where duplicates and reordering arise.

FORMULA

Time and work before a poison message is dead-lettered

$$T_{\text{DLQ}} \approx \sum_{k=1}^{R} (S_k + d_k), \qquad W_{\text{wasted}} = R \cdot \bar{S}$$

Symbol	Meaning	Units
T_{DLQ}	Time from first delivery until the message reaches the DLQ	s
R	Maximum receive count (delivery limit)	deliveries
S_k	Time attempt k runs before failing (up to the visibility timeout if the consumer hangs or crashes)	s
d_k	Delay before the next delivery (backoff; 0 if the lease simply expires)	s
W_{wasted}	Consumer time spent on the message	slot-seconds
$\bar{S}$	Mean time per failed attempt	s

WORKED EXAMPLE

Worked example — A corrupt video in a FIFO lane. The transcoding queue has visibility timeout $V = 60$ s and $R = 5$. A corrupt video makes the transcoder hang until its lease expires.

1. Each attempt costs the full lease: $S_k = 60$ s, $d_k = 0$. $T_{\text{DLQ}} \approx 5 \times 60 = 300$ s.
2. If the consumer instead detects the failure in 2 s and nacks with exponential backoff of 10, 20, 40, 80 and 160 s: $T_{\text{DLQ}} \approx 5 \times 2 + 310 = 320$ s — similar time, but only 10 s of consumer work instead of 300 s.
3. In a FIFO queue grouped by user, that user's other uploads wait behind the poison message for the whole 5 minutes.

Interpretation. Retries cost time and capacity, and in ordered lanes they cost *other messages'* latency. **Engineering implication.** Fail fast on permanent errors; use backoff for transient ones; keep R small (3–5) for ordered queues and larger (10–20) for unordered queues whose dependencies have longer outages. RabbitMQ 4.0 made a delivery limit of 20 the default for quorum queues for exactly this reason [RabbitMQ Docs: Quorum Queues].

INDUSTRY EXAMPLE

Retry topics at Uber. Uber's engineers describe a Kafka-based design in which a consumer that fails a message publishes it to a sequence of **retry topics** with increasing delays, each consumed by a retry consumer that waits until the message's delay has elapsed, and finally to a **dead-letter topic** for manual inspection. Failed messages therefore do not block the main topic's partitions, and the main consumers keep processing new messages [Xia 2018]. *Evidence: Primary* — [Xia 2018]

COMMON MISTAKE

"Infinite retries guarantee eventual success." They guarantee eventual success only for transient errors. For poison messages they guarantee wasted capacity forever and, in ordered lanes, a permanent stall.

30.11 Dead-letter queues

30.11.1 Redrive, alerting and replay

DEFINITION

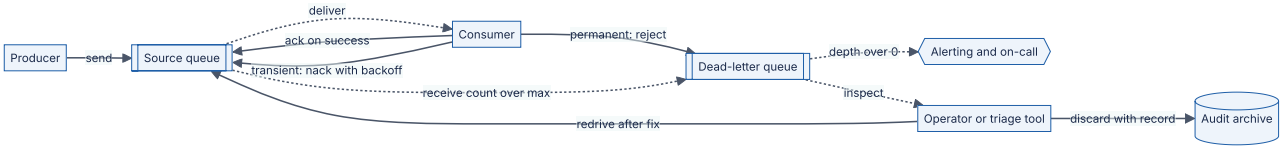
Definition — Dead-letter queue (DLQ). A separate queue or topic to which a broker or consumer moves messages that cannot be processed (delivery limit exceeded, rejected as invalid, expired), preserving them for inspection and later reprocessing instead of losing or endlessly retrying them [Hohpe and Woolf 2003, "Dead Letter Channel"].

A DLQ is a hospital ward, not a graveyard. Its purpose is to get sick messages out of the way of healthy ones while keeping them safe until someone diagnoses and fixes the cause. That gives it three operational duties:

1. **Alerting.** Any message in a DLQ means something is broken. Alert on DLQ depth greater than zero (or on its rate of arrival for noisy domains) and on the age of its oldest message. A DLQ nobody watches converts errors into silent data loss, delayed by the retention period.
2. **Diagnosis.** Keep enough context to understand the failure: the original queue, the receive count, the timestamps and, ideally, the last error. RabbitMQ adds an `x-death` header recording the reason and source queue; Pulsar and Kafka retry patterns add headers; with SQS, consumers should log the error with the message ID before giving up.

3. **Redrive and replay.** After the bug is fixed or the missing data exists, move messages back to the source queue (SQS offers a managed DLQ redrive that moves messages back with a configurable rate; Pub/Sub messages can be republished from the dead-letter subscription; RabbitMQ messages can be shovelled back). Redriven messages arrive *behind* newer messages for the same key, so the consumer must tolerate reordering (§30.9). Retention matters: a message moved from a standard SQS queue keeps its original enqueue timestamp in the DLQ, so set the DLQ's retention longer than the source queue's [AWS Docs: SQS].

Figure 30.13 — Retry, dead-letter and redrive flow.



Reading the diagram. Messages flow from producer to source queue to consumer. The consumer acknowledges successes, negatively acknowledges transient failures with a backoff delay, and rejects permanent failures straight to the DLQ; the broker itself moves messages that exceed the receive count. The DLQ triggers an alert asynchronously and is inspected by an operator or triage tool, which either redrives messages to the source queue after a fix or discards them with a record in an audit archive (the storage boundary for deliberate drops). Failure points: an unmonitored DLQ, a DLQ with shorter retention than the source, and a redrive that re-poisons the consumer because the fix was not deployed. Scaling: redrive at a controlled rate so the backlog does not overload downstream services.

30.11.2 A runnable in-memory queue with visibility timeout and DLQ

The following program implements the mechanics of this chapter in about 100 lines plus tests: competing consumers, leases, receipts, acknowledgments, heartbeats, backoff via visibility changes, a maximum receive count, a dead-letter queue and redrive. It uses a fake clock so the tests can "wait" instantly. Run it with `python3`; it prints `all queue tests passed`.

```
        """In-memory queue with visibility timeout, acks, redelivery and a dead-letter
queue."""
        import heapq
        import itertools
        from dataclasses import dataclass

        class FakeClock:
            """A controllable clock so tests can 'wait' without sleeping."""
            def __init__(self):
                self.now = 0.0

            def __call__(self):
                return self.now

            def advance(self, seconds):
                self.now += seconds

        @dataclass
        class _Message:
            id: int
            body: str
            receive_count: int = 0
            receipt: str = ""      # receipt of the latest delivery; "" = never deliv-
ered
            version: int = 0       # bumps on every reschedule; stale heap entries are
skipped

        @dataclass(frozen=True)
        class Delivery:
            receipt: str
            body: str
            receive_count: int

        class StaleReceipt(Exception):
            """The message was acked already or redelivered under a newer receipt."""

        class InMemoryQueue:
            def __init__(self, clock, visibility_timeout=30.0, max_receive_count=None,
dlq=None):
                if max_receive_count is not None and dlq is None:
                    raise ValueError("max_receive_count needs a dead-letter queue")
                self.clock, self.vt = clock, visibility_timeout
                self.max_receive_count, self.dlq = max_receive_count, dlq
                self._msgs = {}        # id -> _Message, for every message not yet acked
                self._heap = []        # (visible_at, seq, id, version): who becomes
visible when
                self._seq = itertools.count()
                self._ids = itertools.count(1)

            def _make_visible_at(self, msg, t):
                msg.version += 1
```

```
                heapq.heappush(self._heap, (t, next(self._seq), msg.id, msg.version))

            def send(self, body, delay=0.0):
                msg = _Message(next(self._ids), body)
                self._msgs[msg.id] = msg
                self._make_visible_at(msg, self.clock() + delay)
                return msg.id

            def receive(self, max_messages=1):

    test_queue()
```

What to notice:

- **One heap for all timing.** Newly sent, delayed, and in-flight messages all sit in the heap keyed by the time they become visible. A redelivery is not a special code path: an in-flight message whose lease expires simply reaches the top of the heap again.
- **Lazy invalidation.** Acknowledging or rescheduling does not search the heap; it bumps the message's `version` (or deletes it), and `receive` skips heap entries whose version no longer matches.
- **A new receipt per delivery.** `ack` and `change_visibility` require the *latest* receipt, so a slow worker whose lease expired cannot delete a message that another worker now holds. (SQS has a weaker rule — a delete with an old receipt handle may succeed without deleting the message — so do not rely on stale handles there either.)
- **Dead-lettering happens on receive.** As in SQS, a message is moved when it becomes available after its last permitted delivery, not at the moment of failure.
- **What it leaves out:** durability, replication, per-group ordering and concurrency control. Adding a `group_id` that blocks later messages of a group while one is in flight is practical exercise 1.

> RECOMMENDATION
>
> **DLQ checklist.** One DLQ per source queue (or per subscription), of the same type (FIFO for FIFO). Retention longer than the source's. An alert on depth greater than zero routed to the owning team. A runbook for triage, redrive and discard. A rate-limited redrive tool. A dashboard of DLQ arrivals by error class, because a sudden spike usually means a bad deploy rather than bad messages.

30.12 Kafka vs RabbitMQ (and SQS, Pulsar)

30.12.1 Queues versus logs

Brokers fall into two families [Kleppmann 2017, ch. 11]. **Queue-style brokers** (RabbitMQ classic and quorum queues, SQS) track each message individually and delete it once acknowledged; consumers share work message by message, and replay is impossible once a message is gone. **Log-based brokers** (Kafka, Pulsar, RabbitMQ streams) append messages to a partitioned, retained log; a consumer is just a position (an **offset**) in each partition, so many consumer groups can read the same data independently and any of them can rewind and replay. Parallelism in a log is per partition: within a consumer

group each partition is read by one consumer, which gives per-partition ordering for free but means a slow message holds up its whole partition.

Apache Kafka, created at LinkedIn [Kreps et al. 2011], is the dominant log-based broker. As of 2026 Kafka 4.x runs without ZooKeeper (metadata is managed by its own Raft-based KRaft quorum), and **share groups** (KIP-932, “Queues for Kafka”), introduced in the 4.x line, add queue-style consumption with per-message acknowledgment and delivery counts on top of the log. Chapter 31 covers partitions, replication, offsets, transactions and performance.

Table 30.7 — Kafka, RabbitMQ, SQS and Pulsar compared (as of 2026).

	Kafka	RabbitMQ	Amazon SQS (+ SNS)	Apache Pulsar
What it is	Distributed, partitioned, replicated log	General-purpose broker with flexible routing	Fully managed queue (and topic) service	Log-based broker with separate storage layer
How it works	Append to partitions; consumers track offsets	Exchanges route to queues; per-message acks; quorum queues use Raft	HTTPS API; leases via visibility timeout	Stateless brokers over BookKeeper ledgers; durable cursors
Advantages	Very high throughput, replay, many independent readers, stream processing ecosystem	Rich routing, per-message acks, priorities, low latency, many protocols	No operations, elastic scale, pay per use, DLQ and redrive built in	Queue and stream semantics, independent scaling of serving and storage, geo-replication, tiered storage
Disadvantages	Per-partition head-of-line blocking; partition count limits parallelism; no per-message retry (until share groups)	Per-queue throughput bound by one node; large backlogs are costly; replay only with streams	AWS only; standard queues unordered and duplicate-prone; FIFO throughput quotas	Most moving parts (brokers, bookies, metadata store); smaller ecosystem
Performance	Hundreds of MB/s per broker with batching; latency from milliseconds	Low-millisecond latency; tens of thousands of msg/s per queue (order of magnitude)	Effectively unlimited for standard; per-group serial for FIFO; tens of ms per call	Comparable to Kafka; low publish latency
Operational complexity	Medium–high (fewer parts since KRaft)	Medium	Very low	High
Cost	Infrastructure, or managed services	Infrastructure, or managed services	Per request and per GB; cheap at low volume, can be costly at sustained high volume	Infrastructure, or managed services
Use cases	Event streaming, CDC, logs and metrics pipelines, event sourcing	Task queues, RPC over messaging, complex routing	Decoupling AWS services, job queues, fan-out	Multi-tenant platforms, mixed queue and stream workloads, geo-distributed messaging
Choose when	You need retention, replay and many consumers of the same high-volume stream	You need per-message routing, acks and priorities on moderate volume	You are on AWS and want zero broker operations	You need both semantics, multi-tenancy or geo-replication and can operate it

Performance figures are orders of magnitude, not benchmarks: real numbers depend on message size, batching, replication, acknowledgment settings and hardware, so measure your own workload. Google Cloud Pub/Sub sits in the same niche on Google Cloud as SQS plus SNS on AWS, with fan-out and per-subscription queues in one service.

RECOMMENDATION

A default decision path. Start with the question “does more than one consumer need the *same* data, now or later?” If yes, or if you need replay, use a log (Kafka, Pulsar, RabbitMQ streams, or Pub/Sub with retention). If no, and the work is a task to be done once, use a queue (SQS, RabbitMQ quorum queues). Then let operations decide: on a cloud provider with no platform team, prefer the managed service; at sustained high volume with a platform team, self-managed or managed Kafka is usually cheaper per message.

COMMON MISTAKE

“Kafka is a faster RabbitMQ.” They answer different questions. Kafka retains an ordered log that many readers replay; RabbitMQ routes and tracks individual messages until each is acknowledged. Using Kafka as a task queue with slow, variable jobs suffers head-of-line blocking per partition; using RabbitMQ classic queues as a long-term event archive suffers memory and disk pressure.

30.13 Summary and revision notes

SUMMARY

- A **broker** removes time, space and synchronization coupling. A synchronous chain's availability is $\prod A_i$ ($0.999^5 \approx 99.5\%$); a queued design's is front service × broker. Keep synchronous only what the caller needs now.
- **Queues** deliver each message to one of many **competing consumers**. Messages are leased (visibility timeout, ack deadline) and deleted on **acknowledgment**; size the lease as $b \cdot S_{\text{tail}} + \delta$ or use heartbeats.
- Size consumers with Little's Law, $N = \lceil \lambda S/(k\rho) \rceil$; backlogs drain at the surplus, $B/(\mu - \lambda)$. Alert on the age of the oldest message.
- **Pub/sub** copies each message to every subscription; each subscription is usually a queue. Durable subscriptions retain messages while consumers are away and cost storage when abandoned.
- **Commands** ask one receiver to act; **events** state facts to unknown subscribers. Event notification is thin and invites callbacks; event-carried state transfer is fat and self-sufficient.
- **RabbitMQ**: exchanges (direct, topic, fanout, headers), bindings, quorum queues (Raft), streams. **SQS**: standard (at-least-once, best-effort order) or FIFO (message groups, 5-minute deduplication). **Pub/Sub**: topics, pull/push/BigQuery subscriptions, ordering keys, exactly-once delivery. **Pulsar**: stateless brokers over BookKeeper ledgers, four subscription types.
- Delivery: at-most-once (ack first), at-least-once (ack after), effectively-once (at-least-once + idempotent processing, §22.15). Duplicates come from producer retries, lost acks and expired leases; at 0.1% they are $\lambda p/(1-p)$ per second.
- Ordering is per key; parallel consumers, redelivery, producer retries and redrive break it. One key processes at most $1/S$ messages per second.
- Classify failures; back off transient ones; cap deliveries; dead-letter poison messages; alert on any DLQ depth; redrive after the fix.
- Queues (RabbitMQ, SQS) track messages; logs (Kafka, Pulsar, RabbitMQ streams) retain and replay them.

30.14 Knowledge checkpoint

1. Name the three kinds of decoupling a broker provides.
2. Six services each with availability 0.998 are called in series. What is the chain's availability?
3. What happens to an SQS message whose consumer crashes before deleting it?
4. A queue receives 1,200 messages/s, processing takes 250 ms, each consumer runs 8 concurrent jobs at 75% target utilization. How many consumers?

5. Those consumers stop for 20 minutes, and capacity after restart is 1,800 messages/s. How long does draining take?
6. What is the difference between a durable and an ephemeral subscription?
7. Is `ResizeThumbnail` an event or a command? Why?
8. In a RabbitMQ topic exchange, does the routing key `photo.png.uploaded` match `photo.#` and `*.uploaded`?
9. Which three mechanisms produce duplicates in an at-least-once system?
10. Why does an SQS FIFO queue's parallelism depend on the number of message groups?
11. A poison message hangs its consumer until a 45 s lease expires, with a maximum receive count of 4. Roughly when does it reach the DLQ?
12. Why should a DLQ's retention exceed its source queue's?

Answers

1. Time, space and synchronization decoupling [Eugster et al. 2003].
2. $0.998^6 \approx 0.988$, about 8.6 hours of unavailability per 30-day month.
3. It stays invisible until the visibility timeout expires, then becomes visible and is redelivered with an incremented receive count.
4. $L = 1,200 \times 0.25 = 300$; $300/(8 \times 0.75) = 50$ consumers.
5. $B = 1,200 \times 1,200 = 1.44$ million; surplus 600/s; $T = 2,400$ s $= 40$ minutes.
6. A durable subscription retains messages while the subscriber is disconnected; an ephemeral one exists only while it is connected, so messages sent in between are lost to it.
7. A command: it is imperative and addressed to a receiver with a known capability. The event would be `PhotoUploaded`.
8. Yes to `photo.#` (`#` matches zero or more words). No to `*.uploaded`: `*` matches exactly one word, but the key has three.
9. Producer retries after a lost confirm; a consumer crash or lost acknowledgment after the side effect; a lease expiring while a slow consumer still works.
10. Messages of one group are delivered one batch at a time, in order; only different groups can be processed concurrently.
11. About $4 \times 45 = 180$ s after the first delivery, when it next becomes available.
12. Because the message's age may count from its original enqueue time; a shorter DLQ retention can delete it before anyone inspects it.

30.15 Interview questions

Basic

Q1. When would you use a message queue instead of a synchronous API call?
Answer. When the caller does not need the result to continue (sending email, generating

thumbnails), when the receiver may be down or slower than the producer, or when bursts must be smoothed. Keep it synchronous when the user needs the answer now (authorization, search). Mention the availability product, backlog monitoring and idempotent consumers.

Q2. Explain the visibility timeout. Answer. A received message is hidden for a lease period rather than deleted. If the consumer deletes it in time, it is gone; if not, it reappears for another consumer. Too short causes duplicates for slow consumers; too long delays recovery after crashes; heartbeats extend the lease for long jobs.

Intermediate

Q3. Your queue's depth has grown for an hour. Walk through the diagnosis. Answer. Compare arrival and completion rates; check consumer count, errors and processing time per message (a slow dependency raises S and so the required N); look for poison messages consuming retries and for a hot key in ordered lanes; check DLQ arrivals. Mitigate by scaling consumers within downstream limits, shedding optional work, and fixing the cause; estimate drain time with $B/(\mu - \lambda)$.

Q4. How do you guarantee an order is never charged twice when payment requests arrive by queue? Answer. Accept that delivery is at-least-once. Give each request an idempotency key (order ID plus attempt), record it in the same transaction as the charge record, and pass it to the payment provider's idempotency API; on redelivery, look up the stored outcome and acknowledge. Order-sensitive steps go through a per-order lane or check a version number.

Advanced

Q5. Design the messaging for PhotoShare's upload pipeline at 2,000 uploads/s. Answer. The upload service writes metadata and publishes `PhotoUploaded` (event-carried state: IDs, URLs, type) to a topic, ideally via an outbox (§32.5). Subscriptions per consumer: thumbnails (about 43 workers, $V = 40$ s), moderation, search, notifications (video-only filter for transcoding). At-least-once with idempotent writes keyed by photo ID. Per-photo ordering is unnecessary except for edits and deletes, which carry versions. Retries with backoff, $R = 5$, a DLQ per subscription with alerts, autoscaling on age of oldest message, retention of days.

Q6. Kafka or RabbitMQ for a job system with jobs lasting 100 ms to 30 minutes? Answer. Highly variable job lengths suit per-message leasing: RabbitMQ quorum queues (low prefetch, per-message acks, delivery limit, DLX) or SQS with heartbeats. In classic Kafka consumer groups a 30-minute job blocks its partition, and parallelism is capped by partitions; share groups or a separate job queue fed from Kafka avoid that. Choose Kafka if the same events also feed analytics and need replay.

30.16 Practical exercises

1. Add FIFO message groups to the in-memory queue: while any message of a group is in flight, `receive` must skip later messages of that group. Test that two groups proceed in parallel and that a poison message blocks only its group until dead-lettered.
2. Write a consumer loop around the queue that classifies errors as transient or permanent, retries transient ones with full-jitter backoff via `change_visibility`, and rejects permanent ones to the DLQ.
3. Simulate 2,000 messages/s with exponentially distributed processing times and measure duplicate rates for visibility timeouts of 1, 2 and 5 times the mean batch time.
4. Set up RabbitMQ locally with a topic exchange, a quorum queue with a delivery limit of 3 and a dead-letter exchange; send a message the consumer always rejects and inspect its `x-death` header.

30.17 Design challenges

1. **Order notifications for a marketplace.** 20,000 order events per second at peak feed email, SMS, push, analytics and a partner webhook. Choose broker, topology, delivery guarantee, ordering key, retry and DLQ policy, and size each consumer pool.
2. **Migrating from synchronous to asynchronous.** A checkout makes seven synchronous calls with 99.9% availability each. Decide which calls stay synchronous, compute the new availability, and design how the user learns of failures that now happen after checkout returns.

30.19 Open verification items

- SQS figures as of 2026: FIFO quotas (300 calls/s basic; high-throughput mode by region); “fair queues” for standard queues (2025); DLQ enqueue-timestamp behavior for standard versus FIFO queues.
- RabbitMQ 4.0: removal of classic queue mirroring; default quorum-queue delivery limit of 20; consumer timeout default of 30 minutes.

- Pub/Sub limits: ack deadline 10–600 s; 7-day subscription and 31-day topic retention; 5–100 delivery attempts.
- Slack (2020): incident details (Redis memory exhaustion) and URL; Uber (Xia 2018) URL.
- KIP-932 share-group status in Kafka 4.x releases.
- Pulsar metadata-store alternatives (etcd, Oxia) by release.

Chapter 31 — Kafka Deep Dive

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 3 h

Chapter 30 introduced queues, publish/subscribe and delivery guarantees in general terms. This chapter takes one system apart: **Apache Kafka**, the distributed log built at LinkedIn in 2010–2011 that now sits at the center of most large event-driven architectures. Kafka is not "a queue with extra features" but a replicated, partitioned, append-only log, and nearly every behavior you will meet (per-partition ordering, consumers that rewind, durability that depends on three settings, exactly-once that stops at Kafka's edge) follows from that decision. You will follow a record from the producer's batch buffer to a consumer's committed offset and size partitions, disks and brokers with real arithmetic. Version-specific facts are stated **as of 2026** (Kafka 4.x).

31.1 Learning objectives

After this chapter you should be able to:

- Explain the log abstraction and why a shared, ordered, replayable log simplifies data integration.
- Describe a Kafka cluster in KRaft mode, the role of the controller quorum, and why ZooKeeper mode was removed.
- Size a topic's partition count from target throughput, and calculate how many keys move when the partition count changes.
- Configure a producer for throughput (batching, compression) and safety (`acks`, idempotence, in-flight limits), and explain each trade-off.
- Explain consumer groups, partition assignment, offsets and commit strategies, and derive at-least-once or at-most-once behavior from commit timing.
- Trace replication with ISR, log end offset, high watermark and leader epochs; choose `min.insync.replicas`; and explain what unclean leader election costs.
- Choose between time/size retention and log compaction.
- Explain Kafka transactions and `read_committed`, and state precisely where exactly-once ends.
- Compare eager, cooperative and KIP-848 rebalancing.
- Explain Kafka's throughput (sequential I/O, page cache, zero-copy, end-to-end batching) and estimate broker count, disk capacity, lag drain time and end-to-end latency.
- Place Kafka Streams, Kafka Connect and tiered storage in an architecture, and monitor a cluster.

31.2 Prerequisites

- Log-structured storage and compaction — §13.7 and §13.9 (a Kafka partition is a log-structured file set).
- Page cache, `mmap` and `fsync` — §6.6.6 and §6.14.3 (Kafka delegates caching and flushing to the OS).
- Sequential versus random I/O — §5.6 (the root of Kafka's speed).
- Hash partitioning and hot partitions — §14.6 and §14.10.
- Raft, ZooKeeper and fencing tokens — §26.7, §26.8 and §26.13 (KRaft, leader epochs and producer epochs are all fencing schemes).
- Primary–backup replication and failover — §27.4 and §27.11 (Kafka's ISR replication is a variant).
- Two-phase commit — §28.4 (Kafka transactions use it, §28.4.8).
- Idempotency keys and backpressure — §22.15 and §22.10.
- Messaging vocabulary — Chapter 30 (queues, pub/sub, delivery guarantees, ordering, dead-letter queues).
- Units: **KB/MB/GB/TB** are powers of ten in all estimates; **KiB/MiB/GiB** appear only where Kafka's defaults are powers of two (for example, 1 GiB segments). Network speeds are in bits per second: 25 Gb/s = 3.125 GB/s.

31.3 The log abstraction

31.3.1 What a log is

> DEFINITION
>
> **Definition — Log.** An append-only, totally ordered sequence of records. Each record is assigned a monotonically increasing integer position called its **offset** when it is appended. Records are never modified in place; readers read sequentially from any offset they choose.

First-principles explanation

Think of a ship's logbook. Entries are written one after another, each line gets the next number, nobody erases a line, and anyone can read from line 1 or from line 9,000. Two readers can be at different places in the book at the same time without disturbing each other or the writer. If a reader loses its place, it only needs to remember one number.

A database's write-ahead log (§13.5) is a log hidden inside one machine; Raft's replicated log (§26.7) is a log copied across machines to agree on an order. Kafka exposes the same structure to applications, partitions it for scale and replicates it for durability.

Why does this exist?

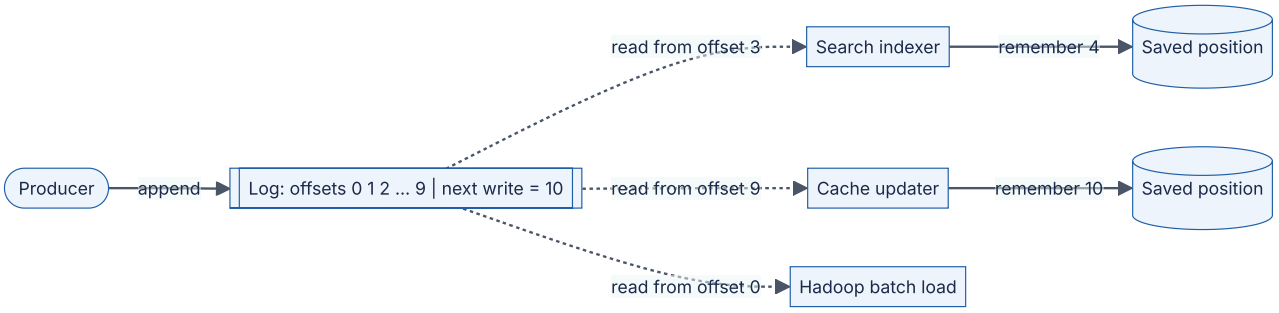
At LinkedIn around 2010, dozens of systems needed the same data: page views, profile updates and metrics flowed into Hadoop, search indexes, the social graph, monitoring and recommendation services. Each pair of systems had its own custom pipeline, so N sources and M destinations needed up to $N \times M$ integrations, each with its own failure modes. Existing message brokers kept messages in memory, deleted them once consumed, and handled neither the volume (billions of events per day) nor slow batch consumers such as Hadoop that read once an hour [Kreps et al. 2011].

Jay Kreps's 2013 essay "The Log" argued for a single abstraction: put every change into an ordered log and let every system **subscribe** at its own pace [Kreps 2013]. Integrations fall from $N \times M$ to $N + M$; a new consumer can **replay** history to build its own copy; a slow consumer does not slow the producer, because the log holds data on disk. And because the order is fixed, two consumers that apply the same log reach the same state: **state machine replication** (§26.3.2) applied to whole data systems.

How it works internally

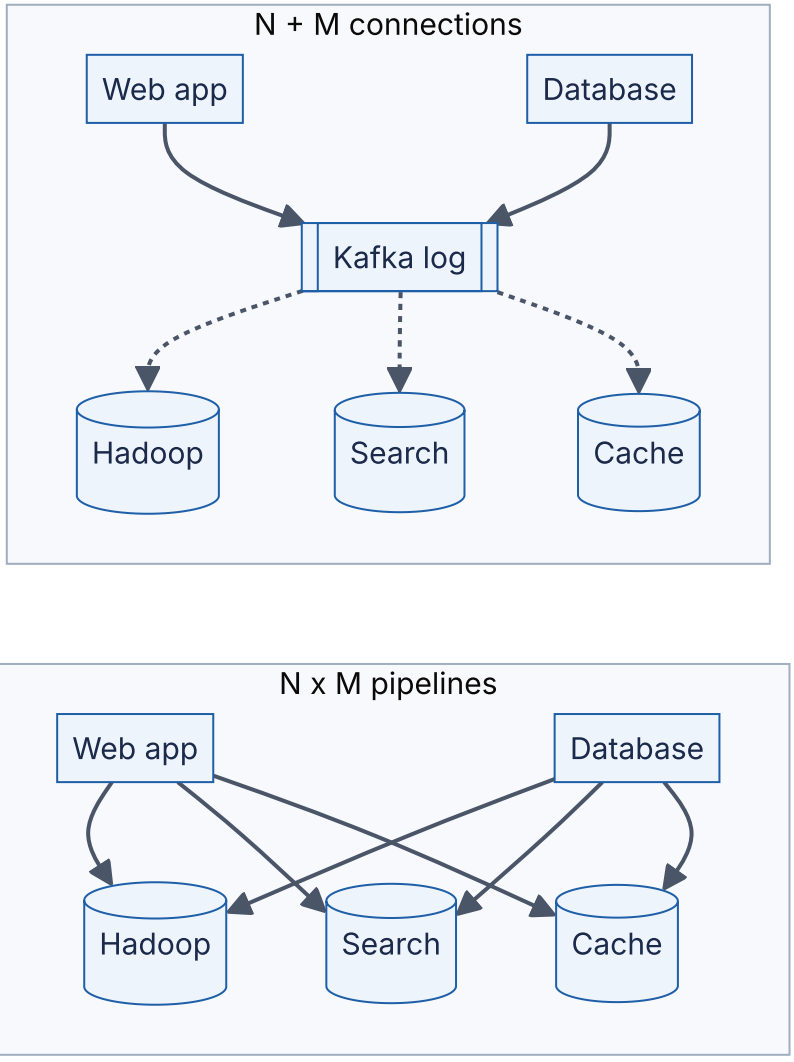
1. A producer appends a record; the log assigns the next offset (0, 1, 2, …).
2. The record is stored durably and becomes visible to readers.
3. Each consumer keeps its own **position**: the offset of the next record it will read.
4. Records are deleted only by a **retention policy** (age, size or compaction, §31.10), never because they were read.

Figure 31.1 — One log, one writer position, many independent readers.



Reading the diagram. The *producer* appends synchronously to the end of the *log*; the next write will get offset 10. Three consumers read asynchronously (dotted arrows) at different positions: the *search indexer* is at offset 3, the *cache updater* is fully caught up, and the *Hadoop batch load* is replaying from the beginning. Each consumer stores only one number, its position, in its own storage boundary. Failure points: a crashed consumer restarts from its saved position and loses nothing; if retention deletes offsets a consumer has not yet read, that consumer has fallen too far behind. Scaling: readers are independent, so adding a reader costs read bandwidth but no coordination with the writer.

Figure 31.2 — Point-to-point integration versus a central log.



Reading the diagram. On the left, every source has a custom pipeline to every destination: six links, each a separate failure point and format. On the right, sources write once to the *Kafka log* and destinations subscribe asynchronously, so a new destination adds one link and can backfill by replaying. The log is a storage boundary decoupling producers and consumers in time and speed; it is also the new single failure point, which is why the rest of the chapter replicates and partitions it.

INDUSTRY EXAMPLE

LinkedIn's activity pipeline. Kafka was built at LinkedIn to collect user activity events and operational metrics for both online consumers and offline Hadoop loads, replacing per-system pipelines. The original design deliberately used a pull model, stored messages in segment files on disk, kept no per-message acknowledgment state on the broker (consumers track offsets), and relied on the OS page cache [Kreps et al. 2011]. Later work added intra-cluster replication and described its design and LinkedIn's production use [Wang et al. 2015]. *Evidence: Primary* — [Kreps et al. 2011]; [Wang et al. 2015]

Common misconceptions

COMMON MISTAKE

"Kafka is a queue, so a message disappears once read." In a classic queue (§30.4) consumption deletes the message. In Kafka, reading only advances that consumer's offset; the record stays until retention removes it, and other consumer groups read it independently. This is why Kafka can replay, and also why "who has processed what" is the consumer's responsibility (§31.8). Kafka 4.x adds share groups for queue-like consumption (§31.7.4), but the log underneath is unchanged.

31.4 Brokers and clusters: ZooKeeper mode versus KRaft

31.4.1 Brokers, controllers and metadata

DEFINITION

Definition — Broker and controller. A **broker** is a Kafka server process that stores partition replicas and serves produce and fetch requests. The **controller** is the component that owns cluster **metadata** (which brokers are alive, which topics and partitions exist, which replica leads each partition, and the in-sync replica sets) and makes decisions such as leader election when a broker fails.

First-principles explanation

A cluster is like a library with many branches, each storing some books (partitions). Someone must keep the catalog of which branch holds the authoritative copy of each book and who takes over when a branch closes. That is the controller, and because the catalog must never have two conflicting versions, the controller itself is a consensus problem (Chapter 26).

Why does this exist? From ZooKeeper to KRaft

From 2011 until KRaft became production-ready in 2022 (and in many clusters until 4.0 removed the option), Kafka stored its metadata in **Apache ZooKeeper** (§26.8). One broker won an election in ZooKeeper to become the controller; it read all metadata from ZooKeeper, made decisions, wrote them back, and pushed them to other brokers with RPCs. This had three costs that grew with scale [KIP-500]:

1. **Two systems to operate**, each with its own configuration, security, monitoring and upgrades.
2. **Slow controller failover.** A new controller had to load every partition's state from ZooKeeper before acting, so recovery time grew linearly with partition count, capping cluster size.
3. **Divergence.** Brokers held cached metadata updated by RPC, which could disagree with ZooKeeper.

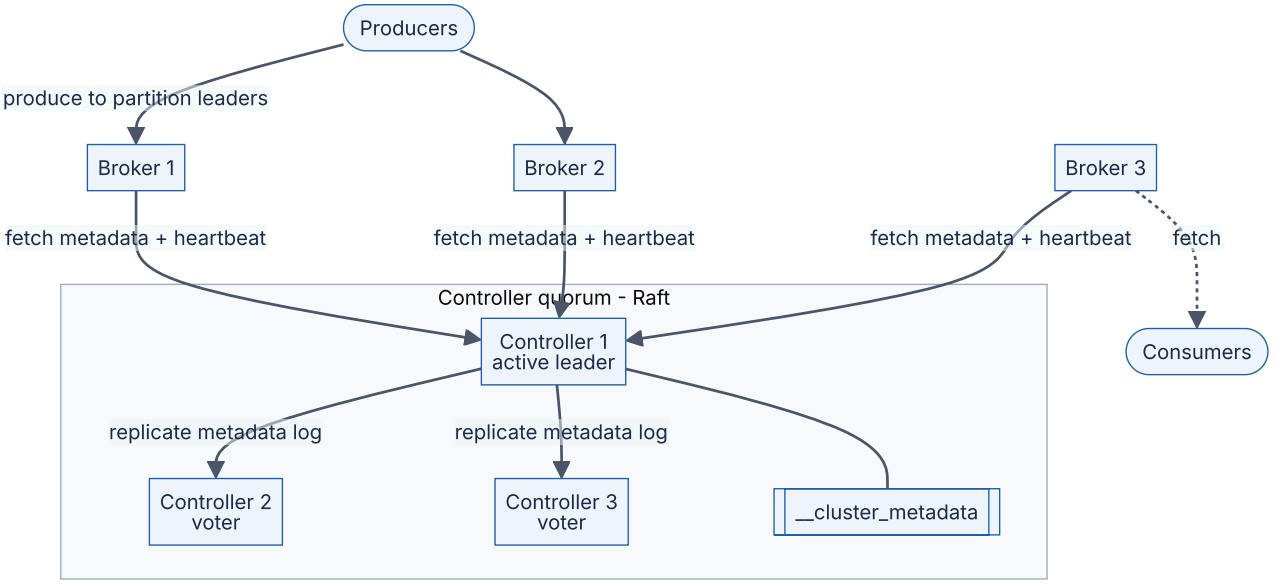
KIP-500 proposed replacing ZooKeeper with a **self-managed metadata quorum** that stores metadata as a Kafka log replicated with a Raft variant. The result, **KRaft** (Kafka Raft), was marked production-ready in Kafka 3.3 (2022); ZooKeeper mode was deprecated in 3.5, and **Kafka 4.0 (March 2025) removed ZooKeeper mode entirely**. As of 2026, every supported Kafka release runs only in KRaft mode, and a ZooKeeper-based cluster must first migrate to KRaft on a 3.x bridge release before upgrading to 4.x [Apache Kafka 4.0 Release Notes].

How it works internally

1. A small set of **controller nodes** (typically 3 or 5) forms a Raft quorum (§26.7). Their elected Raft leader is the **active controller**; the others are hot standbys.
2. All metadata changes (topic creation, partition reassignment, leader changes, ISR changes, broker registrations, configuration) are appended as records to a single-partition internal log, `__cluster_metadata`. A change is committed when a majority of controllers has it.
3. **Brokers** fetch the metadata log from the active controller exactly as followers fetch a partition, and apply records to an in-memory metadata image. Every broker therefore sees the same ordered history; a lagging broker knows exactly how far behind it is (its metadata offset).
4. Brokers **register** with the controller and send **heartbeats**. A broker that stops heartbeating is **fenced**: the controller moves leadership of its partitions to other in-sync replicas by writing new leader records.
5. The quorum takes periodic **snapshots** of the metadata image so the log can be truncated, like Raft snapshotting (§26.7.8).
6. If the active controller fails, a standby that *already has the metadata in memory* becomes Raft leader, so failover no longer reloads state and clusters can hold far more partitions.

Development setups may run broker and controller in one process (**combined mode**); production usually runs dedicated controllers.

Figure 31.3 — A KRaft cluster: controller quorum and brokers.



Reading the diagram. The *controller quorum* replicates `__cluster_metadata` from the active controller to two voters; a record commits when two of three have it, so one controller may fail. *Brokers* pull metadata and send heartbeats over TCP; each request is synchronous, but propagation is eventually consistent, measured by each broker's metadata offset. *Producers* and *consumers* talk only to brokers. Failure points: losing a controller majority stops metadata changes (no elections, no new topics) while existing leaders keep serving; losing a broker triggers leader moves. Scaling: add brokers for capacity; controllers stay at 3 or 5.

Alternatives and trade-offs

Table 31.1 — ZooKeeper mode versus KRaft (as of 2026).

Aspect	ZooKeeper mode (removed in 4.0)	KRaft mode
Metadata store	External ZooKeeper ensemble	Internal `__cluster_metadata` log, Raft quorum
Systems to operate	Two	One
Controller failover	Reload all metadata from ZooKeeper; grows with partitions	Standby already has metadata in memory
Metadata propagation	Controller RPCs to brokers	Brokers fetch an ordered log
Partition scale	Limited by controller reload time	Much higher (KIP-500 targeted millions)
Status	Deprecated 3.5; removed 4.0 (2025)	Only mode in 4.x

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Two of three controllers down	Quorum lost	`ActiveControllerCount` = 0 cluster-wide	Restore a majority	Spread controllers across zones; use 5 for two-failure tolerance
Broker isolated from controller but serving clients	Network partition	Broker fenced; clients get `NOT_LEADER`	Clients refresh metadata and move to new leaders	Leader epochs (§31.9.4) reject the stale leader's replication
Controllers co-located with overloaded brokers	Combined mode in production	Metadata commit latency rises	Separate roles	Dedicated controller nodes

COMMON MISTAKE

"KRaft means Kafka partitions are replicated with Raft." Only the *metadata* log uses Raft. Ordinary partitions still use the leader–follower ISR protocol of §31.9, which commits when all in-sync replicas have a record rather than when a majority does. The two protocols make different trade-offs, compared in Table 31.4.

31.5 Topics and partitions

31.5.1 Topics, partitions and records

DEFINITION

Definition — Topic, partition and record. A **topic** is a named category of records (for example `orders`). A topic is split into **partitions**, each an independent, ordered, replicated log with its own offsets starting at 0. A **record** carries an optional **key**, a **value** (opaque bytes), a **timestamp** and optional **headers**. Kafka guarantees order *within* a partition, not across partitions of a topic.

First-principles explanation

One logbook can be served only as fast as one machine allows, so Kafka gives a topic many logbooks (partitions) on different brokers, written and read in parallel. The price is that there is no order across them: record 5 in partition 0 and record 5 in partition 1 have no "before" relationship. Two events that must stay ordered (an order's "created" before its "paid") must land in the same partition, which is what the record key is for.

How it works internally: segments and indexes

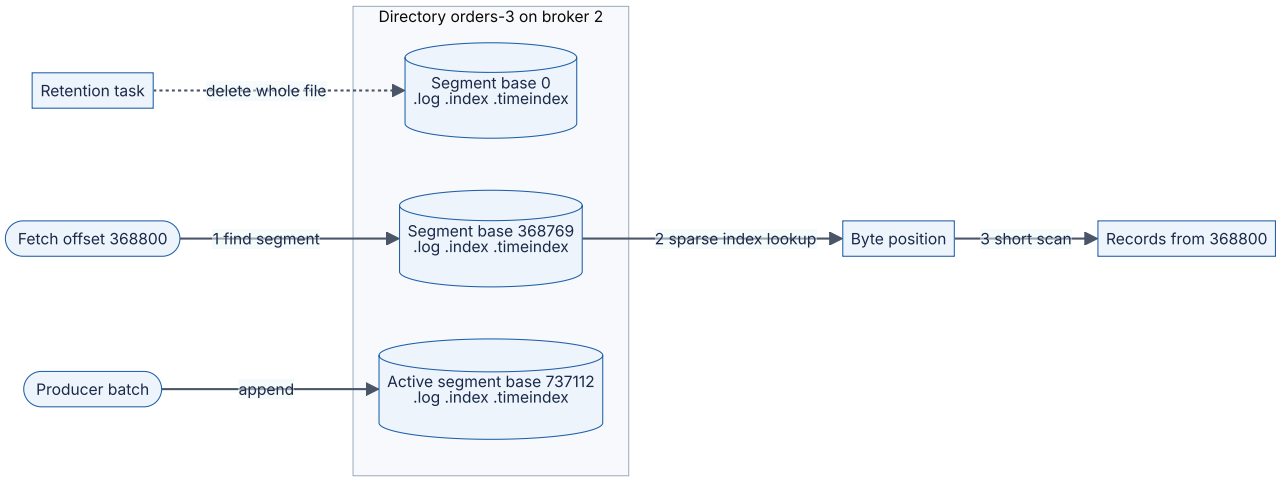
A partition is a directory on the broker's disk, named `<topic>-<partition>` (for example `orders-3/`). Inside, the log is split into **segments**, so old data can be deleted a file at a time:

1. `.log` **files** hold record batches in append order. Each file is named after its **base offset**, the first offset it contains, padded to 20 digits: `00000000000000000000.log`, `00000000000000368769.log`.
2. Only the newest segment, the **active segment**, receives appends. It is **rolled** (closed and a new one opened) when it reaches `segment.bytes` (default 1 GiB) or `segment.ms` (default 7 days).
3. `.index` **files** are **sparse** maps from offset to byte position in the `.log` file. Kafka adds an entry roughly every `index.interval.bytes` (default 4,096 bytes) of appended data, so the index is small enough to memory-map.
4. `.timeindex` **files** map timestamps to offsets, which lets a consumer start "from 09:00 yesterday".
5. `.txnindex` **files** record aborted transactions (§31.11), and a `leader-epoch-checkpoint` file records where each leader epoch began (§31.9.4).

To read offset 368,800, the broker (a) binary-searches the segment list by base offset and picks `00000000000000368769.log`, (b) binary-searches that segment's `.index` for the largest indexed offset ≤ 368,800, and (c) scans forward from that byte position, at most about 4 KB. A lookup is therefore two in-memory binary searches and one short sequential read, regardless of how large the partition is.

Records are written in **record batches**: a header (base offset, count, producer ID and sequence, CRC, compression codec, timestamps) followed by records whose offsets and timestamps are stored as small deltas. The broker validates the batch and assigns offsets but stores the producer's (possibly compressed) bytes as they arrived. Batches are the unit of compression, replication and transfer, which matters for performance (§31.13).

Figure 31.4 — A partition on disk: segments and sparse indexes.



Reading the diagram. Only the *active segment* receives appends. A *fetch* for offset 368,800 picks the segment by base offset, uses the sparse *index* to find a nearby byte position, then scans a few kilobytes. The *retention task* runs asynchronously and deletes whole closed segments. The storage boundary is the local file system and page cache. Failure points: a torn final batch after a crash is detected by CRC and truncated; indexes can be rebuilt from the log. Scaling: smaller segments allow finer deletion but more open files.

31.5.2 Choosing the number of partitions

Why does this exist?

Partitions are Kafka's unit of parallelism. A partition is written by one leader and, within a consumer group, read by at most one consumer (§31.7). So the partition count sets the ceiling on both write and read parallelism for a topic. Too few partitions and you cannot scale consumers; too many and you pay in open files, memory for batches, replication traffic, longer leader elections after a broker failure, and more work for the controller.

Mathematical foundations

FORMULA

Partition count from target throughput

$$P = \lceil h \cdot \max\left(\frac{T}{t_p}, \frac{T}{t_c}\right) \rceil$$

Symbol	Meaning	Units
P	Number of partitions for the topic	count
T	Target peak throughput of the topic	MB/s
t_p	Measured producer throughput into one partition	MB/s per partition
t_c	Measured throughput of one consumer instance on one partition, including its processing	MB/s per partition
h	Headroom factor for growth and uneven keys (≥ 1)	dimensionless

This rule of thumb comes from Kafka's committers [Rao 2015]: measure what one partition can do on the produce side and on the consume side, and provision for the slower of the two. The consumer side is usually the binding constraint because consumers do real work (database writes, enrichment calls), while a broker can append to one partition at tens of MB/s.

WORKED EXAMPLE

Worked example — Partitions for an order-events topic. Peak traffic is 50,000 events/s at 2 KB each, so $T = 100$ MB/s. A load test shows a producer can push $t_p = 20$ MB/s into one partition, and one consumer instance, which writes each event to a database, sustains $t_c = 4$ MB/s. You want headroom $h = 1.5$ for two years of growth.

1. Producer bound: $T/t_p = 100/20 = 5$ partitions.
2. Consumer bound: $T/t_c = 100/4 = 25$ partitions.
3. Take the maximum, 25, and apply headroom: $1.5 \times 25 = 37.5$, so $P = 38$.
4. Round to a number with many divisors so consumer counts divide evenly: 40 or 48. Choose 48 (divisible by 2, 3, 4, 6, 8, 12, 16, 24).

Interpretation. The consumer side needs five times as many partitions as the producer side. With 48 partitions you can run up to 48 consumer instances; a 49th would sit idle. **Engineering implication.** Set the partition count for keyed topics at creation with headroom, because increasing it later breaks key-to-partition mapping (§31.5.3). For unkeyed topics you can add partitions later with little harm.

WARNING / TRADE-OFF

Do not over-partition. Each partition replica is a set of open files, an entry in every broker's metadata image, a slot in leader elections and a separate producer batch. Thousands of partitions per broker are routine, but a topic with 10,000 partitions at 1 MB/s total produces tiny batches, poor compression and higher end-to-end latency, because each partition gets one record every few seconds [Rao 2015].

31.5.3 Keys, hashing and ordering

How it works internally

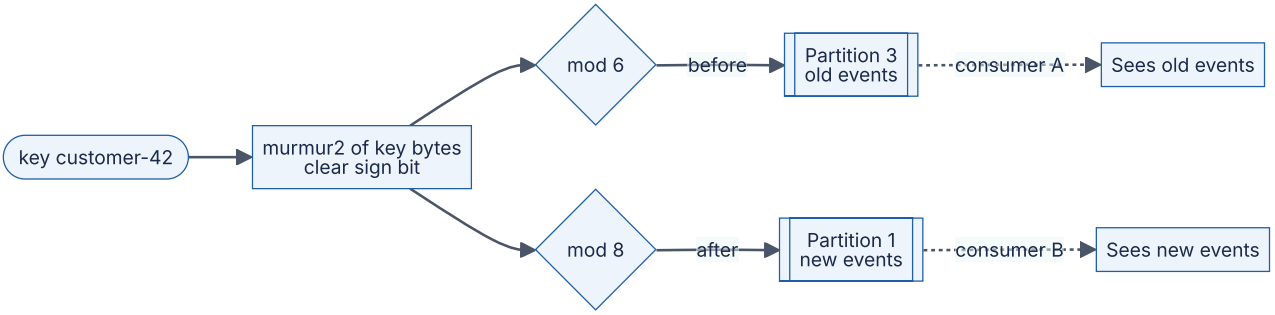
The producer chooses the partition for each record:

1. If the application names a partition explicitly, use it.
2. If the record has a **key**, the default partitioner computes `toPositive(murmur2(keyBytes)) % numPartitions`: a 32-bit MurmurHash2 of the serialized key bytes, with the sign bit cleared, modulo the partition count.
3. If the key is null, the **sticky partitioner** fills a batch for one partition and then switches to another, rather than spraying single records across all partitions (KIP-480, refined in KIP-794 to favor partitions on less loaded brokers). This produces fuller batches and lower latency than round-robin.

Because the same key always hashes to the same partition (while the count is fixed), all events for `customer-42` are totally ordered relative to each other. This is the basis of per-

entity ordering in Kafka.

Figure 31.5 — Key-to-partition hashing, and what changes when partitions are added.



Reading the diagram. The producer hashes the key `customer-42` and takes the result modulo the partition count. With 6 partitions the key maps to partition 3; after the topic grows to 8 partitions the same key maps to partition 1 (the code below computes both). Old events stay in partition 3 and new ones go to partition 1, read asynchronously by possibly different consumers, so a consumer may process a new “paid” event before an old “created” event still waiting in partition 3. The failure point is the moment of the partition change; the storage boundary is unaffected because Kafka never moves existing records between partitions.

Mathematical foundations

FORMULA

Fraction of keys that move when the partition count changes (hash mod P)

$$F_{\text{move}} = 1 - \frac{\min(P, P')}{\operatorname{lcm}(P, P')}$$

Symbol	Meaning	Units
F_{move}	Fraction of keys whose partition changes	fraction
P	Old partition count	count
P'	New partition count	count
lcm	Least common multiple	count

Why: a key stays put when $h \bmod P = h \bmod P' = a$. Then $h - a$ is divisible by both counts, so $h \equiv a \pmod{\operatorname{lcm}(P, P')}$ with $a < \min(P, P')$. Exactly $\min(P, P')$ of every $\operatorname{lcm}(P, P')$ hash values stay, assuming a uniform hash.

WORKED EXAMPLE

Worked example — Growing from 6 to 8, 12 and 13 partitions.

1. $6 \to 8$: $\text{lcm} = 24$, $\min = 6$, so $F = 1 - 6/24 = 0.75$. Three-quarters of keys move.
2. $6 \to 12$: $\text{lcm} = 12$, $F = 1 - 6/12 = 0.50$. Doubling is the friendliest change: each old partition splits into two.
3. $12 \to 13$: $\text{lcm} = 156$, $F = 1 - 12/156 = 0.923$. Adding “just one” partition moves 92% of keys.

Interpretation. Unlike consistent hashing (§14.8), `hash mod P` remaps most keys on almost any change. **Engineering implication.** For keyed topics, either over-provision at creation, or migrate by creating a new topic with the new count, dual-writing or replaying into it, and cutting consumers over once the old topic has drained.

Code example

The following runnable port of Kafka’s default partitioner is checked against test vectors from Kafka’s own unit tests and measures the moved fractions above on 100,000 keys.

```
        """Kafka's default key partitioner: murmur2(key) & 0x7fffffff, mod parti-
tions."""

        M32 = 0xFFFFFFFF

        def murmur2(data: bytes) -> int:
            """Port of org.apache.kafka.common.utils.Utils.murmur2; returns a signed
int32."""
            m, r = 0x5BD1E995, 24
            h = (0x9747B28C ^ len(data)) & M32
            n4 = len(data) // 4
            for i in range(n4):
                k = int.from_bytes(data[4 * i:4 * i + 4], "little")
                k = (k * m) & M32
                k ^= k >> r
                k = (k * m) & M32
                h = (h * m) & M32
                h ^= k
            tail = data[4 * n4:]
            if len(tail) == 3:
                h ^= tail[2] << 16
            if len(tail) >= 2:
                h ^= tail[1] << 8
            if len(tail) >= 1:
                h ^= tail[0]
                h = (h * m) & M32
            h ^= h >> 13
            h = (h * m) & M32
            h ^= h >> 15
            return h - (1 << 32) if h & 0x80000000 else h

        def partition_for(key: str, num_partitions: int) -> int:
            return (murmur2(key.encode()) & 0x7FFFFFFF) % num_partitions

        # Test vectors from Kafka's own unit tests.
        assert murmur2(b"21") == -973932308
        assert murmur2(b"foobar") == -790332482
        assert murmur2(b"a-little-bit-long-string") == -985981536
        assert murmur2(b"a-little-bit-longer-string") == -1486304829
        assert murmur2(b"lkjh234lh9fiuh90y23oiuhsafujhadof229phr9h19h89h8") == -58897971
        assert murmur2(b"abc") == 479470107

        keys = [f"customer-{i}" for i in range(100_000)]
        for old, new in [(6, 8), (6, 12), (12, 13)]:
            moved = sum(partition_for(k, old) != partition_for(k, new) for k in keys)
            print(f"{old:>2} -> {new:>2} partitions: {moved / len(keys):.1%} of keys
change partition")
        print("customer-42 ->", partition_for("customer-42", 6), "with 6,",
              partition_for("customer-42", 8), "with 8")
```

Output:

```
 6 ->  8 partitions: 75.1% of keys change partition
 6 -> 12 partitions: 49.9% of keys change partition
12 -> 13 partitions: 92.3% of keys change partition
customer-42 -> 3 with 6, 1 with 8
```

What to notice:

- Java's `int` arithmetic wraps at 32 bits; masking with `M32` after each multiplication reproduces it, and the asserts prove the port matches Kafka.
- Kafka clears the sign bit rather than taking `abs()`, because `abs(Integer.MIN_VALUE)` is still negative in Java.
- The measured fractions match the formula: 75%, 50% and 92%.
- Every client must use the same hash. Some non-Java clients (for example, librd-kafka-based ones) default to a different hash unless configured for murmur2.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Hot partition	One key (a celebrity, a big tenant) dominates	Per-partition bytes-in skew; one consumer lags	Split the key (salting, §14.10) if order allows	Choose keys with many distinct, balanced values
Out-of-order events after scaling	Partition count changed on a keyed topic	Consumers see "paid" before "created"	Reprocess from a new topic	Fix the count at creation; migrate via a new topic
Mixed-language producers disagree	Different default hash functions	Same key in two partitions	Re-key	Configure all clients for murmur2

31.6 Producers

31.6.1 Batching and compression

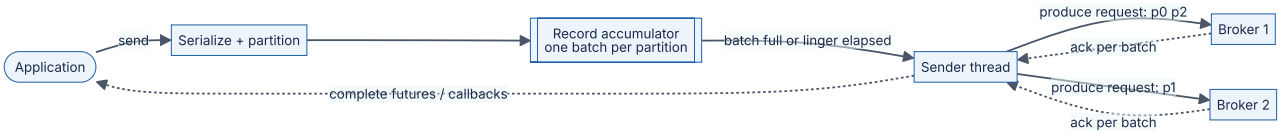
How it works internally

A producer is not a thin RPC client. Calling `send()` only serializes the record, picks a partition and appends it to an in-memory **record accumulator**; a background **sender thread** later ships whole batches.

1. `send()` serializes key and value, runs the partitioner (§31.5.3) and appends the record to the open batch for that partition. It returns a future immediately.
2. A batch becomes sendable when it reaches `batch.size` bytes (default 16,384) or when it has waited `linger.ms` (default 5 ms as of Kafka 4.0; 0 before 4.0, KIP-1030).
3. The sender groups ready batches by destination broker into one produce request per broker, so one network round trip carries batches for many partitions.

4. Each batch is compressed as a unit with `compression.type` (`none`, `gzip`, `snappy`, `lz4` or `zstd`). Compressing 16 records of similar JSON together gives far better ratios than compressing each alone.
5. If `buffer.memory` (default 32 MiB) fills because brokers are slow, `send()` blocks for up to `max.block.ms`: built-in backpressure (§22.10).

Figure 31.6 — Inside the producer: accumulator, sender and per-broker requests.



Reading the diagram. The application thread only serializes and appends to the *accumulator* (memory, not disk). The *sender thread* drains full or expired batches and sends one produce request per broker over TCP, each carrying batches for the partitions that broker leads. Acknowledgments return asynchronously and complete the futures. Failure points: a full accumulator blocks `send()`; a failed request is retried by the sender (§31.6.3). Scaling: larger batches and compression raise throughput per request at the cost of up to `linger.ms` of extra latency.

Mathematical foundations

FORMULA

Records per batch and time to fill a batch

$$n_{\text{batch}} = \min\left(\lambda_p \cdot \ell\,,\ \frac{B}{s}\right), \qquad t_{\text{fill}} = \min\left(\ell\,,\ \frac{B}{s \cdot \lambda_p}\right)$$

Symbol	Meaning	Units
n_{batch}	Records per batch sent	records
λ_p	Record rate into one partition from one producer	records/s
ℓ	`linger.ms`	s
B	`batch.size`	bytes
s	Average serialized record size	bytes
t_{fill}	Time a batch waits before it is sendable	s

WORKED EXAMPLE

Worked example — Is `linger.ms` or `batch.size` the limit? A producer writes 48,000 records/s of $s = 500$ B spread over 48 partitions, so $\lambda_p = 1,000$ records/s per partition. Defaults: $\ell = 5$ ms, $B = 16,384$ B.

1. Linger bound: $1,000 \times 0.005 = 5$ records per batch.
2. Size bound: $16,384/500 = 32$ records.
3. $n_{\text{batch}} = \min(5, 32) = 5$ records (2.5 KB); $t_{\text{fill}} = 5$ ms. Linger is the limit.
4. Batches per second: $48,000/5 = 9,600$ batches/s.
5. Raise ℓ to 20 ms: $n = \min(20, 32) = 20$ records; batches fall to 2,400/s, a 4× cut in per-batch overhead, at the cost of up to 15 ms more latency.

Interpretation. At moderate rates per partition, `linger.ms` decides batch size; `batch.size` matters only for hot partitions. **Engineering implication.** Fewer partitions per producer, or a larger linger, gives bigger batches, better compression and fewer requests. Latency-critical paths keep linger small and accept the overhead.

31.6.2 Acknowledgments: `acks=0`, `1` and `all`

The `acks` setting decides when the leader answers the producer:

Table 31.2 — Producer acknowledgment modes.

Setting	Leader replies when	Latency	Loss window
`acks=0`	Never; producer does not wait	Lowest	Any network or broker failure; no retries possible
`acks=1`	Leader has appended to its log (page cache)	Low	Leader dies before followers copy the record
`acks=all` (`-1`)	Every replica currently in the ISR has the record	Higher (one follower fetch round trip)	None for committed records while one ISR replica survives; needs `min.insync.replicas` (§31.9.3)

Since Kafka 3.0 the producer defaults are `acks=all` and `enable.idempotence=true` (KIP-679). Note that “has the record” means *in memory or the page cache* of each replica, not fsynced to disk; Kafka’s durability comes from copies on several machines, not from flushing one disk (§31.13).

31.6.3 Retries, idempotence and ordering

Why does this exist?

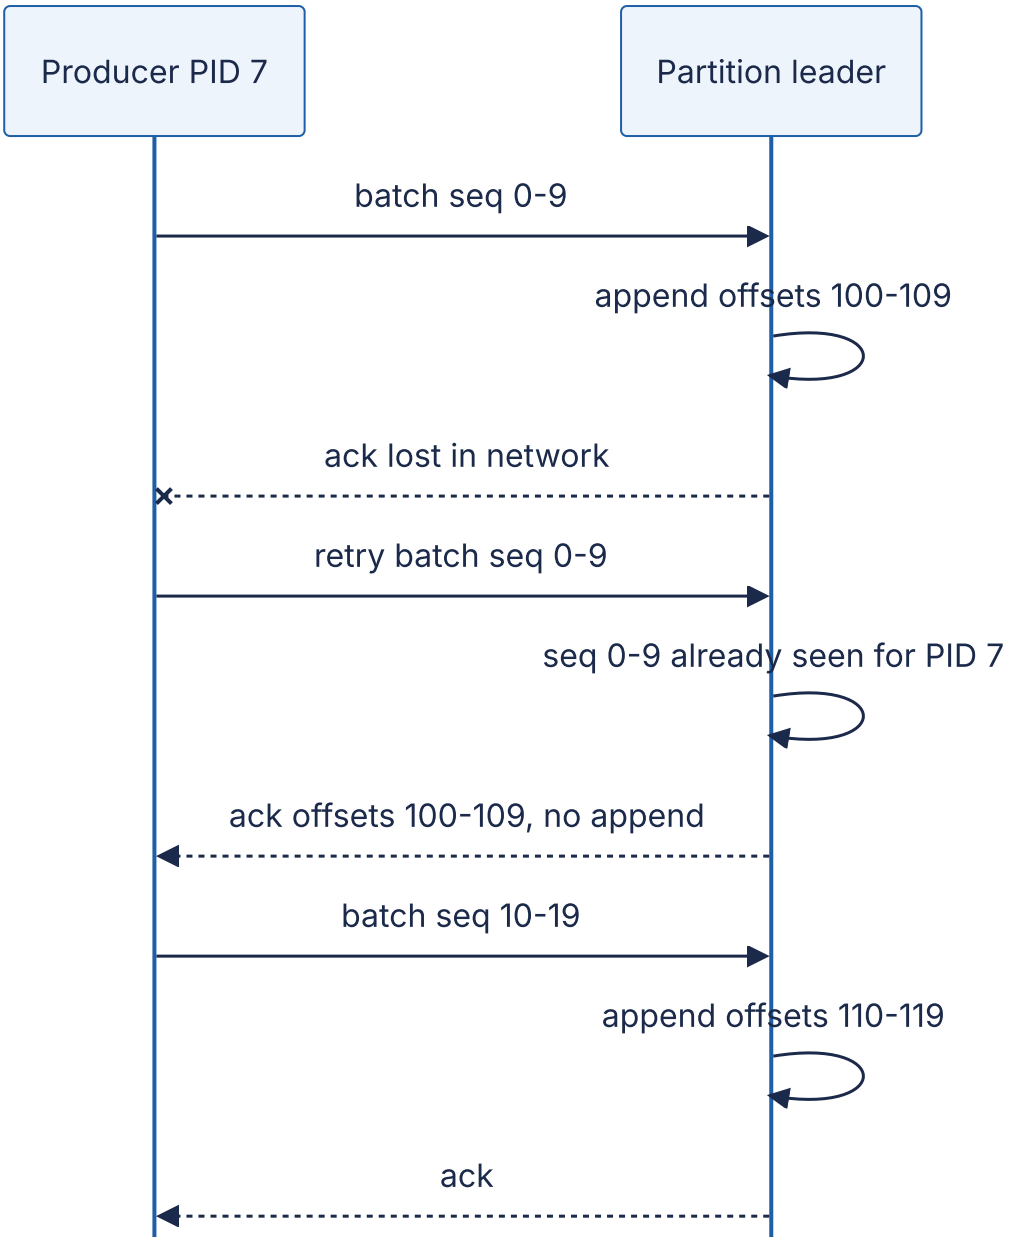
Networks lose acknowledgments. If the broker appended a batch but the reply was lost, the producer retries and the batch is written twice. Retries also threaten ordering: with several requests in flight, batch 1 can fail and be retried after batch 2 succeeds, reversing them.

How it works internally

The **idempotent producer** (KIP-98) applies the idempotency-key idea of §22.15 inside Kafka:

1. On start-up the producer obtains a **producer ID (PID)** and an **epoch** from a broker.
2. Every batch carries the PID, epoch and a **sequence number** per partition, starting at 0 and increasing by the record count.
3. The partition leader remembers, for each PID, the sequence numbers of the last five batches it appended. A batch whose sequence it has already seen is acknowledged again but **not** appended (duplicate). A batch with a gap (sequence too high) is rejected with `OutOfOrderSequenceException` so the producer can resend in order.
4. With idempotence on, up to `max.in.flight.requests.per.connection` = 5 requests may be outstanding and ordering is still preserved, because the leader accepts batches only in sequence order. Without idempotence, preserving order under retries requires `max.in.flight.requests.per.connection=1`, which caps throughput at one batch per round trip.
5. Retries continue until `delivery.timeout.ms` (default 120 s) expires.

Figure 31.7 — Idempotent producer: a lost acknowledgment does not create a duplicate.



Reading the diagram. The producer sends a batch tagged with PID 7 and sequences 0–9; the leader appends it, but the acknowledgment is lost. The retry carries the *same* PID and sequences, so the leader recognizes the duplicate and returns the original offsets without appending. The next batch continues at sequence 10. All calls are synchronous request/response over TCP. Limits: deduplication is per PID and per partition, and a PID is new each time the producer restarts unless it uses a `transactional.id` (§31.11), so idempotence protects against retries inside one producer session, not against an application that crashes and re-sends.

COMMON MISTAKE

"Idempotent producer means exactly-once." It removes duplicates caused by the producer's own retries to one partition during one session. It does not deduplicate an application that restarts and re-sends, does not make a consumer's processing idempotent, and does not make writes to several partitions atomic. Those need transactions (§31.11) and idempotent consumers (§32.10).

31.7 Consumers and consumer groups

31.7.1 The pull model and the poll loop

Kafka consumers **pull** ("partition 3 from offset 5,120"), so each goes at its own speed, batch jobs read in large chunks, and backpressure is automatic [Kreps et al. 2011]. On an idle topic a fetch waits at the broker until `fetch.min.bytes` (default 1 byte) arrive or `fetch.max.wait.ms` (default 500 ms) passes. The application loops: `poll()` returns up to `max.poll.records` (default 500), it processes them, and polls again [Shapira et al. 2021].

31.7.2 Consumer groups and partition assignment

DEFINITION

Definition — Consumer group. A set of consumer instances sharing a `group.id` that divide a topic's partitions among themselves so that **each partition is consumed by exactly one member** at a time. Different groups consume the same topic independently, each with its own offsets.

First-principles explanation

A consumer group is a team sharing a pile of logbooks: each logbook is given to one team member, so no entry is read twice within the team and entries in one logbook stay in order. A second team (another group) gets its own copies of the bookmarks and reads the same logbooks independently. Within a group Kafka behaves like a queue (work is divided); across groups it behaves like publish/subscribe (everyone gets everything), which is how one system provides both models of §30.4–§30.5.

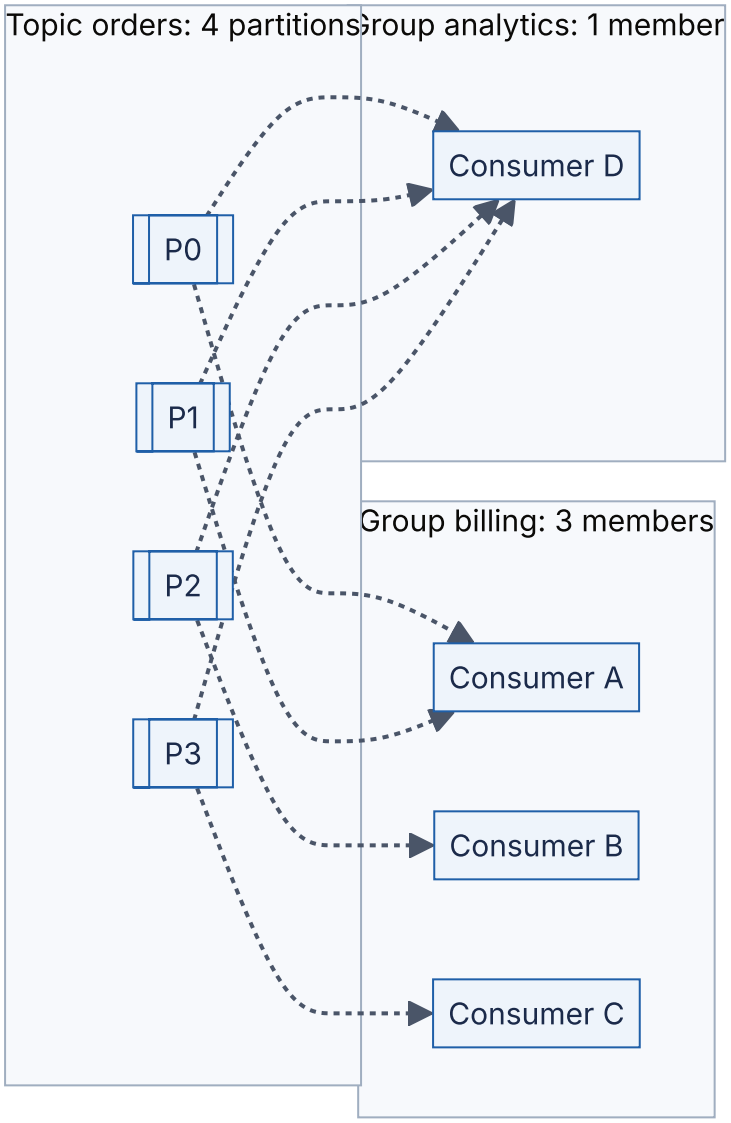
How it works internally

1. Each group has a **group coordinator**: the broker leading the partition of the internal `__consumer_offsets` topic that `hash(group.id)` maps to.
2. Members join the group and heartbeat to the coordinator. A member is considered dead if no heartbeat arrives within `session.timeout.ms` (default 45 s), or if it fails to

call `poll()` within `max.poll.interval.ms` (default 5 minutes), which catches a consumer stuck in processing.

3. When membership or the topic's partitions change, the group **rebalances**: partitions are reassigned by an **assignor** (range, round-robin, sticky or cooperative-sticky). §31.12 covers the protocols.
4. Each member fetches its assigned partitions from their leaders (or, with rack-aware **follower fetching**, KIP-392, from a replica in its own availability zone to avoid cross-zone transfer charges).

Figure 31.8 — Two consumer groups reading one four-partition topic.



Reading the diagram. The *billing* group's three members share four partitions: A owns two, B and C one each. The *analytics* group's single member reads all four independently, with its own offsets. Arrows are asynchronous pull fetches. Failure point: if B crashes, P2 is unconsumed by billing until a rebalance gives it to A or C. Scaling: billing can use at most four members.

31.7.3 Parallelism ceiling and consumer lag

The **parallelism ceiling** of a group is the partition count: with P partitions, at most P members do work. If processing is the bottleneck and members are already at P, the options are more partitions (with the key-remapping cost of §31.5.3), faster processing per record, or concurrency *inside* a member (for example a thread pool keyed by record key to keep per-key order).

DEFINITION

Definition — Consumer lag. For one partition, lag = **log end offset** (or high watermark) minus the group's **committed offset**: the number of records written but not yet processed by the group. Group lag is the sum over partitions.

FORMULA

Lag drain time

$$t_{\text{drain}} = \frac{L}{\mu - \lambda} \quad (\mu > \lambda)$$

Symbol	Meaning	Units
t_{drain}	Time for lag to return to about zero	s
L	Current lag	records
μ	Aggregate consumption rate of the group	records/s
λ	Current production rate	records/s

WORKED EXAMPLE

Worked example — Recovering from a 20-minute consumer outage. Producers write $\lambda = 40,000$ records/s. The consumer group was down for 20 minutes, so $L = 40,000 \times 1,200 = 48,000,000$ records. Twelve members each process 5,000 records/s, so $\mu = 60,000$ records/s.

1. Net drain rate: $\mu - \lambda = 20,000$ records/s.
2. $t_{\text{drain}} = 48,000,000/20,000 = 2,400$ s $= 40$ minutes.
3. If the topic has 24 partitions, scaling to 24 members gives $\mu = 120,000$: $48 \times 10^6/80,000 = 600$ s $= 10$ minutes.
4. With 12 partitions, extra members are idle and recovery stays at 40 minutes.

Interpretation. A 20-minute outage costs 40 minutes of staleness after recovery unless spare capacity exists, and spare consumers help only up to the partition count. **Engineering implication.** Provision consumers for roughly 1.5–2× peak and partitions for the scaled-up count; alert on lag *in seconds* (lag ÷ production rate), which is what users feel, rather than in records. Also check retention: if lag ever exceeds retention, records are deleted before they are read.

31.7.4 Share groups (queues for Kafka)

Consumer groups tie parallelism to partitions and order per partition. Some workloads, such as a pool of workers processing independent jobs, want queue semantics instead: many workers on one partition, per-record acknowledgment and redelivery. **KIP-932** adds **share groups**, in which records of a partition are handed to several consumers with per-record acquisition locks and delivery counts. Share groups arrived as early access in Kafka 4.0 and were still maturing through the 4.x line as of 2026; check your version's documentation before relying on them.

31.8 Offsets

31.8.1 Where offsets live

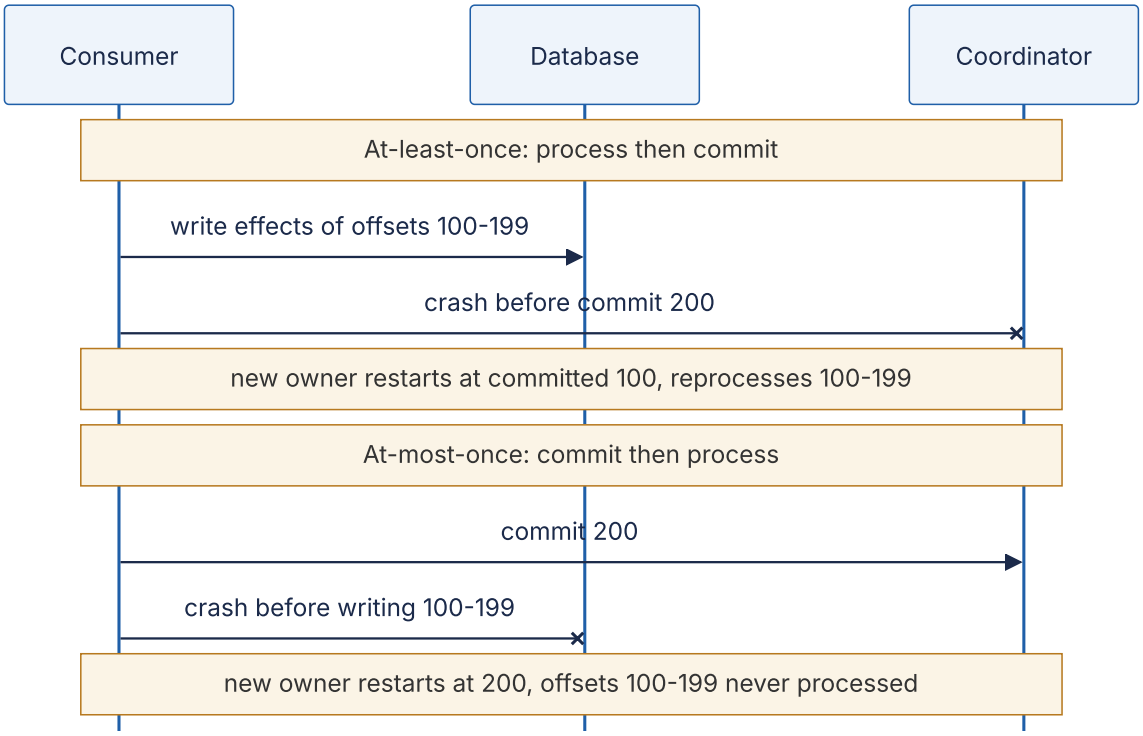
A consumer group's progress is a map from partition to **committed offset**, by convention the offset of the *next* record to read. Since Kafka 0.9 these commits are records in the internal topic `__consumer_offsets` (50 partitions by default, replicated, **compacted** so only the latest commit per group and partition survives, §31.10). Storing offsets in a Kafka log makes commits a cheap append and lets the coordinator rebuild its cache by reading the partition after failover. When a group has no committed offset (or the committed offset has been deleted by retention), `auto.offset.reset` decides where to start: `latest` (the default), `earliest` or `none` (fail).

31.8.2 Commit strategies and delivery semantics

The moment of the commit relative to processing decides the delivery guarantee (§30.8):

- **Commit after processing → at-least-once.** If the consumer crashes after processing but before committing, the next owner of the partition reprocesses those records. Duplicates are possible; loss is not.
- **Commit before processing → at-most-once.** If the consumer crashes after committing but before processing, those records are skipped. Loss is possible; duplicates are not.

Figure 31.9 — Commit timing decides duplicates or loss.



Reading the diagram. Upper half: effects reach the *database* first, the crash prevents the commit, and the new owner reprocesses 100–199, duplicating effects unless writes are idempotent. Lower half: the commit reaches the *coordinator* first, the crash prevents processing, and the new owner starts at 200, silently losing 100–199. Both calls are synchronous; the failure point is the gap between two writes to different storage systems, which cannot be atomic without transactions or an idempotent sink.

Table 31.3 — Offset commit strategies.

Strategy	How	Guarantee	Cost	Use when
Auto commit	Default; commits polled position every 5 s inside `poll()`	At-least-once if processing finishes before the next `poll()`; at-most-once if handed off asynchronously	Up to 5 s reprocessed after a crash	Simple, idempotent processing
Synchronous commit	`commitSync()` after processing	At-least-once; blocks until acknowledged	One round trip per commit; lower throughput	Correctness first, moderate rate
Asynchronous commit	`commitAsync()`	At-least-once; failures not retried (could overwrite a newer offset)	Non-blocking	High throughput; `commitSync()` on shutdown and revocation
Offsets stored with results	Write offset in the same database transaction as the output; seek on start-up	Effectively-once for that sink	Requires transactional sink	Database sinks needing no duplicates
Kafka transactions	`sendOffsetsToTransaction()` (§31.11)	Exactly-once for Kafka-to-Kafka	Transaction overhead	Read-process-write pipelines

RECOMMENDATION

Default to at-least-once with idempotent processing. Disable auto commit for anything non-trivial, commit after processing (synchronously every few hundred records, or asynchronously with a final synchronous commit), and make the processing idempotent with an idempotency key or upsert (§22.15, §32.10). At-most-once is acceptable only for data where loss is cheaper than duplicates, such as some metrics.

31.9 Replication, ISR and leader election

31.9.1 Leaders, followers and the in-sync replica set

DEFINITION

Definition — ISR, LEO and high watermark. Each partition has a **replication factor** (RF) of replicas on different brokers; one is the **leader**, which handles all writes, and the others are **followers**, which fetch from the leader. The **in-sync replica set (ISR)** is the leader plus the followers that have fully caught up within `replica.lag.time.max.ms` (default 30 s). Each replica's **log end offset (LEO)** is the offset its next appended record will get. The **high watermark (HW)** is the offset below which every ISR member has the record; records below the HW are **committed** and are the only ones consumers can read.

How it works internally

1. The leader appends a producer batch, advancing its LEO.
2. Each follower sends fetch requests (the same API consumers use) with its own LEO. The leader returns new records and learns from the fetch offset how far each follower has got.
3. The leader advances the HW to the minimum LEO across the ISR, and tells followers the new HW in the next fetch response; followers' HWs therefore lag the leader's by one fetch round.
4. An `acks=all` produce request waits in a holding area ("purgatory") until the HW passes its last offset, then the leader acknowledges.
5. A follower that has not caught up for `replica.lag.time.max.ms` is removed from the ISR (ISR **shrink**); it rejoins (ISR **expand**) when it catches up again. The leader records ISR changes through the controller.

FORMULA

High watermark

$$\mathrm{HW} = \min_{r \in \mathrm{ISR}} \mathrm{LEO}_r$$

Symbol	Meaning	Units
HW	High watermark: first offset not yet committed	offset
LEO_r	Log end offset of replica r	offset
ISR	Current in-sync replica set, including the leader	set of replicas

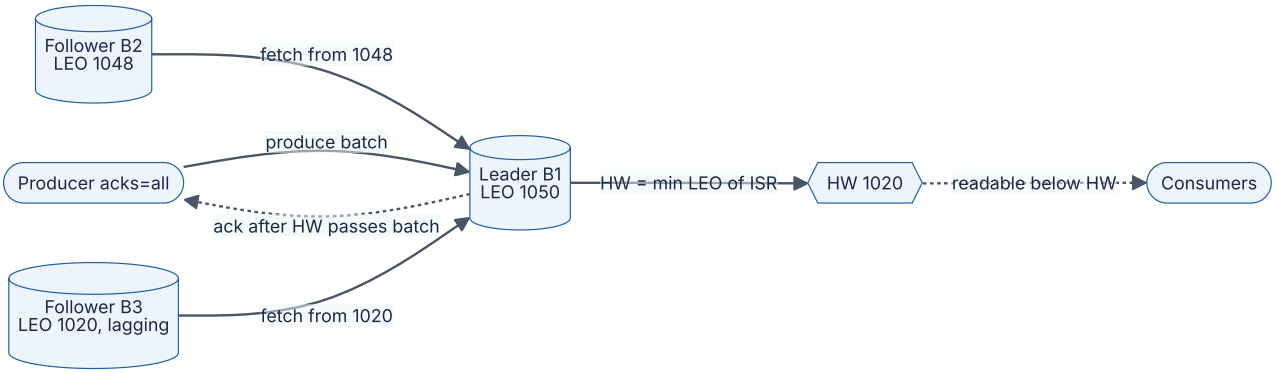
WORKED EXAMPLE

Worked example — What a consumer can see. RF = 3. The leader's LEO is 1,050, follower F1's is 1,048, follower F2's is 1,020, and all three are in the ISR.

1. HW = min(1,050, 1,048, 1,020) = 1,020. Consumers can read offsets up to 1,019.
2. An `acks=all` producer whose batch ended at offset 1,049 is still waiting.
3. F2 has been behind for 35 s, exceeding the 30 s limit, so the leader shrinks the ISR to {leader, F1}. HW jumps to min(1,050, 1,048) = 1,048, and requests up to 1,047 are acknowledged.

Interpretation. A slow follower holds back both visibility and `acks=all` latency until it is dropped; dropping it trades redundancy for progress. **Engineering implication.** Alert on ISR shrink rate and under-replicated partitions (§31.15), because a partition running with ISR = {leader} has no redundancy even though writes still succeed (unless `min.insync.replicas` stops them).

Figure 31.10 — Replica state on one partition with RF = 3.



Reading the diagram. The *producer* writes to the *leader* on broker B1. *Followers* pull with fetches carrying their LEOs, so replication is asynchronous to the write, but the `acks=all` acknowledgment waits until the *HW* passes the batch. *Consumers* read only below the HW, never seeing records that could vanish in a failover. Each replica is a separate broker disk. Failure points: lagging B3 holds back the HW until removed from the ISR; leader failure triggers election (§31.9.3). Scaling: replication traffic is (RF − 1) times produce traffic.

31.9.2 Kafka's ISR versus majority quorums

Table 31.4 — ISR replication versus a Raft-style majority quorum.

Aspect	Kafka ISR (data partitions)	Majority quorum (Raft, KRaft metadata)
Commit rule	All current ISR members have the record	A majority has the record
Replicas to tolerate f failures without losing committed data	$f + 1$	$2f + 1$
Effect of one slow replica	Holds commits until dropped from ISR (up to 30 s)	None; the majority proceeds
Who decides membership	External controller (itself a Raft quorum)	The protocol itself

The ISR design needs fewer copies for the same data safety, because it waits for every in-sync replica, and it relies on the controller to make ISR changes and leader choices consistent [Wang et al. 2015]. The price is sensitivity to slow followers, bounded by the lag timeout.

31.9.3 Leader election, `min.insync.replicas` and unclean election

When a leader's broker is fenced, the controller picks a new leader **from the ISR**, which by definition holds every committed record, increments the partition's **leader epoch**, and records the change in the metadata log. Brokers and clients learn the new leader from metadata. Two settings decide the durability/availability trade-off:

- **`min.insync.replicas`** (topic or broker setting, default 1): an `acks=all` write is rejected with `NOT_ENOUGH_REPLICAS` if the ISR is smaller than this. With RF = 3 and `min.insync.replicas=2`, every acknowledged record is on at least two brokers.
- **`unclean.leader.election.enable`** (default false): if no ISR member is alive, an out-of-sync replica may become leader. The partition comes back online, but every record it lacks, including acknowledged ones, is lost and later truncated from returning replicas.

Mathematical foundations

FORMULA

Write unavailability of one partition (independent broker failures)

$$U_w = \sum_{k=R-m+1}^{R} \binom{R}{k} q^k (1-q)^{R-k}$$

Symbol	Meaning	Units
U_w	Probability that fewer than m replicas are up, so `acks=all` writes are refused	probability
R	Replication factor	count
m	`min.insync.replicas`	count
q	Probability that a given broker is unavailable at a random moment	probability
k	Number of unavailable replicas	count

The formula optimistically treats “up” as “in sync”. Committed data survives as long as at least one ISR replica survives, so data loss on clean election requires all R replicas of the ISR to fail.

WORKED EXAMPLE

Worked example — RF = 3 with `min.insync.replicas` of 1, 2 and 3. Assume each broker is unavailable with $q = 0.01$ (about 7 hours a month, including rolling restarts).

1. $m = 2$: writes stop when 2 or 3 replicas are down.
   $U_w = 3q^2(1-q) + q^3 = 3(0.0001)(0.99) + 0.000001 = 0.000298$, about 0.03% of the time.
2. $m = 3$: writes stop when any replica is down. $U_w = 1 - 0.99^3 = 0.0297$, about 3%, which means every rolling restart blocks writes.
3. $m = 1$: writes stop only when all are down, $q^3 = 10^{-6}$, but an acknowledged write may exist on only one broker; if that broker's disk dies before followers catch up, the record is gone.
4. With $m = 2$ the cluster tolerates one broker failure with no write impact and no committed-data loss; with two failures writes stop but committed data is intact on the survivor.

Interpretation. RF = 3, `min.insync.replicas=2`, `acks=all` is the standard durability configuration because it survives a single failure (including planned restarts) with neither loss nor downtime. **Engineering implication.** RF = 3 with $m = 3$ is a common mistake; it converts every restart into an outage. Spread replicas across racks or availability zones with `broker.rack` so one zone failure removes only one replica.

Table 31.5 — Durability configurations (RF = 3).

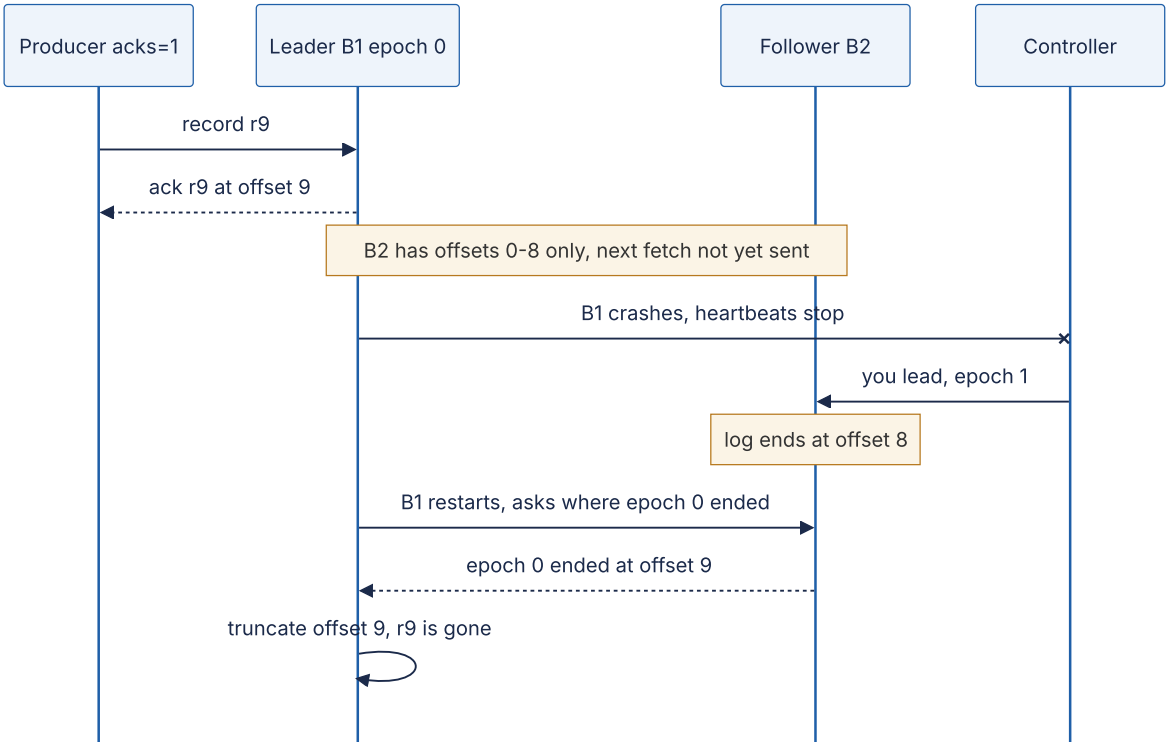
`acks`	`min.insync.replicas`	Unclean election	Acknowledged data lost when	Writes stop when
1	any	false	Leader dies before followers fetch	Leader unavailable (until re-election)
all	1	false	ISR shrank to leader alone, then leader's disk lost	All replicas down
all	2	false	Two brokers holding the record both lost	Two replicas down
all	2	true	Out-of-sync replica elected after ISR loss	Rarely; availability favored

31.9.4 Leader epochs and log truncation

After a leader change, a follower may hold records the new leader never received; those records were never committed and must be removed. Early Kafka truncated each follower to its own high watermark, but because followers learn the HW one fetch late, two failures in quick succession could truncate committed records or leave replicas with divergent logs [KIP-101]. Since Kafka 0.11 each record batch carries its **leader epoch**, every

replica records the start offset of each epoch, and a follower asks the new leader "where did epoch *e* end?" (`OffsetsForLeaderEpoch`). It truncates exactly to that point and then fetches. Leader epochs are fencing tokens (§26.13): a deposed leader with an old epoch cannot get its stale records accepted, and clients include the epoch in fetch requests to detect stale leaders.

Figure 31.11 — Leader failure with `acks=1`: an acknowledged record disappears.



Reading the diagram. With `acks=1` the *leader* acknowledges r9 as soon as it is in its own log. Before the *follower* fetches it, B1 crashes; the *controller* detects missing heartbeats and makes B2 leader in epoch 1. When B1 returns, the leader-epoch exchange tells it that epoch 0 ended at offset 9 on the new leader, so it truncates its own r9. The producer was told r9 succeeded, yet no replica has it. With `acks=all`, the leader would not have acknowledged r9 until B2 had it, so the producer would have retried instead.

31.9.5 A runnable replication simulation

The program below models one partition with RF = 3. One record is produced per tick; followers fetch every few ticks; the leader shrinks the ISR when a follower lags too long, computes the HW, and fails at the end. It reports acknowledged records that the new leader does not have.

```
        """Toy Kafka partition: leader, followers, ISR, high watermark, leader epochs.

        Compares acks=1 and acks=all under leader failure. One record is produced per
        tick; followers copy from the leader every `fetch_every` ticks.
        """

        class NotEnoughReplicas(Exception):
            pass

        class Replica:
            def __init__(self, rid, fetch_every):
                self.rid, self.fetch_every = rid, fetch_every   # fetch_every=0 means
down
                self.log = []               # list of (leader_epoch, value); index =
offset
                self.caught_up_at = 0       # last tick this follower matched the leader

            @property
            def leo(self):                  # log end offset: next offset to be written
                return len(self.log)

        class Partition:
            def __init__(self, fetch_every=(1, 3, 3), min_insync=1, lag_max=4,
unclean=False):
                self.r = {i: Replica(i, f) for i, f in enumerate(fetch_every)}
                self.leader, self.epoch, self.tick = 0, 0, 0
                self.isr = set(self.r)
                self.hw = 0                 # offsets below hw are committed and read-
able
                self.min_insync, self.lag_max, self.unclean = min_insync, lag_max, un-
clean

            def produce(self, value, acks):
                if acks == "all" and len(self.isr) < self.min_insync:

                print(f"  t={t}: write r{t} REJECTED, {e}")
            p.step()
            acked += [v for off, v in pending if p.is_acked(off, acks)]
            pending = [(off, v) for off, v in pending if not p.is_acked(off, acks)]
        print(f"  before crash: leader LEO={p.r[p.leader].leo} HW={p.hw} ISR=
{sorted(p.isr)}")
        try:
            old = p.fail_leader()
        except RuntimeError as e:
            print(f"  acked={len(acked)} unacked(retry)={len(pending)}; leader
crashed: {e}")
            return
        kept = {v for _, v in p.r[p.leader].log}
        lost = [v for v in acked if v not in kept]
        print(f"  leader {old} crashed -> new leader {p.leader}, epoch {p.epoch}, "
              f"log has {len(kept)} records")
        print(f"  acked={len(acked)} unacked(retry)={len(pending)} "
              f"ACKED BUT LOST={len(lost)} {lost}")
```

```
        if __name__ == "__main__":
            run("A: acks=1", "1", fetch_every=(1, 3, 3))
            run("B: acks=all, min.insync.replicas=2", "all", fetch_every=(1, 3, 3),
min_insync=2)
            run("C: acks=all, min.insync=1, followers stalled, unclean election on",
"all",
                fetch_every=(1, 50, 0), min_insync=1, unclean=True)
            run("D: same stall, min.insync.replicas=2", "all",
                fetch_every=(1, 50, 0), min_insync=2)
```

Output:

```
A: acks=1
  before crash: leader LEO=10 HW=9 ISR=[0, 1, 2]
  leader 0 crashed -> new leader 1, epoch 1, log has 9 records
  acked=10 unacked(retry)=0 ACKED BUT LOST=1 ['r9']
B: acks=all, min.insync.replicas=2
  before crash: leader LEO=10 HW=9 ISR=[0, 1, 2]
  leader 0 crashed -> new leader 1, epoch 1, log has 9 records
  acked=9 unacked(retry)=1 ACKED BUT LOST=0 []
C: acks=all, min.insync=1, followers stalled, unclean election on
  before crash: leader LEO=10 HW=10 ISR=[0]
  leader 0 crashed -> new leader 1, epoch 1, log has 0 records
  acked=10 unacked(retry)=0 ACKED BUT LOST=10 ['r0', 'r1', 'r2', 'r3', 'r4', 'r5', 'r6',
'r7', 'r8', 'r9']
D: same stall, min.insync.replicas=2
  t=5: write r5 REJECTED, ISR=[0]
  t=6: write r6 REJECTED, ISR=[0]
  t=7: write r7 REJECTED, ISR=[0]
  t=8: write r8 REJECTED, ISR=[0]
  t=9: write r9 REJECTED, ISR=[0]
  before crash: leader LEO=5 HW=5 ISR=[0]
  acked=0 unacked(retry)=5; leader crashed: no live ISR member: partition OFFLINE
```

What to notice:

- **A versus B** share replication timing. With `acks=1`, r9 was acknowledged from the leader's log alone and vanished in the failover (Figure 31.11). With `acks=all`, r9 was never acknowledged, so the producer retries it against the new leader; nothing acknowledged is lost.
- **C** shows `acks=all` alone is not enough: the ISR shrank to the leader, so "all ISR members" meant one broker, and unclean election then promoted an empty replica, losing ten acknowledged records.
- **D** adds `min.insync.replicas=2`: writes are refused once the ISR shrinks, and the partition goes offline rather than losing data. Availability is traded for durability.
- The model omits HW propagation delay, retries and timeouts, but its safety argument is the one Kafka makes.

31.10 Retention and log compaction

31.10.1 Time and size retention

With `cleanup.policy=delete` (the default), a partition keeps data for `retention.ms` (default 7 days) and, optionally, up to `retention.bytes` per partition (default unlimited). A background task deletes **whole closed segments** whose newest record is older than the limit, or the oldest segments when the partition exceeds the size limit. Because the active segment is never deleted, a low-traffic partition can hold data longer than `retention.ms` until its segment rolls. Retention is independent of consumption: Kafka deletes unread data on schedule and keeps read data until then.

31.10.2 Log compaction

> DEFINITION
>
> **Definition — Log compaction.** A retention policy (`cleanup.policy=compact`) that keeps **at least the latest record for each key** and discards older records with the same key, so the partition converges to a snapshot of the latest value per key while preserving the offsets and order of the records that remain. A record with a null value, a **tombstone**, marks a key as deleted and is itself removed after `delete.retention.ms` (default 24 hours).

First-principles explanation

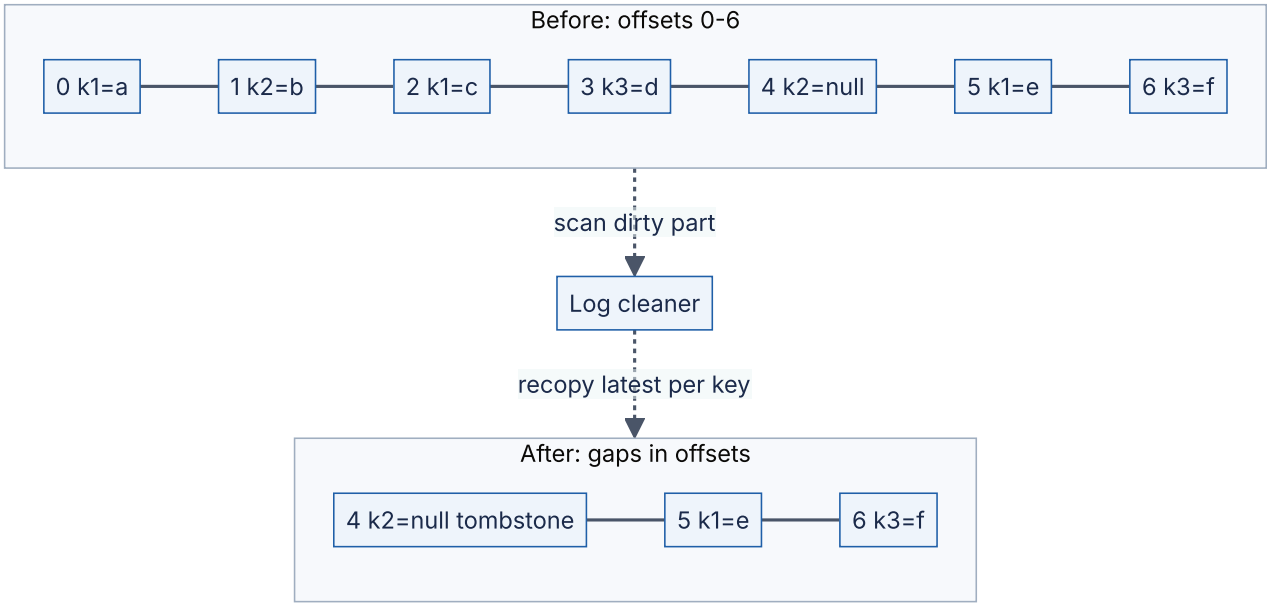
A phone book printed yearly does not list every address a person has ever had, only the current one; but if you photocopy it each day you can still rebuild today's town. A compacted topic is that phone book: it is the **changelog** of a table, and replaying it from offset 0 rebuilds the table's latest state, however long the topic has existed. This is the same idea as log-structured merge compaction (§13.9), applied to a replicated, readable log.

How it works internally

1. The log has a **clean** part (already compacted) and a **dirty** part (written since the last pass). The cleaner runs on a partition when the dirty fraction exceeds `min.cleanable.dirty.ratio` (default 0.5).
2. A cleaner thread scans the dirty part and builds an in-memory map from key to its latest offset.
3. It recopies the clean and dirty segments, keeping a record only if its offset is the latest for its key, and swaps in the new segments. Offsets are not renumbered, so the compacted log has gaps.
4. The active segment is never compacted, so recent history is always complete.

5. Tombstones survive long enough (`delete.retention.ms`) for consumers that are replaying to see the deletion, then disappear.

Figure 31.12 — Compaction keeps the latest value per key.



Reading the diagram. Before compaction, keys k1, k2 and k3 have several versions. The *log cleaner* runs asynchronously and keeps only the latest record per key: k1 = e at offset 5, k3 = f at offset 6, and the tombstone for k2 at offset 4, which will itself be removed after `delete.retention.ms`. Offsets 0–3 are gone but the survivors keep their original offsets and order. Failure points: a consumer that replays slower than `delete.retention.ms` can miss a tombstone and keep a deleted key; compaction needs disk headroom for recopying. Scaling: cleaner threads and their memory bound how fast large compacted topics converge.

Table 31.6 — Delete versus compact retention.

	`delete`	`compact`	`compact,delete`
Keeps	Everything for a time or size window	Latest record per key, forever	Latest per key, within a time window
Typical use	Event streams, logs, clickstream	Changelogs, `__consumer_offsets`, Kafka Streams state, CDC snapshots	Latest-state caches that may expire
Rebuild state by replay	Only within the window	Always	Within the window

INDUSTRY EXAMPLE

The New York Times publishing pipeline. The Times described storing every published asset since 1851 in a single-partition, log-compacted Kafka topic used as the source of truth; services such as search and personalization build their own views by replaying it from the beginning, and new derived systems are created by replay rather than by bulk export. The single partition preserves a total order of edits across assets. *Evidence: Primary* — [Svingen 2017]

COMMON MISTAKE

"Compaction makes Kafka a database." A compacted topic has no secondary indexes, no point reads by key (only sequential scans), and keeps several versions until the cleaner runs. It is a durable changelog from which a database, cache or Kafka Streams state store is built.

31.11 Delivery semantics and transactions

31.11.1 From at-least-once to exactly-once

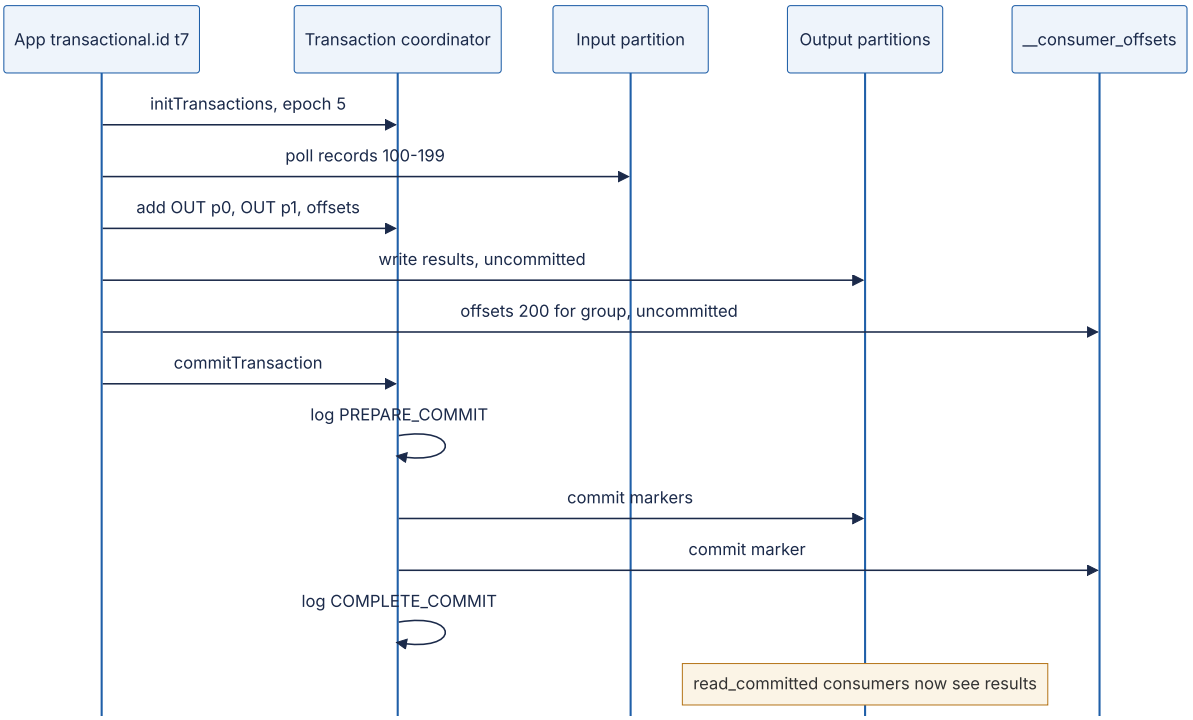
Kafka offers all three guarantees of §30.8: at-most-once (commit before processing, or `acks=0`), at-least-once (the default: retries plus commit after processing), and **exactly-once semantics (EOS)**, which Kafka defines narrowly: in a **read-process-write** pipeline from Kafka topics to Kafka topics, each input record's effects (output records *and* the input offset commit) appear exactly once, even across producer retries and application crashes [KIP-98]. Exactly-once delivery over a network is impossible in general; what Kafka provides is effectively-once *processing* by making the output and the offset commit atomic.

31.11.2 How transactions work

1. The application sets a stable **`transactional.id`** (for example, `billing-processor-7`). On `initTransactions()`, the **transaction coordinator** (the broker leading the partition of `__transaction_state` chosen by hashing the id) returns the producer ID and bumps its **epoch**. Any older instance with the same id now has a stale epoch and is **fenced**: its writes and commits are rejected. This is how a zombie, a paused instance whose replacement has already started, is stopped.
2. `beginTransaction()` starts a transaction locally. Before the first write to each partition, the producer registers that partition with the coordinator.
3. The producer writes output records normally (idempotently). They are in the logs but marked as belonging to an open transaction.

4. `sendOffsetsToTransaction()` adds the consumed input offsets to the same transaction, as writes to `__consumer_offsets`.
5. `commitTransaction()` runs two-phase commit (§28.4.8): the coordinator writes `PREPARE_COMMIT` to its log (the commit point), writes a **commit marker** (a control record) into every involved partition, then writes `COMPLETE_COMMIT`. Aborts write abort markers instead.
6. Consumers with `isolation.level=read_committed` read only up to the **last stable offset (LSO)**, the first offset of any still-open transaction, and skip records of aborted transactions using the `.txnindex`. The default, `read_uncommitted`, returns everything.

Figure 31.13 — A read-process-write transaction.



Reading the diagram. Outputs and input offsets are written inside one transaction with synchronous calls; the coordinator's replicated `__transaction_state` log records the decision. Once `PREPARE_COMMIT` is durable the transaction commits even if the coordinator crashes, because its successor replays the log and finishes the markers. If the application crashes first, the transaction is aborted (on timeout, `transaction.timeout.ms`, default 60 s, or when the restarted instance calls `initTransactions()`); `read_committed` consumers never see the partial output, and the restart resumes from the last committed offsets.

31.11.3 Limits of exactly-once

WARNING / TRADE-OFF

Exactly-once stops at Kafka's boundary. Transactions cover records written to Kafka and offsets committed to Kafka. They do not cover a database write, an email, a payment API call or any other side effect inside the processing step; if the application crashes after calling the payment API but before committing, the retry calls it again. For external sinks you need idempotent writes, offsets stored atomically with the output, or a transactional outbox and CDC; §32.9 examines these limits and §32.10 the idempotent-consumer pattern. Transactions also add latency (a commit every interval) and `read_committed` consumers wait for the slowest open transaction, which a hung producer can hold for up to `transaction.timeout.ms`.

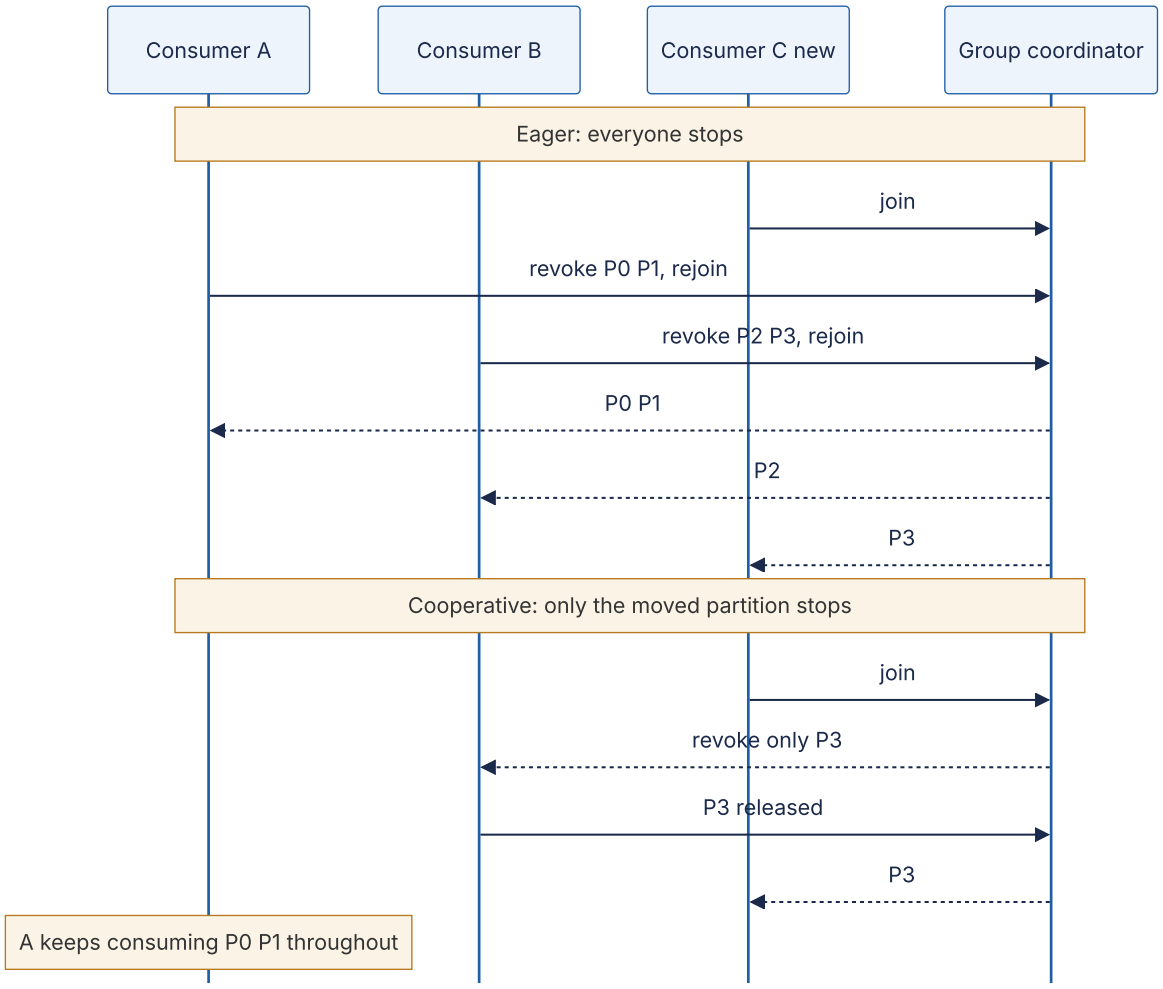
Kafka Streams enables this machinery with one setting, `processing.guarantee=exactly_once_v2`, committing by default every 100 ms under EOS. Stream processors such as Flink achieve the same end-to-end effect by tying Kafka transactions to their checkpoints (§29.9.2).

31.12 Rebalancing protocols

A **rebalance** reassigns partitions when a member joins, leaves, crashes or misses `max.poll.interval.ms`, or when partitions are added. Its cost is a gap in consumption and, if offsets were not committed, reprocessing.

1. **Eager rebalancing (classic protocol).** Every member revokes *all* its partitions, rejoins, the group leader (a client) computes a new assignment, and members resume. The whole group stops even if only one partition moves: "stop the world".
2. **Cooperative incremental rebalancing (KIP-429, Kafka 2.4).** With the `CooperativeStickyAssignor`, members keep partitions that are not moving; only partitions that change owner are revoked, over two shorter rounds. Most members never stop.
3. **Static membership (KIP-345, Kafka 2.3).** A member with a fixed `group.instance.id` that restarts within `session.timeout.ms` gets its old partitions back without any rebalance, which makes rolling deployments cheap.
4. **Next-generation consumer rebalance protocol (KIP-848).** The group coordinator on the broker, not a client leader, computes assignments and drives them incrementally through ordinary heartbeats; there is no group-wide synchronization barrier, so one member's slow join cannot stall the others. KIP-848 reached general availability in Kafka 4.0 and is enabled on brokers by default; as of 2026 Java consumers opt in with `group.protocol=consumer`.

Figure 31.14 — Eager versus cooperative rebalancing when consumer C joins.



Reading the diagram. In the eager half, C's arrival forces A and B to give up all four partitions, so nothing is consumed until the new assignment arrives. In the cooperative half, the coordinator asks only B to release P3, then assigns it to C; A never pauses and B pauses only P3. All messages are synchronous group-protocol calls. Failure point: one member slow to rejoin stretches an eager rebalance for the whole group, a cost that grows with group size.

Table 31.7 — Rebalance protocols (as of 2026).

Protocol	Who assigns	Pause during rebalance	Since
Eager (range, round-robin, sticky)	Client group leader	Whole group	Early versions
Cooperative sticky	Client group leader	Only moved partitions	2.4
Static membership (add-on)	Either	None on quick restart	2.3
KIP-848 consumer protocol	Broker coordinator	Only moved partitions, no global barrier	GA in 4.0

RECOMMENDATION

Reduce rebalances before speeding them up. Keep processing per `poll()` well under `max.poll.interval.ms` (lower `max.poll.records` if needed), use static membership for stateful or slow-starting consumers, commit offsets in the partition-revoked callback, and use a cooperative or KIP-848 protocol.

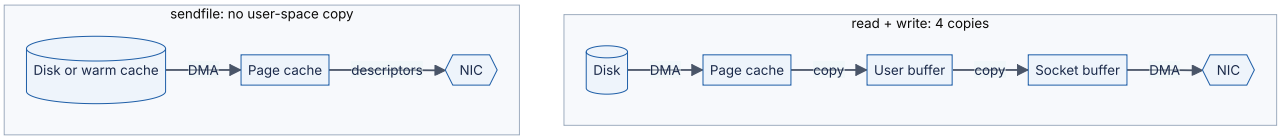
31.13 Performance

31.13.1 Why Kafka is fast

Kafka's throughput comes from a few hardware facts (Chapter 5) applied consistently [Apache Kafka Docs: Design]:

1. **Sequential I/O.** Appends and most reads are sequential, which disks and SSDs serve far faster than random access (§5.6).
2. **The page cache.** Brokers write to the OS page cache rather than a JVM-heap cache and let the kernel flush (§6.6.6); consumers near the head read from memory. This avoids double caching and garbage-collection pressure and survives broker restarts. Kafka does not `fsync` each write by default; durability comes from replication.
3. **Zero-copy transfer.** For plaintext connections the broker uses `sendfile` to move bytes from the page cache to the socket without user-space copies. TLS requires encryption in user space, which loses this (kernel TLS recovers part of it).
4. **End-to-end batching.** The producer's compressed batch is stored, replicated and sent to consumers as-is, so per-record costs are paid once per batch.

Figure 31.15 — Read path with and without zero-copy.



Reading the diagram. In the classic path, data crosses the kernel–user boundary twice, costing CPU copies and system calls. With `sendfile`, the kernel hands page-cache pages straight to the network card, so the broker's CPU barely touches the bytes. Both serve the same synchronous fetch. Failure point: a consumer reading old data causes disk reads that evict hot pages. Scaling: consumers of recent data are served from memory at network speed.

31.13.2 Sizing brokers for throughput

FORMULA

Brokers needed for network and disk throughput

$$N = \lceil \max\left(\frac{WR}{uD_b}, \frac{W(R-1+F)}{uE_b}\right) \rceil$$

Symbol	Meaning	Units
N	Brokers needed	count
W	Total produce throughput into the cluster (after compression)	MB/s
R	Replication factor	count
F	Number of consumer groups reading each record from brokers (fan-out)	count
D_b	Sustained disk write throughput per broker	MB/s
E_b	Network egress capacity per broker	MB/s
u	Target utilization (headroom for failures and catch-up)	fraction

Each byte is written to disk R times and leaves brokers $R-1$ times for replication plus F times for consumers. Network ingress (WR) is usually smaller than egress.

WORKED EXAMPLE

Worked example — A 400 MB/s cluster. $W = 400$ MB/s, $R = 3$, $F = 4$ consumer groups, each broker has $D_b = 1,000$ MB/s of disk write and a 25 Gb/s NIC ($E_b = 3,125$ MB/s), and you target $u = 0.5$ so a failed broker's load fits on the rest.

1. Disk: $400 \times 3 = 1,200$ MB/s cluster-wide; $1,200/(0.5 \times 1,000) = 2.4$.
2. Egress: $400 \times (3 - 1 + 4) = 2,400$ MB/s; $2,400/(0.5 \times 3,125) = 1.54$.
3. $N = \lceil 2.4 \rceil = 3$ brokers for throughput.
4. Storage (§31.15) and partition counts often require more; take the largest requirement.

Interpretation. At this scale disk writes, not the network, set the minimum, and consumers that read from the page cache add egress but almost no disk reads. **Engineering implication.** A lagging consumer that reads from disk adds disk *reads* not in this formula; keep headroom, or use tiered storage so historical reads come from object storage.

31.13.3 End-to-end latency budget

FORMULA

Produce-to-consume latency

$$T_{e2e} = t_{\text{linger}} + t_{\text{send}} + t_{\text{append}} + t_{\text{repl}} + t_{\text{fetch}} + t_{\text{proc}}$$

Symbol	Meaning	Units
t_{linger}	Time a record waits in the producer batch (≤ `linger.ms`)	ms
t_{send}	Network transfer to the leader	ms
t_{append}	Leader validation and append to page cache	ms
t_{repl}	Time until followers fetch it and the HW advances	ms
t_{fetch}	Consumer fetch wait and transfer after the record is committed	ms
t_{proc}	Consumer processing before the effect is visible	ms

WORKED EXAMPLE

Worked example — Budgeting a 50 ms p99 target. Within one region (round trips about 1 ms; cross-zone about 1–2 ms):

1. $t_{\text{linger}} = 5$ ms (default linger at low load).
2. $t_{\text{send}} = 1$ ms; $t_{\text{append}} = 1$ ms.
3. t_{repl}: followers fetch continuously across zones, typically 2–5 ms; at p99 under load, 10 ms.
4. t_{fetch}: a waiting consumer fetch returns as soon as data is committed, about 2 ms.
5. $t_{\text{proc}} = 10$ ms (one database write).
6. Total p99 estimate: $5 + 1 + 1 + 10 + 2 + 10 = 29$ ms, inside 50 ms with 21 ms to spare.

Interpretation. Replication and processing dominate, not disk. Consumers see records only after the HW advances, so with `acks=1` the *producer* is acknowledged sooner but the *consumer* still waits for replication. **Engineering implication.** If p99 is too high, check for slow followers holding back the HW, garbage-collection pauses, `read_committed` waiting on open transactions, and consumer lag, which adds queueing delay far larger than any term above.

INDUSTRY EXAMPLE

“2 million writes per second on three cheap machines.” A 2014 LinkedIn benchmark of Kafka on three commodity brokers reported about two million small-record writes per second with replication, and showed throughput staying flat as stored data grew, because reads and writes remain sequential and unaffected by log size [Kreps 2014]. The exact numbers depend on 2014 hardware and versions; the scaling argument is what transfers. *Evidence: Primary* — [Kreps 2014]

31.14 Kafka Streams and Kafka Connect

31.14.1 Kafka Streams

Kafka Streams is a Java library (not a cluster) for stream processing on Kafka. Its two core abstractions express the **stream–table duality**:

- A **KStream** is an unbounded sequence of independent events (“order 17 was paid”).
- A **KTable** is a changelog interpreted as a table: each record is an upsert for its key, and a tombstone deletes it. Aggregating a KStream produces a KTable; reading a KTable’s changes produces a KStream. A **GlobalKTable** is replicated in full to every instance for joins without repartitioning.

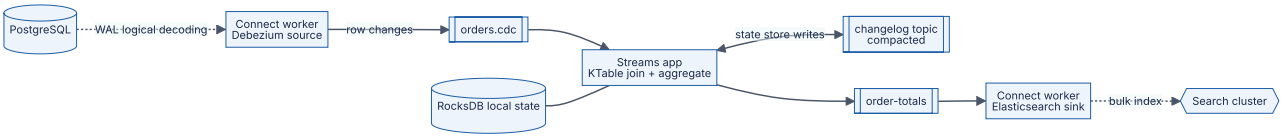
Stateful operations (aggregations, joins, windows, §29.8) keep **state stores**, by default embedded RocksDB instances (§13.14.2) on the instance's local disk. Every store write is also sent to a compacted **changelog topic**, so when an instance dies, another rebuilds the store by replaying the changelog; **standby replicas** (`num.standby.replicas`) keep warm copies to shorten that recovery. Re-keying a stream writes it through an internal **repartition topic** so records with the new key meet in one partition. Scaling is by partitions: each input partition becomes a **task**, and tasks are spread over instances using the consumer-group protocol.

31.14.2 Kafka Connect and Debezium

Kafka Connect is a framework for moving data between Kafka and other systems without custom code. A cluster of **workers** runs **connectors**, each split into **tasks**. **Source connectors** read from an external system into topics; **sink connectors** write topics to an external system. **Converters** serialize data (JSON, Avro or Protobuf, often with a schema registry), **single message transforms** make light per-record changes, and sink errors can be routed to a dead-letter topic (§30.11). In distributed mode, connector configurations, source offsets and status live in three internal compacted topics, so workers are stateless and restartable.

Debezium is a family of source connectors for **change data capture (CDC)**: it reads a database's own replication log (PostgreSQL logical decoding of the WAL, the MySQL binlog), takes an initial snapshot, then emits one event per committed row change, typically to a topic per table keyed by primary key [Debezium Docs]. Chapter 32 builds the transactional outbox and CDC patterns on it (§32.5–§32.6).

Figure 31.16 — Connect, Streams and CDC around one cluster.



Reading the diagram. A *Debezium* source connector tails PostgreSQL's WAL asynchronously and publishes row changes to `orders.cdc`. A *Kafka Streams* application joins and aggregates them, keeping state in local *RocksDB* backed by a compacted *changelog topic*, and writes results to `order-totals`. A *sink connector* bulk-indexes those into a search cluster. Failure points: a dead Streams instance's tasks move elsewhere and restore state from the changelog; a sink outage builds lag but loses nothing within retention. Scaling: add workers or instances up to the partition counts.

31.15 Operating Kafka

31.15.1 What to monitor

Table 31.8 — Core health signals.

Signal	Healthy value	What it means when wrong
`UnderReplicatedPartitions`	0	Followers lagging or a broker down; redundancy reduced
`UnderMinIsrPartitionCount`	0	`acks=all` writes are being refused for those partitions
`OfflinePartitionsCount`	0	No leader: partitions unavailable
`ActiveControllerCount`	1 across the cluster	0 means the KRaft quorum has no leader
ISR shrink/expand rate	Near 0	Flapping followers: network, disk or GC problems
Consumer lag (records and seconds)	Bounded, not growing	Consumers too slow or stuck (§31.7.3)
Produce/fetch request latency p99	Stable	Disk saturation, page-cache misses, overloaded broker

Routine operations include **partition reassignment** (moving replicas to new brokers, throttled so replication does not starve clients), **rolling restarts** with controlled leadership transfer, **quotas** per client to stop one tenant saturating a broker, and automated balancing tools such as LinkedIn's Cruise Control.

31.15.2 Capacity planning for disk

FORMULA

Local disk required for retention

$$S = \frac{W \cdot t_{\text{ret}} \cdot R}{u}$$

Symbol	Meaning	Units
S	Total provisioned broker disk	bytes
W	Average produce throughput after compression	bytes/s
t_{ret}	Retention period	s
R	Replication factor	count
u	Maximum safe disk utilization	fraction

WORKED EXAMPLE

Worked example — Seven days at 200 MB/s. W = 200 MB/s average, t_{ret} = 7 days = $604,800$ s, R = 3, u = 0.7.

1. One copy: $200 \times 10^6 \times 604,800 = 1.2096 \times 10^{14}$ B = 121 TB.
2. Three replicas: 363 TB.
3. Divide by 0.7: $S \approx 518$ TB.
4. With 12 TB usable per broker: 518/12 = 43.2, so 44 brokers, far more than the 2 that throughput needs at 200 MB/s by the formula of §31.13.2 (the 400 MB/s example there needed 3).
5. With **tiered storage** keeping 1 day locally: local $= 200 \times 10^6 \times 86,400 \times 3/0.7 = 74$ TB (7 brokers), plus 121 TB of one logical copy in object storage, whose durability is the object store's.

Interpretation. Retention, not throughput, sized this cluster. **Engineering implication.** Long retention on broker disks couples storage to compute; tiered storage decouples them and makes broker replacement and rebalancing faster because there is less local data to copy.

31.15.3 Tiered storage (KIP-405)

With **tiered storage**, closed segments are copied to a remote store (typically object storage) through a pluggable `RemoteStorageManager`, and deleted locally after `local.retention.ms`; the topic's `retention.ms` still governs total retention. Consumers reading old offsets are served transparently from the remote tier, at higher latency. Tiered storage was early access in Kafka 3.6 and declared production-ready in 3.9 (2024) [KIP-405]; as of 2026 it requires a third-party or vendor plugin for the specific object store.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Disk fills on a broker	Retention too long, skewed partitions	Disk usage alerts	Shorten retention, reassign partitions	Formula above with $u \le 0.7$; tiered storage
Lag grows without bound	Consumers slower than producers, or a poison record	Lag in seconds rising	Scale consumers, skip or dead-letter the record	Capacity headroom; DLQ handling (§30.11)
Under-min-ISR during maintenance	Two brokers restarted at once	`UnderMinIsrPartitionCount` > 0	Bring brokers back	Restart one broker at a time; wait for ISR to recover
Cross-zone transfer cost spike	Consumers fetch from leaders in other zones	Cloud bill, network metrics	Enable follower fetching (KIP-392)	Rack-aware placement and clients

31.16 Summary and revision notes

SUMMARY

- Kafka is a **partitioned, replicated, append-only log**. Consumers track their own offsets, so reading does not delete, many groups read independently, and history can be replayed (§31.3).
- **KRaft** stores metadata in a Raft-replicated `__cluster_metadata` log; ZooKeeper mode was removed in Kafka 4.0 (2025). Data partitions still use ISR replication (§31.4).
- Order holds **within a partition only**. Keys pick partitions by `murmur2 mod P`; changing P moves $1 - \min(P,P')/\operatorname{lcm}(P,P')$ of keys, so size keyed topics up front: $P = \lceil h \max(T/t_p, T/t_c) \rceil$ (§31.5).
- Producers batch by `linger.ms` and `batch.size`, compress per batch, and default to `acks=all` with idempotence (PID + sequence numbers, ordering preserved with up to 5 in-flight requests) (§31.6).
- A consumer group gives each partition to one member; parallelism ≤ partitions; lag drains in $L/(\mu - \lambda)$ (§31.7).
- Commit after processing = at-least-once; commit before = at-most-once; offsets live in compacted `__consumer_offsets` (§31.8).
- HW = min LEO over the ISR; consumers read below it. RF = 3, `min.insync.replicas=2`, `acks=all`, unclean election off survives one failure with no loss and no write outage. Leader epochs fence stale leaders and make truncation safe (§31.9).
- Retention deletes whole segments by time or size; compaction keeps the latest value per key and turns a topic into a changelog (§31.10).
- Transactions (2PC through a coordinator, fenced by `transactional.id` epochs, read via `read_committed`) give exactly-once for Kafka-to-Kafka read-process-write only (§31.11).
- Cooperative rebalancing, static membership and KIP-848 (GA in 4.0) cut rebalance pauses (§31.12).
- Speed comes from sequential I/O, the page cache, `sendfile` zero-copy and end-to-end batching; size brokers by disk, egress and especially retention: $S = Wt_{\text{ret}}R/u$; tiered storage decouples retention from broker disks (§31.13–§31.15).

31.17 Knowledge checkpoint

1. Why can a Kafka consumer replay data that a classic queue consumer cannot?
2. What problem with ZooKeeper-mode controller failover did KRaft solve?
3. How does a broker find offset 368,800 in a partition with many segments?

4. A keyed topic grows from 10 to 15 partitions. What fraction of keys move?
5. With `linger.ms=5` and 400 records/s into a partition, how many records are in each batch?
6. Why does an idempotent producer preserve order with five requests in flight?
7. A group has 8 members and the topic has 6 partitions. What happens?
8. Which commit timing gives at-most-once delivery, and why?
9. Leader LEO 500, follower LEOs 480 and 470, all in the ISR. What is the HW, and what can consumers read?
10. Why is RF = 3 with `min.insync.replicas=3` a poor choice?
11. What does unclean leader election trade?
12. What does a tombstone do in a compacted topic, and why is it kept for a while?
13. What exactly does Kafka's exactly-once guarantee cover?
14. Why does TLS reduce Kafka's zero-copy benefit?
15. Retention 3 days, 50 MB/s, RF = 3, $u = 0.75$: how much disk?

Answers

1. Reading only advances the consumer's own offset; records remain until retention removes them, so any consumer can seek back.
2. A new controller had to reload all metadata from ZooKeeper, taking time proportional to partition count; KRaft standbys already hold the metadata log in memory.
3. Binary-search segments by base offset, binary-search that segment's sparse `.index`, then scan forward a few kilobytes.
4. $\text{lcm}(10, 15) = 30$, $\min = 10$: $1 - 10/30 = 2/3 \approx 67\%$.
5. $400 \times 0.005 = 2$ records (assuming they fit in `batch.size`).
6. The leader accepts batches only in sequence order per producer and partition; an out-of-order batch is rejected and resent.
7. Six members get one partition each; two are idle standbys.
8. Commit before processing: a crash after the commit skips the uncommitted work, losing it but never duplicating it.
9. HW = 470; consumers read offsets 0–469.
10. Any single broker outage, including a rolling restart, shrinks the ISR below 3 and blocks `acks=all` writes.
11. It restores availability by electing an out-of-sync replica, losing acknowledged records that replica lacked.
12. It marks the key deleted; it is retained for `delete.retention.ms` so consumers replaying the log see the deletion before it disappears.
13. Atomic output to Kafka topics plus input offset commits in a read-process-write pipeline, seen by `read_committed` consumers; not external side effects.
14. Data must be encrypted in user space, so the kernel cannot send page-cache pages directly to the socket.
15. $50 \times 10^6 \times 259,200 \times 3/0.75 = 5.18 \times 10^{13}$ B $\approx$ 52 TB.

31.18 Interview questions

Basic

Q1. How does Kafka guarantee ordering? Answer. Only within a partition: the leader assigns increasing offsets and consumers read in offset order. Records that must stay ordered share a key so they hash to one partition. There is no order across partitions, and changing the partition count breaks per-key order for in-flight data.

Q2. What is a consumer group? Answer. Consumers sharing a `group.id` that divide partitions so each partition has one owner; different groups read independently. Parallelism is capped by partition count.

Intermediate

Q3. Configure a topic so an acknowledged write survives any single broker failure without making writes unavailable. Answer. RF = 3 across three racks or zones, `min.insync.replicas=2`, producer `acks=all` with idempotence, unclean leader election disabled. One failure leaves two in-sync replicas, so writes continue and every acknowledged record is on at least two brokers.

Q4. Consumer lag is growing after a deploy. How do you diagnose it? Answer. Check whether lag grows on all partitions (throughput: processing slowed, too few consumers, downstream database slow) or a few (hot key, poison record, stuck consumer). Look for frequent rebalances (processing exceeding `max.poll.interval.ms`), compare production rate with consumption rate, compute drain time, and scale consumers only up to the partition count.

Advanced

Q5. Design exactly-once processing from a Kafka topic into PostgreSQL. Answer. Kafka transactions do not cover PostgreSQL. Either write results and the consumed offset in one PostgreSQL transaction and seek to the stored offset on start-up, or make writes idempotent (upsert keyed by event ID or a processed-events table) with at-least-once commits. Mention zombie consumers after rebalance: the database transaction or a fencing check on partition ownership must reject stale writers.

Q6. Why does Kafka use ISR replication for data but Raft for metadata? Answer. ISR commits when all in-sync replicas have a record, tolerating f failures with $f + 1$ copies, which halves storage relative to majority quorums for large data volumes; it relies on an external authority to manage ISR membership and elections. That authority must itself be consistent without external help, so the metadata quorum uses Raft, where majority commit needs no outside arbiter and slow members do not block progress.

31.19 Practical exercises

1. Run the simulation of §31.9.5 with `fetch_every=(1, 1, 1)` and `acks=1`. Is anything lost? Explain why the loss window depends on replication lag.
2. Extend the simulation with HW propagation delay: followers learn the HW one fetch later. Construct a double failure that loses committed data if followers truncate to their own HW, then fix it with leader-epoch truncation.
3. Using the partitioner code, measure per-partition counts for 1,000,000 keys of the form `tenant-<n>` with 48 partitions, then for keys where 5% of traffic is one tenant. Compute the hottest partition's share.
4. Write a consumer loop (pseudo-code) that commits asynchronously during normal operation and synchronously on revocation and shutdown.
5. Size a cluster for 1 GB/s, 3-day retention, RF = 3, 5 consumer groups, 20 TB disks and 25 Gb/s NICs, using the formulas of §31.13.2 and §31.15.2.

31.20 Design challenges

1. **Order event backbone.** Design topics, keys, partition counts and durability settings for an e-commerce platform with 30,000 orders/s at peak, per-order ordering, a 30-day replay requirement and consumers for billing, search and analytics. Justify each number and plan how to grow partitions in two years.
2. **Multi-region log.** Two regions must both consume all orders, and the platform must survive a region loss with at most 5 seconds of data loss. Compare stretched clusters with asynchronous cross-cluster replication, and state the recovery point and recovery time of each.
3. **Changelog-backed cache.** Replace nightly cache rebuilds with a compacted topic fed by CDC. Specify tombstone handling, bootstrap time for a new cache node, and how consumers detect that they have caught up.

31.22 Open verification items

- Exact Kafka release for each status as of 2026: KRaft production-ready 3.3, ZooKeeper deprecated 3.5, removed 4.0 (March 2025); KIP-848 GA in 4.0 with client opt-in via `group.protocol=consumer`; tiered storage production-ready in 3.9.
- KIP-932 share groups: maturity level in the current 4.x release.

- Defaults quoted: `linger.ms` 5 ms (4.0, KIP-1030), `session.timeout.ms` 45 s, `replica.lag.time.max.ms` 30 s, `__consumer_offsets` 50 partitions, Streams EOS commit interval 100 ms.
- Kreps 2014 benchmark figures and Svingen 2017 details (single-partition compacted topic) against the original posts.
- Exact URLs for KIP-101, KIP-848 and the 4.0 release announcement.
- The brief listed *Kafka: The Definitive Guide* (2nd ed.) as Narkhede, Shapira and Palino; the 2021 edition's authors are Shapira, Palino, Sivaram and Petty (Narkhede co-authored the 2017 first edition).

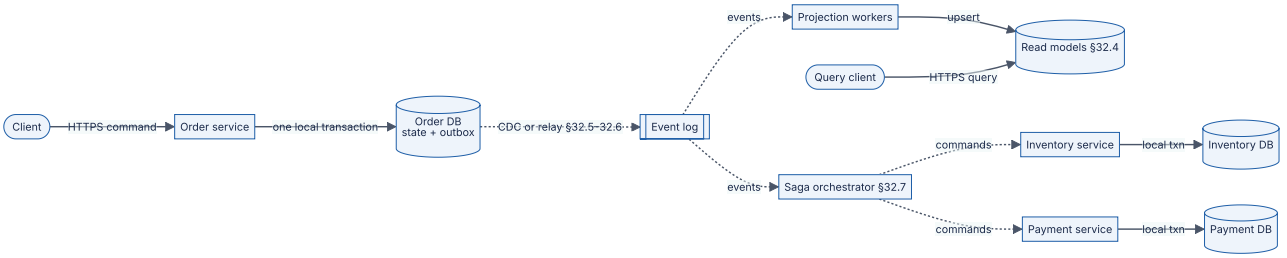
Chapter 32 — Event-Driven Architecture Patterns

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Chapter 30 introduced messages, brokers and delivery guarantees, and Chapter 31 showed how Kafka stores events in a replicated, partitioned log. This chapter is about what you *build* with those tools when a business process spans several services, each owning its own database. Four problems recur. How do you record what happened so that you can rebuild, audit and re-interpret it later (event sourcing)? How do you serve queries that the write model answers badly (CQRS)? How do you change a database *and* tell the world about it without losing or inventing events (the transactional outbox and change data capture)? And how do you keep a multi-step business transaction correct when 2PC is not an option (sagas, choreography, orchestration and workflow engines)?

Underneath all four sits one uncomfortable fact: messages are delivered at least once, so every consumer must be safe to run twice. Sections 32.9 and 32.10 make that precise. The running example is the online shop of Chapter 11, now split into order, inventory, payment and shipping services; it is *illustrative*, not a description of any real company. Two-phase commit is Chapter 28's subject; API idempotency keys are owned by §22.15 and only applied here.

Figure 32.1 — How the patterns in this chapter fit together.



Reading the diagram. The only synchronous write a user waits for is the order service's local transaction, which stores the new state and, in the same transaction, an outbox row (or, with event sourcing, the events themselves). Everything after that is asynchronous (dotted arrows): a relay or change data capture (CDC) process copies committed events to the event log; projection workers build read models; a saga orchestrator sends commands to the inventory and payment services, each of which commits locally. Each database is a separate storage boundary, and no transaction spans two of them. Failure points: the relay, the log, each consumer and each service can crash between any two

steps, so every arrow is retried and every receiver deduplicates. Scaling is per component: partition the log by order ID, run more projection workers per partition, and shard the orchestrator by saga ID.

32.1 Learning objectives

After this chapter you should be able to:

- Design an event-sourced aggregate with optimistic concurrency, snapshots and schema upcasting, and estimate its replay time.
- Explain how event sourcing interacts with the GDPR right to erasure and apply crypto-shredding.
- Build CQRS read models from an event stream, estimate projection lag, and say when CQRS is not worth it.
- Show with a failure sequence why dual writes lose or invent events, and implement a transactional outbox with a polling or log-tailing relay.
- Describe how log-based change data capture (Debezium) snapshots and streams a database, and the role of a schema registry.
- Design a saga with compensating, pivot and retriable steps, analyze a failure at each step, and choose countermeasures for its missing isolation.
- Compare choreography and orchestration, and decide when a workflow engine (Temporal, Step Functions) beats a hand-rolled saga.
- State precisely what “exactly-once” means in Kafka and why end-to-end effectively-once needs idempotent consumers.

32.2 Prerequisites

- Messages, events versus commands, delivery guarantees and dead-letter queues — Chapter 30 (this chapter assumes at-least-once delivery).
- Kafka partitions, offsets, idempotent producers and transactions — §31.5–§31.11 (the event log underneath most examples).
- Local transactions, isolation anomalies and the write-ahead log — §11.11–§11.15 and §13.5 (the outbox and CDC rely on them).
- Logical replication — §14.4 (CDC is a consumer of it).
- Two-phase commit and the saga preview — §28.4 and §28.6 (sagas are the alternative to 2PC).
- Idempotency keys — §22.15 (owned there; applied to consumers here).
- The end-to-end argument — §24.14 (why exactly-once must be finished by the application).

32.3 Event sourcing

32.3.1 Storing facts instead of current state

> DEFINITION
>
> **Definition — Event sourcing.** A persistence pattern in which the system of record for an entity is the append-only, ordered sequence of **domain events** that changed it (`AccountOpened`, `MoneyDeposited`, …). Current state is not stored as truth; it is derived by replaying the events, a **left fold** of a pure function `apply(state, event)` over the sequence [Fowler 2005].

First-principles explanation

An accountant never erases a ledger line. If a payment was booked wrongly, a correcting entry is added, and the balance is the sum of all lines. A bank statement is a *view* computed from the ledger. Event sourcing applies the same discipline to software: instead of `UPDATE accounts SET balance = 4000`, you append `MoneyWithdrawn{amount: 1000}`, and the balance is whatever the events add up to.

Why does this exist?

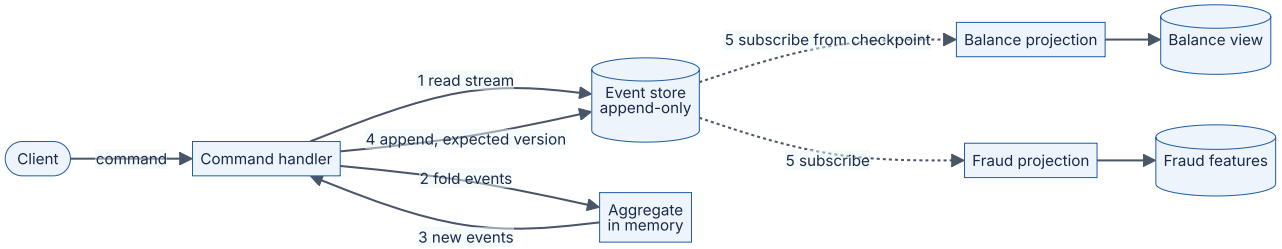
A conventional table that is updated in place answers "what is true now?" and forgets "how did we get here?". Many domains need the second question: auditors, fraud analysts, customer-support agents ("why was I charged twice?"), and engineers who want to build a *new* view of old data, such as "average time from cart to checkout last year", without having logged it in advance. With state-oriented storage, history survives only if someone remembered to write an audit table, and audit tables drift from the truth because they are a second write. With event sourcing the history *is* the truth, so it cannot drift. Other benefits follow: temporal queries ("the balance on 31 March"), debugging by replaying production events, and natural integration, because the events can be published to other services.

How it works internally

1. **Streams and aggregates.** Events are grouped into **streams**, one per **aggregate**: a cluster of objects that is a consistency boundary, such as one account or one order (a term from domain-driven design). An invariant ("balance never negative") is enforced inside one aggregate; nothing is atomic across aggregates.
2. **Command handling.** A command (`Withdraw 4,000`) loads the aggregate by replaying its stream, validates the command against current state, and, if valid, produces new events. The command can be rejected; an event cannot, because it describes something that already happened.

3. **Optimistic concurrency.** The append carries the **expected version**, the stream length the handler saw. If another writer appended in between, the store refuses the append and the handler reloads and retries. This is the event-store equivalent of a compare-and-set, and it serializes writes per aggregate without locks.
4. **The event store.** Any durable, ordered, append-only storage works: a relational table with a unique key on `(stream_id, version)`, a purpose-built store such as EventStoreDB, or a log. Kafka is a poor fit as the *only* store, because it has no per-key expected-version append and loading one aggregate means scanning a partition; it is an excellent transport for the events afterwards [Kleppmann 2017, ch. 11].
5. **Projections.** Subscribers fold events into read-optimized views (§32.4), each tracking a **checkpoint**, the global position of the last event it applied.

Figure 32.2 — The write path of an event-sourced service.

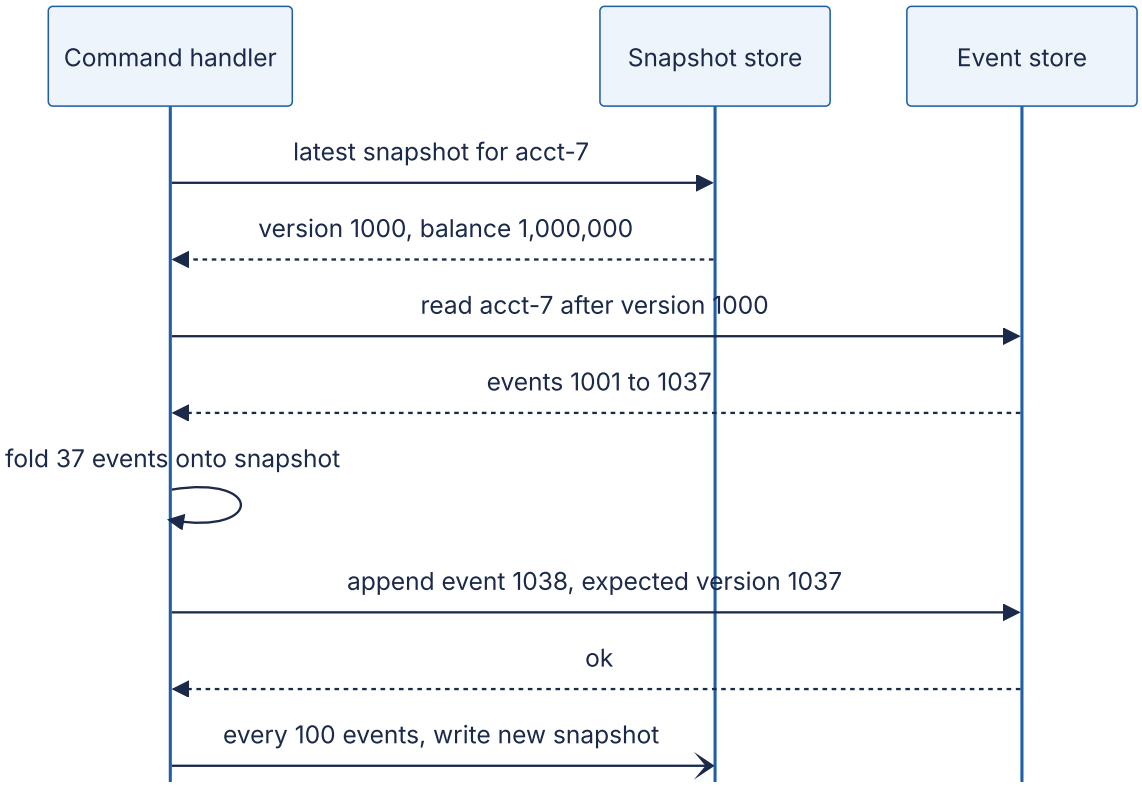


Reading the diagram. Steps 1–4 are synchronous and run inside the command handler; the aggregate exists only in memory, rebuilt from the event store for each command (or cached). The append in step 4 is the single atomic write and the commit point; an expected-version mismatch fails it and the handler retries from step 1. Step 5 is asynchronous: each projection pulls events after its own checkpoint and updates its own store, so views lag the event store and can be deleted and rebuilt. Failure points: a crash before step 4 loses nothing (no event was recorded, the client retries with an idempotency key, §22.15); a projection crash leaves its view stale until it resumes from its checkpoint. Scaling: streams partition naturally by aggregate ID; projections scale by partitioning the event feed.

32.3.2 Rebuilding state and snapshots

Replaying a stream of a few dozen events is cheap. Long-lived aggregates (a merchant account with millions of transactions) and full projection rebuilds are not. A **snapshot** stores the aggregate's state at version v; loading reads the latest snapshot and replays only events after v. A snapshot is a cache: it can be deleted and recomputed, and it must record the schema version of the state it holds, because changing the `apply` logic invalidates old snapshots.

Figure 32.3 — Loading an aggregate from a snapshot plus its tail.



Reading the diagram. Both stores are durable storage boundaries; they may be two tables in one database. The handler reads synchronously from both, folds at most one snapshot interval of events, and appends with the expected version. Writing the snapshot is asynchronous and optional (the half-arrow): if it fails or the process crashes, the next load simply replays more events. The failure to watch is a stale snapshot built with an older `apply` function; version the snapshot schema and discard mismatches. Snapshot frequency trades storage and write work against load latency.

Mathematical foundations

FORMULA

Replay time with and without snapshots

$$T_{\text{full}} = \frac{N}{r} \qquad T_{\text{snap}} \approx t_s + \frac{S}{2r}$$

Symbol	Meaning	Units
N	Events in the stream (or in the whole store, for a projection rebuild)	events
r	Replay throughput: events read and applied per second	events/s
S	Snapshot interval; on average $S/2$ events follow the latest snapshot	events
t_s	Time to read and deserialize one snapshot	s
$T_{\text{full}}, T_{\text{snap}}$	Time to rebuild state from scratch or from a snapshot	s

WORKED EXAMPLE

Worked example — A busy merchant account and a full rebuild.

1. A merchant account has $N = 50,000$ events; the handler replays $r = 20,000$ events/s. $T_{\text{full}} = 50,000/20,000 = 2.5$ s per command, unacceptable for a payment API.
2. Snapshot every $S = 500$ events with $t_s = 2$ ms: $T_{\text{snap}} = 0.002 + 250/20,000 = 0.002 + 0.0125 = 14.5$ ms.
3. A new fraud projection must process the whole store: $N = 2 \times 10^9$ events at $r = 100,000$ events/s gives $T_{\text{full}} = 20,000$ s ≈ 5.6 h on one worker. With 16 partitions processed in parallel at the same per-worker rate, about 21 minutes.

Interpretation: snapshots turn per-command cost from $O(N)$ into $O(S)$; they do nothing for projection rebuilds, which need parallelism. Engineering implication: snapshot long-lived aggregates (or, better, model them so streams stay short, for example one stream per merchant per day), and design projections to be partitionable from the start.

32.3.3 Code example: an event-sourced account with snapshots

The program below implements an event store with expected-version appends, an account aggregate, a repository that snapshots every S events, and an upcaster for an old event schema (§32.3.4).

```
        """Event-sourced bank account with optimistic concurrency, snapshots and upcast-
ing.

        The event store is append-only. Account state is never stored directly: it is
        rebuilt by replaying events, optionally starting from a snapshot.
        Run it directly with python3 to execute the tests.
        """
        import unittest

        class ConcurrencyError(Exception):
            """Another writer appended to the stream since we loaded it."""

        class EventStore:
            def __init__(self):
                self.streams = {}    # stream_id -> list of event dicts (version = index
+ 1)
                self.snapshots = {}  # stream_id -> (version, state dict)
                self.reads = 0       # events read from storage, to measure replay cost

            def append(self, stream_id, events, expected_version):
                stream = self.streams.setdefault(stream_id, [])
                if len(stream) != expected_version:          # optimistic concurrency
check
                    raise ConcurrencyError(f"{stream_id}: expected {expected_version},
at {len(stream)}")
                stream.extend(events)
                return len(stream)

            def read(self, stream_id, after_version=0):
                events = self.streams.get(stream_id, [])[after_version:]
                self.reads += len(events)
                return [upcast(e) for e in events]           # old shapes are upgraded
on read

        def upcast(event):
            """Schema v1 (no "schema" field) stored float dollars; v2 stores integer
cents."""
            if "schema" not in event and "amount" in event:
                event = {"type": event["type"], "schema": 2,
                         "amount_cents": round(event["amount"] * 100)}
            return event                                     # a new dict: storage is
untouched

        class InsufficientFunds(Exception):
            pass

        class Account:
            """Aggregate: decides with current state, records decisions as events."""

            def __init__(self, account_id):

Output (Python 3.13; the timing varies):

```
....
----------------------------------------------------------------------
Ran 4 tests in 0.041s

OK
```

What to notice:

- `apply` never validates and never fails; validation lives in the command methods. Replaying history must always succeed, even for events that today's rules would reject.
- `test_concurrent_writers_conflict` is the lost-update anomaly of §11.13 prevented by the expected version: both writers saw 5,000, only the first append wins, and the reloaded second writer is refused by the invariant.
- With a snapshot every 100 events, loading reads 1 event instead of 1,001. The snapshot is written *after* the append succeeds, so it never contains uncommitted state.
- The upcaster converts the stored v1 event into a new dictionary on every read; the stored history is never rewritten.

32.3.4 Schema evolution and upcasting

Events are kept for years, but the code that reads them changes weekly. A message schema in Chapter 30 must survive only until its consumers drain the queue; an event schema must survive forever. Every change must therefore be **backward compatible for readers**: the current code must understand every version ever written.

Table 32.1 — Strategies for evolving event schemas.

Strategy	How it works	Use when	Cost
Additive change	Add optional fields with defaults; never rename or retype	Most changes	Lowest; enforce with a schema registry (§32.6.3)
Weak schema	Readers map JSON by name and ignore unknown fields	Polyglot consumers	Silent misreads if meaning changes
Upcasting	A function converts version k to $k+1$ at read time; chain them	Renames, unit changes, splits	Every read pays the conversion; chains grow
New event type	`OrderShippedV2` alongside the old type	Meaning changed	Every consumer handles both forever
Copy-and-transform migration	Write a new store with converted events, switch over	Accumulated upcasters slow reads	A large batch job; history now differs from what was originally written

Young's guidance is to prefer additive changes and upcasting, and to treat rewriting history as a last resort, because the event log is also an audit record [Young 2017].

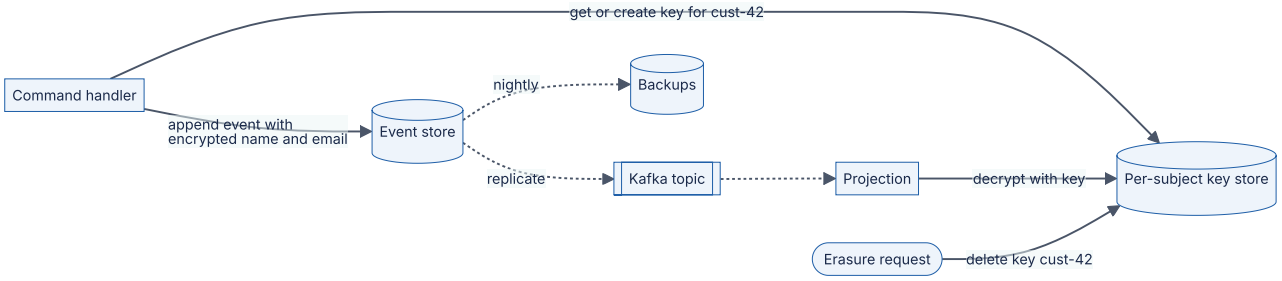
32.3.5 Deletion, the GDPR and crypto-shredding

Immutability collides with law. The EU General Data Protection Regulation gives people a **right to erasure** (Article 17) of their personal data in many circumstances [EU 2016/679]. An append-only store that holds `CustomerRegistered{name, email}` cannot simply delete it, and neither can the Kafka topics, backups and projections that copied it.

Three techniques, usually combined:

1. **Keep personal data out of events.** Events carry an opaque `customer_id`; the name and address live in a mutable store that can delete rows. This is the cleanest answer but not always possible (a shipping event needs an address).
2. **Crypto-shredding.** Encrypt each data subject's personal fields with a per-subject key held in a key store. To erase, delete the key: every copy of the ciphertext, in every log, backup and replica, becomes unreadable at once.
3. **Compaction or rewriting** for systems where events can be replaced, such as a Kafka compacted topic with a tombstone (§31.10). This removes data only where compaction reaches; backups still need handling.

Figure 32.4 — Crypto-shredding personal fields in an event store.



Reading the diagram. Only the key store is mutable and deletable; the event store, the Kafka topic and the backups hold ciphertext. Writes and decrypting reads call the key store synchronously; replication and backup are asynchronous copies. After the erasure request deletes the key, projections replaying old events receive a “key not found” error and must render the fields as erased rather than fail. Failure points: the key store becomes a critical dependency on every read and write (cache keys with a short TTL, and replicate the key store), and a key leaked before deletion defeats the scheme. Scaling: one key per subject means millions of keys, so use envelope encryption with a key-management service.

WARNING / TRADE-OFF

Warning — Crypto-shredding is an argument, not a guarantee. Whether deleting a key satisfies erasure under a particular regulator’s reading is a legal question; non-personal fields (amounts, timestamps) remain and may still identify someone in combination. Involve your privacy counsel, and keep personal data out of events where you can.

32.3.6 Trade-offs, industry use and failure scenarios

INDUSTRY EXAMPLE

LMAX exchange — event sourcing in memory. LMAX’s retail trading platform runs its business logic on a single thread over in-memory state. Every input event is journaled and replicated before processing, and state is recovered after a restart by loading a nightly snapshot and replaying the journal. Fowler reports the business logic processor handling about six million orders per second, possible because no business step waits on a database. *Evidence: Primary* — [Fowler 2011a]

Advantages. A complete, trustworthy audit trail; the ability to build new read models from old history; temporal queries; replay for debugging; natural event publication; append-only writes that are cheap and contention-free across aggregates.

Disadvantages. A steep learning curve; eventual consistency for every read model; schema evolution forever; hard deletion; no ad hoc queries against the event store; and

aggregate boundaries that are expensive to change once events exist.

Table 32.2 — Event sourcing failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Lost update	Append without expected version	Invariant violations in reconciliation	Compensating events	Always append with expected version
Replay crashes on old event	`apply` validates, or code dropped an old type	Rebuild jobs fail	Hotfix the upcaster, replay	Never validate in `apply`; replay tests over production samples
Stale or corrupt snapshot	Snapshot written by older logic	Snapshot-vs-replay comparison	Delete snapshots, rebuild	Version snapshots; sample-verify against full replay
Commands slow down over time	Streams grow without bound	Load latency vs stream length	Add snapshots	Short-lived streams; "closing the books" events
Projection serves wrong data	Bug in projection code	Diffs against a rebuilt view	Fix and rebuild from position 0	Blue-green projections

COMMON MISTAKE

Common misconception — "Event sourcing means using Kafka as the database." Event sourcing needs per-aggregate reads and expected-version appends; a Kafka topic offers neither directly. Store events in a database or event store and *publish* them to Kafka (§32.5, §32.6).

COMMON MISTAKE

Common misconception — "Every service should be event sourced." Most CRUD data (user preferences, product descriptions) gains nothing from history and pays every cost above. Use event sourcing for the few aggregates where history *is* the business: ledgers, orders, inventory movements.

32.4 CQRS

32.4.1 Separating the write model from read models

DEFINITION

Definition — Command Query Responsibility Segregation (CQRS). An architecture that uses one model to process commands (writes that enforce invariants) and one or more separate models to answer queries, each read model shaped for the queries it serves and typically updated asynchronously from the write side's events [Young 2010; Fowler 2011b].

First-principles explanation

A restaurant kitchen works from order tickets organized for cooking; the front-of-house display shows "table 12: mains in 5 minutes", organized for waiters. Nobody makes the chefs rearrange tickets to answer waiters' questions; a runner copies the relevant facts to the display. CQRS gives the "runner" a name: a **projection** that copies facts from the write model into views built for readers.

Why does this exist?

One schema rarely serves both sides well. The order write model is normalized around invariants (an order, its lines, a version column). The queries are varied: "a customer's last 20 orders with product images" (a document per customer), "full-text search over orders" (Chapter 16), "revenue per region per hour" (a column store). Forcing all of them through one schema means heavy joins on the write database and indexes that slow every write. Read and write load also scale differently: shops commonly serve tens to hundreds of reads per write. Bertrand Meyer's **command-query separation** applied the idea to methods; Young applied it to whole models [Young 2010].

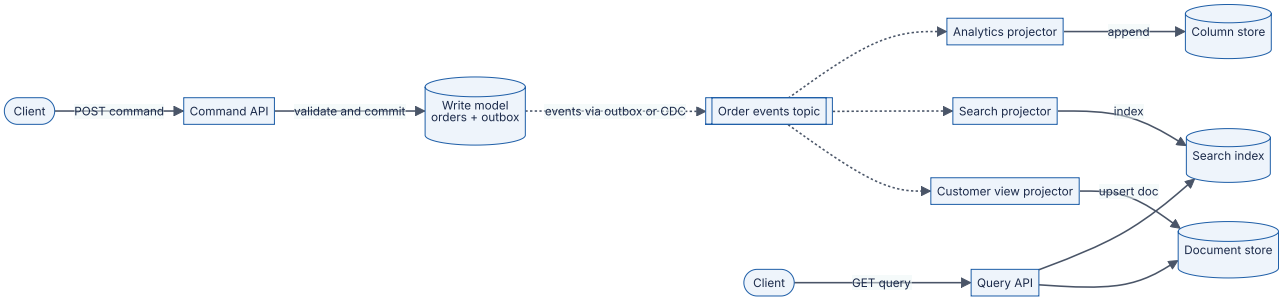
How it works internally

1. Commands go to the write model, which validates them and commits state changes (and, in an event-sourced system, events).
2. Each change is published as an event, through the event store's subscription, an outbox (§32.5) or CDC (§32.6).
3. A **projection** consumes events in order per aggregate and updates its read store with idempotent upserts, recording its checkpoint in the *same* transaction as the update, so a restart neither skips nor double-applies an event.
4. Queries read only from read stores. Each store can be a different technology.
5. To add or fix a view, deploy a new projection that starts from position 0 (or from a snapshot of the source data), let it catch up, then switch readers to it (**blue-green**

projection).

CQRS does not require event sourcing, and event sourcing does not strictly require CQRS, but they are usually paired: an event store cannot answer “orders over $100 last week”, so event-sourced systems almost always need projections.

Figure 32.5 — CQRS with three read models.



Reading the diagram. The command side (top left) is synchronous and strongly consistent within one database. The event topic decouples it from three projectors, each consuming at its own pace (dotted arrows) and writing to its own storage boundary. The query API reads only read models, so a query never touches the write database. Failure points: a projector that falls behind serves stale data; a projector bug corrupts only its own view, which can be rebuilt from the topic. Scaling: read models are replicated and scaled independently, and projectors scale by topic partition (§31.5).

32.4.2 Eventual consistency of reads

Every read model lags the write model by the **projection lag**: the time from commit to visibility in the view. In steady state it is the sum of relay or CDC delay, broker latency and projector processing, typically tens to hundreds of milliseconds. After an outage or a deploy pause it can be minutes.

The classic symptom is **read-your-writes** failure: a customer places an order, is redirected to “My orders”, and the list does not show it. Remedies, cheapest first:

- Return the new state in the command response and render it on the client.
- Return the write’s **position** (log offset or version) and have the query API wait until the projection’s checkpoint passes it, with a timeout (a *consistency token*).
- Route that user’s reads to the write model for a few seconds after a write.
- Show the item as “processing” in the UI, which is honest and often sufficient.

FORMULA

Catch-up time of a lagging projection

$$T_{\text{catch}} = \frac{\lambda D}{\mu - \lambda} \qquad (\mu > \lambda)$$

Symbol	Meaning	Units
λ	Event arrival rate on the source topic	events/s
μ	Maximum processing rate of the projection	events/s
D	Duration of the pause or outage	s
λD	Backlog accumulated during the pause	events
T_{catch}	Time after resuming until lag returns to steady state	s

WORKED EXAMPLE

Worked example — A projector paused by a bad deploy.

1. The order topic carries $\lambda = 2,000$ events/s. A projector with capacity $\mu = 5,000$ events/s is stopped for $D = 10$ min $= 600$ s.
2. Backlog: $2,000 \times 600 = 1,200,000$ events.
3. It drains at the spare rate $\mu - \lambda = 3,000$ events/s: $T_{\text{catch}} = 1,200,000/3,000 = 400$ s, almost 7 minutes, so total staleness peaks at about 17 minutes.
4. If peak traffic reaches $\lambda = 4,500$ events/s, the spare rate is 500 events/s and the same backlog takes 40 minutes.

Interpretation: catch-up time explodes as λ approaches μ, the same $1/(1-\rho)$ shape as queueing delay (§4.10). Engineering implication: provision projectors at two to three times peak rate, alert on lag measured in *time* (age of the oldest unapplied event), not only in events, and check that topic retention far exceeds the longest outage you plan to survive.

32.4.3 When not to use CQRS

Fowler's own warning is that CQRS adds risky complexity and suits only specific parts of a system [Fowler 2011b].

Table 32.3 — When CQRS pays off.

Use CQRS when	Avoid it when
Read shapes differ sharply from the write model (search, feeds, analytics)	Reads are CRUD views of the same rows
Read and write loads differ by orders of magnitude	One database with a few indexes and replicas meets the load (§14.4)
You already publish events (event sourcing, outbox)	Users must always see their writes immediately and you cannot add consistency tokens
Several teams need different views of the same facts	The team has no experience operating asynchronous pipelines

COMMON MISTAKE

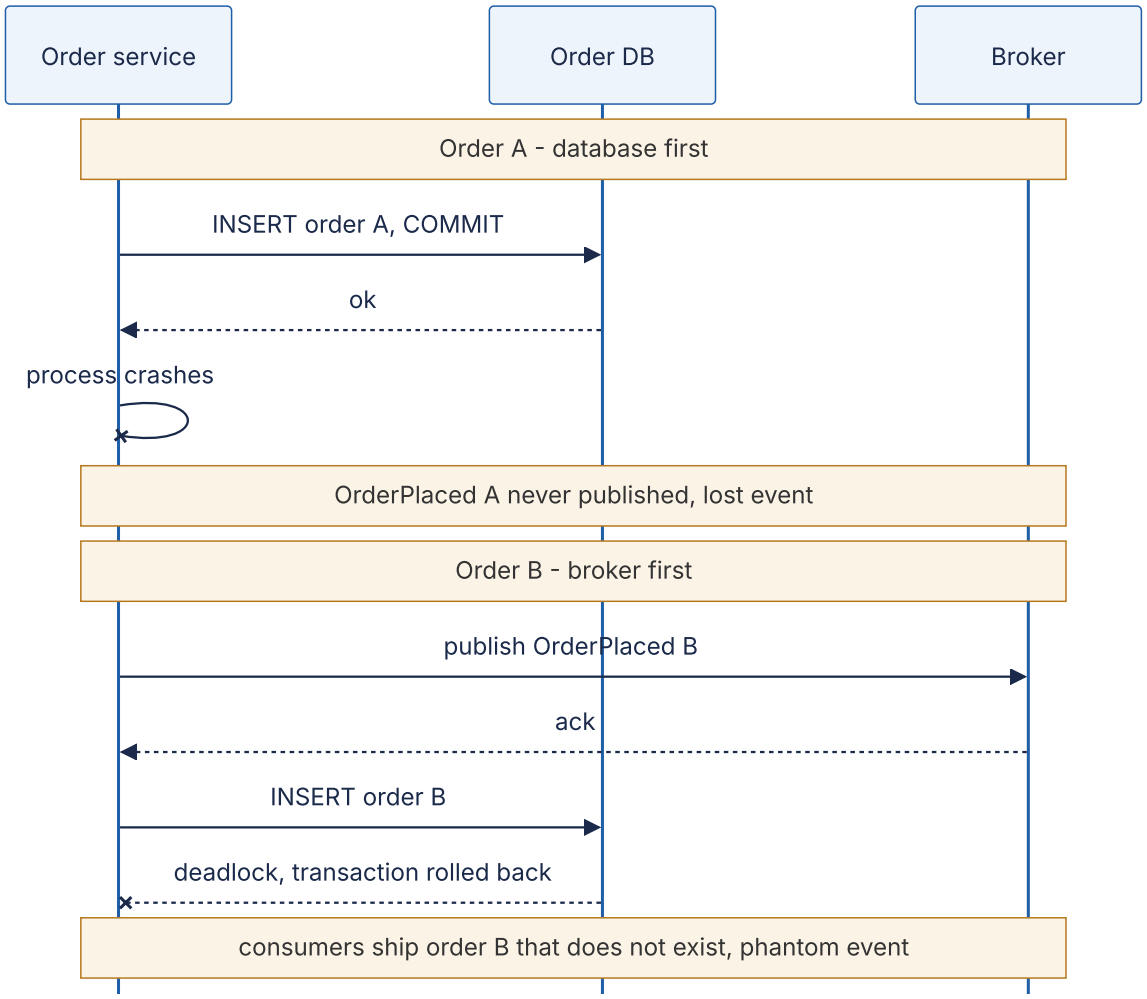
Common misconception — "CQRS means two databases." The essence is two *models*. A materialized view or a read replica with denormalized tables inside the same database is a legitimate, much simpler CQRS. Separate stores are a later step, taken when the view needs a different technology.

32.5 Transactional outbox

32.5.1 The dual-write problem

A service that changes its database and must tell other services faces two independent systems, the database and the broker, with no shared transaction. Writing to both from application code is a **dual write**, and every ordering of the two writes has a failure window.

Figure 32.6 — Two ways a dual write goes wrong.



Reading the diagram. Both scenarios use synchronous calls to two storage boundaries. In the first, the database commits and the process dies before publishing: the order exists but no consumer ever hears of it, so it is never shipped. In the second, the broker accepts the event and the database then rolls back: consumers act on a **phantom event**. Retrying does not close either window, because the crash can happen during the retry too; even a successful publish can time out and be retried, producing a duplicate. Scaling makes it worse: at 1,000 orders/s, a failure window hit once per million writes occurs about 86 times a day.

Distributed transactions (XA, §28.4.6) could commit both, but most brokers do not support XA, and 2PC couples the service's availability to the broker's. The outbox removes the second write instead.

32.5.2 The outbox table and the relay

DEFINITION

Definition — Transactional outbox. A pattern in which a service writes the events it wants to publish into an **outbox table** in its own database, in the same local transaction as the state change, and a separate **message relay** later reads committed outbox rows and publishes them to the broker, retrying until the broker acknowledges [Richardson 2018].

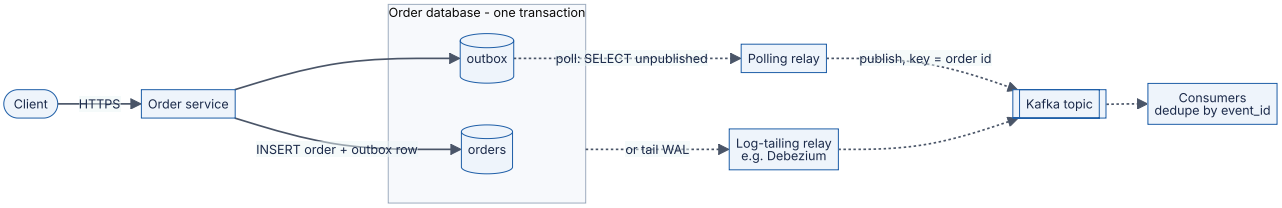
The local transaction makes “state changed” and “event recorded” atomic: both commit or neither does. The relay then turns “recorded” into “published” with at-least-once delivery. A crash anywhere loses nothing (the row is durable) and invents nothing (rolled-back transactions leave no row). The remaining imperfection is duplicates, when the relay publishes and crashes before marking the row, which idempotent consumers absorb (§32.10).

```
        CREATE TABLE outbox (
          id            BIGSERIAL PRIMARY KEY,         -- relay order
          event_id      UUID NOT NULL UNIQUE,          -- consumers deduplicate on this
          aggregate_id  TEXT NOT NULL,                 -- becomes the Kafka message key
          event_type    TEXT NOT NULL,
          payload       JSONB NOT NULL,
          created_at    TIMESTAMPTZ NOT NULL DEFAULT now(),
          published_at  TIMESTAMPTZ                    -- NULL until the relay publishes
        );
        CREATE INDEX outbox_unpublished ON outbox (id) WHERE published_at IS NULL;

        BEGIN;
        INSERT INTO orders (id, customer_id, status, total_cents) VALUES ('o-981', 'c-
42', 'PLACED', 4599);
        INSERT INTO outbox (event_id, aggregate_id, event_type, payload)
          VALUES (gen_random_uuid(), 'o-981', 'OrderPlaced', '{"order_id": "o-981",
"total_cents": 4599}');
        COMMIT;
```

What to notice: the partial index keeps the relay’s scan cheap even when the table holds millions of published rows; `aggregate_id` becomes the message key so all events of one order land in one partition (§31.5); `gen_random_uuid()` is built into PostgreSQL 13 and later. Delete published rows in batches, or drop time-based partitions, to keep the table small.

Figure 32.7 — Outbox with a relay, polling or log-tailing.



Reading the diagram. The client waits only for the single local transaction inside the database boundary. A relay, either a polling process or a log-tailing CDC connector (choose one), copies committed rows to Kafka asynchronously, keyed by order ID. Failure points: the relay can crash after publishing and before recording progress, so the broker can receive duplicates; consumers therefore deduplicate by `event_id`. If the relay is down, events wait safely in the table and their latency grows; nothing is lost. Scaling: one relay per database (or per outbox partition) with leader election so that two relays do not race (§26.5, §26.11).

32.5.3 Polling versus log-tailing relays

Table 32.4 — Polling versus log-tailing relays.

	Polling publisher	Log-tailing (CDC) relay
How it works	`SELECT ... WHERE published_at IS NULL ORDER BY id LIMIT n`, publish, then `UPDATE`	Reads committed outbox inserts from the WAL or binlog (§32.6)
Latency	Poll interval / 2 plus cycle time when idle	Tens of milliseconds
Database load	A query every interval plus an update per batch	Reads the log; no queries on the table
Ordering	By `id`; but sequence values are assigned at insert, not commit, so a concurrent slower transaction can commit a lower `id` after the relay has passed it	Commit order, exactly as the database applied it
Operational complexity	Low: a small process	Higher: replication slots, connectors, CDC monitoring
Choose when	Moderate volume, simplicity first	High volume, strict ordering, many tables

The polling ordering trap deserves emphasis. If transaction T1 takes `id = 100` and T2 takes `id = 101`, but T2 commits first, a relay that remembers “last published id = 101” will never see 100. The schema above avoids that by selecting on `published_at IS NULL` instead of a high-water mark; per-aggregate order still holds when each aggregate’s writes are serialized (row lock or version check), because its later event cannot commit before its earlier one. Log tailing avoids the issue entirely.

FORMULA

Polling relay throughput and added latency

$$X = \frac{B}{t_q + B\,t_p + t_m} \qquad L_{\text{relay}} \approx \frac{I}{2} + t_q + B\,t_p + t_m$$

Symbol	Meaning	Units
B	Batch size: rows fetched per cycle	events
t_q	Time to query the batch	s
t_p	Amortized publish time per event (pipelined, batched sends)	s/event
t_m	Time to mark the batch published	s
I	Polling interval when the outbox is empty	s
X	Maximum relay throughput	events/s
L_{relay}	Typical extra delivery latency at low load	s

WORKED EXAMPLE

Worked example — Sizing one relay for 5,000 events/s.

1. Batched, pipelined sends: $B = 500$, $t_q = 4$ ms, $t_p = 0.04$ ms ($500 \times 0.04 = 20$ ms per batch), $t_m = 6$ ms. Cycle $= 4 + 20 + 6 = 30$ ms; $X = 500/0.030 \approx 16,700$ events/s, over three times the required rate.
2. Naive relay that sends each event synchronously and waits for `acks=all` at $t_p = 2$ ms: cycle $= 4 + 1,000 + 6 = 1,010$ ms; $X \approx 495$ events/s, ten times too slow.
3. Latency at low load with $I = 100$ ms: $L \approx 50 + 30 = 80$ ms.

Interpretation: batching dominates relay throughput, and the poll interval dominates its latency. Engineering implication: send asynchronously with the producer's batching and wait for all acknowledgments before marking the batch; if 80 ms of extra latency is too much, poll more often (more load) or switch to log tailing.

32.5.4 Code example: dual writes versus the outbox under crashes

The simulation injects crashes, with probability 5 % at each marked point, into the order service, the broker, the relay and the consumer. Durable objects (database, broker log, the consumer's dedup table and offset) survive; a crash only aborts the current call.

```
        """Dual writes versus the transactional outbox, under randomly injected crashes.

        The database and the broker log are durable; process memory is not. A Crash
        can strike the order service, the relay or the consumer at any marked point.
        Run it directly with python3 to execute the tests.
        """
        import random
        import unittest

        class Crash(Exception):
            """The current process died at an injected crash point."""

        class Chaos:
            def __init__(self, seed, p):
                self.rng, self.p = random.Random(seed), p

            def point(self, name):
                if self.rng.random() < self.p:
                    raise Crash(name)

        class Database:
            """Durable tables. transaction() applies all of its writes or none."""

            def __init__(self):
                self.orders, self.outbox, self.next_id = {}, [], 1

            def transaction(self, order_id, status, event=None):
                if self.orders.get(order_id) == status:
                    return                                  # natural idempotency: al-
ready done
                self.orders[order_id] = status
                if event is not None:                       # same transaction as the
state change
                    self.outbox.append(dict(event, id=self.next_id, published=False))
                    self.next_id += 1

        class Broker:
            """An append-only log. A crash may strike after the append but before the
ack."""

            def __init__(self, chaos):

            unittest.main(verbosity=1)
```

Output (Python 3.13; the timing varies):

```
.....
----------------------------------------------------------------------
Ran 5 tests in 0.332s

OK
```

What to notice:

- With seed 1, each dual-write variant fails about 22 times in 200 orders: database-first loses events, broker-first invents them. No retry inside `dual_write` could fix this, because the crash ends the process that would retry.
- In `run_outbox`, across 50 seeds and about 2,000 crash opportunities each, the set of effects equals the set of committed state changes. Seed 3 puts 428 messages on the broker for 385 effects: duplicates are real and harmless.
- `Database.transaction` is naturally idempotent (setting a status that is already set does nothing), so a client that retries after an ambiguous failure does not create a second order or a second outbox row (§22.15).
- The consumer's `seen` set, `applied` list and `offset` model durable state in the consumer's own database. Because the dedup record commits with the effect, the crash between effect and offset commit only causes a redelivery that is skipped.
- Per-order ordering holds because the relay always republishes from the oldest unpublished row; a relay that skipped a failed row and continued would break it.

Table 32.5 — Outbox failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate events	Relay crashed between publish and mark	Consumer dedup hit rate	None needed if consumers are idempotent	Unique `event_id`; idempotent consumers (§32.10)
Growing delivery latency	Relay down or slower than the write rate	Age of oldest unpublished row	Restart or scale the relay	Alert on outbox age; *X* sized above peak
Skipped events	High-water-mark polling past an uncommitted lower `id`	Gaps in per-aggregate sequence numbers	Republish from the gap	Select on `published_at IS NULL`, or tail the log
Two relays publish out of order	No single-writer guarantee	Out-of-order sequence numbers at consumers	Consumers reorder or reject by version	Leader election with fencing
Outbox table bloat	Published rows never deleted	Table size, slow relay queries	Batch delete, vacuum	Time-partitioned outbox with partition drops

32.6 Change data capture

32.6.1 Reading the database's own log

DEFINITION

Definition — Change data capture (CDC). Extracting every committed insert, update and delete from a database, in commit order, as a stream of change events that other systems consume. **Log-based CDC** reads the database's replication log (PostgreSQL's write-ahead log via logical decoding, MySQL's binary log) rather than querying tables.

First-principles explanation

A database already keeps a diary of every change, because it needs one for crash recovery and replication (§13.5, §14.4). CDC asks the database for a copy of that diary, decoded into rows. Since the diary contains only committed changes in the order they were applied, anything built from it agrees with the database by construction.

Why does this exist?

Search indexes, caches, data warehouses and other services all need to know when data changes. The alternatives are worse: dual writes from application code (§32.5.1); periodic queries on an `updated_at` column, which miss hard deletes, miss intermediate states and load the database; or database triggers, which add latency to every transaction. Log-based CDC has none of these problems, and it captures changes made by *any* writer, in-

cluding batch jobs and manual fixes that bypass the application [Kleppmann 2017, ch. 11]. LinkedIn's Databus, an early large-scale CDC system, was built for exactly this purpose: keeping search indexes, caches and replicas consistent with the primary databases [Das et al. 2012].

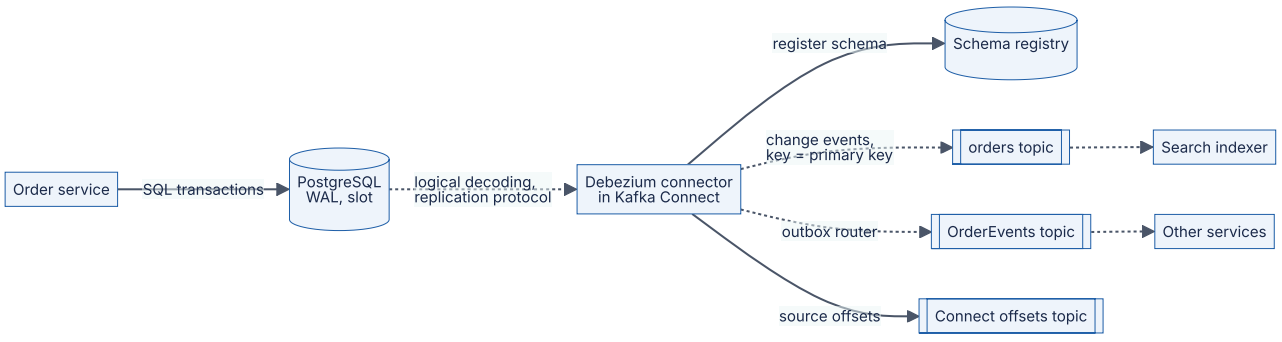
How it works internally

1. **Enable a logical log.** PostgreSQL needs `wal_level = logical` and a **replication slot**, which records how far the consumer has read and makes the server retain WAL until then. MySQL needs the binary log in `ROW` format, so each event carries row images rather than SQL statements.
2. **Initial snapshot.** The connector reads existing table contents in a consistent snapshot and notes the log position at which the snapshot was taken.
3. **Streaming.** It then reads the log from that position onward, decoding each change into an event with the row *before* and *after* the change, the operation (`c`reate, `u`pdate, `d`elete, or `r`ead for snapshot rows) and source metadata such as the log position and commit timestamp.
4. **Publishing.** Events go to a topic per table, keyed by primary key, so all changes to one row stay ordered in one partition. A delete is followed by a **tombstone** (null value) so that log compaction can eventually remove the key (§31.10).
5. **Progress.** The connector periodically records the last log position it published. After a crash it resumes from there, so events after the last recorded position are published again: delivery is at-least-once.

32.6.2 Debezium architecture

Debezium is an open-source CDC platform built as a set of Kafka Connect source connectors (§31.14), one per database type; it can also run standalone as Debezium Server for non-Kafka destinations [Debezium Docs].

Figure 32.8 — Debezium capturing PostgreSQL changes into Kafka.



Reading the diagram. The application writes only to PostgreSQL. The connector streams decoded WAL records over PostgreSQL's replication protocol (asynchronous), registers each record schema with a schema registry, and publishes change events keyed

by primary key. Rows of the outbox table can be routed by Debezium's outbox event router to per-aggregate topics, which is how §32.5's log-tailing relay is usually built. Progress (the last WAL position) is stored in Kafka Connect's offsets topic. Failure points: if the connector is down, the replication slot forces PostgreSQL to keep WAL, which can fill the disk; after a restart, events since the last stored offset are re-sent. Scaling: one connector task per database (the log is a single ordered stream), with throughput limited by WAL decoding, and many independent consumers downstream.

Snapshot plus stream, without stopping the world. A naive initial snapshot of a large table takes hours and holds a long transaction open. Netflix's DBLog showed how to interleave chunked table reads with log streaming using low and high **watermarks** written to the log, so that a chunk's rows are reconciled with concurrent changes and snapshots can be paused, resumed or re-run for one table [Andreakis and Papapanagiotou 2020]. Debezium's **incremental snapshots**, triggered through a signaling table, use the same idea [Debezium Docs].

> WARNING / TRADE-OFF
>
> **Warning — An abandoned replication slot fills the disk.** A PostgreSQL slot whose consumer has stopped retains WAL indefinitely. Monitor slot lag in bytes (`pg_replication_slots`), alert well before disk exhaustion, and on PostgreSQL 13 and later set `max_slot_wal_keep_size` to cap retention, accepting that the connector then needs a fresh snapshot.

32.6.3 Schema registry and evolution

A CDC topic exposes your table schema to every consumer, which turns a column rename into a cross-team breaking change. A **schema registry** stores each version of a topic's schema (Avro, Protobuf or JSON Schema); producers register a schema and embed its ID in each message, and consumers fetch the schema by ID to decode. The registry enforces a **compatibility mode** at registration: *backward* (new readers can read old data; Confluent Schema Registry's default), *forward* (old readers can read new data), *full* (both), with *transitive* variants that check against all earlier versions rather than only the previous one [Confluent Docs: Schema Registry]. For event streams that are replayed from the beginning, as in §32.3.4, use a transitive mode.

RECOMMENDATION

Recommendation — Do not publish your tables as your API. Raw CDC events couple consumers to internal column names and normalization. For integration between teams, publish deliberate domain events through an outbox (routed by CDC if you like) and keep raw table CDC for derived data you own: caches, search indexes, the warehouse.

INDUSTRY EXAMPLE

Netflix DBLog. Netflix needed to keep many derived stores, such as search indexes, in sync with MySQL and PostgreSQL sources, including full re-syncs without pausing writes. DBLog streams the transaction log and interleaves chunked selects bounded by watermarks, so dumps can be triggered at any time per table. Trade-off: the connector must write watermark rows into the source database. *Evidence: Primary* — [Andreakis and Papapanagiotou 2020]

Table 32.6 — Change data capture failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Source disk fills	Stalled slot retains WAL	Slot lag bytes	Restart connector or drop slot and re-snapshot	`max_slot_wal_keep_size`, alerts
Consumers break on deploy	Column renamed or retyped	Deserialization errors	Roll back schema; upcast	Registry compatibility checks in CI
Missing intermediate states	Query-based polling instead of log	Audits	Switch to log-based CDC	Log-based CDC
Duplicates after restart	Offsets stored periodically	Dedup counters	None if idempotent	Idempotent sinks keyed by primary key and log position

32.7 The saga pattern

32.7.1 Long-lived transactions without distributed locks

Section 28.6 previewed the saga. This section owns the deep treatment.

DEFINITION

Definition — Saga. A long-lived transaction (LLT) written as a sequence of local transactions $T_1, \ldots, T_n$, each of which commits independently and releases its resources, where each T_i (except possibly the last) has a **compensating transaction** C_i. The system guarantees that either $T_1, T_2, \ldots, T_n$ executes, or $T_1, \ldots, T_j, C_j, \ldots, C_1$ executes for some $j < n$ [Garcia-Molina and Salem 1987].

First-principles explanation

Booking a trip with a hotel, a flight and a car is a saga. You book the hotel, then the flight; if no car is available, you cancel the flight and the hotel. Nobody locks the hotel's whole reservation system while you shop for cars, and nobody expects the cancellation to erase the booking from history: you get a cancellation record and perhaps a fee. That is **semantic atomicity**: the end state is "all done" or "equivalently undone" by the business's definition.

Why does this exist?

Garcia-Molina and Salem observed in 1987 that long-lived transactions, which hold locks for minutes or hours, delay every other transaction that touches the same data and are more likely to abort. Their proposal was to break an LLT into ordinary transactions that may interleave with others, and to undo committed work with application-defined compensations rather than rollbacks [Garcia-Molina and Salem 1987]. Microservices recreate the same problem at a larger scale: each service owns its database, external APIs (payment providers) cannot join a 2PC, and a coordinator that blocks while holding locks across services (§28.4.3) couples their availability. Helland argued that at scale, applications must live without distributed transactions and coordinate entities through messages, tentative operations and confirmations or cancellations [Helland 2007]; the saga is the standard shape for that.

How it works internally

Richardson classifies saga steps into three kinds, which determine how failures are handled [Richardson 2018]:

1. **Compensatable transactions** come before the point of no return and have a compensation (create order → reject order; reserve stock → release stock).
2. The **pivot transaction** is the go/no-go step. If it commits, the saga will complete; if it fails, the saga compensates. It is often the step that cannot be undone or is the most likely to fail, such as charging a card.
3. **Retriable transactions** follow the pivot and are guaranteed to succeed eventually if retried (approve order, notify shipping). They never compensate; they retry forward.

Compensations must themselves be idempotent and retriable until they succeed, because the saga has no other way out. Garcia-Molina and Salem call undoing **backward recovery**; with save points, a saga can also use **forward recovery**, retrying from the last save point instead of compensating.

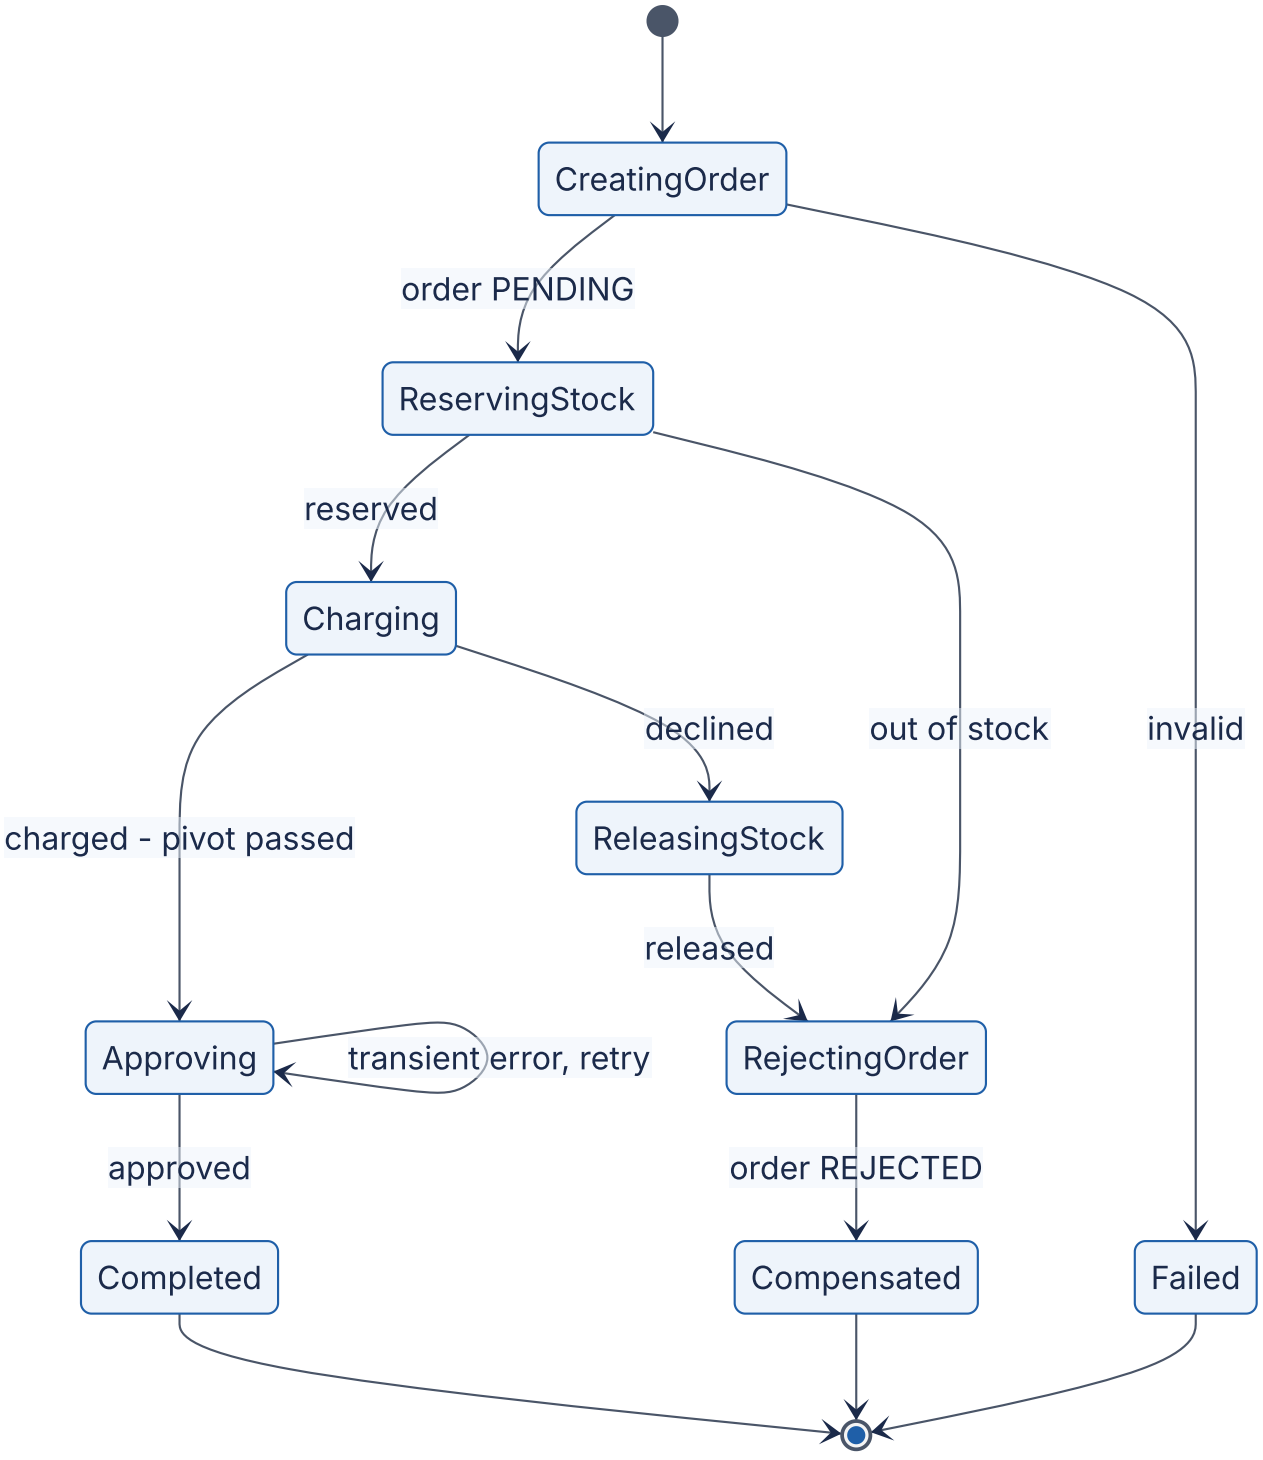
32.7.2 Worked example: order, inventory and payment

The shop's checkout saga has four steps. Table 32.7 lists each step and what happens if it fails.

Table 32.7 — The checkout saga and a failure at each step.

Step	Service	Action	Kind	Compensation	If this step fails
T_1	Order	Create order in `PENDING`	Compensatable	C_1: set `REJECTED`	Validation error to client; nothing to undo
T_2	Inventory	Reserve 2 units	Compensatable	C_2: release reservation	Out of stock: run C_1
T_3	Payment	Charge card $300	Pivot	(refund only by a new business process)	Declined: run C_2, then C_1
T_4	Order	Set `APPROVED`, emit `OrderApproved`	Retriable	—	Retry until it succeeds; never compensate
—	Orchestrator	Crash between any two steps	—	—	Resume from the saga log; steps are idempotent
—	Any	Compensation C_i fails transiently	—	—	Retry C_i; after a limit, alert a human

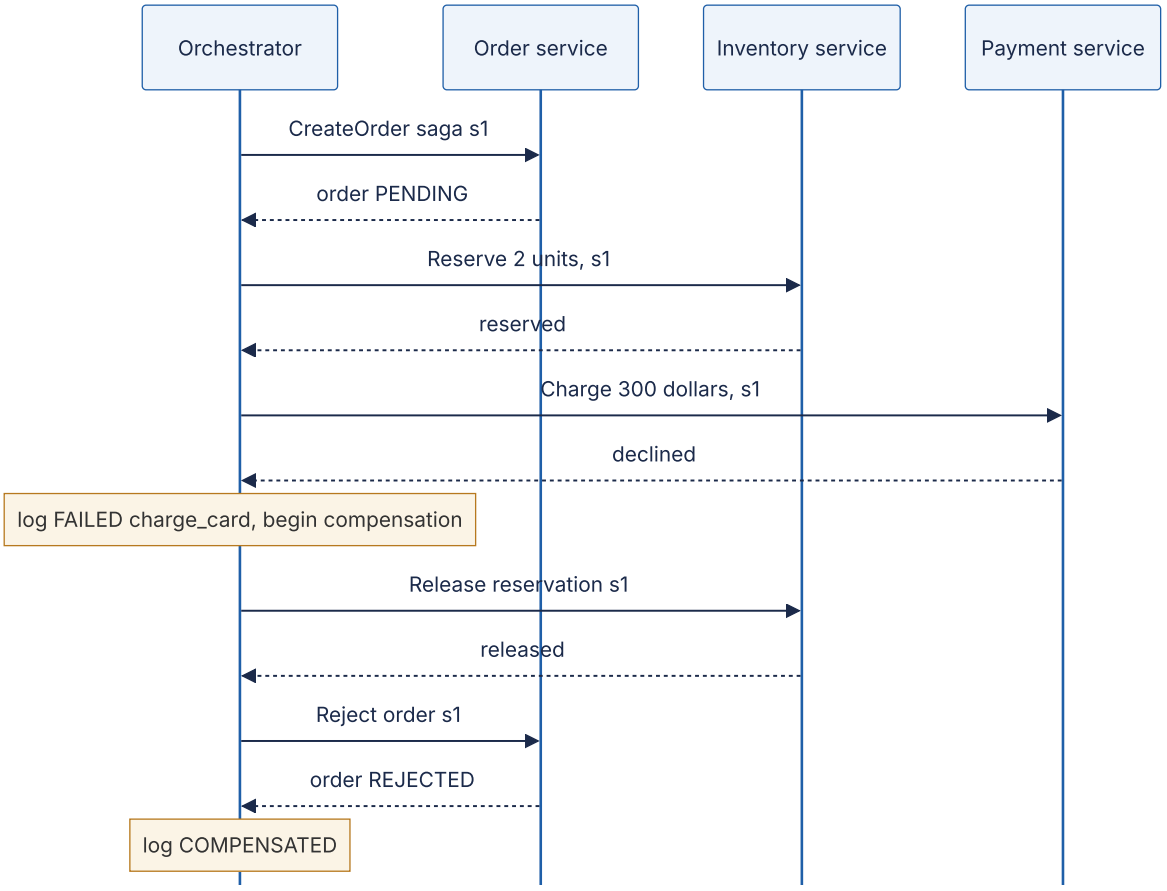
Figure 32.9 — State machine of the checkout saga orchestrator.



Reading the diagram. Each state is persisted in the orchestrator's saga log (a table in its own database) before the next command is sent, so a restarted orchestrator re-enters the same state and re-sends the same command; the receiving services deduplicate by saga ID. Transitions are triggered by asynchronous replies from the order, inventory and payment services. The left branch (before `Charging` succeeds) is backward recovery through compensations in reverse order; after the pivot the only exit is forward, with retries. Failure points: a compensation that keeps failing leaves the saga stuck in

`ReleasingStock` or `RejectingOrder`, which must raise an alert. Scaling: sagas are independent, so partition the saga log by saga ID across orchestrator instances.

Figure 32.10 — The card is declined: compensation in reverse order.



Reading the diagram. Each arrow is a command or a reply, usually sent as messages through a broker with the request–reply pattern, so the whole exchange is asynchronous even though it reads like calls. Each service runs one local transaction per command and stores the saga ID to make retries idempotent. The orchestrator writes a log record after every reply. Between “reserved” and “released”, two units are invisible to other shoppers, an intermediate state that a saga cannot hide (§32.7.3). If the orchestrator crashes after logging the failure, it restarts compensation from the log; if the inventory service is down, the release is retried until it succeeds.

32.7.3 Living without isolation

A saga is ACD without I: atomic in the semantic sense, consistent within each service, durable, but not isolated. Other transactions see its intermediate states, which causes three anomalies: **lost updates** (another saga overwrites a change, and a compensation later overwrites theirs), **dirty reads** (a reader sees stock reserved by a saga that will be compensated) and **fuzzy reads** (two steps of one saga read different versions of the same

data). Richardson collects countermeasures, drawing on Frank and Zahle's work on semantic ACID properties in multidatabases [Richardson 2018; Frank and Zahle 1998].

Table 32.8 — Countermeasures for the lack of isolation.

Countermeasure	How it works	Checkout example
Semantic lock	A compensatable step sets an application-level flag (`*_PENDING`) that other requests check	Canceling an order in `PENDING` is refused or queued until the saga ends
Commutative updates	Design operations so their order does not matter	`reserve(+2)` and `release(-2)` as deltas, not "set stock = 8"
Pessimistic view	Reorder steps so that risky reads happen in retriable steps	Increase a loyalty balance only after the pivot
Reread value	Reread data before overwriting and abort if it changed (optimistic locking)	Approve only if order version is unchanged
Version file	Record operations so out-of-order arrivals can be reordered	Payment service tolerates `Cancel` arriving before `Authorize`
By value	Choose the mechanism by business risk	High-value orders use a 2PC-backed path or manual review

KEY CONCEPT

Key insight — Reservations are the saga-friendly form of locking. "Reserve 2 units for 15 minutes" is a semantic lock with a timeout, held in business data rather than in a database lock manager. It survives crashes, is visible to other users ("2 left, 1 in someone's cart"), and expires on its own if a saga dies. Helland's tentative operations followed by confirmation or cancellation are the same idea [Helland 2007].

32.7.4 Code example: an orchestrated saga with compensation

```
        """An orchestrated order saga: order -> inventory -> payment, with compensation.

        Each service owns its data and exposes idempotent operations keyed by saga ID.
        The orchestrator persists its progress in a durable saga log, so a crashed
        orchestrator resumes where it stopped. Run with python3 to execute the tests.
        """
        import unittest

        class Crash(Exception):
            """The orchestrator process died."""

        class Rejected(Exception):
            """A business failure: the step cannot succeed, so the saga must compen-
sate."""

        class Unavailable(Exception):
            """A transient failure: retry the same step later."""

        class Orders:
            def __init__(self):
                self.status = {}

            def create(self, saga):                          # T1, compensatable
                self.status.setdefault(saga, "PENDING")      # PENDING is the semantic
lock

            def reject(self, saga):                          # C1
                self.status[saga] = "REJECTED"

            def approve(self, saga):                         # T4, retriable

```

Output (Python 3.13; the timing varies):

```
.......
----------------------------------------------------------------------
Ran 7 tests in 0.001s

OK
```

What to notice:

- `record` writes to the saga log *before* the orchestrator moves on, and `run` reconstructs its position from the log alone. That is what lets

`test_crash_at_every_point_then_resume` kill the orchestrator after every step and still finish with exactly one reservation and one charge.

- `test_step_executed_but_not_logged_is_not_doubled` covers the other crash window: the action ran but its `DONE` record did not. The re-sent `reserve` is a no-op because the inventory service deduplicates by saga ID.
- `Unavailable` after the pivot is retried forever; a `Rejected` before the pivot triggers compensation in reverse order. A real orchestrator would back off between retries (§22.12) and alert after a limit.
- `release` and `reject` tolerate being called twice or for work that never happened, so a crash during compensation is also recoverable (`test_crash_during_compensation_then_resume`).
- The order's `PENDING` status is the semantic lock of Table 32.8.

32.7.5 Failure scenarios and misconceptions

Table 32.9 — Saga failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Double charge or double reservation	Retried step not idempotent	Reconciliation between services	Refund, release	Idempotency by saga ID in every participant
Saga stuck in compensation	Compensation fails permanently (e.g. refund rejected)	Saga age by state	Human workflow	Design compensations that cannot fail for business reasons
Compensation runs before the action	Messages reordered; action arrives after cancel	Orphaned reservations	Timeout-based cleanup	Participants record "canceled" tombstones for the saga ID
Oversold stock	Dirty read of uncommitted reservations	Negative stock alarms	Back-order process	Semantic locks, commutative updates
Lost saga	Orchestrator state only in memory	Orders stuck in `PENDING`	Sweep and resume	Persist the saga log before each command

COMMON MISTAKE

Common misconception — "Compensation is rollback." A rollback makes it as if nothing happened; a compensation is a new transaction that others can observe, which may itself have effects (a refund email, a fee). Some actions have no compensation at all (an email sent, a parcel dispatched); place them after the pivot.

COMMON MISTAKE

Common misconception — "A saga gives the same guarantees as a distributed transaction, just faster." It gives semantic atomicity and eventual consistency without isolation. If an invariant must never be visibly violated, even briefly, keep the data in one database (§28.11).

32.8 Choreography versus orchestration

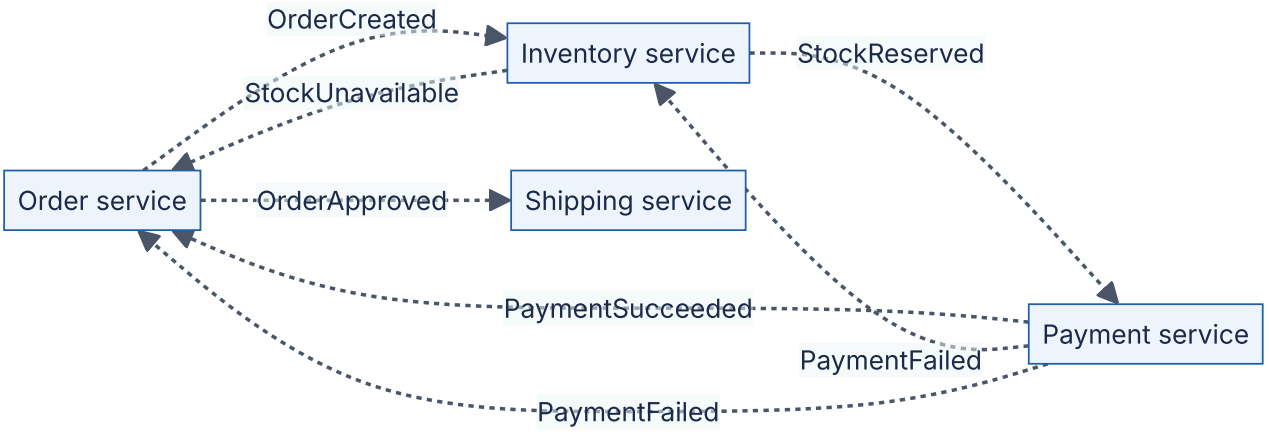
A saga needs something to decide which step runs next. There are two styles.

DEFINITION

Definition — Choreography and orchestration. In **choreography**, each service reacts to other services' events and publishes its own; the saga's control flow is distributed across the participants and exists nowhere as one piece of code. In **orchestration**, a dedicated **orchestrator** sends commands to participants, receives their replies and decides the next step; the control flow lives in one place [Richardson 2018].

The analogy is a dance troupe versus an orchestra. Dancers who know their cues need no conductor, which works beautifully for four dancers and becomes chaos for forty. An orchestra has a conductor who is a single point of control, and of failure, but anyone can read the score.

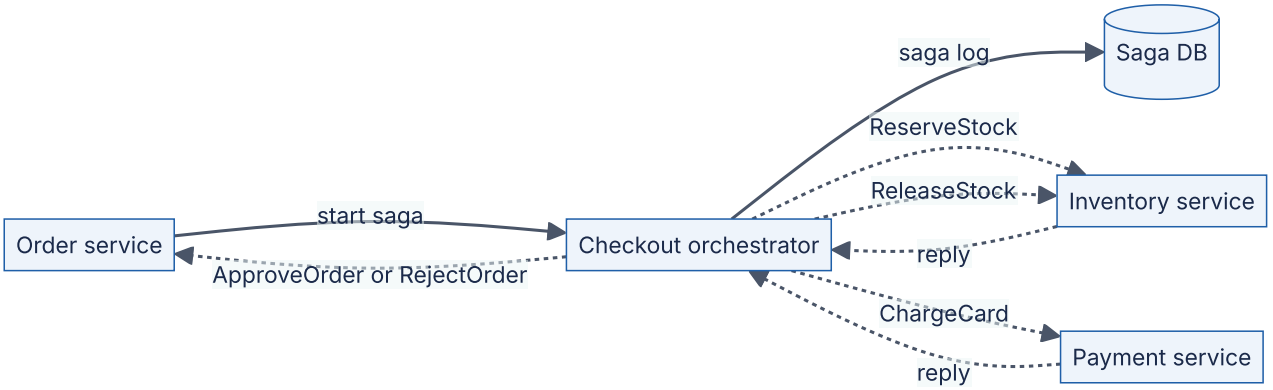
Figure 32.11 — The checkout saga by choreography.



Reading the diagram. Every arrow is an asynchronous event published to the broker (omitted for clarity) through each service's outbox; no service calls another. Each service subscribes to the events it cares about: inventory reacts to `OrderCreated` and to `PaymentFailed` (its compensation trigger), and the order service reacts to the final out-

come. Each service keeps its own saga state in its own database. Failure points: a lost subscription or a consumer bug silently stalls a saga, and nobody owns the end-to-end view; cyclic dependencies (order ↔ payment) make deploys and schema changes harder. Scaling is excellent, since there is no central component.

Figure 32.12 — The same saga by orchestration.



Reading the diagram. The orchestrator persists its state in its own database (synchronous, solid arrow) and exchanges asynchronous commands and replies with participants over request and reply channels. Participants know nothing about the saga; they expose commands such as `ReserveStock` and `ReleaseStock`. Failure points: the orchestrator is a central dependency, so it must be stateless apart from the saga log and run as several instances; a slow participant delays only the sagas waiting on it. Scaling: partition sagas by ID across orchestrator instances.

Table 32.10 — Choreography versus orchestration.

	Choreography	Orchestration
What it is	Services react to each other's events	A coordinator issues commands
Coupling	Each service knows which events to react to	Participants know nothing of the flow; orchestrator knows all
Visibility	Flow is implicit; needs tracing (§40.6) to reconstruct	Flow is explicit in one place; saga state is queryable
Adding a step	Change several services	Change the orchestrator
Failure handling	Compensation logic scattered across services	Centralized, testable
Single point of failure	None	The orchestrator, mitigated by replication
Risk	Cyclic dependencies, "event spaghetti"	Orchestrator accumulating business logic
Choose when	2–4 steps, stable flow, autonomous teams	Many steps, branching, timeouts, compliance audits

RECOMMENDATION

Recommendation — Choreograph between domains, orchestrate within a process. Broadcast facts (`OrderPlaced`) by choreography so other domains (analytics, loyalty, email) can subscribe without coordination. Model a business process with compensations and deadlines, such as checkout or loan approval, as an orchestrated saga, preferably on a workflow engine (§32.11). Keep business rules in participants; the orchestrator should sequence, not compute.

INDUSTRY EXAMPLE

Netflix Conductor. Netflix's content and media-processing pipelines grew into flows that were hard to follow when implemented as peer-to-peer events. Netflix built Conductor, a JSON-defined workflow orchestrator with a central server that schedules tasks onto worker queues and tracks every execution's state, and open-sourced it in 2016. The stated motivations were visibility into flows, the ability to pause, resume and restart them, and reuse of workers across flows. *Evidence: Primary* — [Netflix Technology Blog 2016]

32.9 Exactly-once processing and its limits

The phrase "exactly-once" causes more confusion than any other in messaging. Be precise about *what* happens exactly once, and *where*.

- **Exactly-once delivery** over an unreliable network is impossible. A sender that gets no acknowledgment cannot know whether the message arrived (the two generals problem, §24.3.3), so it must either resend (risking duplicates) or not (risking loss).
- **Exactly-once processing**, better called **effectively-once**, is achievable: a message may be delivered and processed several times, but its *effect* on state is applied once. By the end-to-end argument (§24.14), only the endpoint that owns the state can guarantee this, with at-least-once delivery plus deduplication or idempotence.

effectively-once = at-least-once delivery + idempotent effect

32.9.1 What Kafka's exactly-once semantics cover

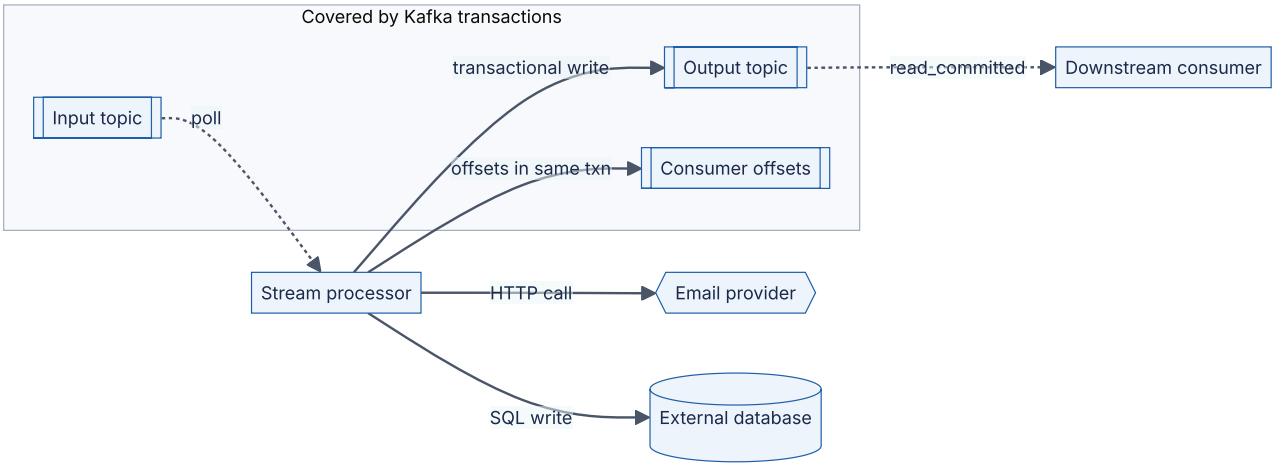
Kafka's exactly-once semantics (EOS) combine three mechanisms [Kafka KIP-98 2017; §31.11]:

1. **Idempotent producer.** The broker assigns a producer ID, and the producer numbers each batch per partition; the broker discards a retried batch whose sequence number it has already written. This removes duplicates caused by producer retries, within one producer session.

2. **Transactions.** A transactional producer writes to several partitions *and* commits the consumer's input offsets in one atomic transaction (`sendOffsetsToTransaction`), using the replicated transaction coordinator described in §28.4.8.
3. **`read_committed` consumers** see only committed transactional data.

Together these make a **consume-transform-produce** loop inside Kafka effectively-once: input offsets and outputs commit together, so a crash replays input but aborted outputs are never seen. Kafka Streams enables this with `processing.guarantee=exactly_once_v2`.

Figure 32.13 — The boundary of Kafka's exactly-once guarantee.



Reading the diagram. Everything inside the subgraph lives in Kafka and commits atomically: the output records and the input offsets. A crash before commit aborts both, and the replayed input produces the same outputs again, which `read_committed` consumers see once. The two arrows leaving the boundary are outside the guarantee: if the processor sends an email or writes a database row and then crashes before committing, the replay sends the email again. Failure points therefore cluster at external side effects. Scaling: transactions add a few milliseconds per commit, amortized by committing every 100 ms or so rather than per record.

Table 32.11 — What Kafka exactly-once does and does not cover.

Covered	Not covered
Duplicates from producer retries (idempotent producer)	A producer application that restarts and resends with a new producer ID, unless it uses a stable `transactional.id`
Atomic writes to several partitions	Writes to databases, caches, search indexes, HTTP APIs
Atomic commit of outputs with input offsets	Consumers using `read_uncommitted`
Kafka Streams state stores (changelog topics)	Side effects in user code: emails, payments, logs

COMMON MISTAKE

Common misconception — "We enabled Kafka EOS, so our payment consumer is exactly-once." EOS ends where Kafka ends. A consumer that charges a card through an API and commits its offset afterwards will charge twice after a crash between the two. Pass an idempotency key derived from the event ID to the provider (§22.15), or record the charge and the offset in one database transaction (§32.10).

32.10 Idempotent consumers

DEFINITION

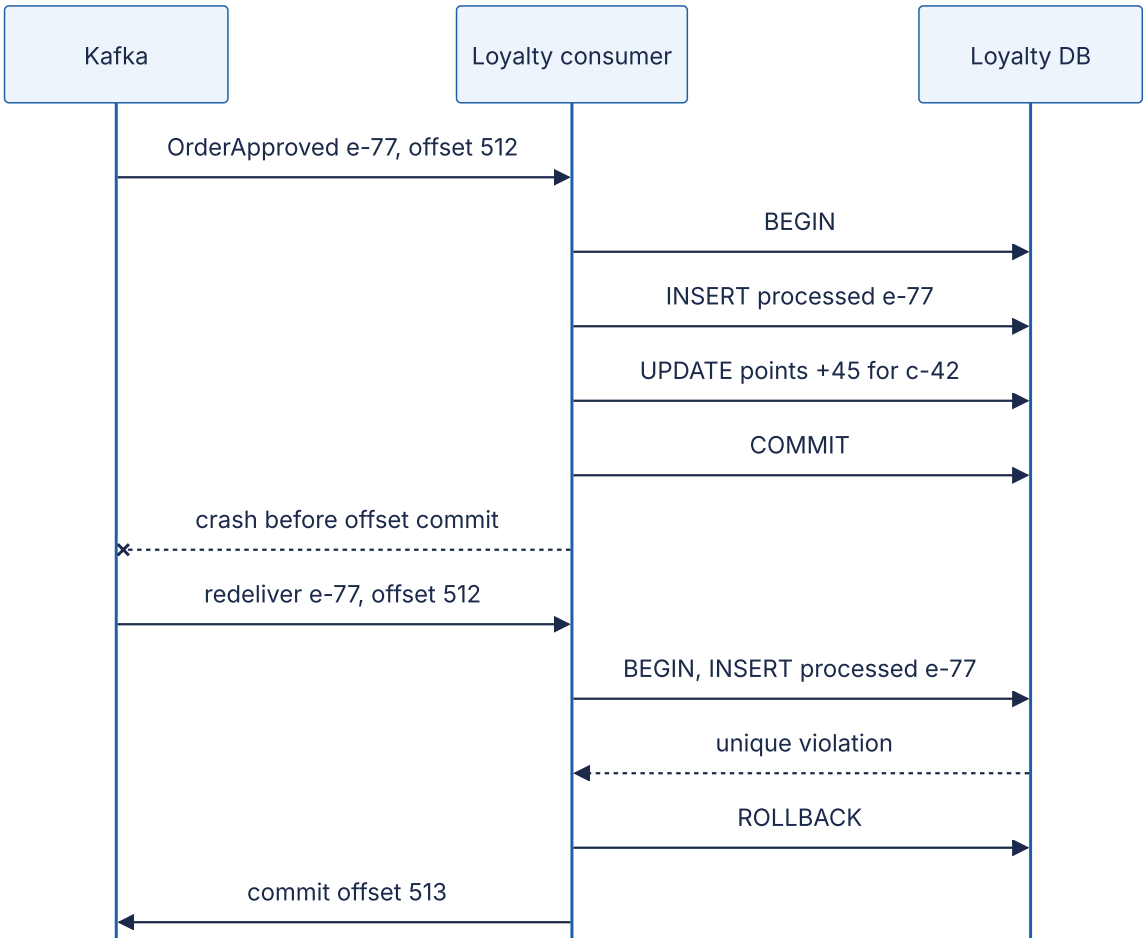
Definition — Idempotent consumer. A message consumer whose effect on state is the same whether a given message is processed once or many times, achieved either because the operation is naturally idempotent or because the consumer detects and skips messages it has already processed.

Section 22.15 owns idempotency keys for APIs; consumers use the same idea with the **event ID** as the key. Three techniques cover nearly every case.

Table 32.12 — Idempotent consumer techniques.

Technique	How it works	Strength	Limitation
Natural idempotency	Operation is idempotent by nature: `SET status = 'SHIPPED'`, upsert by key, add to a set	No extra state	Not available for increments, sends, charges
Dedup table	`INSERT INTO processed(event_id)` in the same transaction as the effect; a unique-key conflict means "already done"	Works for any effect in the same database	Storage grows with rate × window; useless if the effect is outside that database
Versioned (conditional) writes	Store the last applied version per entity; apply only if `event.version > stored.version`	Constant storage per entity; also rejects reordered stale events	Needs a per-entity monotonic version from the producer

Figure 32.14 — A consumer that deduplicates in the same transaction as its effect.



Reading the diagram. The broker delivers at least once; the consumer's database is the storage boundary where deduplication happens. The dedup row and the points increment commit in one local transaction, so they cannot diverge. The crash after commit but before the offset commit causes redelivery, and the unique key on `event_id` turns the duplicate into a no-op. Failure points: an effect outside the database (an email) cannot join this transaction and needs a downstream idempotency key or an outbox. Scaling: partition the dedup table with the consumer's data and expire old rows.

An alternative is to store the consumer's **offset** in the same database as the effect (and seek to it on startup), which deduplicates without per-message rows, provided one consumer owns each partition.

FORMULA

Storage needed by a dedup table

$$S = \lambda \times W \times b$$

Symbol	Meaning	Units
λ	Messages consumed per second	messages/s
W	Dedup window: how long an ID must be remembered	s
b	Bytes per dedup row including index overhead	bytes
S	Storage required	bytes

WORKED EXAMPLE

Worked example — How long to remember event IDs.

1. The loyalty consumer handles $\lambda = 5,000$ messages/s. Redeliveries normally arrive within minutes, but a replay from a backup may resend a week of events, so $W = 7$ days $= 604,800$ s.
2. Rows: $5,000 \times 604,800 = 3.024 \times 10^{9}$. At $b = 60$ bytes (16-byte UUID, timestamp, B-tree overhead): $S \approx 1.8 \times 10^{11}$ bytes ≈ 181 GB (decimal).
3. With $W = 24$ h: $5,000 \times 86,400 \times 60 \approx 26$ GB.

Interpretation: a long window is expensive. Engineering implication: partition the dedup table by day and drop old partitions; or switch to versioned writes, which need one row per *entity* (a few million customers, a few hundred megabytes) and remember forever.

COMMON MISTAKE

Common misconception — "Checking whether we processed the message, then processing it, is idempotent." A check followed by a separate write is a race: two redeliveries processed concurrently both pass the check. The dedup insert must be atomic with the effect, enforced by a unique constraint.

32.11 Workflow engines

32.11.1 Durable execution

The orchestrator in §32.7.4 is about 60 lines of saga logic, and a production version needs much more: timers ("cancel the reservation if unpaid in 15 minutes"), backoff, versioning

while thousands of sagas are in flight, visibility ("where is order 981?"), and a scalable, replicated saga log. **Workflow engines** package all of it.

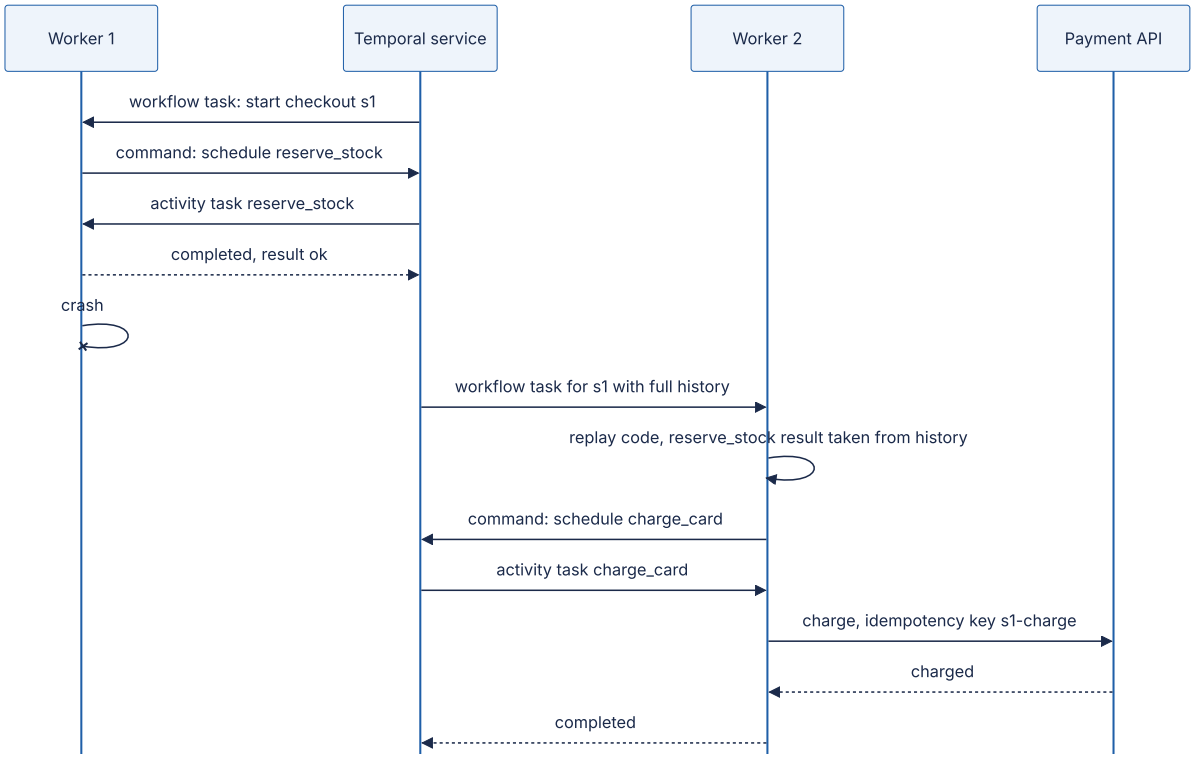
> DEFINITION
>
> **Definition — Durable execution.** A programming model in which a function's progress is persisted by an engine as it runs, so that the function survives process crashes, deploys and arbitrarily long waits and continues exactly where it left off, as if the process had never died [Temporal Docs].

How Temporal works internally

Temporal, a fork of Uber's Cadence by Cadence's original authors, implements durable execution with **event-history replay** [Temporal Docs].

1. **Workflow code** is ordinary code (Go, Java, Python, TypeScript, .NET and others) that orchestrates; **activities** are functions that do the side-effecting work (call the payment API, write a database).
2. The Temporal service stores, for each workflow execution, an append-only **event history**: `WorkflowExecutionStarted`, `ActivityTaskScheduled`, `ActivityTaskCompleted` with its result, `TimerFired`, and so on.
3. **Workers** in your own deployment poll **task queues**. When a workflow needs to make progress, a worker runs the workflow code until it blocks on an activity or timer, and returns the resulting **commands** ("schedule activity `charge_card`"), which the service records as events.
4. If the worker crashes or evicts the workflow from its cache, any other worker **replays** the history: it re-runs the workflow code from the start, and whenever the code asks for an activity that the history says already completed, the SDK returns the recorded result instead of executing it. The code reaches the same point with the same local variables, then continues.
5. Activities run at least once and are retried per a **retry policy** (initial interval, back-off coefficient, maximum interval, maximum attempts, non-retryable error types) bounded by timeouts: *Start-To-Close* (one attempt), *Schedule-To-Close* (all attempts) and *Heartbeat* (liveness of long activities). So activities must be idempotent (§32.10).

Figure 32.15 — A Temporal worker crashes and another worker replays the history.



Reading the diagram. The Temporal service owns durable state (the history, in its own replicated database); workers are stateless and in the application's network, connected over gRPC long polls. Workflow tasks run deterministic orchestration code; activity tasks perform side effects. When worker 1 crashes, worker 2 receives the history and replays: `reserve_stock` is *not* executed again because its completion is recorded. The failure point that remains is an activity that crashes after calling the payment API but before reporting completion; it will be retried, which is why the call carries an idempotency key. Scaling: add workers per task queue; the service shards histories by workflow ID.

The determinism constraint

Replay works only if the workflow code, given the same history, issues the same commands in the same order. Workflow code must therefore not read the wall clock, generate random numbers, call the network or the file system, use threads, or iterate over unordered collections in ways that change between runs; SDKs provide deterministic substitutes (`workflow.now()`, deterministic random, durable timers). Changing workflow code while executions are in flight needs explicit **versioning** (a patch marker that lets old executions follow the old branch), or old histories will fail to replay with a *non-determinism error*. Histories also have size limits, so a workflow that loops indefinitely periodically starts a fresh execution with **Continue-As-New**.

The checkout saga as a Temporal workflow in Python:

```
        # illustrative: needs the temporalio package, a Temporal service and a worker
        from datetime import timedelta

        from temporalio import workflow
        from temporalio.common import RetryPolicy
        from temporalio.exceptions import ActivityError

        with workflow.unsafe.imports_passed_through():
            from shop.activities import (approve_order, charge_card, create_order,
                                         reject_order, release_stock, reserve_stock)

        STEP = dict(start_to_close_timeout=timedelta(seconds=30),
                    retry_policy=RetryPolicy(maximum_attempts=3))       # then give up
and compensate
        FOREVER = dict(start_to_close_timeout=timedelta(seconds=30),
                       retry_policy=RetryPolicy(maximum_interval=timedelta(minutes=5)))
# no attempt cap

        @workflow.defn
        class CheckoutWorkflow:
            @workflow.run
            async def run(self, order: dict) -> str:
                await workflow.execute_activity(create_order, order, **STEP)
                undo = []
                try:
                    await workflow.execute_activity(reserve_stock, order, **STEP)
                    undo.append(release_stock)
                    await workflow.execute_activity(charge_card, order, **STEP)      #
pivot
                except ActivityError:
                    for compensation in reversed(undo):
                        await workflow.execute_activity(compensation, order, **FOREVER)
                    await workflow.execute_activity(reject_order, order, **FOREVER)
                    return "COMPENSATED"
                await workflow.execute_activity(approve_order, order, **FOREVER)    #
retriable
                return "COMPLETED"
```

What to notice: compensation is a `try`/`except` with a list of undo steps, readable top to bottom; the pivot and retriable distinctions of §32.7 become retry policies (`STEP` gives up after three attempts, `FOREVER` never does); there is no saga log in user code, because the engine's event history is the saga log.

32.11.2 AWS Step Functions

AWS Step Functions defines workflows as state machines in the JSON-based **Amazon States Language** (ASL): `Task`, `Choice`, `Parallel`, `Map`, `Wait`, `Pass`, `Succeed` and `Fail` states, with `Retry` and `Catch` fields on tasks [AWS Docs: Step Functions]. **Standard workflows** run for up to one year with exactly-once execution of each state transition and are priced per transition; **Express workflows** run for up to five minutes with at-least-

once (asynchronous) or at-most-once (synchronous) semantics and are priced per request and duration, suiting high-volume event processing (as of 2026).

```
        {
          "Comment": "Checkout saga: compensate before the pivot, retry after it",
          "StartAt": "CreateOrder",
          "States": {
            "CreateOrder": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:create-order",
              "Next": "ReserveStock"
            },
            "ReserveStock": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:reserve-
stock",
              "Retry": [{"ErrorEquals": ["States.Timeout"], "IntervalSeconds": 1,
"MaxAttempts": 3, "BackoffRate": 2.0}],
              "Catch": [{"ErrorEquals": ["States.ALL"], "ResultPath": "$.error",
"Next": "RejectOrder"}],
              "Next": "ChargeCard"
            },
            "ChargeCard": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:charge-card",
              "Catch": [{"ErrorEquals": ["States.ALL"], "ResultPath": "$.error",
"Next": "ReleaseStock"}],
              "Next": "ApproveOrder"
            },
            "ApproveOrder": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:approve-or-
der",
              "Retry": [{"ErrorEquals": ["States.ALL"], "IntervalSeconds": 2,
"MaxAttempts": 20, "BackoffRate": 2.0}],
              "End": true
            },
            "ReleaseStock": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:release-
stock",
              "Retry": [{"ErrorEquals": ["States.ALL"], "IntervalSeconds": 2,
"MaxAttempts": 20, "BackoffRate": 2.0}],
              "Next": "RejectOrder"
            },
            "RejectOrder": {
              "Type": "Task",
              "Resource": "arn:aws:lambda:us-east-1:123456789012:function:reject-order",
              "Retry": [{"ErrorEquals": ["States.ALL"], "IntervalSeconds": 2,
"MaxAttempts": 20, "BackoffRate": 2.0}],
              "Next": "OrderRejected"
            },
            "OrderRejected": {"Type": "Fail", "Error": "OrderRejected", "Cause": "Saga
compensated"}
          }
        }
```

What to notice: `Catch` routes a failure before the pivot into the compensation chain (`ReleaseStock` → `RejectOrder`); states after the pivot and all compensations use generous `Retry` blocks instead of `Catch`; `ResultPath` keeps the original input so compensations still know the order. Each Task invocation is at-least-once from the function's point of view, so the functions must be idempotent.

32.11.3 When to use an engine

Table 32.13 — Hand-rolled saga versus workflow engine.

	Hand-rolled (saga table + messages)	Temporal or Cadence	AWS Step Functions
How it works	Your orchestrator, your saga log, your timers	Code-first durable execution with history replay	JSON state machine, managed service
Advantages	No new infrastructure; full control	Arbitrary logic in a real language; timers, signals, versioning, visibility	Fully managed; deep AWS integrations; visual console
Disadvantages	You rebuild retries, timers, visibility, versioning	Operate a cluster (or buy the cloud service); determinism discipline	AWS lock-in; complex logic awkward in JSON; per-transition cost
Performance	As fast as your broker	Tens of milliseconds per step	Tens of milliseconds per transition; Express faster
Choose when	2–3 steps, no timers, team already runs a broker	Many long-running processes, complex branching, multi-cloud	Serverless AWS workloads, simple to moderate flows

RECOMMENDATION

Recommendation — Count your sagas' features, not their steps. Once a process needs two of {timers longer than a request, human approval, more than four steps, versioned rollouts while instances are in flight, an operator UI to find and repair stuck instances}, a workflow engine is cheaper than building those features yourself.

INDUSTRY EXAMPLE

Uber Cadence and Temporal. Cadence was built at Uber to run long-lived, fault-tolerant business workflows as code and was open-sourced; its original creators later forked it as Temporal and founded a company around it. The core design, event-history replay with deterministic workflow code and retried idempotent activities, is shared by both. *Evidence: Primary* — [Temporal Docs]

COMMON MISTAKE

Common misconception — "A workflow engine gives exactly-once side effects." It gives exactly-once *workflow progress*: each step's completion is recorded once and never replayed. The activity itself is at-least-once, so a payment activity still needs an idempotency key.

32.12 Summary and revision notes

SUMMARY

- **Event sourcing** stores an aggregate's append-only events as the source of truth; state is a fold of `apply` over them. Appends carry an **expected version** (optimistic concurrency). Replay costs N/r; **snapshots** cut per-command cost to about $t_s + S/(2r)$ but do not speed up projection rebuilds.
- Events live forever: evolve schemas additively, **upcast** old versions on read, and treat rewriting history as a last resort. Keep personal data out of events or **crypto-shred** it with per-subject keys.
- **CQRS** separates the write model from read models built by projections; reads are eventually consistent. Catch-up after a pause takes $\lambda D/(\mu - \lambda)$. Use consistency tokens for read-your-writes. Do not use CQRS for plain CRUD.
- **Dual writes** to a database and a broker lose events (database first) or invent them (broker first). The **transactional outbox** writes the event in the same local transaction; a relay publishes it at least once. Polling relays are simple; log-tailing relays give commit order and lower latency. Relay throughput is $B/(t_q + Bt_p + t_m)$.
- **Log-based CDC** (Debezium) snapshots tables, then streams the WAL or binlog in commit order with before and after images; watch replication-slot retention and enforce schema compatibility with a registry.
- A **saga** is $T_1 \dots T_n$ or $T_1 \dots T_j, C_j \dots C_1$. Steps are compensatable, the **pivot**, or retriable. Sagas lack isolation; use semantic locks, commutative updates, reread values and reservations.
- **Choreography** suits short, stable flows and broadcasting facts; **orchestration** suits complex processes with compensations and deadlines.
- Exactly-once *delivery* is impossible; **effectively-once = at-least-once + idempotent effect**. Kafka EOS covers Kafka-to-Kafka processing only.
- **Idempotent consumers** use natural idempotency, a dedup table committed with the effect ($S = \lambda W b$), or versioned writes.
- **Workflow engines** (Temporal, Step Functions) provide durable execution: the event history is the saga log, workflow code must be deterministic, and activities are at-least-once.

32.13 Knowledge checkpoint

1. Why must an event-sourced `apply` function never validate?
2. What does the expected version prevent, and what does a writer do when it fails?
3. A stream has 80,000 events, replay runs at 40,000 events/s, snapshots every 1,000 events with $t_s = 1$ ms. Compute load time with and without snapshots.

4. Name two ways to evolve an event schema without rewriting history.
5. How does crypto-shredding erase data from backups you cannot modify?
6. A projection at $\mu = 3,000$ events/s, with $\lambda = 1,000$ events/s, was down for 30 minutes. How long does it take to catch up?
7. Give the two failure sequences of a dual write and the anomaly each causes.
8. Why can a polling relay that remembers the highest published `id` skip events?
9. What does a Debezium change event contain, and why is delivery at-least-once?
10. What is a pivot transaction, and how are failures before and after it handled?
11. Name three countermeasures for the missing isolation of sagas.
12. When would you choose choreography over orchestration?
13. What exactly does a Kafka transaction make atomic?
14. A consumer handles 2,000 messages/s and must remember IDs for 3 days at 50 bytes each. How much storage?
15. Why must Temporal workflow code be deterministic, and what happens if it is not?

Answers

1. Replay must always reproduce history. An old event that today's rules reject still happened; if `apply` throws, the aggregate can never be loaded.
2. Lost updates from concurrent writers on the same aggregate. The writer reloads the stream, re-validates the command against the new state, and retries or rejects.
3. Without: $80,000/40,000 = 2$ s. With: $0.001 + 500/40,000 = 0.001 + 0.0125 = 13.5$ ms.
4. Additive optional fields with defaults; upcasters that convert old versions on read (or a new event type).
5. Backups contain only ciphertext; deleting the per-subject key from the key store makes every copy unreadable.
6. Backlog $1,000 \times 1,800 = 1.8 \times 10^6$ events; $T = 1.8 \times 10^6 / 2,000 = 900$ s, 15 minutes.
7. Database commit then crash before publish: lost event. Publish then database rollback or crash: phantom event.
8. IDs are assigned at insert but become visible at commit; a transaction with a lower `id` can commit after the relay has passed it.
9. Before and after row images, operation type, and source metadata (log position, commit time, table). Offsets are stored periodically, so after a restart events since the last stored offset are re-sent.
10. The go/no-go step after which the saga must complete. Failures before or at the pivot trigger compensations in reverse order; failures after it are retried forward.
11. Any three of: semantic lock, commutative updates, pessimistic view, reread value, version file, by value.
12. For short, stable flows of two to four steps across autonomous teams, and for broadcasting facts that many domains consume.
13. Writes to several partitions plus the consumer's input offsets, made visible together to `read_committed` consumers.
14. $2,000 \times 259,200 \times 50 \approx 2.6 \times 10^{10}$ bytes ≈ 26 GB.

15. A replaying worker must regenerate exactly the commands recorded in the history to rebuild state. Nondeterminism produces different commands and a non-determinism error that stalls the execution.

32.14 Interview questions

Basic

Q1. What is the transactional outbox and why is it needed? Answer. A service must update its database and publish an event, but there is no transaction across the two systems, so a crash between writes loses an event or publishes a phantom. The outbox inserts the event into a table in the same local transaction as the state change; a relay (polling or CDC) publishes committed rows and marks them, at least once. Consumers deduplicate by event ID. Mention ordering by aggregate key and monitoring outbox age.

Q2. What is the difference between event sourcing and CQRS? Answer. Event sourcing is a storage choice: events are the source of truth and state is derived. CQRS is a model split: commands and queries use different models. They pair well because an event store cannot answer ad hoc queries, but either can be used alone. Both introduce eventual consistency in read models.

Intermediate

Q3. Design checkout across order, inventory and payment services without 2PC. Answer. An orchestrated saga: create order `PENDING` (compensate: reject), reserve stock with a 15-minute expiry (compensate: release), charge card (pivot), approve order (retriable). Persist saga state before each command; every participant deduplicates by saga ID; commands and events flow through outboxes. Walk through a failure at each step, the semantic lock on `PENDING`, and what users see during compensation. Consider a workflow engine if timers and visibility matter.

Q4. Your team says Kafka exactly-once makes the email consumer safe. Respond. Answer. EOS makes Kafka-to-Kafka read-process-write atomic. Sending an email is an external side effect: a crash after sending and before committing offsets re-sends it. Make it effectively-once by recording the send in a database with the event ID in the same transaction as the decision, using an outbox for the email request, and passing an idempotency key to the provider if it supports one. Some duplicates may remain possible; quantify and accept or reconcile.

Advanced

Q5. An event-sourced ledger has 3 billion events and a new regulatory report needs a projection over all of them by next week. Plan it. Answer. Estimate: at 100,000 events/s per worker, a single pass takes about 8.3 hours; partition by account into 32 workers to bring it under 20 minutes, subject to event-store read bandwidth. Build the projection blue-green beside existing ones, checkpoint per partition, make upserts idempotent, verify against sampled full replays, then switch readers. Watch upcaster cost on old events, read load on the production store (replay from a replica or an archive copy), and snapshot schema versions.

Q6. When would you choose Temporal over a hand-rolled saga, and what discipline does it impose? Answer. Choose it when processes are long-running, have timers, human steps, many branches, or need operator visibility and safe versioning. It imposes determinism in workflow code (no clocks, randomness or I/O except through SDK APIs), explicit versioning for code changes while executions are in flight, idempotent activities with sensible retry policies and timeouts, history-size management with Continue-As-New, and operating the service or paying for the cloud service.

32.15 Practical exercises

1. Extend the event-sourced account of §32.3.3 with a `snapshot_schema` field and make `load` ignore snapshots whose schema differs; add a test that changes `apply` and still loads correctly.
2. Modify the outbox simulation to use a high-water-mark relay with two concurrent writers whose commits can reorder, and show a test that loses events; then fix it.
3. Add a 15-minute reservation timeout to the saga in §32.7.4 so that a crashed orchestrator’s reservations expire, and test that a late `charge_card` after expiry is refused.
4. Run Debezium against a local PostgreSQL, stop the connector for ten minutes under write load, and graph replication-slot lag in bytes.
5. Implement the loyalty consumer of Figure 32.14 with SQLite: a dedup table, then versioned writes; compare storage after one million messages.

32.16 Design challenges

1. **Ride-hailing trip lifecycle.** Model a trip (request, match, pickup, drop-off, payment, rating) as either an event-sourced aggregate or a workflow. Identify the pivot, the compensations, and the read models drivers and riders need, with their acceptable lag.

2. **Search index for 500 million products.** Keep it consistent with a sharded MySQL catalog using CDC. Plan the initial load without downtime, schema changes, and the response to a connector outage of six hours.
3. **Cross-border payment.** A transfer debits a local account, converts currency through a partner, and credits a foreign bank via an API that may take two days to confirm. Choose choreography, orchestration or a workflow engine, and specify every idempotency key.

Part VII — Software Architecture and Design

Chapter 33 — Architecture Patterns

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 2.5 h

An **architecture pattern** (or **architectural style**) is a reusable answer to the question "how should the parts of this system be arranged, and how may they depend on each other?" Each pattern trades some properties for others: a monolith buys simplicity with coupling, microservices buy team independence with network calls, cells buy a small blast radius with duplicated infrastructure. None is best in general. This chapter shows eleven patterns on one running example, **Folio**, a fictional online bookstore that sells books from a catalog, takes payments through an external payment provider, reserves inventory, ships parcels and emails customers. You will see Folio drawn in each style, so the differences are about structure rather than about the problem. Chapter 34 then goes deep on microservices and domain-driven design.

33.1 Learning objectives

After this chapter you should be able to:

- Distinguish logical layers from physical tiers, strict from relaxed layering, and recognize the architecture sinkhole anti-pattern.
- State the real benefits of a monolith and quantify how deployment coupling grows with the number of teams.
- Design a modular monolith with explicit module interfaces and mechanically enforced dependency rules.
- Contrast service-oriented architecture (SOA) with microservices, and place event-driven architecture among the styles.
- Explain serverless execution, cold starts and concurrency, and compute the break-even request rate against always-on servers.
- Implement a port and two adapters in Python and test the domain core with a fake.
- Explain the dependency rule of clean architecture and relate hexagonal, onion and clean architecture.
- Size cells, compute blast radius, and calculate shuffle-sharding overlap probabilities.
- Choose between monolith, modular monolith and microservices using team size, deployment frequency, domain maturity and Conway's law.

33.2 Prerequisites

- Decomposition, components and weighted decision matrices — §2.3 and §2.8 (patterns are pre-packaged decompositions).
- Availability in series and parallel — §4.14.2 (why network hops reduce availability).
- Little's Law — §4.11 (serverless concurrency).
- Combinations and probability — §4.6 (shuffle-sharding arithmetic).
- Stateless services and the scale cube — §18.5 and §18.10 (cells are Z-axis splits).
- Bulkheads — §22.14 (cells are bulkheads for whole stacks).
- Messaging and events — §30.3–§30.6 (event-driven architecture in brief).

33.3 Layered architecture

33.3.1 Layers, tiers and the flow of a request

> DEFINITION
>
> **Definition — Layered architecture.** A style that organizes code into horizontal **layers**, each with one kind of responsibility (presentation, business logic, persistence), where each layer may depend only on layers below it. A **tier** is a *physical* deployment boundary (browser, application server, database server); an **n-tier architecture** maps layers onto separately deployed tiers.

First-principles explanation

Think of a restaurant. The waiter takes orders and presents dishes but never cooks. The kitchen applies the recipes but never talks to diners. The storeroom keeps ingredients but has no idea what a recipe is. Each group can be trained, replaced or reorganized without retraining the others, because each talks only to its neighbor through a narrow interface: an order ticket, a requisition slip. Software layers apply the same idea. The **presentation layer** renders pages and parses requests; the **business layer** (also called the service or domain layer) enforces rules such as "you cannot order more copies than are in stock"; the **persistence layer** turns objects into SQL; the **database** stores rows.

Why does this exist?

Layering was the default enterprise style from the 1990s because it matched how organizations were staffed: UI developers, back-end developers and database administrators. It gives **separation of concerns** (a page designer does not need SQL), **layers of isolation** (replacing the persistence technology touches one layer), and a structure every new hire already recognizes [Richards and Ford 2020]. It is also the natural starting point of most

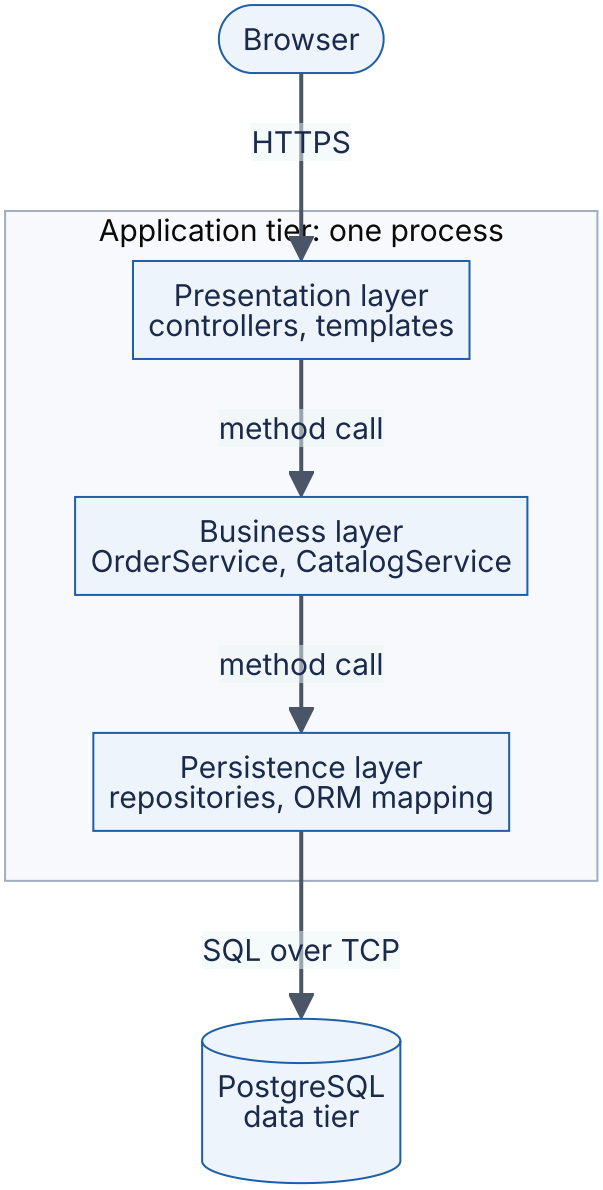
web frameworks, whose project templates already contain `controllers`, `services` and `repositories` folders.

How it works internally

1. A browser sends `POST /orders` to the presentation layer, which validates the input format and converts it into a call such as `order_service.place(isbn, qty)`.
2. The business layer checks stock, computes the price, applies discounts and decides whether the order is valid.
3. The persistence layer converts the decision into SQL statements, inside a transaction.
4. The database executes the statements; the result returns upward through the same layers.

Layers may be **closed** or **open**. A closed layer must be passed through: presentation may call business but not persistence. An open layer may be skipped. **Strict layering** makes every layer closed; **relaxed layering** opens some, typically a shared “utilities” or persistence layer, so upper layers can reach it directly [Richards and Ford 2020; Bass et al. 2021].

Figure 33.1 — Folio as a strict layered application deployed on three tiers.



Reading the diagram. The browser is the client tier; it sends HTTPS requests to the application tier. Inside that one process, three logical layers call each other synchronously with ordinary method calls (solid arrows), always downward: no layer knows about the one above it. Only the persistence layer crosses the storage boundary, speaking SQL over TCP to PostgreSQL in the separate data tier. Failure points are the application process (a crash takes all three layers with it) and the database (every request depends on it). The application tier scales by running identical copies behind a load balancer (§18.4); the data tier scales with replicas and partitioning (Chapter 14). Note that the three layers are not three deployments: layers are logical, tiers are physical.

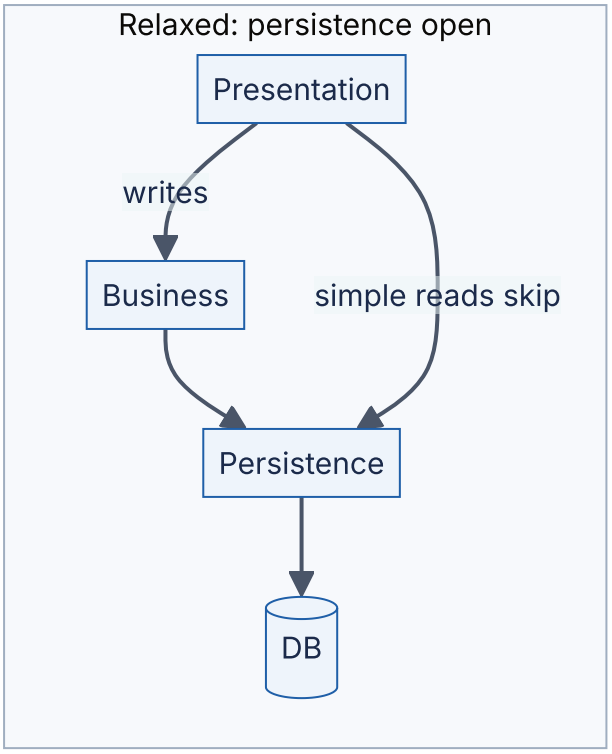
33.3.2 Strict versus relaxed layering and the sinkhole anti-pattern

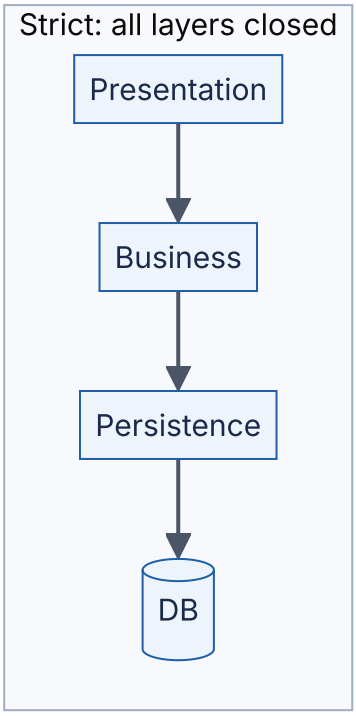
Strict layering maximizes isolation: if every query must go through the business layer, then replacing the ORM touches only persistence, and every rule is enforced in one place.

Its cost is boilerplate. Consider Folio's "show book details" page. The controller calls `CatalogService.get_book(isbn)`, which does nothing but call `BookRepository.find(isbn)`, which runs one `SELECT`. The business layer adds no logic; it only forwards. This is the **architecture sinkhole anti-pattern**: requests that fall through layers without any processing [Richards and Ford 2020]. Each pass-through costs code, a mapping between nearly identical objects, and a test, and multiplies the files you touch for a small change.

Every layered system has *some* sinkholes; simple reads are pass-throughs by nature. Richards suggests an 80–20 heuristic: if roughly 20% of requests are sinkholes that is normal, but if most are, the layering is not paying for itself, and you should either open the layer for those paths or choose a different style [Richards 2015]. Opening a layer is a deliberate trade: the presentation layer now depends on persistence directly, so a persistence change can break the UI.

Figure 33.2 — Strict layering, relaxed layering and a sinkhole path.





Reading the diagram. On the left, every request traverses each layer in order; for a book-detail read the business layer only forwards the call, which is the sinkhole. On the right, the persistence layer is marked open: writes still go through the business layer, where rules live, while simple reads skip it. All calls are synchronous in-process calls; the only storage boundary is the database. The relaxed variant has one more dependency edge (presentation to persistence), which is the failure point to watch: a schema change

can now break pages directly. Neither variant changes how the system scales; layering is a code-organization decision.

Advantages and disadvantages

Layering is easy to understand, matches framework conventions, isolates technology choices, and lets specialists work in parallel. Its central weakness is that it partitions code by *technical* role rather than by *business domain*. Adding "audiobook" as a new product format at Folio touches a template, a controller, a service, a repository and a migration: one feature, five layers, often several teams. Richards and Ford call this **technical partitioning**, as opposed to **domain partitioning**, where code is grouped by business capability (catalog, ordering, shipping) [Richards and Ford 2020]. Most of the remaining patterns in this chapter are, in one way or another, domain-partitioned. Layering also says nothing about deployment, fault isolation or scaling: a layered application is usually a monolith (§33.4).

Failure scenarios

Table 33.1 — Layered architecture failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Business rules leak into controllers or SQL	Deadline pressure; open layers	Same rule implemented twice; inconsistent behavior	Move logic into the business layer	Code review rule; architecture tests
Sinkhole bloat	Strict layering applied to CRUD paths	Most service methods are one-line forwards	Open the layer for reads	Apply the 80–20 check during design
Lower layer depends upward	Callback or import "just this once"	Import cycle between packages	Invert with an interface (§36.7)	Automated dependency checks (§33.5)
Schema change breaks every layer	Database types used as domain objects	Large diffs for small schema changes	Introduce mapping at the persistence boundary	Keep persistence types inside persistence

COMMON MISTAKE

"Layered means n-tier." Three layers can run in one process on one machine, and a three-tier deployment can contain a single tangled layer. Layers describe code dependencies; tiers describe where processes run. Say which one you mean in a design review.

33.4 Monolithic architecture

33.4.1 What a monolith is, and what it is good at

DEFINITION

Definition — Monolith. A system whose functionality is built, tested and deployed as **one deployable unit**, typically one process image running as identical replicas and backed by one shared database. “Monolith” describes the *deployment* unit; it says nothing about whether the code inside is well structured.

First-principles explanation

A monolith is a single building that houses every department of a company. Walking from sales to accounting takes seconds, everyone shares one mailroom, and renovating means closing the whole building for a weekend. For a company of twenty people this is the best possible arrangement; for twenty thousand it becomes a problem. The same is true of code. Folio’s first version is one Python or Java application containing catalog, cart, ordering, payments and shipping code, deployed as one artifact.

Why does this exist?

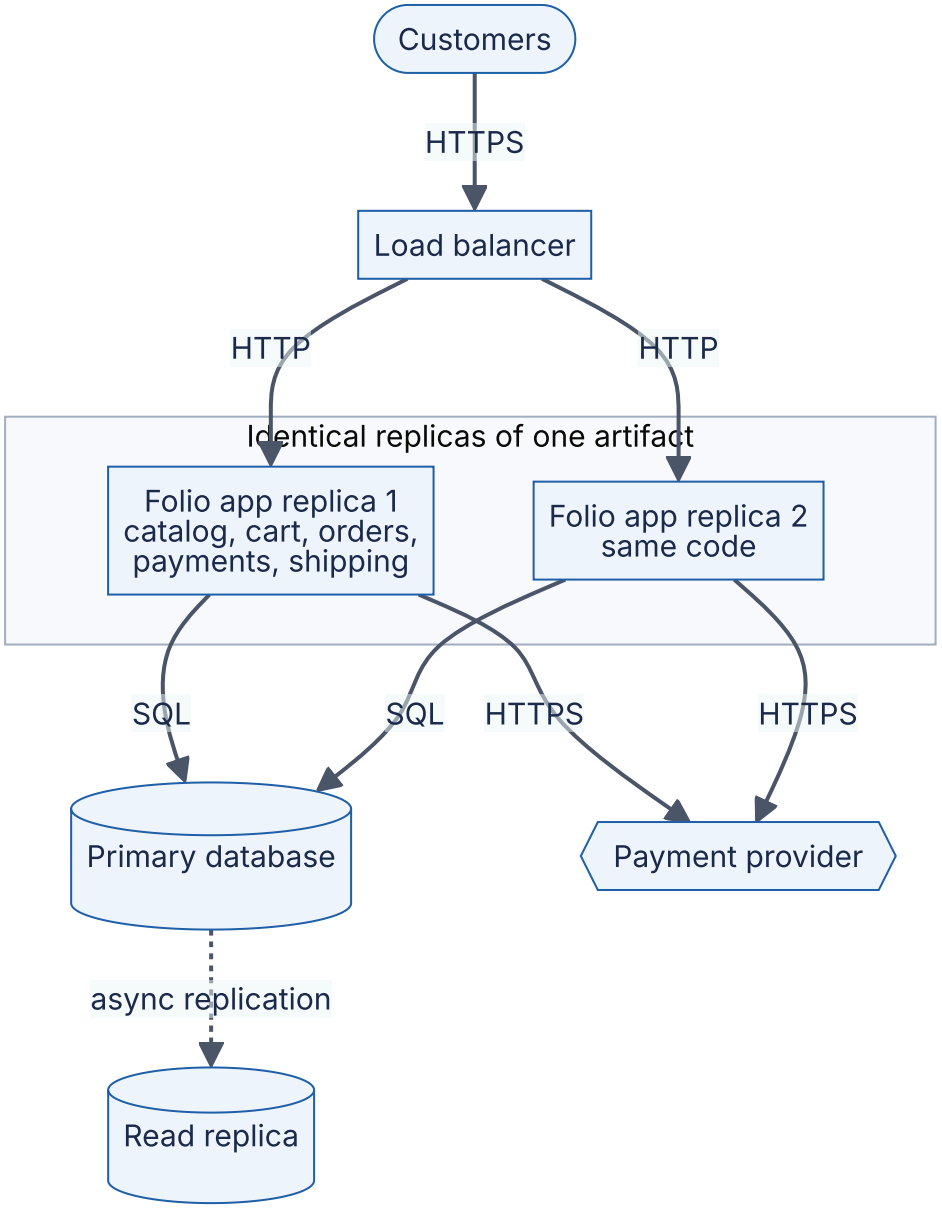
The monolith is not a mistake that later styles corrected; it is the default because its benefits are large and immediate. Stated honestly:

- **Calls are cheap and reliable.** An in-process function call costs nanoseconds and cannot time out. A call over the network within a datacenter costs roughly 0.5 ms round trip and can fail in ways an in-process call cannot (§24.5).
- **Transactions are easy.** Placing an order, decrementing stock and recording a payment intent can share one ACID transaction (§11.12). Across services, the same operation needs a saga (§32.7).
- **Refactoring is cheap.** Renaming a function or moving a field is an IDE operation checked by the compiler or test suite, not a versioned API migration across teams.
- **Operations are simple.** One build pipeline, one deployment, one log stream, one stack trace that shows the whole request.
- **It scales further than people expect.** A stateless monolith scales horizontally behind a load balancer exactly as a stateless microservice does (§18.4–§18.5).

Fowler’s “MonolithFirst” argues that almost all successful microservice systems he had seen started as monoliths that were split later, and that projects started as microservices often ran into trouble, because the right service boundaries are only visible once the domain is understood [Fowler 2015].

How it works internally

Figure 33.3 — Folio deployed as a monolith.



Reading the diagram. Customers reach a load balancer over HTTPS, which spreads synchronous HTTP requests across identical replicas of one artifact; every replica contains every feature. All replicas share one primary database (the storage boundary), which streams changes asynchronously (dotted arrow) to a read replica for reporting and failover. The payment provider is an external system called synchronously. Failure points: a bug that crashes the process crashes every feature on that replica at once, and the primary database is shared by all features. Scaling is by adding replicas (all features scale together) and by database replicas; you cannot scale only the catalog.

33.4.2 The cost: deployment coupling

The monolith's costs grow with the number of people working in it rather than with traffic. Every change, from every team, ships in the same artifact. If any one change is bad, the release is held or rolled back for everyone. This is **deployment coupling**.

Mathematical foundations

FORMULA

Probability that a coupled release is clean

$$P_{\text{clean}} = (1 - p)^{m}, \qquad m = T \times c$$

Symbol	Meaning	Units
P_{clean}	Probability a release contains no release-blocking defect	probability (0–1)
p	Probability that one change contains a release-blocking defect (assumed independent)	probability
m	Number of changes bundled in one release	changes
T	Number of teams contributing to the release	teams
c	Changes per team per release	changes/team

WORKED EXAMPLE

Worked example — Folio's release train at 12 teams. Folio has grown to $T = 12$ teams, each landing $c = 4$ changes into a weekly release; historically $p = 1\%$ of changes contain a defect serious enough to stop a release.

1. Changes per release: $m = 12 \times 4 = 48$.
2. $P_{\text{clean}} = 0.99^{48} = e^{48 \ln 0.99} = e^{48 \times (-0.01005)} = e^{-0.4824} \approx 0.617$.
3. So about 38% of weekly releases are held or rolled back, and when that happens all 12 teams wait.
4. If each team deployed its own unit with its own 4 changes: $0.99^4 \approx 0.961$. Only 4% of releases fail, and a failure delays one team.

Interpretation. Coupling turns one team's defect into everyone's delay; the clean-release probability decays exponentially in the number of teams. **Engineering implication.** Before splitting the deployment, attack p and c: better tests lower p, and deploying smaller batches more often lowers c. With $c = 1$ (continuous deployment of single changes) the 12-team monolith ships clean $0.99^{12} \approx 0.886$ of the time and a failure blocks only the next change. When neither lever is enough, independent deployment units (§33.7) remove the coupling.

Real-world industry applications

INDUSTRY EXAMPLE

Stack Overflow. Stack Overflow has publicly described serving its question-and-answer sites from a monolithic .NET application on a small fleet of web servers, with heavy caching and a large SQL Server installation, rather than from many services. The design works because the team is small relative to traffic, the domain is stable, and the database is tuned and scaled vertically [Craver 2016]. *Evidence: Primary* — [Craver 2016]

Advantages and disadvantages

Beyond deployment coupling, a monolith has three structural costs. **Scaling granularity**: a memory-hungry recommendation feature forces every replica to be sized for it. **Fault isolation**: a memory leak in shipping-label generation exhausts the heap of the process that also serves checkout. **Technology lock-in**: every module uses the same language, runtime and library versions; upgrading the framework is an all-or-nothing project. Build and test times also grow with the code base, which slows every team's feedback loop.

Table 33.2 — Monolith failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
One feature's leak crashes all features	Shared process and heap	Memory alarms; correlated errors on unrelated pages	Roll back; restart replicas	Resource limits per worker pool; bulkheads (§22.14)
Release train blocked	Deployment coupling	Release failure rate rises with team count	Revert offending change	Feature flags (§43.7), smaller batches
"Big ball of mud"	No enforced internal boundaries	Every change touches many packages	Modularize incrementally	Modular monolith (§33.5)
Shared database hot spot	All features share one primary	Lock waits, CPU saturation on primary	Read replicas, caching	Per-module schemas; later partitioning

COMMON MISTAKE

"A monolith is a big ball of mud." Foote and Yoder's **big ball of mud** is code without structure [Foote and Yoder 1997]. A monolith is a deployment choice. A well-modularized monolith can be cleaner than a set of microservices whose boundaries cut through the domain.

When the monolith is right

Choose a monolith when the team fits in one or two groups that can coordinate in a single stand-up (very roughly, up to 10–20 engineers), when the domain is new and its boundaries will move, when strong consistency across features matters, and when there is no platform team to run service infrastructure. That describes most new products.

33.5 Modular monolith

33.5.1 Domain modules inside one deployable

DEFINITION

Definition — Modular monolith. A monolith whose code is divided into **modules** aligned with business domains, where each module exposes a small **public interface**, hides its internals and data, and may depend only on an explicitly declared, acyclic set of other modules. Boundaries are enforced by tooling, not just convention.

First-principles explanation

Return to the single building. A modular monolith keeps one building but gives each department a locked suite with a reception desk. Other departments may leave requests at

the desk (the public interface); they may not walk into the filing room (internal classes and tables). You keep the short walking distance, and you gain the ability to reorganize a suite without the rest of the building noticing. If a department later moves to its own building (a separate service), its reception desk becomes its API.

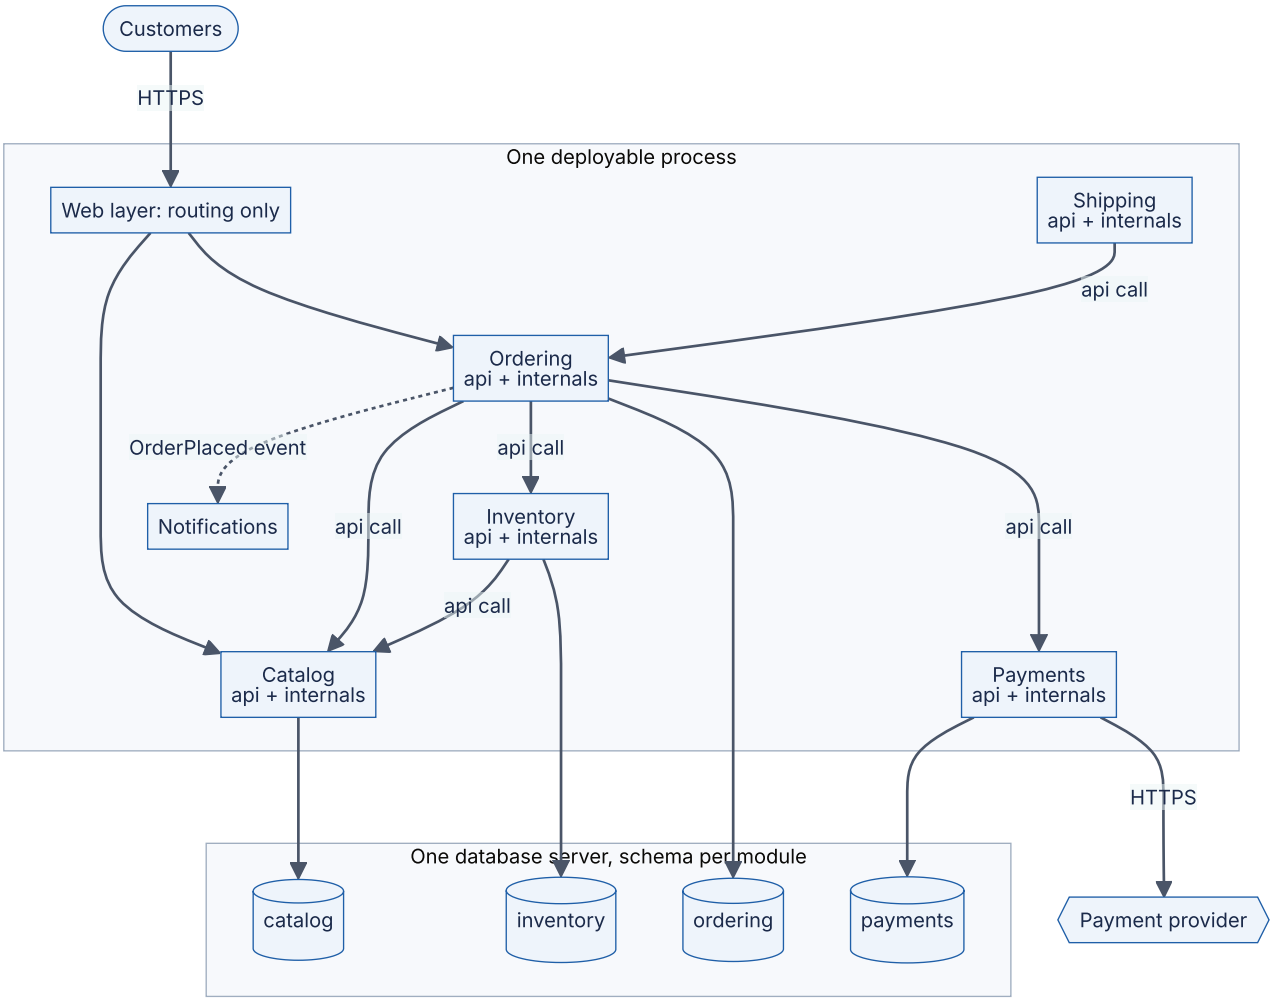
Why does this exist?

It captures most of the monolith's operational simplicity and most of the microservices' maintainability. The idea is old: Parnas argued in 1972 that modules should be chosen to hide design decisions likely to change ("information hiding"), not to mirror steps of processing [Parnas 1972]. The modular monolith applies that rule at the level of business domains, which is why Chapter 2 chose it for QuickBite v1 (§2.8.1).

How it works internally

1. **Partition by domain.** Folio's modules are Catalog, Inventory, Ordering, Payments, Shipping and Notifications. Each owns a package or directory.
2. **Publish a narrow interface.** Each module exposes an `api` package (functions, data-transfer objects, events). Everything else is internal.
3. **Own your data.** Each module owns its tables, ideally in its own database schema. No module joins another module's tables; it calls the other module's interface instead. This is the rule that makes later extraction possible.
4. **Declare dependencies.** A configuration lists which modules each module may use; the graph must be acyclic.
5. **Enforce mechanically.** A build step fails on any import that crosses a boundary illegally. Tools include ArchUnit (Java), Spring Modulith, the Java Platform Module System, `internal` packages in Go and .NET, import-linter (Python) and Packwerk (Ruby).
6. **Decouple with in-process events where order does not matter.** Ordering publishes `OrderPlaced`; Notifications subscribes. Same process, no broker, but the dependency points the right way.

Figure 33.4 — Folio as a modular monolith with declared, acyclic dependencies.



Reading the diagram. All modules run in one process; solid arrows are synchronous in-process calls through each target's public `api`, and every arrow appears in the declared dependency list. The dotted arrow is an in-process event: Ordering does not depend on Notifications, so adding a new subscriber needs no change to Ordering. The storage boundary is one database server divided into schemas, each touched by exactly one module; there are no cross-schema joins. The graph has no cycles: Shipping depends on Ordering, never the reverse. Failure points remain those of a monolith (shared process, shared database server). Scaling is still whole-process, but any module whose interface is clean, Payments for example, can be extracted to its own service by replacing its in-process `api` with a network client (§34.13).

Code example

The enforcement step is simple enough to write yourself. This sketch parses Python imports and checks them against declared dependencies; production teams use import-linter or an equivalent, but the logic is the same.

```
        """Fail the build when a module imports another module's internals or an unde-
clared module."""
        import ast

        # Declared dependencies of Folio's modules (must form a DAG).
        ALLOWED = {
            "catalog": set(),
            "inventory": {"catalog"},
            "ordering": {"catalog", "inventory", "payments"},
            "payments": set(),
            "shipping": {"ordering"},
        }

        # A tiny in-memory "source tree": path -> code.
        SOURCES = {
            "ordering/service.py": "from catalog.api import get_price\n"
                                   "from inventory.api import reserve\n",
            "shipping/service.py": "from ordering.api import order_details\n"
                                   "from ordering.models import OrderRow\n",      #
reaches into internals
            "inventory/service.py": "import shipping.api\n",                     # unde-
clared dependency
        }

        def imported_modules(code: str):
            for node in ast.walk(ast.parse(code)):
                if isinstance(node, ast.Import):
                    yield from (alias.name for alias in node.names)
                elif isinstance(node, ast.ImportFrom) and node.module:
                    yield node.module

        def violations(sources, allowed):
            for path, code in sources.items():
                owner = path.split("/")[0]
                for name in imported_modules(code):
                    target, _, sub = name.partition(".")
                    if target == owner or target not in allowed:
                        continue                                  # own code or third-
party library
                    if target not in allowed[owner]:
                        yield f"{path}: '{owner}' may not depend on '{target}'"
                    elif sub != "api":
                        yield f"{path}: '{name}' is internal to '{target}'; use
'{target}.api'"

        for v in violations(SOURCES, ALLOWED):
            print("VIOLATION", v)
```

Output:

```
VIOLATION shipping/service.py: 'ordering.models' is internal to 'ordering'; use
'ordering.api'
VIOLATION inventory/service.py: 'inventory' may not depend on 'shipping'
```

What to notice:

- Two rules cover most erosion: *only declared dependencies* and *only through* `api`. Ordering's imports pass both.
- The check reads source, not running code, so it runs in seconds in continuous integration and fails the pull request before the coupling exists.
- Imports of names outside `ALLOWED` (standard library, third-party packages) are ignored; a fuller tool would also check that `ALLOWED` itself is acyclic.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Shopify's modular monolith.** Shopify has written publicly about its large Ruby on Rails monolith. Rather than splitting it into microservices, Shopify reorganized the code into components aligned with business domains, each with a public interface, and built tooling to detect references that cross component boundaries; it later open-sourced Packwerk, a static-analysis tool for enforcing such boundaries in Rails applications [Westeinde 2019; Shopify Packwerk]. The stated motivation was developer productivity: keeping the benefits of one code base and one deployment while making ownership and boundaries explicit. *Evidence: Primary* — [Westeinde 2019], [Shopify Packwerk]

Advantages and disadvantages

A modular monolith keeps in-process calls, single deployment and the option of ACID transactions (used sparingly, since cross-module transactions are coupling). It localizes change, makes ownership visible, and makes later extraction a mechanical step. It does *not* fix deployment coupling, scaling granularity or fault isolation; those still require separate processes. Its main risk is erosion: without enforcement, boundaries decay one "temporary" import at a time.

Table 33.3 — Modular monolith failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Boundary erosion	Unchecked imports of internals	Dependency-graph diff in CI	Refactor to use `api`	Fail the build on violations
Cross-module SQL joins	Shared database makes it easy	Query log shows tables of two modules	Replace with interface call or read model	Schema-per-module with restricted grants
Dependency cycle	Two modules call each other	Cycle detection in CI	Extract shared concept or invert via event	Acyclic dependency rule
Wrong boundaries	Modules chosen by technical layer	Features always touch many modules	Re-partition by domain (§34.4)	Domain analysis before coding

33.6 Service-oriented architecture

33.6.1 Services, the enterprise service bus and the reuse goal

DEFINITION

Definition — Service-oriented architecture (SOA). An enterprise integration style, prominent from roughly 2000 to 2010, in which business capabilities are exposed as coarse-grained, reusable **services** with formal contracts, typically SOAP web services described in WSDL, connected through an **enterprise service bus (ESB)** that routes, transforms and orchestrates messages between them.

First-principles explanation

Picture a large company whose departments each bought their own software: an ERP for inventory, a CRM for customers, a mainframe for billing. SOA is the attempt to make these systems talk through a common switchboard. Each system wraps its capability in a service (“get customer”, “reserve stock”), and the switchboard (the ESB) knows who to call, how to translate one system’s message format into another’s, and in what sequence to call several services to complete a business process.

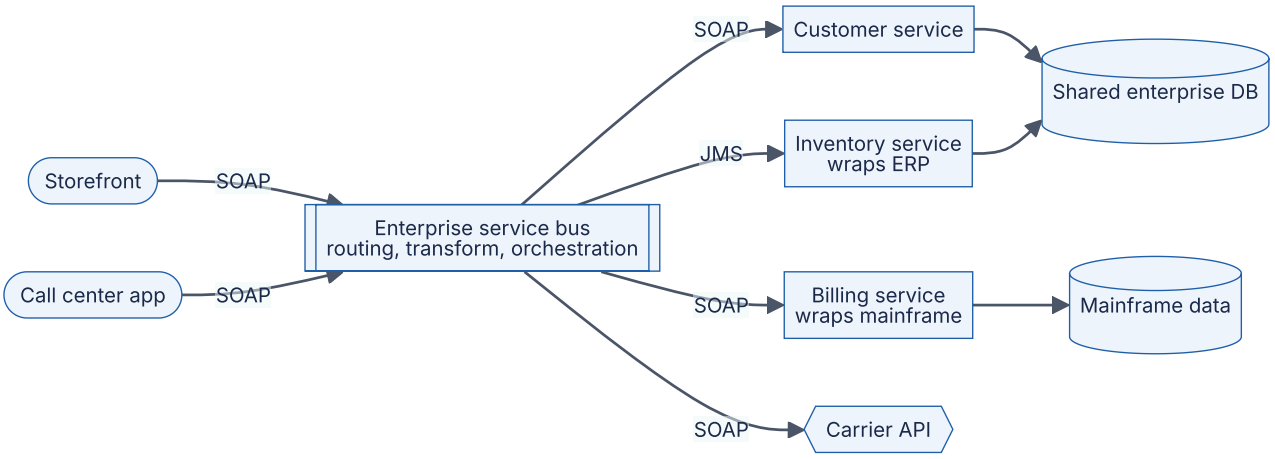
Why does this exist?

SOA answered an integration problem, not a scaling problem. Enterprises had dozens of incompatible applications and point-to-point integrations growing as $n(n-1)/2$; with 30 systems that is up to 435 links. A bus reduces each system to one connection. The second goal was **reuse**: build “customer service” once and have every application call it.

How it works internally

1. Each provider publishes a contract (WSDL) and, in the original vision, registers it in a directory (UDDI).
2. Consumers send SOAP messages to the ESB, not to providers.
3. The ESB performs **protocol mediation** (HTTP to message queue to mainframe), **transformation** (into a **canonical data model** shared by the enterprise), **routing** and often **orchestration** of multistep processes, sometimes expressed in BPEL.
4. Cross-cutting policies (security, reliable messaging, transactions) are standardized by the WS-* specifications.

Figure 33.5 — Folio integrated in the SOA style through an ESB.



Reading the diagram. Two consumer applications send SOAP messages to the ESB, drawn as a message channel because it is middleware. The bus translates each request into the canonical model and calls providers with whatever protocol they speak: SOAP for the customer service, a JMS queue for the ERP wrapper, SOAP for billing and the carrier. Calls are mostly synchronous request–response, though JMS legs may be asynchronous. Two services share an enterprise database, a common SOA pattern that couples them at the storage boundary. The ESB is the obvious failure point and bottleneck: every interaction passes through it, and every change to routing or transformation is made by the team that owns it. Scaling means scaling the bus product, usually vertically.

33.6.2 SOA versus microservices

Microservices share SOA's core idea of independently useful services with contracts, and Lewis and Fowler describe them partly by contrast: **"smart endpoints and dumb pipes"** instead of a smart bus, decentralized data instead of shared databases, and decentralized governance instead of an enterprise architecture board [Lewis and Fowler 2014]. Table 33.4 summarizes the contrast.

Table 33.4 — SOA (ESB era) compared with microservices.

Dimension	SOA (ESB era)	Microservices
Primary goal	Integrate existing enterprise applications; reuse	Independent change and deployment of one product's parts
Scope	Enterprise-wide	One application or product line
Communication	Smart pipe (ESB) with routing and transformation	Dumb pipes (HTTP, gRPC, a log or broker); logic in endpoints
Data	Often shared enterprise databases; canonical model	Database per service; each service owns its model
Contracts	SOAP, WSDL, WS-* standards	REST/JSON, gRPC/protobuf, event schemas
Governance	Central architecture board and ESB team	Team-owned services within platform guardrails
Granularity	Coarse (a whole ERP capability)	Smaller (one bounded context, Ch 34)
Typical failure	ESB becomes bottleneck and change queue	Distributed monolith; operational sprawl (§34.14)

WARNING / TRADE-OFF

The ESB recreates Conway's problem. When all routing and transformation logic lives in the bus, every cross-team change queues behind the bus team. The architecture's coupling point becomes an organizational bottleneck. Microservices moved that logic back into the services, at the price of each team handling more operations itself.

33.7 Microservices (overview)

33.7.1 Independently deployable services

DEFINITION

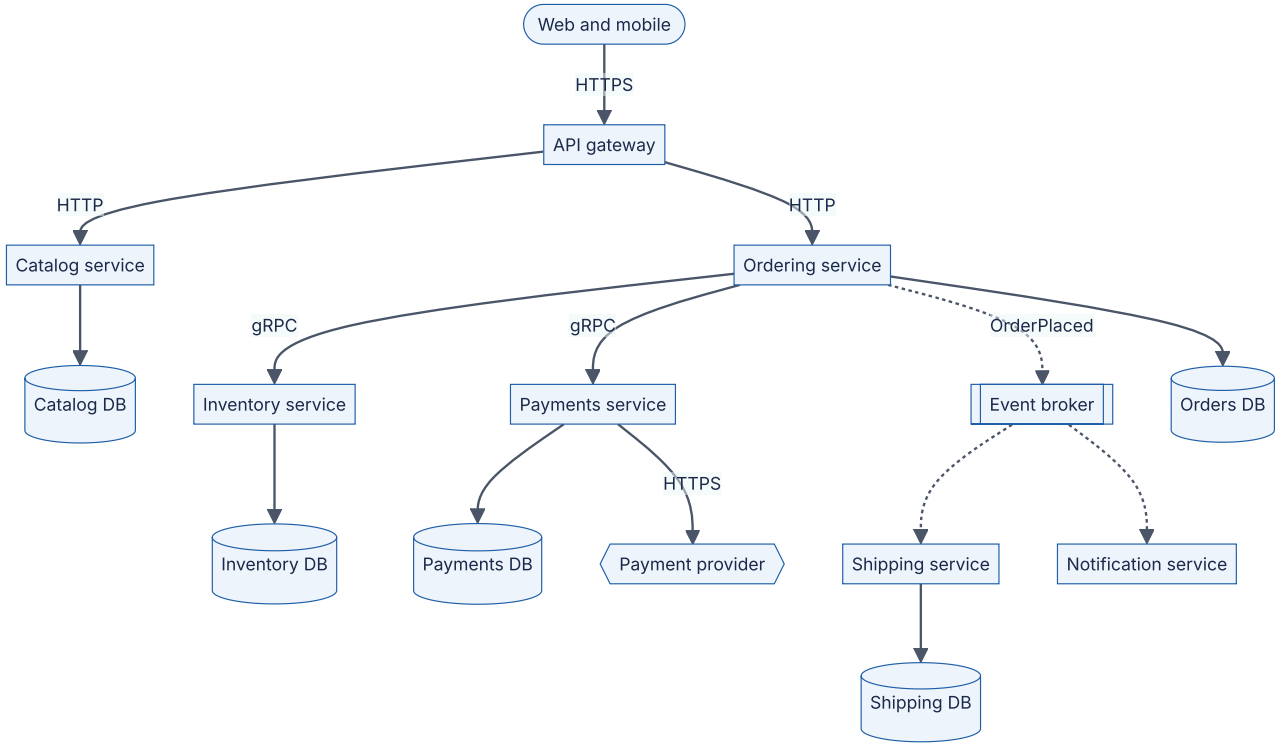
Definition — Microservices. An architectural style that builds one application as a suite of small services, each running in its own process, owning its own data, communicating over lightweight network mechanisms, built around a business capability, and **independently deployable** by the team that owns it [Lewis and Fowler 2014].

First-principles explanation and why it exists

Return to the building analogy: microservices give each department its own building with its own mailroom and its own front door. Departments renovate whenever they like, but every interaction becomes a letter rather than a walk down the corridor. The style exists

because, beyond a certain number of teams, the coordination cost of one deployable (§33.4.2) exceeds the cost of distribution. Removing deployment coupling, scaling hot services independently, isolating failures to one process and allowing different technologies per service are the benefits.

Figure 33.6 — Folio as microservices.



Reading the diagram. Clients call an API gateway over HTTPS (§34.6), which routes to catalog and ordering. Ordering calls inventory and payments synchronously over gRPC, so a checkout depends on all three being up; it also publishes an `OrderPlaced` event asynchronously to a broker, from which shipping and notifications consume at their own pace. Each service has its own database, so there are five storage boundaries and no shared tables; consistency between them is eventual or coordinated by a saga (§32.7). Failure points multiply: any network hop can time out, and the broker is shared infrastructure. Each service scales independently, so the catalog can run 40 replicas while payments runs 3.

The price in numbers

Distribution has a measurable cost. If checkout makes three sequential synchronous calls and each callee is available 99.9% of the time, the chain's availability is at most $0.999^3 \approx 0.997$ (§4.14.2), and each hop adds roughly 0.5–1 ms of network latency plus serialization, against nanoseconds for an in-process call. Data that was joined in SQL must now be fetched from two services or replicated by events. Each service needs a pipeline, dash-

boards, alerts and on-call ownership. Chapter 34 covers how to choose boundaries, communicate, own data and migrate; the comparison and decision framework are in §33.13.

COMMON MISTAKE

"Microservices are about small code size." The defining property is independent deployability by an owning team, not lines of code. A tiny service that must be deployed in lockstep with three others is part of a **distributed monolith** (§34.14): all the costs of distribution and none of the benefits.

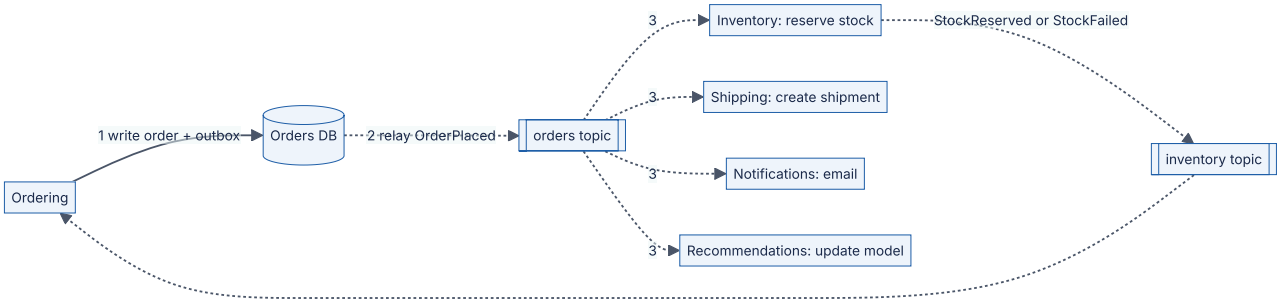
33.8 Event-driven architecture (overview)

DEFINITION

Definition — Event-driven architecture (EDA). A style in which components communicate mainly by producing and consuming **events**, immutable records of facts that happened ("OrderPlaced"), through a broker or log, so that producers do not know which consumers exist or when they will run.

Think of a newspaper: the publisher prints the news once and has no idea who reads it or when. Contrast a phone call, where the caller waits for the callee to answer. EDA exists to decouple components in **time** (the consumer may be down when the event is published) and in **knowledge** (adding a consumer does not change the producer). Richards and Ford distinguish two topologies [Richards and Ford 2020]: in the **broker topology**, components react to each other's events with no central coordinator (choreography); in the **mediator topology**, an orchestrator receives an initiating event and directs the steps (orchestration). Chapter 32 compares the two in depth (§32.8).

Figure 33.7 — Folio's order flow, event-driven with a broker topology.



Reading the diagram. Ordering writes the order and an outbox row in one local transaction (§32.5), then a relay publishes `OrderPlaced` to the orders topic; everything after step 1 is asynchronous (dotted arrows). Four consumers each react independently; recommendations was added last without changing ordering. Inventory reports success or

failure on its own topic, which ordering consumes to confirm or cancel the order, a choreographed saga (§32.7). Storage boundaries are each component's own store plus the broker's durable log (Chapter 31). Failure points: a slow consumer builds lag but does not slow ordering; a poison message needs a dead-letter queue (§30.11); duplicates require idempotent consumers (§32.10). The topic scales by partitions, consumers by consumer-group size.

EDA's advantages are loose coupling, natural buffering of load spikes, easy extension and an audit trail of facts. Its costs are eventual consistency (the customer may see "order received" before stock is confirmed), harder debugging because no single stack trace shows the whole flow (distributed tracing, §40.6, becomes necessary), and the need to reason about ordering, duplicates and schema evolution. EDA combines with any deployment style: a modular monolith can use in-process events (§33.5), and microservices commonly use a broker. Chapters 30–32 own the details.

33.9 Serverless architecture

33.9.1 Functions, managed services and scale to zero

DEFINITION

Definition — Serverless. An architecture built from **functions as a service (FaaS)**, short-lived functions that the platform runs in response to events, combined with **managed services** (databases, queues, object storage, authentication) that the provider operates, such that the team provisions no servers, capacity scales automatically including **to zero**, and billing is per request and per unit of execution time rather than per running machine [Jonas et al. 2019].

First-principles explanation

Owning servers is like owning a car: you pay for it whether it is parked or driving. Serverless is a taxi: you pay per trip, someone else maintains the vehicle, and at 2 a.m. when nobody travels you pay nothing. Taxis are cheaper for occasional trips and far more expensive for a daily 100 km commute, and you wait for one to arrive. The same three facts, per-use pricing, no maintenance and a wait, define serverless.

Why does this exist?

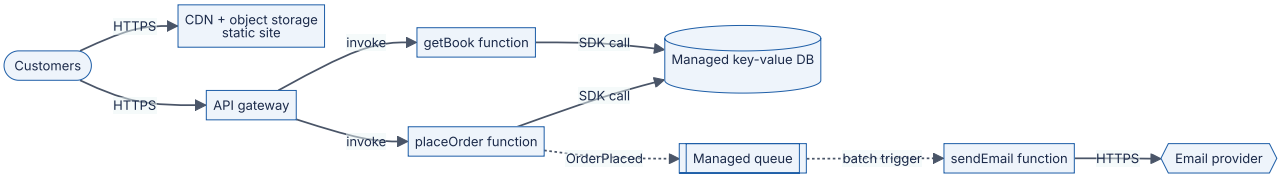
Most services are idle most of the time, yet a server must be sized for peak and kept running. FaaS removes capacity planning, patching and idle cost, and makes event wiring trivial: "run this function when a file lands in this bucket". The Berkeley view of server-

less argued that it does for cloud programming what high-level languages did for assembly, by hiding resource management [Jonas et al. 2019].

How it works internally

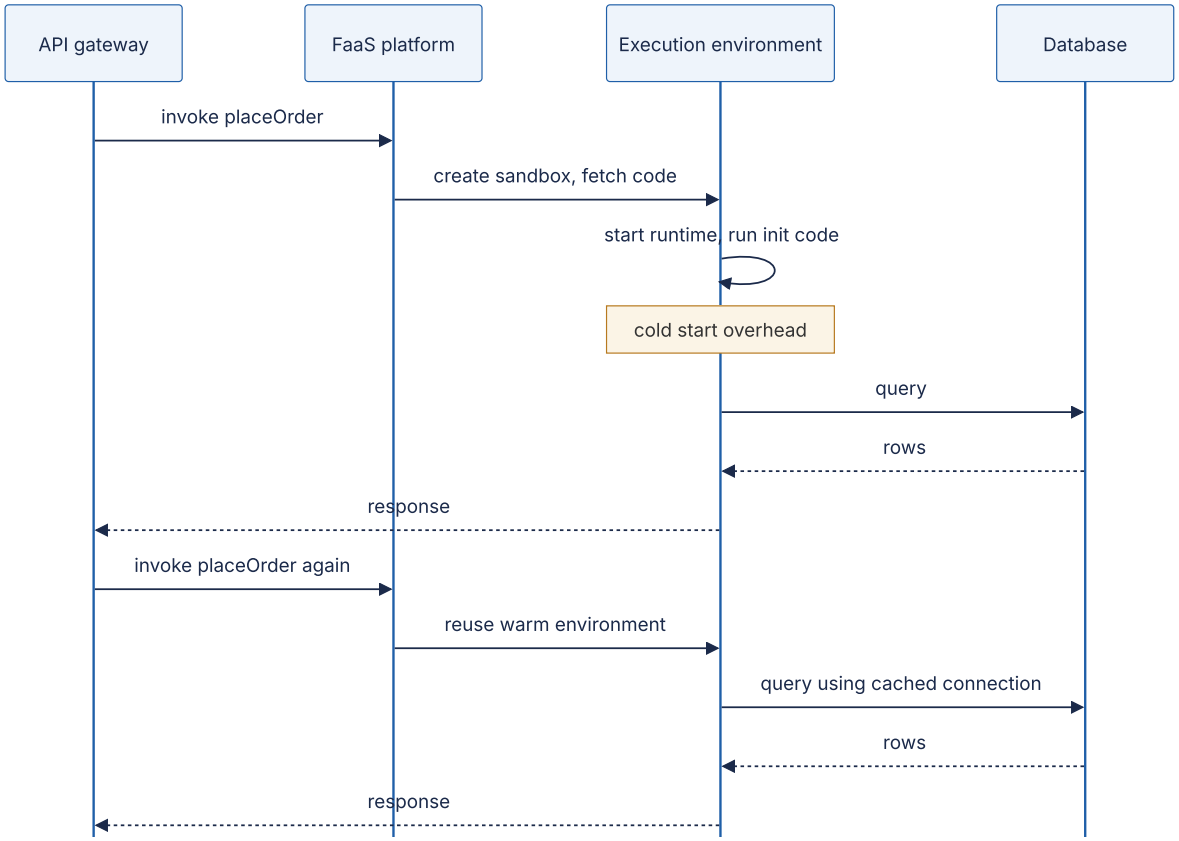
1. An event arrives: an HTTP request through an API gateway, a message on a queue, an object upload.
2. The platform looks for an idle, already initialized **execution environment** (a lightweight sandbox; AWS Lambda uses Firecracker microVMs, Chapter 48) for that function version.
3. If one exists, it runs the handler immediately: a **warm start**.
4. If none exists, the platform performs a **cold start**: allocate a sandbox, download the code package or image, start the language runtime, and run the function's initialization code (imports, SDK clients, database connections). Only then does the handler run.
5. Each environment processes one request at a time on AWS Lambda; concurrent requests need concurrent environments. By Little's Law (§4.11), concurrency = arrival rate × duration, so 200 RPS at 100 ms needs about $200 \times 0.1 = 20$ environments.
6. Environments idle for a while are reclaimed, so traffic that pauses produces cold starts again.

Figure 33.8 — Folio's order path built serverless.



Reading the diagram. Static pages come from a CDN backed by object storage. API calls go through a managed API gateway, which invokes functions synchronously; `placeOrder` and `getBook` call a managed key-value database through the provider's SDK. `placeOrder` also enqueues a message (dotted, asynchronous), and the queue triggers `sendEmail` in batches. Every box except the functions is a managed service; the storage boundaries are the database and the queue. Failure points: cold starts add latency on the synchronous path; account-level concurrency limits can throttle all functions at once; downstream systems that are not elastic (a relational database with a connection limit) can be overwhelmed when functions scale out. Scaling is automatic per request up to those limits.

Figure 33.9 — A cold start compared with a warm start.



Reading the diagram. The first invocation finds no idle environment, so the platform creates a sandbox, fetches code and starts the runtime; the function's initialization code then runs before the handler. All calls shown are synchronous. The second invocation, arriving while the environment is still alive, skips straight to the handler and reuses objects created during initialization, such as database connections. The failure point is the cold path: if initialization is slow or a dependency is unreachable, the first request in each new environment pays for it. Scaling out creates more environments, so a burst produces a burst of cold starts.

33.9.2 Cold starts

Cold-start time depends mostly on package size, runtime and initialization work. As of 2026, small functions in interpreted runtimes commonly cold-start in a few hundred milliseconds, while large JVM functions with heavy frameworks can take seconds; warm invocations add only milliseconds of platform overhead. Mitigations, in order of preference: keep packages small and initialization lazy; choose a fast-starting runtime for latency-sensitive paths; use **provisioned concurrency** (pre-initialized environments, billed while idle); use snapshot-based start (AWS Lambda SnapStart restores a snapshot of an initialized environment); and keep cold starts off the critical path by putting asynchronous work behind queues. "Keep-warm" pings are a weak workaround: they keep one environment warm, not the twenty a burst needs. Chapter 48 covers the internals.

33.9.3 The cost model and the break-even point

Mathematical foundations

FORMULA

Serverless versus always-on monthly cost

$$C_{\text{FaaS}} = R\,(c_{\text{req}} + M D c_{\text{GBs}}), \qquad C_{\text{srv}} = n c_{\text{inst}}, \qquad R^{*} = \frac{C_{\text{srv}}}{c_{\text{req}} + M D c_{\text{GBs}}}$$

Symbol	Meaning	Units
C_{FaaS}	Monthly cost of the functions	$/month
R	Invocations per month	requests/month
c_{req}	Per-request charges (function, plus gateway if used)	$/request
M	Memory allocated to the function	GB
D	Billed duration per invocation	s
c_{GBs}	Price per GB-second of execution	$/GB-s
C_{srv}	Monthly cost of always-on servers	$/month
n	Number of always-on instances (including redundancy)	instances
c_{inst}	Monthly price of one instance	$/instance-month
R^{*}	Break-even invocations per month	requests/month

WORKED EXAMPLE

Worked example — Folio's `getBook` API. Prices (AWS Lambda x86 list prices in us-east-1, as of 2026 [AWS Lambda Pricing]; verify for your region): $c_{\text{GBs}} = \$0.0000166667$, function requests \$0.20 per million so $c_{\text{req}} = \$2 \times 10^{-7}$. The function uses $M = 0.5$ GB and $D = 0.1$ s. The always-on alternative is $n = 2$ small instances (two for availability) at an illustrative \$60/month each, so $C_{\text{srv}} = \$120$. Assume two instances can carry the load in question. Free tiers are ignored.

1. GB-seconds per invocation: $0.5 \times 0.1 = 0.05$ GB-s.
2. Compute cost per invocation: $0.05 \times 0.0000166667 = \$8.33 \times 10^{-7}$.
3. Total per invocation: $8.33 \times 10^{-7} + 2.0 \times 10^{-7} = \$1.033 \times 10^{-6}$.
4. Break-even: $R^* = 120/(1.033 \times 10^{-6}) \approx 116$ million invocations per month.
5. As an average rate over a 30-day month (2.592×10^6 s): $116 \times 10^6 / 2.592 \times 10^6 \approx 45$ RPS.
6. Add an API gateway at an illustrative \$1.00 per million requests: per invocation $\$2.033 \times 10^{-6}$, so $R^* \approx 59$ million per month, about 23 RPS.
7. Check two points. At 10 RPS average (25.9 million/month) with the gateway: $25.9 \times 10^6 \times 2.033 \times 10^{-6} \approx \$53$, cheaper than \$120. At 200 RPS (518 million/month): about \$1,054, nearly nine times the servers' cost.

Interpretation. Below roughly 20–45 RPS of *average* load, serverless is cheaper; above it, always-on capacity wins, and the gap widens linearly. Spiky traffic favors serverless because servers must be sized for the peak while functions bill only the average. **Engineering implication.** Compute R^* with your real duration and memory, and remember the omitted terms on both sides: engineer time to operate servers (favoring serverless) and per-request charges of other managed services, data transfer and logging (often favoring servers at high volume). Re-run the numbers as traffic grows.

Real-world industry applications

INDUSTRY EXAMPLE

Prime Video's audio/video monitoring service. Amazon's Prime Video team described a stream-quality monitoring tool first built as distributed components orchestrated by AWS Step Functions with Lambda functions passing frames through object storage. At high volume, per-transition orchestration charges and storage round trips dominated cost and limited scale. The team moved the components into a single process running on containers, passing data in memory, and reported infrastructure cost falling by about 90% [Kolny 2023]. The lesson is the cost model above: a fine-grained serverless design suited a low-volume start, and a consolidated always-on design suited sustained high volume. *Evidence: Primary* — [Kolny 2023]

Advantages, disadvantages and failure scenarios

Serverless removes server operations, scales automatically, costs nothing when idle and suits event glue, spiky APIs, scheduled jobs and prototypes. Its disadvantages are cold-start latency, execution limits (for example, a 15-minute maximum duration on AWS Lambda, as of 2026), no local state between invocations, provider lock-in through event formats and managed services, harder local testing, and costs that exceed servers at sustained load.

Table 33.5 — Serverless failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
p99 latency spikes after quiet periods	Cold starts	Init-duration metric; p99 vs p50 gap	Provisioned concurrency on hot paths	Small packages; lazy init; async paths
Database connection exhaustion	Hundreds of environments each open connections	DB connection count at limit	Throttle function concurrency	Connection proxy; reserved concurrency
Throttling of unrelated functions	Shared account concurrency limit	Throttle metrics across functions	Raise or partition limits	Reserved concurrency per critical function
Runaway bill	Recursive trigger or retry loop	Cost and invocation anomaly alerts	Disable trigger	Guard against self-triggering; budgets
Duplicate side effects	At-least-once event delivery and retries	Duplicate emails or charges	Compensate	Idempotency keys (§22.15)

33.10 Hexagonal architecture (ports and adapters)

33.10.1 Ports, adapters and a technology-free core

DEFINITION

Definition — Hexagonal architecture (ports and adapters). A style, described by Alistair Cockburn, in which the application's core logic interacts with the outside world only through **ports**, interfaces defined by and in the language of the core, and each external technology (web framework, database, message broker, test harness) connects through an **adapter** that implements or calls a port [Cockburn 2005]. **Driving (primary) ports** are how the outside asks the application to do something; **driven (secondary) ports** are how the application asks the outside for something.

First-principles explanation

A laptop has a USB-C port. The laptop's designers defined what the port expects; they did not design your monitor, charger or keyboard. Each device connects through a cable or dongle that adapts it to the port. You can test the laptop with a cheap test fixture plugged into the same port, and you can switch monitor brands without opening the laptop. In software, the core is the laptop, interfaces such as `OrderRepository` are the ports, and `SqliteOrderRepository` or `InMemoryOrderRepository` are the dongles.

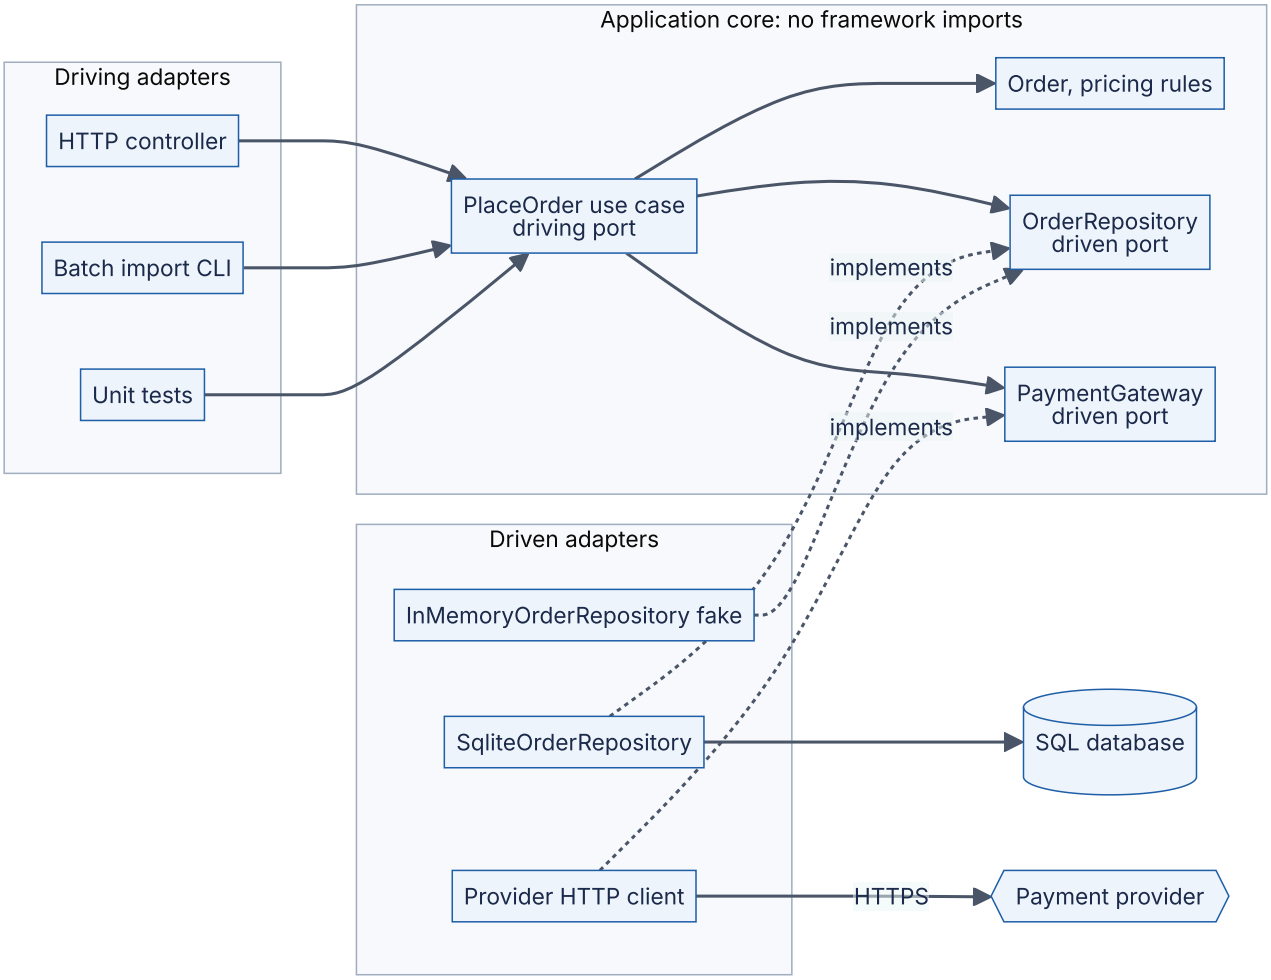
Why does this exist?

Cockburn's motivation was that business logic kept leaking into user-interface code and depending directly on databases, so it could not be tested automatically or driven by anything except the UI. His goal was an application that can be driven equally by users, programs, automated tests or batch scripts, and developed and tested in isolation from its eventual devices and databases [Cockburn 2005]. The hexagon shape has no meaning beyond leaving room to draw several ports; the point is that there is an inside and an outside instead of a top and a bottom. Unlike layering, where business logic depends downward on persistence, here persistence depends inward on an interface the core owns: this is the dependency inversion principle (§36.7) applied to a whole application.

How it works internally

1. The core defines use cases (driving ports) such as `PlaceOrder`, and the interfaces it needs (driven ports) such as `OrderRepository` and `PaymentGateway`. The core imports no framework or database library.
2. Driving adapters (an HTTP controller, a CLI command, a message consumer, a test) translate an external request into a call on a driving port.
3. Driven adapters (a SQL repository, a payment-provider client, a fake) implement driven ports.
4. A **composition root**, usually `main`, constructs the adapters and injects them into the core (dependency injection, §37.14).

Figure 33.10 — Folio's ordering core with ports and adapters.



Reading the diagram. On the left, three driving adapters call the same use case synchronously; the core does not know which one is calling. Inside the core, the use case applies domain rules and calls two driven ports, which are interfaces. On the right, adapters implement those ports; the dotted “implements” edges are source-code dependencies pointing *into* the core, not runtime calls. Only the SQL adapter crosses the storage boundary and only the provider client crosses the network to the payment provider, so those are the failure points; the core itself has none beyond its own logic. Scaling is unaffected: hexagonal architecture is a code structure that can live inside a monolith, a microservice or a function.

Code example

The program below shows the core with one driven port, two adapters (SQLite and an in-memory fake) and one contract test suite that runs against both. It uses only the standard library; run it with `python3`.

```
        """Folio checkout in ports-and-adapters style (single file for teaching)."""
        import sqlite3
        import unittest
        from dataclasses import dataclass
        from typing import Optional, Protocol

        # ---------- Domain core: no imports from frameworks or databases ----------
        @dataclass(frozen=True)
        class Order:
            order_id: str
            isbn: str
            quantity: int
            total_cents: int

        class OutOfStock(Exception):
            pass

        class OrderRepository(Protocol):          # a driven (secondary) port
            def stock_of(self, isbn: str) -> int: ...
            def price_of(self, isbn: str) -> int: ...
            def save(self, order: Order) -> None: ...   # must also decrement stock
            def find(self, order_id: str) -> Optional[Order]: ...

        class PlaceOrder:                          # a use case; its method is the driv-
ing port
            def __init__(self, repo: OrderRepository) -> None:
                self.repo = repo

            def __call__(self, order_id: str, isbn: str, quantity: int) -> Order:
                if quantity <= 0:
                    raise ValueError("quantity must be positive")
                if self.repo.stock_of(isbn) < quantity:
                    raise OutOfStock(isbn)
                order = Order(order_id, isbn, quantity, self.repo.price_of(isbn) * quan-
tity)
                self.repo.save(order)
                return order

        # ---------- Adapter 1: SQLite (production-like) ----------
        class SqliteOrderRepository:
            def __init__(self, conn: sqlite3.Connection) -> None:
                self.conn = conn
                conn.execute("CREATE TABLE IF NOT EXISTS books"
                             "(isbn TEXT PRIMARY KEY, price_cents INT, stock INT)")
                conn.execute("CREATE TABLE IF NOT EXISTS orders"
                             "(id TEXT PRIMARY KEY, isbn TEXT, qty INT, total INT)")

            def add_book(self, isbn: str, price_cents: int, stock: int) -> None:
                self.conn.execute("INSERT INTO books VALUES (?, ?, ?)", (isbn,
price_cents, stock))
```

```
            def stock_of(self, isbn: str) -> int:
                row = self.conn.execute("SELECT stock FROM books WHERE isbn=?",
(isbn,)).fetchone()
                return row[0] if row else 0

            def price_of(self, isbn: str) -> int:
                return self.conn.execute("SELECT price_cents FROM books WHERE isbn=?",
                                         (isbn,)).fetchone()[0]

            def save(self, order: Order) -> None:
                with self.conn:                     # one ACID transaction
                    cur = self.conn.execute(
                        "UPDATE books SET stock = stock - ? WHERE isbn=? AND stock >=
?",
                        (order.quantity, order.isbn, order.quantity))
                    if cur.rowcount != 1:
                        raise OutOfStock(order.isbn)
                    self.conn.execute("INSERT INTO orders VALUES (?, ?, ?, ?)",
                                      (order.order_id, order.isbn, order.quantity,
order.total_cents))

            def find(self, order_id: str) -> Optional[Order]:
                row = self.conn.execute("SELECT id, isbn, qty, total FROM orders WHERE
id=?",
                                        (order_id,)).fetchone()
                return Order(*row) if row else None

        # ---------- Adapter 2: in-memory fake (for tests and local runs) ----------
        class InMemoryOrderRepository:
            def __init__(self) -> None:
                self.books: dict[str, list[int]] = {}   # isbn -> [price_cents, stock]
                self.orders: dict[str, Order] = {}

            def add_book(self, isbn: str, price_cents: int, stock: int) -> None:
                self.books[isbn] = [price_cents, stock]

            def stock_of(self, isbn: str) -> int:
                return self.books.get(isbn, [0, 0])[1]

            def price_of(self, isbn: str) -> int:
                return self.books[isbn][0]

            def save(self, order: Order) -> None:
                if self.books[order.isbn][1] < order.quantity:
                    raise OutOfStock(order.isbn)
                self.books[order.isbn][1] -= order.quantity
                self.orders[order.order_id] = order

            def find(self, order_id: str) -> Optional[Order]:
                return self.orders.get(order_id)

        # ---------- Tests: the same contract runs against both adapters ----------
        class PlaceOrderContract:
            def make_repo(self):
                raise NotImplementedError
```

```
        def setUp(self):
            self.repo = self.make_repo()
            self.repo.add_book("978-0", price_cents=2500, stock=3)
            self.place = PlaceOrder(self.repo)

        def test_places_order_and_decrements_stock(self):
            order = self.place("o-1", "978-0", 2)
            self.assertEqual(order.total_cents, 5000)
            self.assertEqual(self.repo.stock_of("978-0"), 1)
            self.assertEqual(self.repo.find("o-1"), order)

        def test_rejects_when_out_of_stock(self):
            with self.assertRaises(OutOfStock):
                self.place("o-2", "978-0", 4)
            self.assertIsNone(self.repo.find("o-2"))

    class TestWithFake(PlaceOrderContract, unittest.TestCase):
        def make_repo(self):
            return InMemoryOrderRepository()

    class TestWithSqlite(PlaceOrderContract, unittest.TestCase):
        def make_repo(self):
            return SqliteOrderRepository(sqlite3.connect(":memory:"))

    if __name__ == "__main__":
        unittest.main(verbosity=2)
```

Running it prints four passing tests: two against the fake, two against SQLite.

What to notice:

- `PlaceOrder` imports nothing from `sqlite3`; it depends only on the `OrderRepository` protocol. The port is defined by what the core needs, in the core's vocabulary (`stock_of`, `save`), not by what SQL offers.
- The two adapters differ completely inside, yet both satisfy the same port. The SQLite adapter uses a conditional `UPDATE ... WHERE stock >= ?` inside a transaction, so a concurrent order cannot oversell; the fake checks in memory.
- The **contract test** (`PlaceOrderContract`) is written once and run against each adapter. This is what makes a fake trustworthy: if the fake ever behaves differently from the real adapter, the SQLite run of the same test catches it.
- Tests of the use case through the fake need no database and run in milliseconds, so business rules can be tested exhaustively; the slower SQLite run is reserved for the adapter contract.

Advantages, disadvantages and misconceptions

Hexagonal architecture makes the core testable, keeps technology decisions reversible, and lets new delivery mechanisms (a queue consumer next to an HTTP API) reuse the same use cases. Its costs are indirection and mapping code; for a thin CRUD service whose "logic" is the SQL itself, ports add ceremony without benefit, the sinkhole of §33.3.2 in another form.

COMMON MISTAKE

"Every class needs an interface." Ports are needed at the boundary to things that are slow, nondeterministic, external or likely to change: databases, networks, clocks, randomness. Domain classes inside the core call each other directly. Wrapping everything in interfaces adds cost and hides the real boundaries.

33.11 Clean architecture

33.11.1 The dependency rule

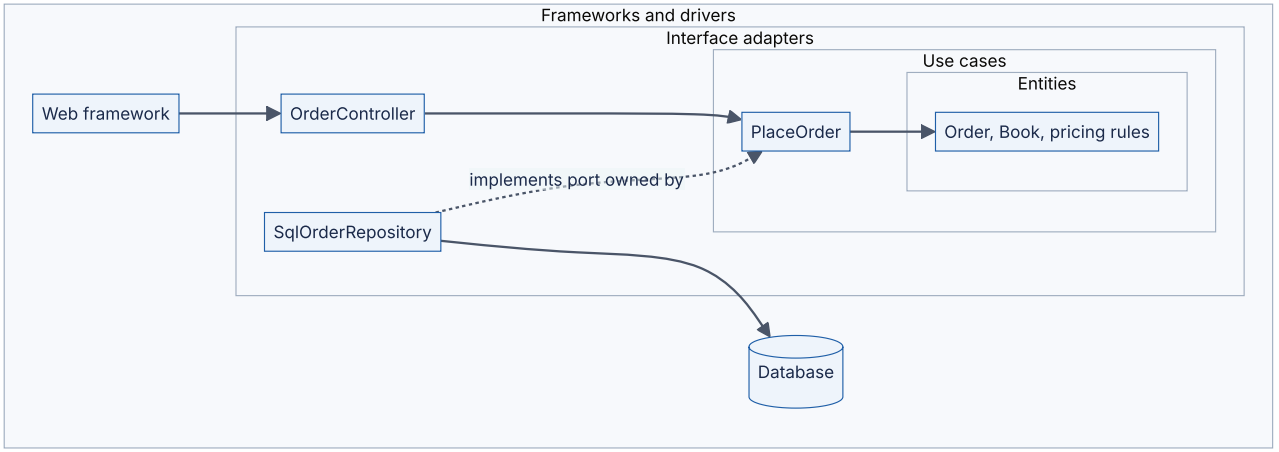
DEFINITION

Definition — Clean architecture. Robert C. Martin's synthesis of hexagonal, onion and similar architectures, drawn as concentric circles: **entities** (enterprise business rules) at the center, then **use cases** (application business rules), then **interface adapters** (controllers, presenters, gateways), then **frameworks and drivers** (web, database, devices) at the edge, governed by one **dependency rule**: source-code dependencies point only inward [Martin 2017].

First-principles explanation and why it exists

Imagine the policies of a bank written down in a rulebook. The rulebook does not mention which brand of teller software the branches use; the teller software is written to follow the rulebook. If the software changes, the rulebook does not. Martin's argument is that the most stable, most valuable code (business rules) should not depend on the most volatile code (frameworks, UI, database drivers), so the details plug into the policy, never the reverse. When data must flow outward, for example a use case presenting results, the inner circle defines an interface (an output port) that the outer circle implements: control flows outward while the source-code dependency still points inward.

Figure 33.11 — Clean architecture's circles for Folio, with the dependency rule.



Reading the diagram. Nested boxes are the circles: entities innermost, then use cases, interface adapters and frameworks. Every solid arrow is a synchronous call that also points inward as a source dependency: the web framework calls the controller, the controller calls the use case, and the use case uses entities. The repository is the interesting edge: at run time the use case calls it, but in source code the repository implements a port owned by the use-case circle (dotted arrow), so the dependency still points inward. The database is the only storage boundary and sits at the outermost circle with other details. Failure points and scaling are those of whatever deployment hosts the code.

33.11.2 Onion, hexagonal and clean compared

Jeffrey Palermo's **onion architecture** (2008) makes the same move with different labels: the domain model at the center, then domain services, then application services, with UI, infrastructure and tests in the outer ring, and all coupling toward the center [Palermo 2008]. Table 33.6 relates the three.

Table 33.6 — Hexagonal, onion and clean architecture.

Aspect	Hexagonal (2005)	Onion (2008)	Clean (2012 blog, 2017 book)
Central metaphor	Inside versus outside, ports	Concentric rings	Concentric circles
Prescribes inner structure	No; "the application"	Domain model, domain services, application services	Entities, use cases
Key rule	Core talks to outside only via ports	Coupling toward the center	Dependencies point inward only
Emphasis	Symmetry of driving and driven sides; testability	Domain model at center; infrastructure outermost	Policy versus detail; use cases as first-class

All three are applications of dependency inversion around a technology-free core; they differ in vocabulary and in how much inner layering they prescribe. In practice, the deci-

sions that matter are the same: which interfaces the core owns, and where the composition root lives.

WARNING / TRADE-OFF

Ceremony is a real cost. Clean architecture applied literally to a small CRUD service produces request models, response models, presenters and mappers for data that passes through unchanged. Use the full structure where business rules are rich and long-lived; use a thin hexagonal boundary, or plain layering, where they are not.

33.12 Cell-based architecture

33.12.1 Cells, the cell router and blast radius

DEFINITION

Definition — Cell-based architecture. A style in which a workload is deployed as multiple independent, complete copies called **cells**, each with its own compute and data and each serving a fixed subset of customers (or other partition key), placed behind a thin **cell router** that sends each request to its customer's cell. Cells share nothing at run time, so a failure, bad deployment or poison request affects only one cell. The fraction of customers affected by a failure is its **blast radius** [AWS 2023].

First-principles explanation

A ship is divided into watertight compartments so that a hole floods one compartment rather than sinking the vessel. Bulkheads (§22.14) apply that idea to thread pools inside one service. Cells apply it to the entire stack: load balancer, services, caches, queues and databases are all duplicated per compartment. Every architecture so far, even microservices, has shared components whose failure affects every customer: the one orders database, the one broker. Cells remove that sharing.

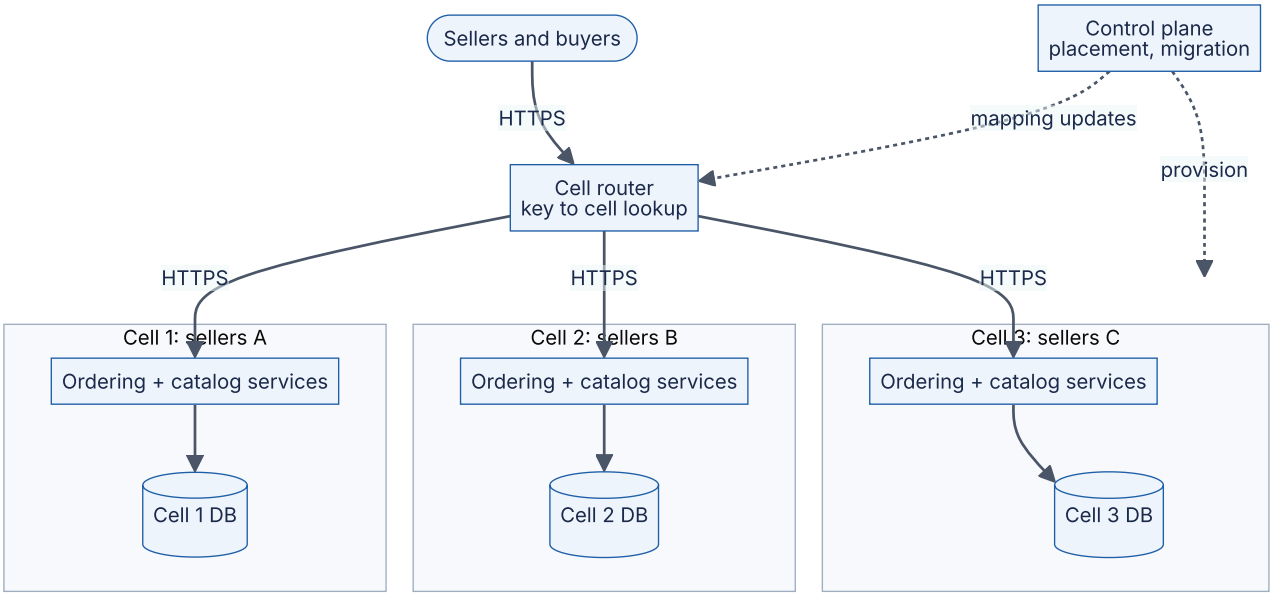
Why does this exist?

At large scale the dominant causes of outages are not hardware failures, which redundancy handles, but correlated failures: a bad configuration push, a software bug triggered by one customer's unusual request, a capacity overload. Redundant replicas of the same code share the same bug, and a load balancer will happily send a crashing "poison pill" request to every replica in turn until all are down. Cells limit such events to one partition of customers, and they bound the size of each copy, so a cell's maximum load can be tested in advance instead of being discovered in production [AWS 2023].

How it works internally

1. **Choose a partition key**: usually the customer or tenant ID; for Folio's marketplace, the seller account.
2. **Size cells** to a fixed maximum (customers, requests per second, data volume) that you have load-tested. Grow by adding cells, not by growing cells.
3. **Route**: the cell router looks up the key in a mapping table (cached aggressively) and forwards the request. The router must be the simplest, most reliable component in the system; it contains no business logic.
4. **Control plane**: a separate service places new customers into cells, provisions new cells and migrates customers between cells. Its failure must not stop the data plane from serving.
5. **Deploy in waves**: release to one cell, watch, then progressively more. The first wave's exposure equals one cell's blast radius.
6. **Handle what cannot be partitioned** (global search, cross-customer analytics) with separate, asynchronously fed systems.

Figure 33.12 — Folio's seller platform as cells behind a cell router.



Reading the diagram. The router receives every request over HTTPS, maps the seller ID to a cell and forwards the request synchronously; it holds no other logic. Each cell is a complete stack with its own services and its own database, so there are as many storage boundaries as cells and no shared data path between them. The control plane updates the router's mapping and provisions cells asynchronously (dotted); if it fails, routing continues from the cached mapping, a property called **static stability** [Weiss and Furr 2020]. Failure points: a fault inside a cell stays inside it; the router is the one shared component and must be kept minimal and redundant. Scaling is by adding cells; a single customer larger than a cell is the main limit.

Mathematical foundations

FORMULA

Blast radius of a cell failure

$$B = \frac{1}{N_c}, \qquad N_c = \lceil \frac{U}{u_{\max}} \rceil$$

Symbol	Meaning	Units
B	Fraction of customers affected when one cell fails (customers evenly spread)	fraction
N_c	Number of cells	cells
U	Total customers	customers
$u_{\max}$	Tested maximum customers per cell	customers/cell

WORKED EXAMPLE

Worked example — Sizing Folio's seller cells. Folio has $U = 1,000,000$ sellers and has load-tested one cell up to $u_{\max} = 50,000$ sellers.

1. $N_c = \lceil 1,000,000/50,000 \rceil = 20$ cells.
2. $B = 1/20 = 5\%$: a poison-pill request or bad deploy that crashes one cell affects 50,000 sellers instead of 1,000,000.
3. Deployment waves of 1, 2, 4, 8 and 5 cells expose 5%, then 10%, 20%, 40% and 25% of sellers at each stage; a defect caught in wave 1 touches 5%.
4. Cost check: if each cell carries a fixed overhead of, say, 3 instances for redundancy and control functions, 20 cells carry 60 instances of overhead against perhaps 2 or 3 for an unpartitioned design.

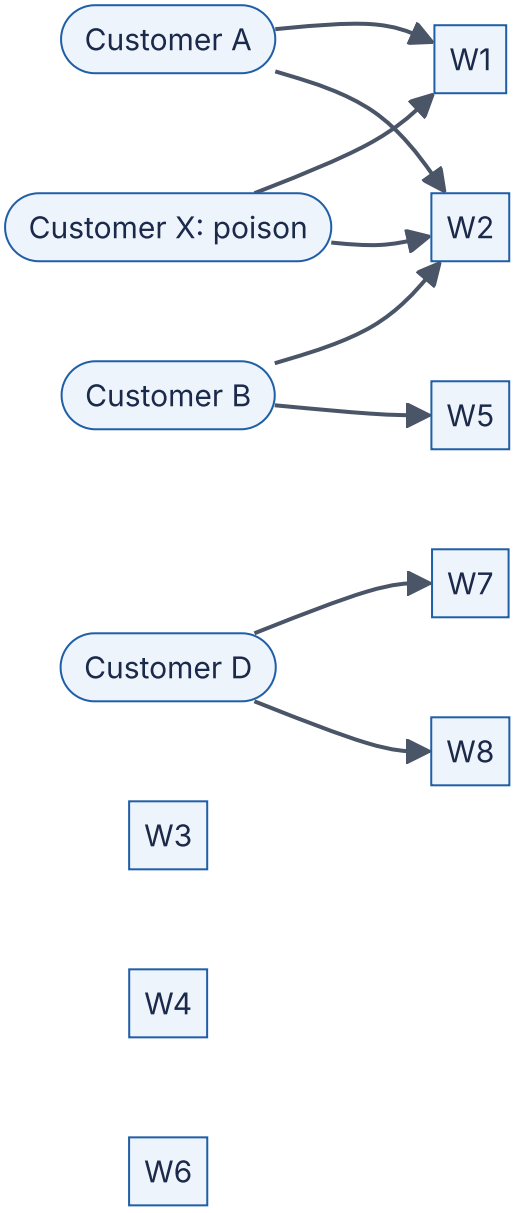
Interpretation. Blast radius falls as $1/N_c$, but per-cell fixed cost rises linearly in N_c. **Engineering implication.** Choose $u_{\max}$ from load tests and business tolerance for a partial outage, not as small as possible; make each cell large enough that its fixed overhead is a small fraction of its useful capacity.

33.12.2 Shuffle sharding

Cells give each customer exactly one compartment. **Shuffle sharding** does better for stateless fleets: assign each customer a random *combination* of k workers out of N, so that two customers rarely share the same full set [MacCárthaigh 2019]. If one customer's requests crash workers, only that customer's k workers are hit, and another customer is

fully cut off only if its entire combination is contained in the failed set; any customer with at least one healthy worker continues, provided clients retry on another worker in their shard.

Figure 33.13 — Shuffle sharding: eight workers, two per customer.



Reading the diagram. Eight stateless workers serve all customers; each customer's requests may go only to its two assigned workers, chosen at random when the customer is onboarded and resolved by the router. Calls are synchronous. Customer X sends requests that crash workers, taking out W1 and W2. Customer A, whose shard is exactly {W1, W2}, loses service. Customer B shares only W2, so its retries succeed on W5. Customer D shares nothing and is unaffected. There is no storage boundary here (workers are stateless); the failure point is the overlap between shards, and capacity scales by adding workers, which also increases the number of possible combinations.

FORMULA

Shuffle-sharding overlap

$$S = \binom{N}{k}, \qquad P(\text{overlap} = j) = \frac{\binom{k}{j}\binom{N-k}{k-j}}{\binom{N}{k}}, \qquad P(\text{full overlap}) = \frac{1}{\binom{N}{k}}$$

Symbol	Meaning	Units
N	Workers in the fleet	workers
k	Shard size: workers assigned to each customer	workers
S	Number of distinct shards (combinations)	count
j	Workers that another customer shares with the failed shard	workers
$P(\text{overlap} = j)$	Probability a random other customer shares exactly j workers	probability

WORKED EXAMPLE

Worked example — Isolation from a poison customer.

Small fleet, $N = 8$, $k = 2$.

1. $S = \binom{8}{2} = 28$ combinations.
2. Full overlap (all of another customer's workers fail): $1/28 \approx 3.6\%$ of customers. Compare a design without sharding, where all workers serve everyone and the poison request eventually crashes all eight: 100%.
3. No overlap: $\binom{6}{2}/28 = 15/28 \approx 53.6\%$ unaffected; the remaining $12/28 \approx 42.9\%$ share one worker and survive by retrying on their other worker.

Larger fleet, $N = 100$, $k = 5$, *10,000 customers.*

1. $S = \binom{100}{5} = 75,287,520$.
2. Full overlap: $1/S \approx 1.3 \times 10^{-8}$; expected fully affected customers among the other 9,999: $9,999 \times 1.3 \times 10^{-8} \approx 0.0001$.
3. Overlap of 3 or more workers (at most 2 of 5 left): $P(3) + P(4) + P(5) = 5.93 \times 10^{-4} + 6.3 \times 10^{-6} + 1.3 \times 10^{-8} \approx 6.0 \times 10^{-4}$, about 6 customers, who keep service at reduced capacity.
4. $P(0) = \binom{95}{5}/\binom{100}{5} \approx 77.0\%$ share no worker at all.

Interpretation. With the same 100 workers, 20 cells of 5 would put each customer in one of 20 compartments, so a poison customer fully affects 5% of the others; shuffle sharding makes full overlap a one-in-75-million event. **Engineering implication.** Shuffle sharding needs clients or routers that retry across the shard and workers that are interchangeable; for stateful partitions holding a customer's data, use cells, and combine the two by shuffle sharding within or across cells.

Real-world industry applications

INDUSTRY EXAMPLE

AWS cells and shuffle sharding. AWS's Well-Architected guidance describes cell-based architecture, including cell routers, cell sizing, placement and migration, as a way to reduce the scope of impact of failures [AWS 2023], and its Builders' Library describes shuffle sharding with the eight-worker, two-per-customer illustration used above [MacCárthaigh 2019]. Route 53 is described as using shuffle sharding to assign name servers to hosted zones. *Evidence: Primary* — [AWS 2023], [MacCárthaigh 2019]

Table 33.7 — Cell-based architecture failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Router outage takes down all cells	Router is the one shared component	Global error rate, all cells healthy	Fail over router; serve from cached map	Minimal router logic; static stability
Hot customer outgrows its cell	Uneven customer sizes	Cell nearing tested limits	Migrate customer to a larger or dedicated cell	Placement by size; per-customer quotas
Same bug in every cell	Simultaneous global deploy	Errors rise in all cells together	Roll back	Wave deployments, one cell first
Cross-cell dependency appears	Shared service added “temporarily”	Dependency map shows shared component	Duplicate it per cell	Review rule: cells share nothing in the data plane

Chapter 44 extends cells across regions, and Chapter 47 treats tenant placement and isolation levels.

33.13 Monolith versus microservices

33.13.1 Side-by-side comparison

Table 33.8 compares the three deployment styles that most teams actually choose between. Serverless and cells are orthogonal: a modular monolith can run in cells, and microservices can be built from functions.

Table 33.8 — Monolith, modular monolith and microservices.

Row	Monolith	Modular monolith	Microservices
What it is	One deployable, unstructured or layered inside	One deployable, domain modules with enforced boundaries	Many independently deployable services
How it works	In-process calls, one shared database	In-process calls through module APIs; schema per module	Network calls and events; database per service
Advantages	Simplest to build, debug and deploy; ACID everywhere	Monolith's simplicity plus clear ownership and cheap extraction	Independent deploys, scaling, failure isolation, technology choice
Disadvantages	Coupling grows with team count; erosion	Deployment and scaling still coupled	Network failures, distributed data, sagas, operational load
Performance	Nanosecond calls; joins in SQL	Same as monolith	~0.5–1 ms per hop; fan-out tail latency (§4.8.4)
Operational complexity	Low: one pipeline, one service	Low, plus boundary tooling	High: per-service pipelines, tracing, discovery, on-call
Cost	Lowest at small scale	Low	Higher baseline (platform, per-service overhead)
Use cases	Early products; small teams; stable small domains	Most products up to several teams	Many teams; heterogeneous scaling or isolation needs
Choose when	One team; domain still moving	2–8 teams sharing one release; boundaries known	Release coordination is the bottleneck and a platform exists

33.13.2 Conway's law and the cost of coordination

Conway observed that organizations which design systems are constrained to produce designs that copy their communication structures [Conway 1968]. The practical reading is that architecture and team structure must match: if Ordering and Inventory are separate services owned by one team, they will be changed together and drift into a distributed monolith; if one module is owned by three teams, it will grow three internal sub-architectures. The **inverse Conway maneuver** designs team boundaries first, so that the desired architecture is the one the organization naturally produces [Skelton and Pais 2019].

Mathematical foundations

FORMULA

Communication paths among teams

$$L_{\text{all}} = \frac{T(T-1)}{2}, \qquad L_{\text{declared}} = \frac{T\bar{d}}{2}$$

Symbol	Meaning	Units
L_{all}	Pairwise coordination paths when every team may need every other	paths
T	Number of teams	teams
L_{declared}	Paths when teams coordinate only along declared module or service dependencies	paths
$\bar{d}$	Average number of neighbor teams per team in the dependency graph	teams

WORKED EXAMPLE

Worked example — Folio at 3 and 12 teams.

1. At $T = 3$: $L_{\text{all}} = 3 \times 2/2 = 3$ paths. Everyone can attend one planning meeting; a monolith is fine.
2. At $T = 12$ with one shared code base and release: $L_{\text{all}} = 12 \times 11/2 = 66$ paths.
3. At $T = 12$ with enforced boundaries where each team depends on about $\bar{d} = 2$ others: $L_{\text{declared}} = 12 \times 2/2 = 12$ paths, an 82% reduction.

Interpretation. Coordination grows quadratically with team count unless the architecture limits who must talk to whom. **Engineering implication.** Module boundaries (§33.5) already cut L from 66 to 12 for code changes; independent deployment (§33.7) additionally removes the release-train coupling of §33.4.2. Split deployments when that second effect is what is hurting.

33.13.3 A decision framework

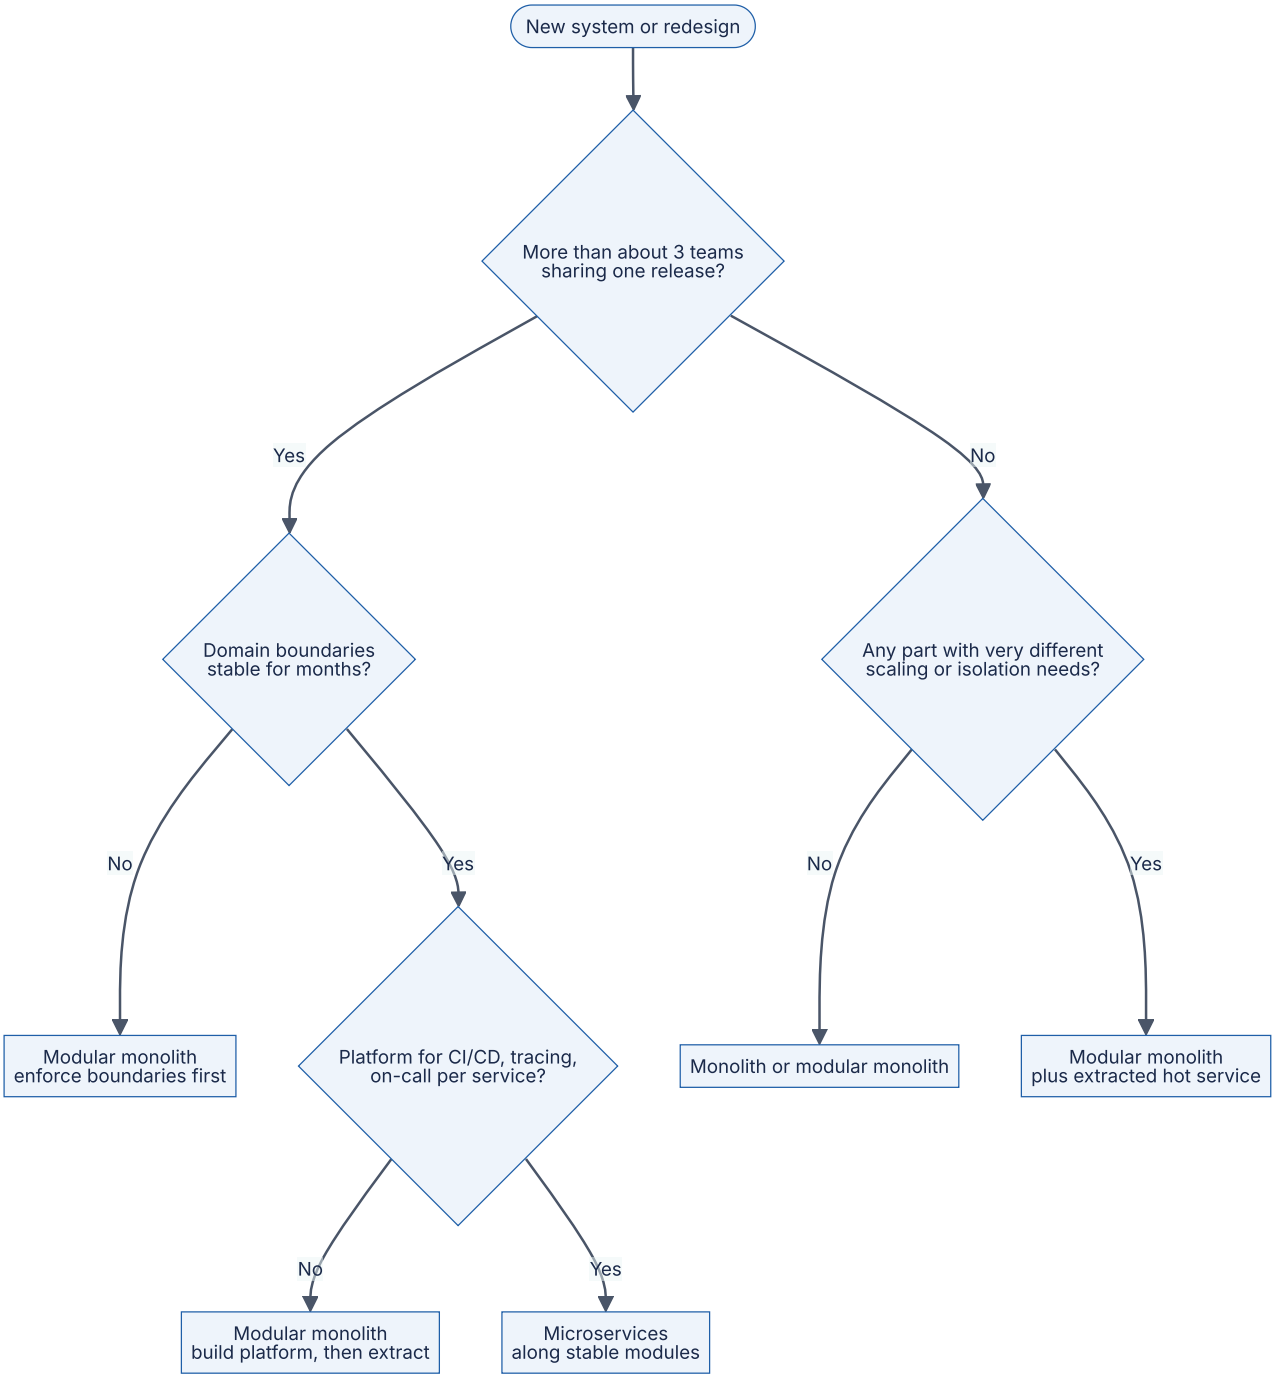
Use four questions, in order. Each has a measurable signal.

1. **Team size and structure.** One or two teams: monolith or modular monolith. More teams than can share one release without regular blocking (from §33.4.2, release failure rates above roughly 20–30%, or queues to merge): consider independent deployment for the teams most blocked.

2. **Deployment frequency.** If teams want to deploy several times a day and the shared pipeline or test suite takes hours, independent deployables help. If the business releases monthly, they do not.
3. **Domain maturity.** If boundaries are still moving (a new product, frequent changes that touch many modules), keep them in-process where moving a boundary is a refactor. Extract only modules whose interfaces have been stable for months [Fowler 2015; Newman 2019].
4. **Heterogeneous runtime needs.** If one part needs very different scaling, technology, security isolation or availability (Folio's search indexing, payment-card handling), extract *that part* first.

Fowler's "MonolithFirst" and Tilkov's counterargument "Don't start with a monolith" (both 2015) disagree mainly on question 3: Tilkov argues that when the domain is well understood, for example a rewrite of an existing system, starting with separate services avoids a costly later split [Fowler 2015; Tilkov 2015].

Figure 33.14 — Choosing a deployment style.



Reading the diagram. Decision diamonds are evaluated top to bottom; each answer leads to the next question or to a recommendation. The first split is organizational: few teams lead to a monolith or modular monolith, with a hybrid when one component has distinct runtime needs (as QuickBite's location service did in §2.8.1). Many teams lead to microservices only when boundaries are stable and a platform exists; otherwise the answer is still a modular monolith, with extraction deferred. There are no runtime components, protocols or storage boundaries here; the failure point the chart guards against is the premature split, and "scaling" means revisiting the chart as teams and traffic grow.

Real-world industry applications

INDUSTRY EXAMPLE

Segment's return to a monolith. Segment described splitting its event-delivery destinations into well over a hundred separate services, one per destination, each with its own queue. Shared-library versions drifted across services, operational load grew with each new destination, and a small team could not keep them all healthy. Segment consolidated the destinations into a single service with a shared test suite and reported large gains in developer productivity [Noonan 2018]. The case illustrates the decision framework: service count far exceeded team count, so the coordination microservices remove was not the problem they had. *Evidence: Primary* — [Noonan 2018]

RECOMMENDATION

Default path for a new product. Start with a modular monolith with enforced boundaries and per-module schemas. Instrument release failure rate, lead time and cross-module change frequency. Extract a module into a service when a measured signal (blocked releases, a scaling or isolation need) justifies the operational cost, and use the strangler fig pattern for the extraction (§34.13).

COMMON MISTAKE

"Microservices are what large companies use, so they are more scalable." Request throughput scales by replication in every style. Microservices scale *organizations*, by letting many teams deploy independently, and permit per-component scaling. A 10-engineer team adopting them pays the costs without the organizational benefit.

33.14 Summary and revision notes

SUMMARY

- **Layered**: horizontal technical layers; layers are logical, tiers physical. Strict layering isolates, relaxed layering opens chosen layers; most requests passing through without logic is the **sinkhole** anti-pattern. Layering is technical partitioning, so one feature touches every layer.
- **Monolith**: one deployable. Real benefits: in-process calls, ACID transactions, easy refactoring, simple operations. Main cost is **deployment coupling**: $P_{\text{clean}} = (1-p)^{Tc}$ falls exponentially with team count.
- **Modular monolith**: domain modules, public `api`, schema per module, acyclic declared dependencies, enforced in CI. Keeps the monolith's simplicity; makes extraction cheap.
- **SOA**: enterprise integration through a smart ESB and canonical model; microservices invert it to smart endpoints, dumb pipes and database per service.
- **Microservices**: independently deployable, team-owned services; pay in network hops, distributed data and operations (Ch 34).
- **Event-driven**: producers emit facts; consumers react asynchronously; broker versus mediator topology; eventual consistency (Ch 30–32).
- **Serverless**: FaaS plus managed services; scale to zero; cold starts; concurrency = rate × duration. Break-even $R^{*} = C_{\text{srv}}/(c_{\text{req}} + MDc_{\text{GBs}})$, about 23–45 RPS in the worked example.
- **Hexagonal**: the core owns ports; adapters implement them; test the core with fakes validated by contract tests. **Clean**: dependencies point inward only; onion, hexagonal and clean are variants of dependency inversion.
- **Cells**: complete independent stacks per customer partition behind a thin router; blast radius $1/N_c$; deploy in waves. **Shuffle sharding**: full-overlap probability $1/\binom{N}{k}$.
- **Choosing**: Conway's law; coordination paths $T(T-1)/2$; default to a modular monolith and extract on measured signals.

33.15 Knowledge checkpoint

1. What is the difference between a layer and a tier?
2. Define the architecture sinkhole anti-pattern and give one remedy.
3. Why does layered architecture make adding a new product type expensive?
4. A release bundles 30 changes, each with a 2% chance of a blocking defect. What is the probability the release is clean?
5. Name the two rules a modular-monolith boundary checker enforces.
6. What does "smart endpoints and dumb pipes" contrast with?

7. A function receives 300 RPS and runs for 200 ms. How many concurrent execution environments does it need?
8. Using the worked-example prices, what is the per-invocation cost of a 1 GB, 250 ms function without a gateway?
9. In hexagonal architecture, what is the difference between a driving and a driven port?
10. Why should a fake adapter be run through the same contract tests as the real adapter?
11. State the dependency rule. How does a use case send data outward without violating it?
12. A service has 2,000,000 customers and a tested cell size of 80,000. How many cells, and what is the blast radius?
13. With $N = 10$ workers and $k = 3$, what fraction of customers share all three workers with a poison customer?
14. How many coordination paths do 8 teams have if every team may need every other?

Answers

1. A layer is a logical grouping of code by responsibility; a tier is a physical deployment boundary where a process runs. Several layers can share one tier.
2. Requests that pass through layers without any processing. Open the layer for those paths, or adopt a style with less ceremony where most operations are simple.
3. Code is partitioned by technical role, so a new domain concept needs changes in the presentation, business and persistence layers and the schema, often owned by different people.
4. $0.98^{30} = e^{30 \ln 0.98} = e^{-0.606} \approx 0.545$.
5. A module may depend only on its declared modules, and only through their public `api`.
6. SOA's enterprise service bus, which contains routing, transformation and orchestration logic in the middleware.
7. $300 \times 0.2 = 60$ environments (Little's Law).
8. $1 \times 0.25 = 0.25$ GB-s; $0.25 \times 0.0000166667 = \$4.17 \times 10^{-6}$; plus $\$2 \times 10^{-7}$ gives about $\$4.37 \times 10^{-6}$.
9. A driving port is how external actors invoke the application (its use cases); a driven port is how the application calls external resources (repositories, gateways). Driving adapters call the core; driven adapters are called by it.
10. To prove the fake behaves like the real adapter; otherwise fast tests may pass against behavior production never exhibits.
11. Source-code dependencies point only inward. The inner circle defines an output interface that an outer-circle presenter or gateway implements, so control flows outward while the dependency points inward.
12. $\lceil 2,000,000/80,000 \rceil = 25$ cells; blast radius $1/25 = 4\%$.
13. $1/\binom{10}{3} = 1/120 \approx 0.83\%$.
14. $8 \times 7/2 = 28$.

33.16 Interview questions

Basic

Q1. When is a monolith the right choice? Answer. When one or two teams own the product, the domain is still being discovered, strong consistency across features matters and there is no platform for running many services. It offers in-process calls, ACID transactions, easy refactoring and simple operations. Structure it as a modular monolith so that extraction stays possible.

Q2. What is hexagonal architecture? Answer. The core defines ports, interfaces in its own vocabulary, for use cases it offers and resources it needs. Adapters connect technologies: HTTP controllers drive the core, SQL repositories and API clients implement driven ports. The core imports no framework, so it can be tested with fakes and its technologies replaced.

Intermediate

Q3. Your 15-team organization ships one monolith weekly and half the releases are delayed. What do you do? Answer. Measure first: change failure rate, batch size, pipeline duration and which modules cause holds. Reduce p with better tests and c with smaller, more frequent deploys and feature flags. Enforce module boundaries and per-module schemas. Then extract the modules whose teams are most blocked and whose interfaces are stable, one at a time with the strangler fig pattern, on a platform providing pipelines, tracing and on-call tooling.

Q4. Should an API with 5 RPS average and 500 RPS spikes be serverless? Answer. Likely yes. At 5 RPS average, serverless costs a fraction of the break-even (about 23–45 RPS in the chapter's example), while servers would be sized for 500 RPS. Check cold-start impact on the latency SLO during spikes, concurrency limits ($500\times$ duration environments), and whether downstream databases can absorb connection bursts; add provisioned concurrency or a connection proxy if not.

Advanced

Q5. Design fault isolation for a multi-tenant API where one tenant's malformed request has crashed the whole fleet. Answer. Explain that redundancy fails because every replica runs the same code and retries spread the poison request. Partition into cells with a thin, statically stable router and tested cell size; blast radius is $1/N_c$. Within cells, shuffle-shard stateless workers so full overlap is $1/\binom{N}{k}$. Add per-tenant quotas, wave deployments, and quarantine of request signatures that crash workers.

Q6. Contrast SOA, microservices and cells. Answer. SOA integrates enterprise applications through a smart ESB and canonical model, centralizing logic and governance. Microservices split one product by business capability into independently deployable services with their own data and dumb pipes, optimizing team autonomy. Cells duplicate an entire stack, monolith or microservices, per customer partition to limit blast radius. They answer integration, organizational and fault-isolation problems respectively and can be combined.

33.17 Practical exercises

1. Extend the boundary checker to detect cycles in `ALLOWED` and to read real files from a directory tree; run it on a project you know.
2. Add a `PaymentGateway` driven port to the hexagonal example with a fake that can be told to decline, and test that a declined payment leaves stock unchanged in both repository adapters.
3. Write a script that computes R^* for memory sizes from 128 MB to 2 GB and durations from 20 ms to 1 s, and plot the break-even RPS.
4. Simulate shuffle sharding: assign 10,000 customers random 5-of-100 shards, fail one shard, and compare the measured overlap distribution with the hypergeometric formula.

33.18 Design challenges

1. **Folio’s growth plan.** Folio has 6 engineers today and expects 60 in three years, in eight countries with data-residency rules. Propose an architecture for year one and the measured triggers for each later step (module extraction, cells per country), with an ADR (§2.12.4) for each.
2. **Serverless or containers for image processing.** Folio generates cover thumbnails: 2 million uploads a month, bursty around publisher catalog drops, 1.5 GB memory and 3 s per image. Compare serverless and always-on costs, latency and failure handling, and recommend a design.

Chapter 34 — Microservices

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

Chapter 33 placed microservices among the architecture styles. This chapter is about doing microservices well, and about recognizing when not to. Most microservice failures come from where the lines are drawn, not from the technology. Split a system along the wrong seams and every feature needs five teams, every release needs a coordinated deploy, and every request crosses a dozen network hops. Split it along the right seams and teams ship independently, failures stay contained, and each part scales on its own.

The chapter has three parts. **Boundaries**: cohesion, change coupling, team ownership and domain-driven design. **Plumbing**: gateways, backends for frontends, discovery, communication, contract testing, tracing and service meshes, each with its latency and cost arithmetic. **Data and change**: database-per-service, independent deployment, monolith migration and anti-patterns. QuickBite, the food-delivery platform of Chapter 2, is the running example.

34.1 Learning objectives

After this chapter you should be able to:

- Choose service boundaries using cohesion, change coupling, team ownership and sizing heuristics.
- Apply entities, value objects, aggregates and domain events, and size an aggregate with a contention estimate.
- Draw a context map and implement an anticorruption layer.
- Place an API gateway and backends for frontends, and compute the latency saved by aggregating calls.
- Compare client-side and server-side discovery and compute a registry’s stale-endpoint window.
- Choose synchronous or asynchronous communication, version APIs and write a consumer-driven contract test.
- Explain trace context propagation and service-mesh data and control planes, including ambient mode, and estimate mesh overhead.
- Apply database-per-service, and query across services with API composition or CQRS views.

- Plan a strangler-fig migration and diagnose anti-patterns, including the A^n availability of call chains.

34.2 Prerequisites

- Monolith, modular monolith and microservices overview — §33.4, §33.5, §33.7.
- Conway's law and the QuickBite decomposition — §1.4, §2.3.
- Fan-out tail latency and series availability — §4.8.4, §4.14.2.
- REST, gRPC and API versioning — §8.6, §8.8, §8.15.
- Client-side load balancing — §19.10.
- Timeouts, retries, circuit breakers and idempotency — §22.11–§22.15.
- Messaging, outbox and sagas — Chapters 30 and 32 (summarized here, not repeated).

34.3 Service boundaries

34.3.1 What a microservice is

> DEFINITION
>
> **Definition — Microservice.** A service built around one business capability, owned by one team, deployable independently, and the sole owner of its data, which others reach only through its API or events. Lewis and Fowler describe the style as "an approach to developing a single application as a suite of small services, each running in its own process and communicating with lightweight mechanisms," built around business capabilities and independently deployable [Lewis and Fowler 2014].

First-principles explanation

A large restaurant kitchen is divided into **stations**: grill, sauce, pastry. Each has its own staff, tools and ingredients, and stations communicate through one fixed protocol, the ticket. The pastry chef can change suppliers without asking the grill. The division is by *outcome* (desserts), not by *activity* (one person chops for everyone), because outcomes change together: a new dessert touches only pastry. A microservice is a station: it owns an outcome, its data and its team, and others reach it only through its API.

Why does this exist?

A monolith shares one codebase, one deployable and one database. Beyond a few dozen engineers this causes **release coupling** (every change waits for the slowest change in the deploy), **scaling coupling** (the hottest component forces the whole application to scale) and **failure coupling** (a reporting job's memory leak takes down checkout).

Microservices trade these for distributed-systems pains. Newman's summary: microservices buy options, chiefly independent deployability, at a substantial cost in complexity [Newman 2021].

34.3.2 Cohesion and coupling at service scale

DEFINITION

Definition — Cohesion and coupling (service level). Cohesion is the degree to which code inside one service changes together for the same reasons. **Coupling** is the degree to which a change in one service forces a change, redeploy or coordinated release in another. Newman's shorthand: "the code that changes together, stays together" [Newman 2021].

Newman orders coupling from mild to damaging: **domain** coupling (A uses B's capability; unavoidable), **temporal** coupling (B must be up now; removed by events, §34.8), **pass-through** coupling (A carries data only because C needs it), **common** coupling (shared data) and **content** coupling (A changes B's database directly, the worst) [Newman 2021].

How it works internally: measuring change coupling

Version-control history records which code changes together: every commit touching two modules is evidence that they change for the same reason. Tornhill popularized mining such change-coupling metrics from Git [Tornhill 2015].

FORMULA

Change coupling between two modules (Jaccard index of co-changes)

$$C(A,B) = \frac{n_{AB}}{n_A + n_B - n_{AB}}$$

Symbol	Meaning	Units
n_A	Number of commits (or pull requests) that touch module A in the window	commits
n_B	Number of commits that touch module B in the window	commits
n_{AB}	Number of commits that touch both A and B	commits
$C(A,B)$	Fraction of all changes to either module that touched both; 0 = independent, 1 = always together	dimensionless

WORKED EXAMPLE

Worked example — Should QuickBite's payment code be its own service? In six months of monolith history, 120 pull requests touched `ordering`, 80 touched `payments` and 60 touched both; 90 touched `catalog`, of which 6 also touched `ordering`.

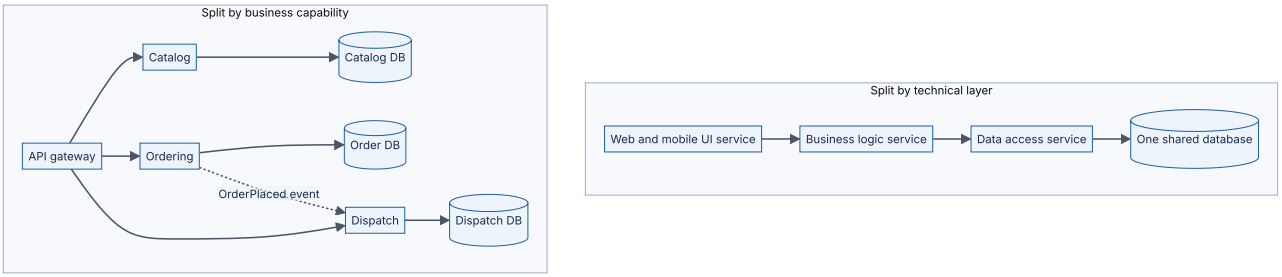
1. Ordering–payments: $C = 60/(120 + 80 - 60) = 60/140 = 0.43$.
2. Ordering–catalog: $C = 6/(120 + 90 - 6) = 6/204 = 0.029$.

Interpretation. As separate services, ordering and payments would need cross-team coordination on 43% of their changes; ordering and catalog on 3%. **Engineering implication.** Extract catalog first. Before splitting payments, inspect the 60 shared pull requests and redesign the interface (for example a `PaymentAuthorized` event) until the co-change disappears; otherwise you build a distributed monolith (§34.14). Treat $C > 0.2$ as a prompt to investigate, not a rule.

34.3.3 Team ownership and Conway's law

Conway observed that systems copy the communication structure of the organizations that build them [Conway 1968] (§1.4; §33.13.2 counts the coordination paths). The **inverse Conway maneuver** shapes teams first so the desired architecture is the natural outcome. Skelton and Pais add that a service should fit within one **stream-aligned team's** cognitive load [Skelton and Pais 2019]. Practical rules: one owning team per service (a team may own several); a change in one business capability should land in one team; and teams with high communication cost (time zones, companies) need stable, documented interfaces between them.

Figure 34.1 — Two ways to split QuickBite: by technical layer and by business capability.



Reading the diagram. The top split follows technical layers: UI, logic and data-access services call each other synchronously over one shared database, so a feature such as "scheduled orders" changes all three services and the schema, every request crosses two extra hops, and each service is a single failure point for every capability. The bottom split follows capabilities: the gateway routes each request to one service (synchronous HTTPS or gRPC), each service owns its database (separate storage boundaries), and ordering in-

forms dispatch asynchronously with an `OrderPlaced` event (dotted), so a dispatch outage does not block ordering. Each capability scales independently: read-heavy catalog adds replicas and caches; dispatch scales with courier activity.

34.3.4 Sizing heuristics

Size follows from boundaries, not lines of code. Each heuristic below is a test you can apply to a proposed boundary.

Table 34.1 — Service sizing heuristics.

Heuristic	The test	Too big when	Too small when
Business capability	Nameable in two or three business words?	Name needs “and”	Name is a verb on another’s noun (“order-validator”)
Team ownership	One stream-aligned team can own it?	Several teams commit weekly	One team owns twenty services
Change coupling	Changes usually stay inside?	Many unrelated reasons to change	Most changes also change a neighbor
Data ownership	Owns its data outright?	Unrelated tables with separate invariants	Needs another service’s data on every request
Transaction boundary	Invariants enforced inside?	—	An invariant spans it and a neighbor, forcing sagas
Independent deployability	Ships on its own schedule?	Blocked by unrelated work inside	Always deploys with a neighbor

The most important row is the **transaction boundary**: if two candidates must change state atomically for a business rule to hold, they belong together, because splitting them turns one local transaction into a saga with compensations (§32.7).

RECOMMENDATION

Recommendation — Start coarse, split on evidence. Begin with a modular monolith (§33.5) or a few coarse services. Split when there is a concrete reason (team boundary, scaling profile, failure isolation, release cadence) and history shows low change coupling. Merging services later costs far more than splitting a well-modularized module.

COMMON MISTAKE

Common misconception — "Micro means small, so smaller is better." *Micro* refers to scope of responsibility. A service that is too small moves its complexity into the network: more calls, failure modes, versioned interfaces and pipelines. Fowler's "Microservice Premium" argues that the style carries a fixed productivity cost that pays off only above a certain system complexity [Fowler 2015].

34.4 Domain-driven design

Domain-driven design (DDD) is the most widely used discipline for finding and modeling business capabilities. Evans wrote it for complicated domains such as shipping and banking, a decade before microservices [Evans 2003]. **Strategic design** divides a domain into models and relates them (§34.5); **tactical design** builds one model well (this section).

DEFINITION

Definition — Domain-driven design (DDD). An approach that places a model of the business domain, built jointly by developers and domain experts, at the center of the design, expresses it directly in code, and divides large domains into explicitly bounded models [Evans 2003; Vernon 2013].

34.4.1 Ubiquitous language

Ask three people at QuickBite what an "order" is. Support means the thing a customer complains about, refund included; restaurant operations means a ticket the kitchen accepts; finance means a settlement line that is final 14 days after delivery. Code serving all three with one `Order` class becomes a 4,000-line class with 60 nullable fields.

DEFINITION

Definition — Ubiquitous language. A rigorous vocabulary built by developers and domain experts for one model and used consistently in conversation, tests and code, so that each term means exactly one thing within that model [Evans 2003].

The language is ubiquitous *within a boundary*. In ordering, `Order.accept()` means the restaurant confirmed it can cook; finance has no `accept`, only `Settlement.finalize()`. When code says `status = 3` and the business says "accepted", translation happens in people's heads and fails silently.

34.4.2 Entities and value objects

DEFINITION

Definition — Entity and value object. An **entity** has a continuous identity that persists as its attributes change: two orders for the same pizza are two orders. A **value object** is defined entirely by its attributes, has no identity and is usually immutable: `Money(24.50, "USD")`, `Address` [Evans 2003].

Prefer value objects. A bare `float` loses its currency and precision; a `Money` value object that refuses negative amounts makes whole classes of bugs impossible to write.

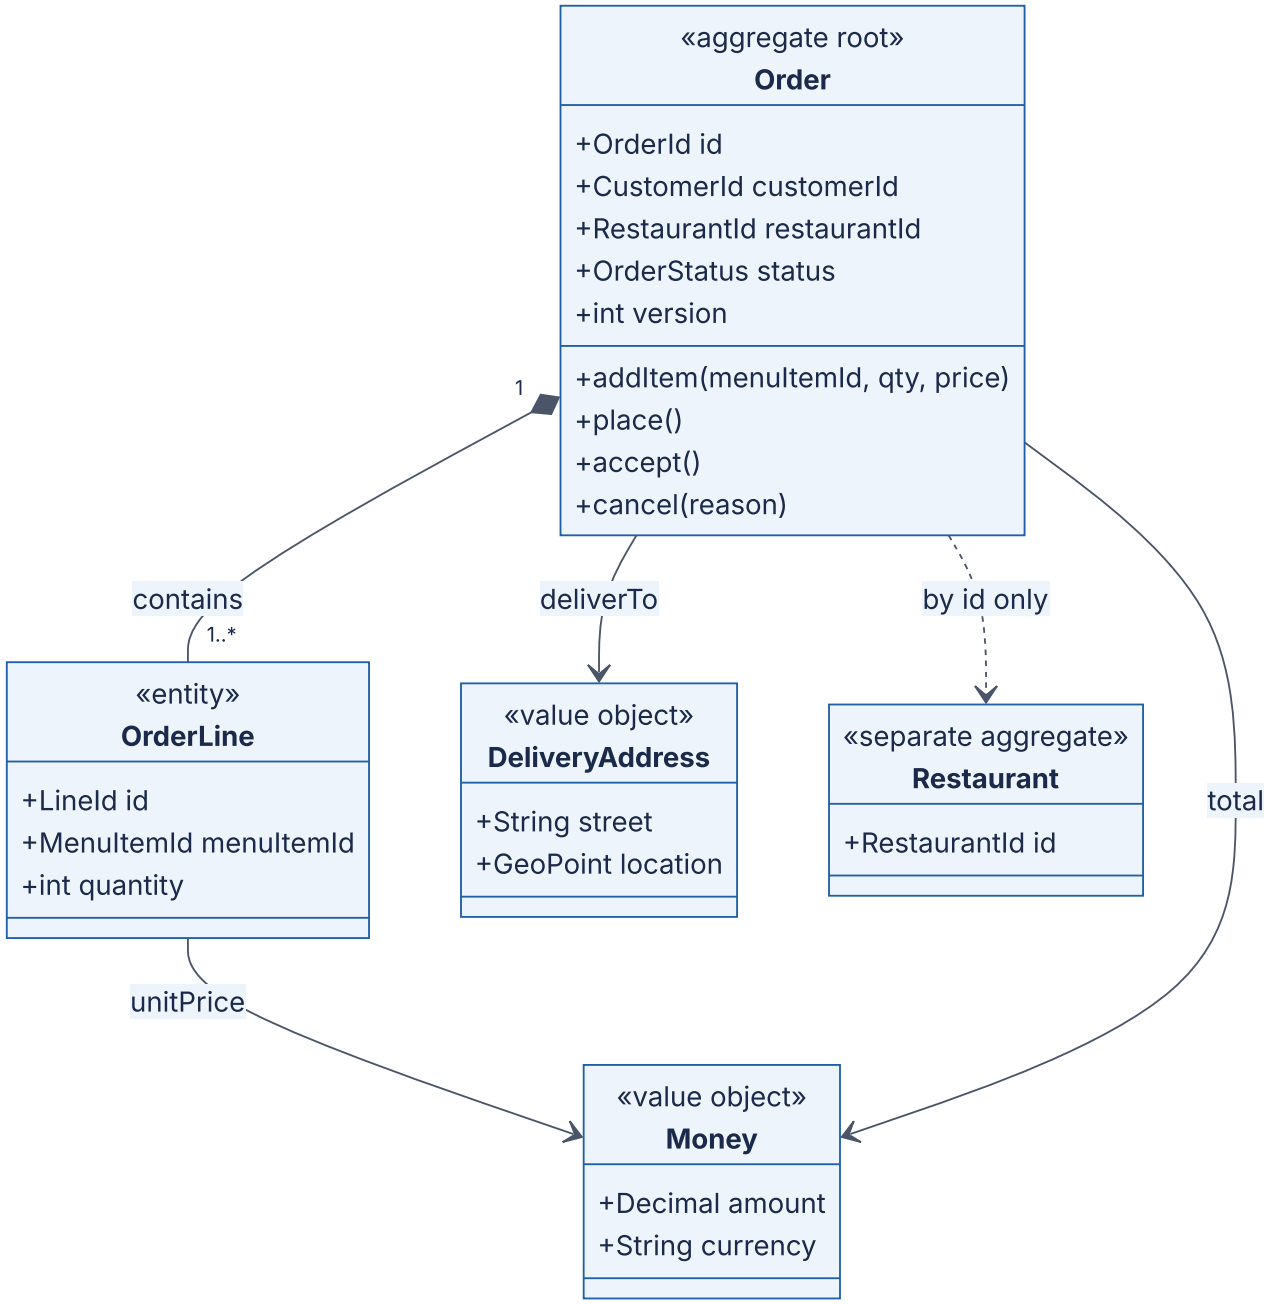
34.4.3 Aggregates and consistency boundaries

DEFINITION

Definition — Aggregate. A cluster of entities and value objects treated as one unit for data changes, with one **root** entity. Outside objects reference only the root, every change goes through it, and it enforces the aggregate's **invariants**. One transaction modifies one aggregate [Evans 2003; Vernon 2013].

In a large object graph any code can change anything, so nobody can say which rules hold, and locking the whole graph does not scale. An aggregate draws a small boundary around exactly the data one invariant needs: consistency is immediate inside (one ACID transaction) and eventual across boundaries (via domain events). Vernon's rules: model true invariants in consistency boundaries; design small aggregates; reference other aggregates by identity; use eventual consistency outside the boundary [Vernon 2013].

Figure 34.2 — The QuickBite `Order` aggregate.



Reading the diagram. The `Order` root is the only entry point; `OrderLine` entities live and die with it (composition). `Money` and `DeliveryAddress` are immutable value objects. `Restaurant` is a separate aggregate referenced only by identifier (dotted), so loading an order never loads a menu, and the two are stored and locked separately. The root enforces invariants such as “total equals the sum of lines”. The `version` field supports optimistic concurrency: a write commits only if the version is unchanged since the read. The aggregate is the unit of storage, locking and partitioning (all its data shares the `OrderId` key).

Mathematical foundations: how big may an aggregate be?

FORMULA

Optimistic-concurrency conflict probability for one aggregate

$$P_{\text{conflict}} = 1 - e^{-\lambda w}$$

Symbol	Meaning	Units
λ	Rate of *other* writes to the same aggregate (Poisson assumption)	writes/s
w	Read-modify-write window of one transaction (read version to commit)	s
P_{conflict}	Probability that at least one other write commits inside the window, so this write must retry	dimensionless

WORKED EXAMPLE

Worked example — A restaurant aggregate versus an order aggregate. A first design made `Restaurant` one aggregate containing all active orders, to enforce "at most 30 open orders" in one transaction. At the Friday peak a busy restaurant receives $\lambda = 2$ writes/s; each command takes $w = 100$ ms from read to commit.

1. Big aggregate: $\lambda w = 0.2$; $P = 1 - e^{-0.2} = 0.181$. About 18% of writes retry, and retries raise λ further.
2. Order as its own aggregate: about 4 updates over a 40-minute life, $\lambda \approx 4/2,400 = 0.00167$ writes/s; $P \approx 0.00017$, one write in 6,000.

Interpretation. Splitting cut conflicts about 1,000-fold. **Engineering implication.** The capacity rule becomes an eventually consistent counter fed by `OrderPlaced` events, or a tiny `KitchenCapacity` aggregate. Ask the business whether 31 open orders for a few seconds is truly unacceptable; the answer decides the boundary.

34.4.4 Domain events

DEFINITION

Definition — Domain event. An immutable record of something domain experts care about that happened, named in the past tense (`OrderPlaced` , `CourierAssigned`), carrying the identifiers and facts its consumers need [Evans 2003; Vernon 2013].

Inside a service, aggregates record events that handlers apply to other aggregates after commit. Across services, the same events go to a broker (Chapter 30), published reliably with the **transactional outbox**: the event row is written in the same local transaction as the aggregate change and relayed afterwards (§32.5). An *event* states a fact; a *command* asks for something and may be refused (§30.6).

COMMON MISTAKE

Common misconception — "DDD means repositories and factories." Most of DDD's value is strategic: finding boundaries and naming things in the business's language. A codebase full of `OrderRepository` classes that still has one "order" model for support, kitchen and finance has adopted the vocabulary without the design (the Repository and Factory patterns themselves are in §37.13 and §37.3). Evans reserves the full investment for the **core domain**, the part that differentiates the business [Evans 2003].

34.5 Bounded contexts and context maps

34.5.1 Bounded contexts

DEFINITION

Definition — Bounded context. An explicit boundary (in code, data and team ownership) within which one domain model and its ubiquitous language apply consistently. The same word may mean different things in different contexts [Evans 2003].

A "ticket" means different things at a railway station, in a police car and in a sprint backlog; nobody is confused because each word lives in a context. QuickBite's order therefore becomes several models keyed by a shared `order_id`: in **Ordering**, lines, a status machine and a total; in **Kitchen**, a `Ticket` with a promised-ready time; in **Delivery**, pickup, drop-off and courier; in **Billing**, a `Charge` and later a `Settlement`. Single enterprise-wide models, the goal of 1990s data modeling, became so general that they served nobody; bounded contexts make the translation between legitimate models explicit.

KEY CONCEPT

Concept — A bounded context is the best first candidate for a service boundary. It already has high cohesion and a deliberately narrow interface. Newman recommends contexts as the starting point: one context may later become several services, but a service should rarely span two contexts [Newman 2021].

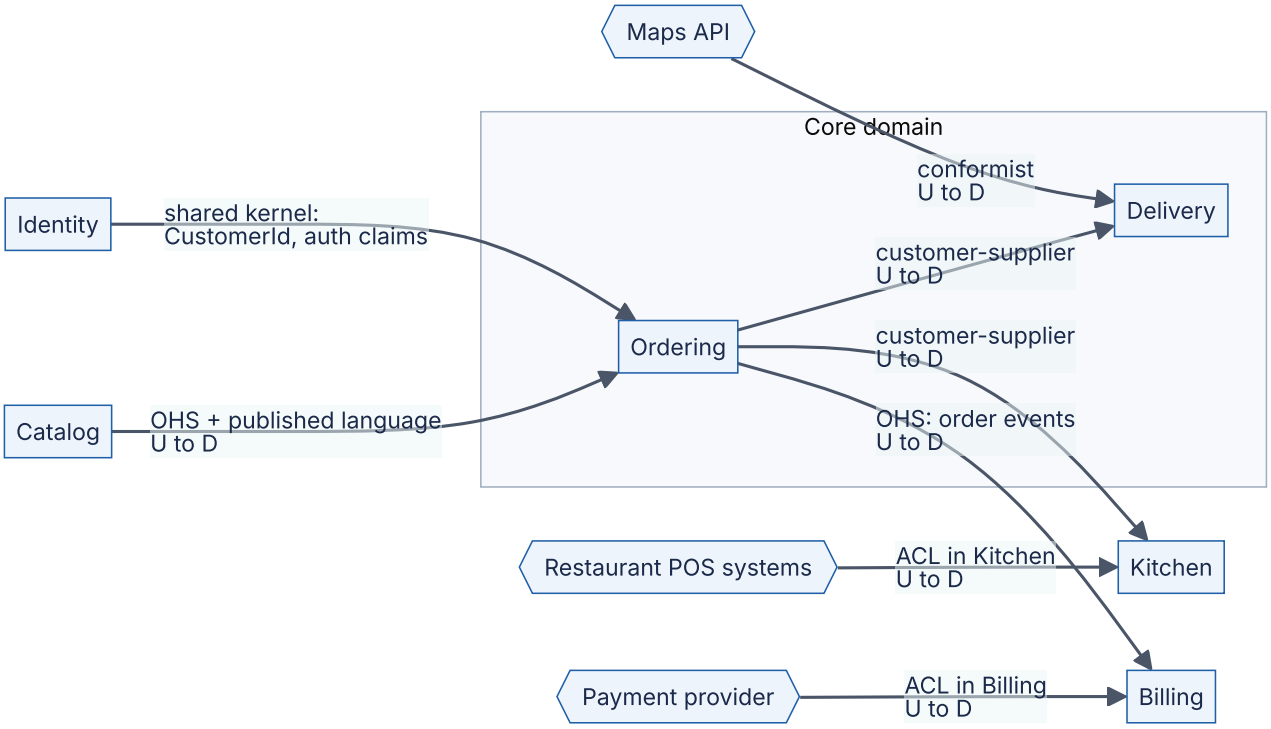
34.5.2 Context maps

A **context map** shows the bounded contexts and their relationships. Each relationship pattern describes both an integration style and a team relationship: **upstream** contexts influence **downstream** ones [Evans 2003; Vernon 2013].

Table 34.2 — Context-map relationship patterns.

Pattern	What it is	Choose when	Risk
Shared kernel	Small, jointly owned subset of the model	Two closely cooperating teams	Kernel grows into shared-library coupling
Customer–supplier	Upstream plans for downstream's needs	Teams with aligned goals	Supplier overwhelmed by customers
Conformist	Downstream adopts upstream's model	Upstream is large or external and acceptable	Upstream model distorts downstream
Anticorruption layer	Downstream translates upstream's model into its own	Upstream is legacy, poor or external	Translation code to maintain
Open host service	Upstream offers one stable protocol for all	Many consumers	Protocol must evolve compatibly
Published language	Documented shared exchange format	Many parties exchange data	Format governance
Separate ways	No integration	Integration costs more than it returns	Duplicated effort
Partnership	Two teams coordinate releases	Jointly delivered capability	Coupled release cadence

Figure 34.3 — QuickBite context map.



Reading the diagram. Arrows run from upstream to downstream and are labeled with the pattern; this models influence and translation, not request direction. Catalog's **open host service** publishes a menu schema that Ordering consumes. Ordering is a **supplier** to Delivery and Kitchen, which consume its events asynchronously. Billing receives order events through Ordering's open host service and shields itself from the payment provider with an **anticorruption layer**; Kitchen does the same for many restaurant point-of-sale systems. Delivery is **conformist** toward the maps provider, whose geometry types are acceptable. Identity and Ordering share a tiny **kernel**. Each box is a storage and ownership boundary. Failure points: Kitchen's ACL must stop malformed POS data; a maps model change forces Delivery to change. Each context scales independently.

34.5.3 The anticorruption layer in code

> DEFINITION
>
> **Definition — Anticorruption layer (ACL).** A layer owned by a downstream context that translates between an upstream model and its own, so the upstream's concepts, codes and quirks never appear in the downstream model [Evans 2003].

The payment provider speaks in statuses such as `AUTHORISED`, `CAPTURED`, `REFUSED` and `PENDING_3DS`, numeric refusal codes and string amounts in minor units. Billing knows three outcomes: authorized, declined (with a business reason) and "customer must act". The ACL below is the only code that knows the provider's vocabulary.

```
from dataclasses import dataclass
from decimal import Decimal
from enum import Enum

# ---- Billing context: the model we want to protect ------------------------
@dataclass(frozen=True)
class Money:                        # value object: equality by value, immutable
    amount: Decimal
    currency: str

    def __post_init__(self):
        if self.amount < 0 or len(self.currency) != 3:
            raise ValueError(f"invalid money {self.amount} {self.currency}")

class DeclineReason(Enum):
    INSUFFICIENT_FUNDS = "insufficient_funds"
    CARD_EXPIRED = "card_expired"
    SUSPECTED_FRAUD = "suspected_fraud"
    OTHER = "other"

@dataclass(frozen=True)
class PaymentAuthorized:
    order_id: str
    amount: Money
    provider_ref: str

@dataclass(frozen=True)
class PaymentDeclined:
    order_id: str
    reason: DeclineReason

@dataclass(frozen=True)
class PaymentNeedsCustomerAction:  # e.g. a 3-D Secure challenge
    order_id: str
    redirect_url: str

# ---- Anticorruption layer: the only code that knows the provider's model --
MINOR_UNITS = {"USD": 2, "EUR": 2, "JPY": 0}
DECLINE_CODES = {"51": DeclineReason.INSUFFICIENT_FUNDS,
                 "54": DeclineReason.CARD_EXPIRED,
                 "59": DeclineReason.SUSPECTED_FRAUD}

class ProviderTranslationError(Exception):
    pass

def translate(raw: dict):
    """Map one provider response (their language) to one domain outcome."""
    order_id = raw.get("merchant_reference")
```

```
            if not order_id:
                raise ProviderTranslationError("missing merchant_reference")
            status = raw.get("status", "").upper()
            if status in ("AUTHORISED", "CAPTURED"):          # two words, one meaning
                cur = raw["currency"].upper()
                if cur not in MINOR_UNITS:
                    raise ProviderTranslationError(f"unsupported currency {cur}")
                amount = Decimal(int(raw["amount_minor"])).scaleb(-MINOR_UNITS[cur])
                return PaymentAuthorized(order_id, Money(amount, cur), raw["psp_ref"])
            if status == "REFUSED":
                reason = DECLINE_CODES.get(str(raw.get("refusal_code")),
DeclineReason.OTHER)
                return PaymentDeclined(order_id, reason)
            if status == "PENDING_3DS":
                return PaymentNeedsCustomerAction(order_id, raw["action"]["url"])
            raise ProviderTranslationError(f"unknown provider status {status!r}")

        # ---- Tests --------------------------------------------------------------
        if __name__ == "__main__":
            ok = translate({"merchant_reference": "ord-17", "status": "Authorised",
                            "amount_minor": "2450", "currency": "usd", "psp_ref":
"PSP9"})
            assert ok == PaymentAuthorized("ord-17", Money(Decimal("24.50"), "USD"),
"PSP9")

            yen = translate({"merchant_reference": "ord-18", "status": "CAPTURED",
                             "amount_minor": "1500", "currency": "JPY", "psp_ref":
"PSP10"})
            assert yen.amount == Money(Decimal("1500"), "JPY")

            assert translate({"merchant_reference": "ord-19", "status": "REFUSED",
                              "refusal_code": 51}).reason is
DeclineReason.INSUFFICIENT_FUNDS
            assert translate({"merchant_reference": "ord-20", "status": "REFUSED",
                              "refusal_code": "99"}).reason is DeclineReason.OTHER

            action = translate({"merchant_reference": "ord-21", "status": "PENDING_3DS",
                                "action": {"url": "https://psp.example/3ds/abc"}})
            assert isinstance(action, PaymentNeedsCustomerAction)

            for bad in ({"status": "AUTHORISED"},
                        {"merchant_reference": "ord-22", "status":
"PARTIALLY_AUTHORISED"}):
                try:
                    translate(bad)
                    raise AssertionError("expected ProviderTranslationError")
                except ProviderTranslationError as e:
                    print("rejected:", e)
            print("all ACL tests passed")
```

Running it with `python3` prints:

```
rejected: missing merchant_reference
rejected: unknown provider status 'PARTIALLY_AUTHORISED'
all ACL tests passed
```

What to notice:

- **Two upstream words, one meaning.** `AUTHORISED` and `CAPTURED` both become `PaymentAuthorized`.
- **Units are translated at the edge.** The currency's exponent is applied, so a yen amount is not divided by 100.
- **Unknown codes are mapped deliberately.** An unknown refusal code safely becomes `OTHER`, but an unknown *status* raises, because guessing whether money moved is never safe; route it to a dead-letter queue and alert (§30.11).
- **Isolation.** When the provider changes, one file and its tests change, not Billing's model.

34.5.4 Event storming

DEFINITION

Definition — Event storming. A collaborative workshop technique created by Alberto Brandolini in which domain experts and developers place domain events (past tense, on sticky notes) along a timeline, then add commands, actors, policies ("whenever X, then Y"), external systems and hotspots (open questions), and group the result into aggregates and candidate bounded contexts [Brandolini: Introducing EventStorming].

How it works internally

1. **Chaotic exploration.** Everyone writes the events they know and sticks them roughly in time order.
2. **Enforce the timeline.** Sort, remove duplicates and mark disagreements as **hotspots**; disagreements reveal where one word has two meanings.
3. **Add causes.** For each event, add the command and actor, policy or external system that caused it.
4. **Find aggregates and boundaries.** Group commands around what decides whether they are allowed (aggregates); draw lines where the language or the owning department changes (candidate contexts).

Figure 34.4 — Event-storming output for QuickBite's order flow (simplified).

Reading the diagram. This is a modeling artifact: arrows show causality, not network calls. Stadiums are actors, parallelograms commands, rectangles domain events and hexagons policies. A customer's *Place order* produces `OrderPlaced`; a policy reacts with *Authorize payment*, and so on. The dotted arrow marks a human waiting step, where latency and timeouts will appear in the system. The vocabulary shifts around `PaymentAuthorized` (Billing), at "ticket" (Kitchen) and at "courier" (Delivery): these are the candidate boundaries of Figure 34.3. The final hotspot (support says delivery, finance says 14 days later) becomes a design decision instead of a production bug.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Upstream model leaks downstream	Accidental conformist	Upstream codes in downstream domain classes	Introduce an ACL	Decide each relationship explicitly
Shared kernel grows	Convenient home for common code	Kernel changes in most releases	Move code to owners	Kernel limited to identifiers and stable values
ACL silently mistranslates	Unknown codes mapped to defaults	"Declined: other" spikes	Fix mapping; replay dead letters	Fail loudly on unknown statuses

34.6 API gateways and backends for frontends

34.6.1 The API gateway

DEFINITION

Definition — API gateway. A reverse proxy (§7.12) that is the single entry point for external clients into a set of services. It routes requests and applies **edge concerns** once: TLS termination, authentication, rate limiting, request validation, caching, protocol translation and sometimes aggregation [Richardson 2018].

A hotel guest asks the front desk rather than searching the corridors for housekeeping; the desk checks who they are, knows where everything is and enforces house rules in one place. Without a gateway, a mobile app must know every service's address, every service must validate tokens and enforce rate limits in every language, and every internal refactoring breaks published clients. The gateway decouples the **external API**, which must stay stable for years because old app versions persist (§8.4.3), from the **internal topology**, which should be free to change weekly.

For each request it terminates TLS; authenticates (validates a JWT, §8.13, and attaches a verified identity header); applies rate limits (Chapter 22) and validation; matches the route and resolves the target through discovery (§34.7); optionally aggregates; and starts

or continues a trace (§34.9). Common choices include Kong, Envoy-based gateways, NGINX, cloud API gateways and Kubernetes Gateway API implementations (§42.10). The gateway holds no business state and scales horizontally.

WARNING / TRADE-OFF

Warning — Keep business logic out of the gateway. Every team needs route changes, so a gateway accumulating business rules becomes a shared monolith owned by one overloaded team. Lewis and Fowler's principle is "smart endpoints and dumb pipes" [Lewis and Fowler 2014].

34.6.2 Backends for frontends (BFF)

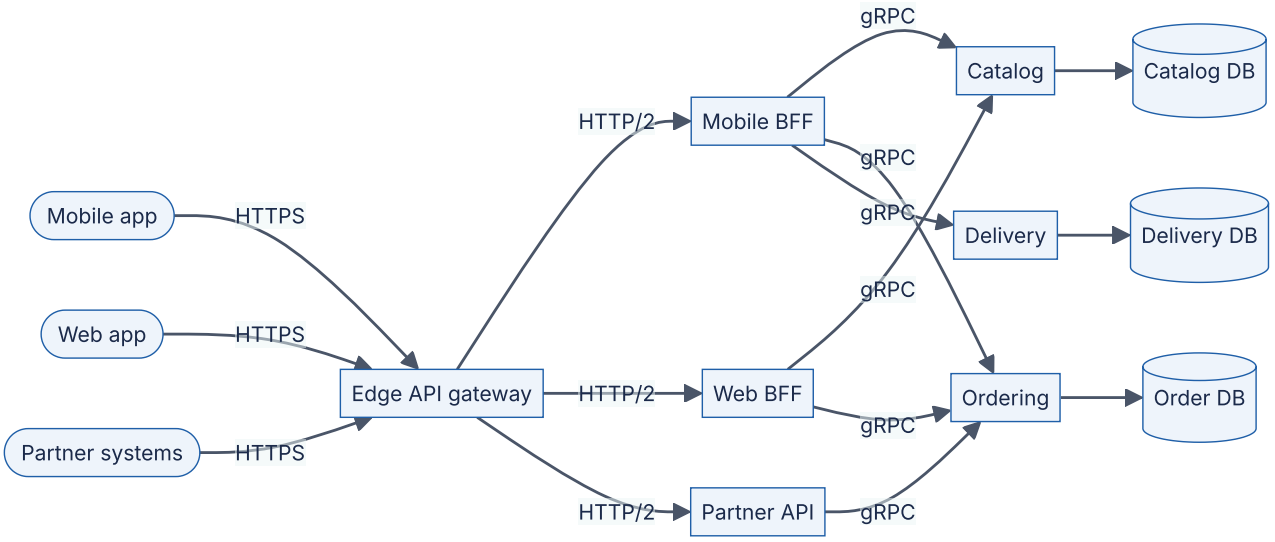
DEFINITION

Definition — Backend for frontend (BFF). A server-side component dedicated to one kind of user interface (iOS, web, partner API), owned by or aligned with that interface's team, which aggregates and reshapes downstream calls into exactly the API that interface needs [Newman 2015].

One general-purpose API serves no client well. The mobile home screen needs 6 fields from 5 services in one round trip over a cellular network; the web dashboard needs 40 fields; a partner needs a stable, versioned contract. A single gateway serving all three accumulates per-client conditionals and makes every UI change wait for the gateway team.

Origins, cited carefully. At **Netflix**, the API was redesigned around 2012 so that device-specific adapter code, written by each device's UI team, ran on the server and called general-purpose backend services, letting each device fetch what its screens needed in one request [Jacobson 2012]. At **SoundCloud**, per-client backends emerged from about 2013 during the move from a monolith to services; Lukasz Plotnicki described them, and Sam Newman, who interviewed SoundCloud engineers, named and popularized the pattern in 2015 [Plotnicki 2015; Newman 2015].

Figure 34.5 — Edge gateway with one BFF per client type.



Reading the diagram. All clients reach one edge gateway over HTTPS; it terminates TLS, authenticates, rate-limits and routes to a BFF over HTTP/2. Each BFF calls domain services synchronously over gRPC and merges the responses into a client-shaped payload. Domain services own their databases; BFFs own no business data, so they scale horizontally with their client's traffic. Failure points: a BFF's availability and tail latency are bounded by its dependencies (§34.8.3), so it needs deadlines, partial responses and fallbacks (Chapter 22).

Mathematical foundations: why aggregation near the services pays off

FORMULA

Latency of sequential and parallel call sequences

$$L_{\text{seq}} = \sum_{i=1}^{n} (R_i + s_i) \qquad L_{\text{par}} = \max_i (R_i + s_i)$$

Symbol	Meaning	Units
n	Number of calls needed to build one response	calls
R_i	Network round-trip time of call i (including connection reuse)	ms
s_i	Server processing time of call i	ms
L_{seq}	Total latency when each call waits for the previous one	ms
L_{par}	Total latency when independent calls run concurrently	ms

WORKED EXAMPLE

Worked example — The QuickBite home screen over a mobile network. The screen needs 8 calls, each taking $s = 20$ ms in its service. The phone's round trip is $R_{\text{mobile}} = 100$ ms; inside the datacenter $R_{\text{dc}} = 1$ ms.

1. Phone calls sequentially: $L = 8 \times (100 + 20) = 960$ ms.
2. Phone calls in parallel: $100 + 20 = 120$ ms in theory, but dependent calls (recommendations need the address) typically force about three waves: $3 \times 120 = 360$ ms.
3. BFF, one phone round trip, sequential inside: $L = 100 + 8 \times (1 + 20) = 268$ ms.
4. BFF with three parallel waves inside: $L = 100 + 3 \times 21 = 163$ ms.

Interpretation. Paying the expensive round trip once and the cheap ones many times saves 0.8 s against the naive design and 0.2 s against the best realistic client design. **Engineering implication.** Aggregate where round trips are cheapest, parallelize independent calls, and give each a deadline so late optional data (promotions) is dropped rather than awaited.

Table 34.3 — Gateway, BFF and GraphQL compared.

	Single API gateway	Gateway + BFF per client	GraphQL federation (§8.7)
Advantages	Simple; one place for policy	UI teams shape their APIs; fewer round trips	Clients choose fields; one endpoint
Disadvantages	Accumulates per-client logic	Duplication across BFFs; more deployables	Query cost control; harder caching
Choose when	Few, similar client types	Several client types and teams	Many clients with varied data needs

The main BFF risk is **duplication**: "is this restaurant open?" implemented three times and diverging. Push domain logic into the owning service; keep BFFs to aggregation and presentation.

34.7 Service discovery

DEFINITION

Definition — Service discovery. The mechanism by which a client finds the current network locations of healthy instances of a service. A **service registry** stores instances, locations and health; a **lookup** path lets a client (client-side discovery) or a router (server-side discovery) query it [Richardson 2018].

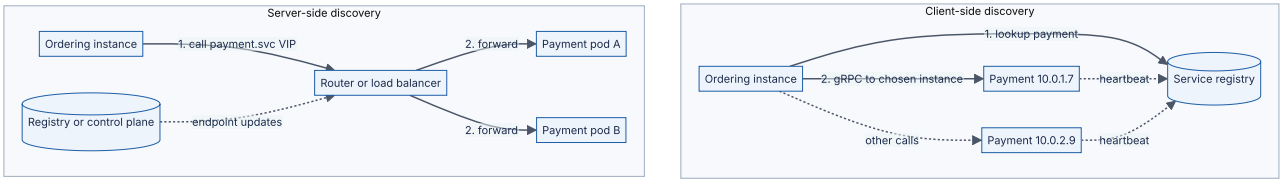
In containers, instances appear and disappear with autoscaling, deploys and failures, and each gets a new IP address; hard-coded addresses cannot keep up. Think of a hospital switchboard: doctors check in when they reach a ward and out when they leave, and the operator connects callers to wherever the doctor is. A doctor who forgets to check out gets calls put through to an empty room until someone notices. Registration is checking in; health checks are how the operator notices.

34.7.1 Registration and health

With **self-registration**, an instance registers on start-up, sends heartbeats and deregisters on shutdown; missing heartbeats expire its lease (Netflix Eureka) [Netflix Eureka Docs]. With **third-party registration**, the platform registers instances: Kubernetes maintains **EndpointSlices** for each Service, including only pods whose **readiness probe** passes [Kubernetes Docs: Services; Kubernetes Docs: Probes], and Consul agents register local services and run their checks [HashiCorp Consul Docs]. A registry listing dead instances is worse than none, so distinguish liveness (restart?), readiness (send traffic?) and **passive** health, where callers eject an instance after consecutive errors (Envoy's outlier detection) (§19.5).

34.7.2 Client-side versus server-side discovery

Figure 34.6 — Client-side and server-side service discovery.



Reading the diagram. Client-side (top): Ordering queries the registry (a replicated store, the storage boundary), caches the list, picks an instance with a client-side policy (§19.10) and calls it directly over gRPC; instances heartbeat asynchronously (dotted). Server-side (bottom): Ordering calls one stable name or virtual IP; a router (load balancer, `kube-proxy` rules or a sidecar) receives endpoint updates asynchronously and forwards the request. Failure points: stale entries send traffic to dead instances in both designs; the server-side router is an extra hop that must be redundant. Scaling: registries are read-heavy and serve cached lookups; clients must keep working on their last-known list if the registry is unreachable.

Table 34.4 — Client-side versus server-side discovery.

	Client-side	Server-side
Advantages	No extra hop; per-request balancing	Simple, language-agnostic clients
Disadvantages	Discovery logic in every language's library	Extra hop; router must be highly available
Examples	Eureka client; gRPC name resolvers; Consul API	Kubernetes Services and DNS; cloud load balancers; mesh sidecars
Choose when	Few languages, latency-sensitive RPC	Polyglot fleet, platform-managed infrastructure

A service mesh (§34.10) blurs the line: the sidecar balances client-side on the application's behalf.

34.7.3 Registries: Consul, Eureka and Kubernetes DNS

- **Consul** replicates its catalog across server nodes with Raft (§26.7), so catalog writes are strongly consistent; per-node agents run health checks and gossip membership. Lookups use an HTTP API or DNS (`payment.service.consul`) and return only passing instances [HashiCorp Consul Docs].
- **Eureka** favors availability: servers replicate asynchronously, clients cache the registry and keep using it if Eureka is unreachable, and in **self-preservation mode** Eureka stops expiring instances when heartbeats drop suddenly, assuming a network problem rather than mass death. It is an AP design (§25.8) [Netflix Eureka Docs].
- **Kubernetes DNS** gives each Service the name `<service>.<namespace>.svc.cluster.local`. A normal Service resolves to a virtual IP spread by `kube-proxy`; a **headless** Service resolves to pod IPs, suiting client-side balancing such as gRPC's [Kubernetes Docs: DNS for Services and Pods].

> WARNING / TRADE-OFF
>
> **Warning — DNS caching and long-lived connections defeat fast discovery.** DNS is only as fresh as its TTL, and some clients cache longer. A gRPC client that resolved a headless Service once keeps its connections to old pods until they close. Use short TTLs, connection maximum ages or push-based discovery.

Mathematical foundations: how long does a dead instance keep receiving traffic?

FORMULA

Stale-endpoint window and failed requests

$$T_{\text{stale}} \le k \cdot h + t_{\text{prop}} + t_{\text{cache}} \qquad F \approx \frac{\lambda}{m} \cdot T_{\text{stale}} \cdot (1 - q)$$

Symbol	Meaning	Units
h	Heartbeat or health-check interval	s
k	Consecutive missed checks before the instance is removed	count
t_{prop}	Time for the registry change to reach clients or routers	s
t_{cache}	Maximum additional client cache age	s
T_{stale}	Worst-case time a dead instance stays in some client's list	s
λ	Total request rate to the service	requests/s
m	Number of instances (traffic share of the dead one is $1/m$)	count
q	Fraction of failed calls rescued by a retry on another instance or by passive ejection	dimensionless
F	Requests that fail during the window	requests

WORKED EXAMPLE

Worked example — A Payment instance dies abruptly. Payment receives $\lambda = 2,000$ requests/s over $m = 20$ instances. Option A: heartbeats with $h = 10$ s, $k = 3$, propagation 2 s, client caches refreshed every 30 s. Option B: Kubernetes readiness defaults (`periodSeconds: 10` , `failureThreshold: 3`), about 2 s propagation, no client cache.

1. Option A: $T = 3 \times 10 + 2 + 30 = 62$ s; the dead instance's share is $2,000/20 = 100$ requests/s, so without retries $F = 100 \times 62 = 6,200$ failed requests.
2. Option B: $T = 30 + 2 = 32$ s; $F = 3,200$. (Kubernetes often notices a crashed pod sooner through its container or node status.)
3. Add passive ejection after 5 consecutive errors per caller and one retry elsewhere for idempotent calls ($q \approx 0.99$): option A falls to about $6,200 \times 0.01 \approx 62$ failures.

Interpretation. Periodic detection plus caching leaves tens of seconds of failures. **Engineering implication.** Do not rely on the registry for fast failure handling: combine it with passive ejection and bounded retries of idempotent calls (§22.12, §22.15). Shortening checks to 1 s with $k = 1$ would eject healthy instances during every garbage-collection pause.

INDUSTRY EXAMPLE

Eureka at Netflix. Netflix built Eureka for AWS, where instance addresses changed constantly and the load balancers of the time did not suit mid-tier service-to-service traffic. Its availability-first design (client caching, self-preservation) reflects the judgment that during a network problem a possibly stale list beats no list. *Evidence: Primary* — [Netflix Eureka Docs]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Traffic to dead instances	Stale registry or caches	Errors to specific IPs	Passive ejection; retry elsewhere	Short leases; push updates
Registry outage	Lost quorum or overload	Lookup and registration errors	Clients use cached lists	Replicated registry; tolerate its absence
Mass deregistration	Health check tests a shared dependency	Zero healthy endpoints	Fail open: keep last endpoints	Readiness tests the instance only (§19.5.2)

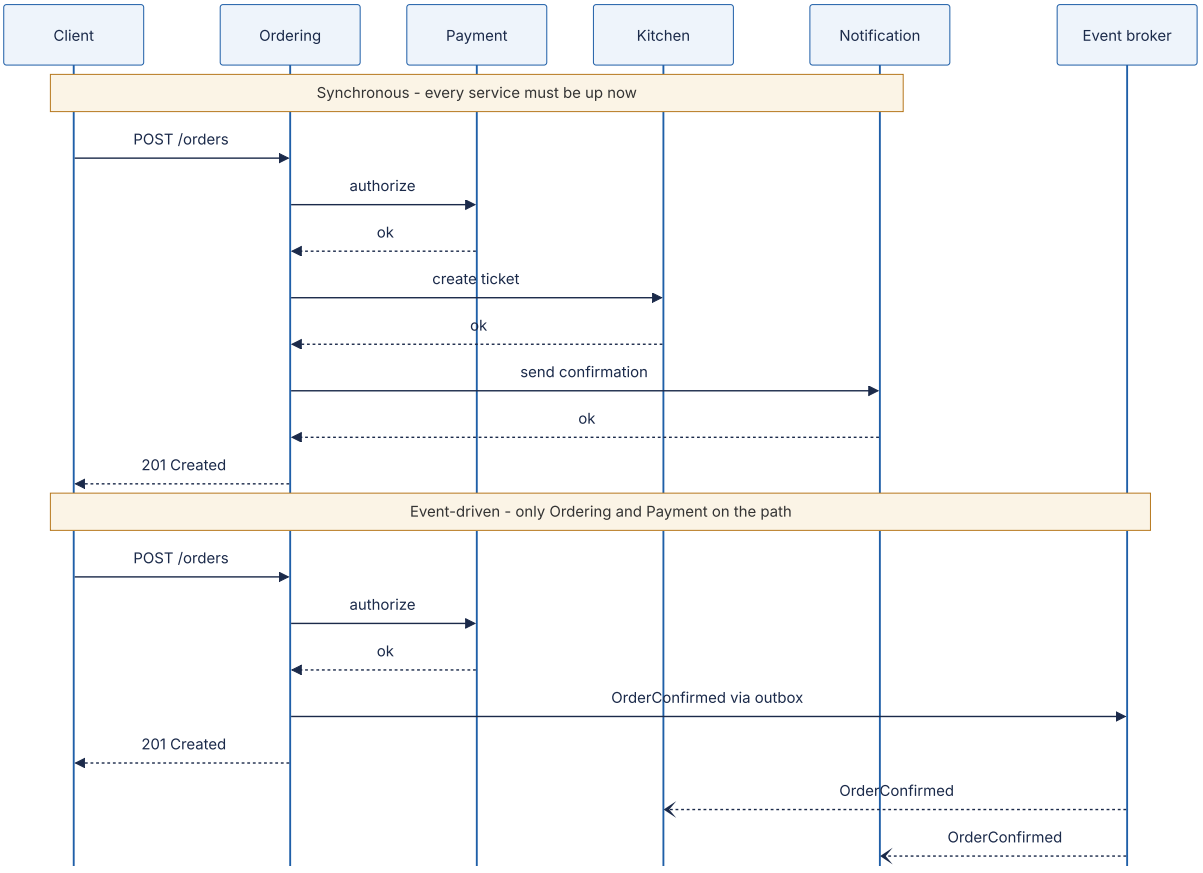
34.8 Inter-service communication

34.8.1 Synchronous versus asynchronous

DEFINITION

Definition — Synchronous and asynchronous inter-service communication. In **synchronous** communication the caller sends a request (REST, gRPC) and cannot complete its work until the response arrives, so caller and callee must be available at the same time. In **asynchronous** communication the sender publishes a message (event or command) to a broker or log and continues; the receiver processes it later (§30.3).

Figure 34.7 — Placing an order: synchronous chain versus event-driven flow.



Reading the diagram. In the first half, Ordering calls Payment, Kitchen and Notification synchronously in sequence; latencies add, and the request fails if any of four services is down. In the second half only payment authorization stays synchronous (the customer must know whether the card worked); Ordering commits the order and an outbox row in one local transaction (§32.5) and responds. A relay publishes `OrderConfirmed` to the broker, the durable boundary between services, and Kitchen and Notification consume it asynchronously (open arrowheads); if Notification is down for ten minutes, confirmations

are late but orders still succeed. The cost is eventual consistency, and failures after the response need retries, dead-letter queues and, where steps can fail, sagas (§32.7). Consumers scale on their backlog.

Table 34.5 — Choosing a communication style.

	Synchronous (REST, gRPC)	Asynchronous (events via broker)
Use for	Queries; commands whose result is needed now	Propagating facts; work nobody waits for
Advantages	Simple model; immediate errors	Temporal decoupling; load leveling; easy new consumers
Disadvantages	Availability and latency compound along chains	Eventual consistency; duplicates; harder debugging
Failure handling	Timeouts, retries, circuit breakers (Chapter 22)	Idempotent consumers, dead-letter queues (§30.11, §32.10)

REST over HTTP/JSON dominates at the edge; **gRPC** with Protocol Buffers (§8.8) is common internally for its compact encoding, generated stubs, streaming and built-in deadlines. For asynchronous paths, choose a log such as Kafka when you need replay and per-key ordering, and a broker such as RabbitMQ for routed work queues (§30.12).

RECOMMENDATION

Recommendation — Keep one synchronous call on the critical path where you can. For each synchronous call, ask whether the caller needs the answer before it can respond. If not, publish an event. If it needs data rather than an action (a restaurant's name), keep a local event-fed copy (§34.11.2).

34.8.2 Chatty calls

A function call in a monolith can become an expensive **N+1 call** pattern across the network. QuickBite's order-history page shows 50 orders, and a naive Ordering service calls Catalog once per order line for item names.

WORKED EXAMPLE

Worked example — Chatty versus batched calls. A Catalog call costs $R = 0.5$ ms plus $s = 2$ ms; a batched call costs $0.5 + 5$ ms. The page has 150 order lines.

1. One call per line, sequential: $L = 150 \times 2.5 = 375$ ms (formula of §34.6.2).
2. Ten concurrent: $15 \times 2.5 = 37.5$ ms, but at 200 page views/s Catalog receives $150 \times 200 = 30,000$ RPS for this one page.
3. One batched `GetItems(ids)` call: $L = 5.5$ ms and 200 RPS.
4. A local copy of item names fed by `MenuItemChanged` events: no network call at read time.

Interpretation. Batching is 68 times faster and puts 150 times less load on Catalog. **Engineering implication.** Design inter-service APIs for the caller's access pattern (batch lookups, coarse operations, pagination). Dozens of calls to one service per page signal an API that is too fine-grained or a misplaced boundary.

34.8.3 Fan-out and tail latency

A composer that calls N services in parallel waits for the slowest. By §4.8.4, if each is fast with probability p, all are fast with probability p^N.

WORKED EXAMPLE

Worked example — The home-screen fan-out. The Mobile BFF calls 6 services in parallel, each with p99 = 50 ms.

1. $P(\text{all six} \le 50 \text{ ms}) = 0.99^6 = 0.9415$.
2. So 5.9% of requests wait longer than 50 ms for some dependency: the BFF's p94 is roughly the dependencies' p99.
3. At 100-way fan-out, $0.99^{100} = 0.366$, the *Tail at Scale* example of §4.8.4.

Interpretation. Each parallel dependency pulls the overall tail toward the dependencies' tails. **Engineering implication.** Give each call a deadline, render without optional data when it is late, hedge idempotent reads (§23.6), and above all reduce the number of dependencies per request.

34.8.4 API versioning across services

The rules of §8.15 apply, with one advantage: you can know every internal consumer and verify compatibility before deploying.

1. **Additive changes by default.** Add optional fields; never remove, rename, retype or tighten in place. Consumers are **tolerant readers** that ignore unknown fields

[Fowler 2011: TolerantReader]. In Protobuf, removed tags are marked `reserved`.
2. **Expand and contract** for breaking changes: add the new form, migrate consumers, confirm the old form has no traffic, then remove it, each step a separate release.
3. **Explicit versions only when needed** (`/v2/payments`, `payments.v2`), keeping at most two alive.
4. **Version events too.** Consumers may replay old events, so use a schema registry with compatibility checks (§8.9, §30.6).

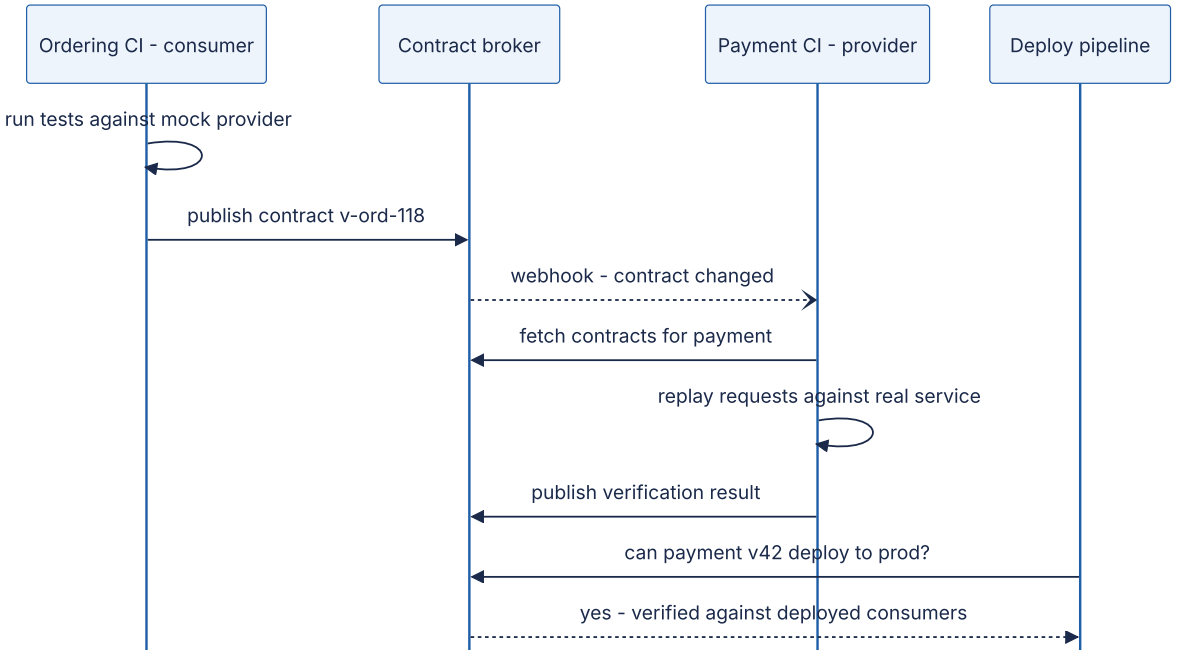
34.8.5 Contract testing with consumer-driven contracts

End-to-end tests that deploy every service together are slow, flaky and reintroduce the coordination microservices were meant to remove. Hand-written mocks test the consumer only against its own assumptions, which drift.

> DEFINITION
>
> **Definition — Consumer-driven contract (CDC).** A specification, generated by the consumer's tests, of the requests a consumer sends to a provider and the parts of the responses it relies on. The provider verifies every consumer's contract against its real implementation in its own build, so a breaking change fails before deployment [Robinson 2006; Pact Docs].

1. **Consumer test.** Ordering's tests run its real client code against a mock provider generated from declared interactions ("given payment p-1 is authorized, `GET /payments/p-1` returns 200 with a string `status`"), producing a contract (a *pact*).
2. **Publish** the contract to a **broker**, tagged with the consumer's version.
3. **Provider verification.** Payment's CI sets up each **provider state**, replays each request against the real service and checks the response, matching by type where the consumer asked.
4. **Deployment gate.** Before deploying, ask the broker whether this version is verified against the versions deployed in the target environment (Pact's `can-i-deploy`) [Pact Docs].

Figure 34.8 — Consumer-driven contract testing workflow.



Reading the diagram. The consumer's CI publishes the contract synchronously; the broker notifies the provider's CI asynchronously by webhook; the provider verifies against its real service and publishes the result. The broker is the storage boundary recording which versions are verified and deployed where, and the deploy pipeline queries it. Failure points: over-specified contracts (literal values) fail on harmless changes, under-specified ones miss breakage, and the broker becomes a release dependency. Cost grows with real consumer–provider pairs, not with the square of the number of services.

Code example

The program below implements the mechanism in about 60 lines (Pact adds many matchers, HTTP mock servers, message contracts and the broker). Provider version 1 passes despite returning extra fields; version 2 renames `status` to `state` and fails its own build.

```
        import json

        # ---- A tiny consumer-driven contract library (the idea behind Pact) --------
        def like(example):
            """Matcher: any value of the same type as the example is acceptable."""
            return {"$like": example}

        def matches(expected, actual, path="body"):
            """Return a list of mismatches; extra fields in `actual` are allowed."""
            if isinstance(expected, dict) and "$like" in expected:
                ex = expected["$like"]
                return [] if type(actual) is type(ex) else [f"{path}: expected
{type(ex).__name__}, got {actual!r}"]
            if isinstance(expected, dict):
                if not isinstance(actual, dict):
                    return [f"{path}: expected object"]
                errs = []
                for key, sub in expected.items():
                    if key not in actual:
                        errs.append(f"{path}.{key}: missing")
                    else:
                        errs += matches(sub, actual[key], f"{path}.{key}")
                return errs
            return [] if expected == actual else [f"{path}: expected {expected!r}, got
{actual!r}"]

        def example_of(expected):
            """Turn matchers back into a concrete example response for the mock."""
            if isinstance(expected, dict) and "$like" in expected:
                return expected["$like"]
            if isinstance(expected, dict):
                return {k: example_of(v) for k, v in expected.items()}
            return expected

        class Contract:
            def __init__(self, consumer, provider):
                self.doc = {"consumer": consumer, "provider": provider, "interactions":
[]}

            def given(self, state, request, response):
                self.doc["interactions"].append(
                    {"state": state, "request": request, "response": response})

            def mock_provider(self, request):
                for i in self.doc["interactions"]:
                    if i["request"] == request:
                        r = i["response"]
                        return r["status"], example_of(r["body"])
                raise AssertionError(f"unexpected request {request}")

        def verify(contract_json, provider_handler, set_state):
            """Provider side: replay every interaction against the real handler."""
```

```
            failures = []
            for i in json.loads(contract_json)["interactions"]:
                set_state(i["state"])
                status, body = provider_handler(i["request"])
                if status != i["response"]["status"]:
                    failures.append(f"[{i['state']}] status {status} != {i['response']
['status']}")
                failures += [f"[{i['state']}] {m}" for m in matches(i["response"]
["body"], body)]
            return failures

        # ---- Consumer side (Ordering service) ---------------------------------------
        def fetch_payment_status(http_get, payment_id):     # the consumer's real code
            status, body = http_get({"method": "GET", "path":
f"/payments/{payment_id}"})
            if status == 404:
                return None
            return body["status"], body["amount"]["minor"]

        contract = Contract("order-service", "payment-service")
        contract.given("payment p-1 is authorized",
                       {"method": "GET", "path": "/payments/p-1"},
                       {"status": 200, "body": {"id": "p-1", "status":
like("AUTHORIZED"),
                                                "amount": {"minor": like(2450),
                                                           "currency": like("USD")}}})
        contract.given("payment p-404 does not exist",
                       {"method": "GET", "path": "/payments/p-404"},
                       {"status": 404, "body": {}})

        # Consumer test runs against the mock built from the contract, then publishes
it.
        assert fetch_payment_status(contract.mock_provider, "p-1") == ("AUTHORIZED",
2450)
        assert fetch_payment_status(contract.mock_provider, "p-404") is None
        published = json.dumps(contract.doc)               # would go to a contract bro-
ker

        # ---- Provider side (Payment service), two versions --------------------------
        DB = {}

        def set_state(state):
            DB.clear()
            if state == "payment p-1 is authorized":
                DB["p-1"] = {"status": "AUTHORIZED", "minor": 9900, "currency": "EUR"}

        def handler_v1(req):
            pid = req["path"].rsplit("/", 1)[1]
            if pid not in DB:
                return 404, {}
            p = DB[pid]
            return 200, {"id": pid, "status": p["status"], "created_at": "2026-10-
30T12:00:00Z",
                         "amount": {"minor": p["minor"], "currency": p["currency"]}}
```

```
        def handler_v2(req):                    # a refactor renames status -> state
            status, body = handler_v1(req)
            if status == 200:
                body["state"] = body.pop("status")
            return status, body

        print("v1 failures:", verify(published, handler_v1, set_state))
        print("v2 failures:", verify(published, handler_v2, set_state))
        assert verify(published, handler_v1, set_state) == []
        assert verify(published, handler_v2, set_state) == [
            "[payment p-1 is authorized] body.status: missing"]
        print("contract tests behave as expected")
```

Running it with `python3` prints:

```
v1 failures: []
v2 failures: ['[payment p-1 is authorized] body.status: missing']
contract tests behave as expected
```

What to notice:

- **The consumer's real client code runs** against the mock, so the contract cannot claim what the client does not use.
- **Matching by type.** The provider returns 9900 EUR against an example of 2450 USD and still passes, because the consumer declared `like(...)`. Literal values are the commonest cause of brittle contracts.
- **Extra fields are allowed** (`created_at`): only what the consumer relies on is checked.
- **Provider states** seed data per interaction, making verification repeatable.
- **The breaking rename fails in Payment's build**, naming the consumer's expectation, before deployment.

> COMMON MISTAKE
>
> **Common misconception — "Contract tests replace provider functional tests."** A contract checks shape, not business correctness: it passes if Payment returns `AUTHORIZED` for a card that should be declined. Contracts replace most cross-service end-to-end tests, not unit tests [Pact Docs].

34.9 Distributed tracing (introduction)

A slow "place order" request passes through the gateway, BFF, Ordering, Payment and an external provider, each logging on a different machine. Which made it slow? This section

introduces the concepts the chapter needs; Chapter 40 (§40.6–§40.7) covers sampling, storage, OpenTelemetry and analysis.

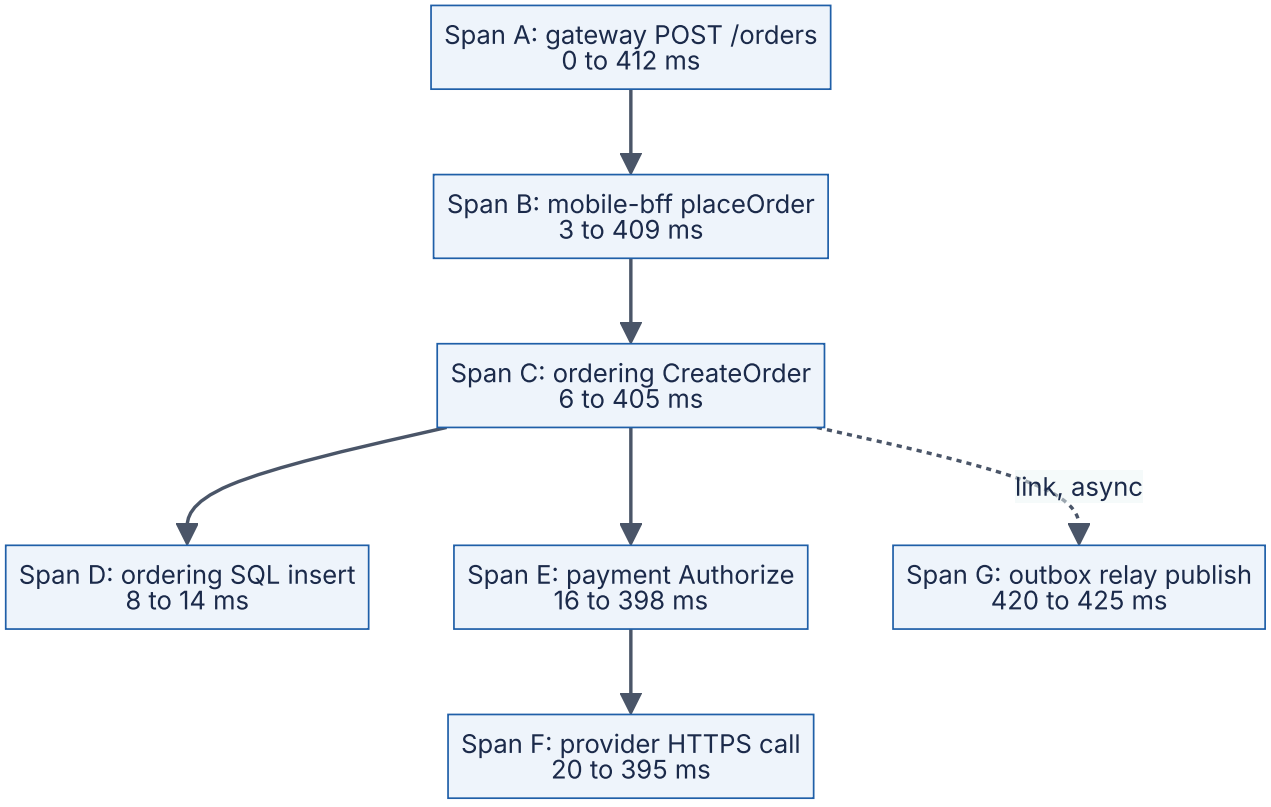
34.9.1 Traces, spans and context propagation

DEFINITION

Definition — Trace, span and context propagation. A **trace** records one request's path through a distributed system under a unique **trace ID**. It is a tree of **spans**, each recording one unit of work (an inbound request, an outbound call, a query) with service, operation, start time, duration, status, its span ID and its **parent span ID**. **Context propagation** passes the trace ID and current span ID from caller to callee (in HTTP headers or message metadata) so the callee's spans join the trace [Sigelman et al. 2010; W3C Trace Context].

Google's Dapper paper describes the motivating problem: a web search touched many services built by different teams, and engineers could not tell which caused a slow query. Dapper aimed for low overhead and application transparency by instrumenting shared RPC and threading libraries, and sampled requests (its first production version used a uniform probability of 1/1024) [Sigelman et al. 2010].

Figure 34.9 — A trace of "place order" as a span tree.



Reading the diagram. Each box is a span; solid arrows point from parent to child, all under one trace ID, with times as offsets from the root. Span F, the external provider's HTTPS call, takes 375 ms of 412 ms, so tuning Ordering's 6 ms SQL insert would not help. Span G starts after the response (420 ms) because the outbox relay publishes asynchronously; it is attached by a **span link** (dotted) rather than as a child. Services export spans asynchronously to a collector and trace store, never on the request path. Failure points: any hop that drops the context splits the trace. Scaling: traces are sampled (Chapter 40).

The first instrumented component creates the trace ID, root span and sampling decision. Each outbound call carries the W3C `traceparent` header with a version, 16-byte trace ID, 8-byte parent span ID and flags, for example `traceparent: 00-4bf92f3577b34da6a3ce929d0e0e4736-00f067aa0ba902b7-01` [W3C Trace Context]. Callees create child spans; message consumers usually start linked spans.

WARNING / TRADE-OFF

Warning — Propagation is only as good as the weakest hop. Thread pools, queues and proxies that drop headers break traces; use shared instrumentation (OpenTelemetry, §40.7). A service mesh emits spans per hop but cannot connect an inbound request to the application's outbound calls: the application must still forward the context headers [Istio Docs: Distributed Tracing].

34.10 Service mesh

34.10.1 What a mesh is and why it exists

Every inter-service call needs discovery and balancing (§34.7), timeouts, retries and circuit breaking (Chapter 22), mutual TLS (§10.10.2), telemetry (§34.9) and traffic control for canaries (§34.12). Libraries can provide all of this, as Netflix's Java libraries did, but that ties features to one language and makes every fix a fleet-wide library upgrade. A **service mesh** moves them into infrastructure.

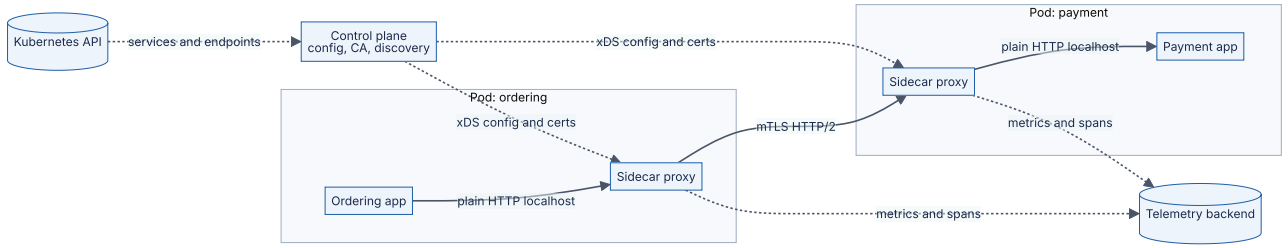
DEFINITION

Definition — Service mesh. An infrastructure layer for service-to-service communication. Its **data plane** is a set of proxies through which all service traffic passes (a **sidecar** per workload instance, or shared per-node proxies); its **control plane** configures the proxies, issues certificates and collects state. It provides traffic management, security (mutual TLS, authorization) and telemetry without application changes [Istio Docs: Architecture; Linkerd Docs: Architecture].

How it works internally

1. **Interception.** The mesh injects a proxy into each pod and redirects the pod's inbound and outbound TCP traffic through it (iptables or a CNI plugin). The application still connects in plain text to `payment:8080`.
2. **Outbound.** The caller's sidecar picks an instance from control-plane endpoints, opens or reuses an mTLS connection to the destination's sidecar, applies timeouts and retries, and records metrics and a span.
3. **Inbound.** The callee's sidecar terminates mTLS, verifies the caller's workload identity (a SPIFFE ID, §10.10.2), enforces policy ("only `ordering` may call `POST /charge`") and forwards on localhost.
4. **Control plane.** It watches services, endpoints and policy resources, pushes proxy configuration (Istio over Envoy's xDS APIs), and acts as a certificate authority issuing short-lived, automatically rotated certificates [Istio Docs: Architecture].

Figure 34.10 — Sidecar service mesh: data plane and control plane.



Reading the diagram. The Ordering application sends a plain request to localhost; its sidecar carries it over mutual TLS (HTTP/2) to the Payment sidecar, which checks identity and policy and forwards to the application. Solid arrows are the synchronous path: one logical call crosses two proxies. Dotted arrows are asynchronous: the control plane reads services and endpoints from the Kubernetes API (a storage boundary) and pushes configuration and certificates; proxies export telemetry. Failure points: if the control plane is down, proxies keep their last configuration, so traffic flows but deploys and certificate rotation stall; a bad pushed configuration can affect every service at once. Scaling: data-plane cost grows with pods; control-plane push cost grows with proxies times configuration size.

34.10.2 Features

- **Mutual TLS everywhere** with automatic certificates and identity-based authorization: often the main reason to adopt a mesh, since it delivers zero-trust service security without code changes.
- **Traffic management.** Per-route retries, timeouts, circuit breaking and outlier detection; **traffic shifting** by weight (5% to `payment` v2, §34.12); header-based routing; mirroring live traffic to a new version.

- **Telemetry.** Uniform request rate, error and latency metrics for every service pair, in any language.

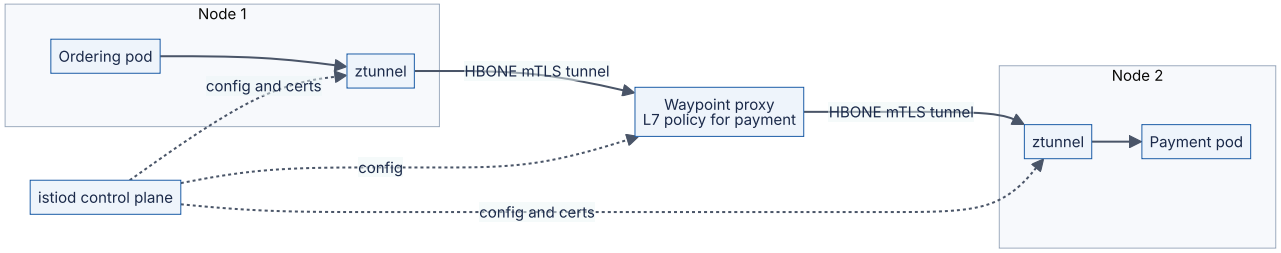
> WARNING / TRADE-OFF
>
> **Warning — Mesh retries multiply with application retries.** Three application attempts times three sidecar attempts is nine at the destination, more down a chain (§22.12.3). Choose one retrying layer.

34.10.3 Istio, Linkerd and sidecarless (ambient) mode

Istio uses Envoy sidecars and the `istiod` control plane. **Linkerd** uses its own lightweight Rust proxy, `linkerd2-proxy`, built specifically as a sidecar, emphasizing simplicity and low resource use [Linkerd Docs: Architecture]. Both offer automatic mTLS, retries, timeouts, traffic splitting and golden metrics; Istio has the larger feature and configuration surface.

Sidecars cost one proxy per pod, two proxy traversals per call, pod restarts for proxy upgrades and start-up ordering problems. As of 2026, Istio's **ambient mode**, generally available since Istio 1.24 (November 2024), removes the sidecar and splits the data plane in two [Istio Blog 2024]: **ztunnel**, a per-node Rust proxy providing L4 features (mTLS, identity, L4 authorization, TCP telemetry), and **waypoint proxies**, Envoy-based and deployed per namespace or service only where L7 features (HTTP routing, retries, L7 policy) are needed. Linkerd, as of 2026, remains sidecar-based; other sidecarless designs, such as Cilium's, move parts of the data plane into the kernel with eBPF. This area changes quickly; check current documentation.

Figure 34.11 — Istio ambient mode: per-node ztunnel with an optional waypoint.



Reading the diagram. Pods contain no proxy. Ordering's traffic is redirected to its node's ztunnel, which wraps it in an mTLS tunnel (HBONE) and, because Payment has L7 policy, sends it to Payment's waypoint, which applies HTTP routing, retries and authorization before forwarding through Node 2's ztunnel. Without L7 policy, traffic goes ztunnel to ztunnel. The control plane configures all three asynchronously. Failure points: a ztunnel failure affects every pod on its node, a larger blast radius than one sidecar; the waypoint is a shared hop to scale and replicate. Scaling: proxy count grows with nodes, not pods, and only services needing L7 pay for it.

Mathematical foundations: what does the mesh cost?

FORMULA

Mesh latency and resource overhead

$$\Delta L_{\text{chain}} \approx h \cdot \delta_{\text{hop}} \qquad C_{\text{CPU}} = \frac{\Lambda \cdot x}{1,000} \cdot c \qquad M = P \cdot m$$

Symbol	Meaning	Units
h	Number of sequential service-to-service hops on the request path	hops
δ_{hop}	Latency added per hop by the proxies on that hop (two sidecars, or two ztunnels)	ms
ΔL_{chain}	Added latency along the chain (an approximation: percentiles do not add exactly)	ms
Λ	Total internal service-to-service request rate	requests/s
x	Proxies traversed per call (2 for sidecar-to-sidecar)	count
c	Proxy CPU per 1,000 requests/s	vCPU
C_{CPU}	Fleet-wide CPU spent in proxies	vCPU
P	Number of proxies (pods for sidecars, nodes for ztunnels)	count
m	Memory per proxy	MB
M	Fleet-wide proxy memory	MB

WORKED EXAMPLE

Worked example — Meshing QuickBite. QuickBite runs 400 pods on 40 nodes, with $\Lambda = 20,000$ internal requests/s and a longest synchronous path of $h = 4$ hops. Istio's published measurements (1 KB HTTP requests, mutual TLS, specific hardware; as of 2026) report: two sidecars per hop add about 0.18 ms at p90 and 0.25 ms at p99; two ztunnels add about 0.17 ms and 0.20 ms; a two-worker sidecar uses about 0.20 vCPU and 60 MB per 1,000 requests/s; a ztunnel about 0.06 vCPU and 12 MB [Istio Docs: Performance and Scalability].

1. Sidecar latency on the longest path: $\Delta L \approx 4 \times 0.25 = 1.0$ ms at p99.
2. Sidecar CPU: $C = (20,000 \times 2/1,000) \times 0.20 = 8$ vCPU.
3. Sidecar memory: $M = 400 \times 60 = 24,000$ MB $= 24$ GB (an under-load figure; it grows with configuration size).
4. Ambient, L4 only: CPU $= (20,000 \times 2/1,000) \times 0.06 = 2.4$ vCPU (two ztunnels per call); memory $= 40 \times 12 = 480$ MB; latency $\approx 4 \times 0.20 = 0.8$ ms at p99, plus waypoints where L7 is needed.

Interpretation. About 1 ms of p99 is negligible in a 300 ms budget but half of a 2 ms cache-path budget; 8 vCPU and 24 GB is two or three extra nodes. **Engineering implication.** The mesh suits typical request/response services; for very high-rate, low-latency paths, measure first. Ambient mode cuts the per-pod memory cost most. Vendor numbers are best cases; benchmark on your hardware and payloads.

Advantages and disadvantages. A mesh gives uniform mTLS and policy without code changes, consistent retries and telemetry across languages, and traffic shifting. It costs a complex system to operate and upgrade, latency and resources, fleet-wide blast radius for configuration errors, and overlap with library features that must be reconciled.

RECOMMENDATION

Recommendation — Adopt a mesh for a specific problem: mandatory service-to-service encryption and authentication, a polyglot fleet needing uniform telemetry and traffic policy, or fine-grained traffic shifting. With ten services in one language, a well-configured RPC library is simpler.

34.11 Data ownership and database-per-service

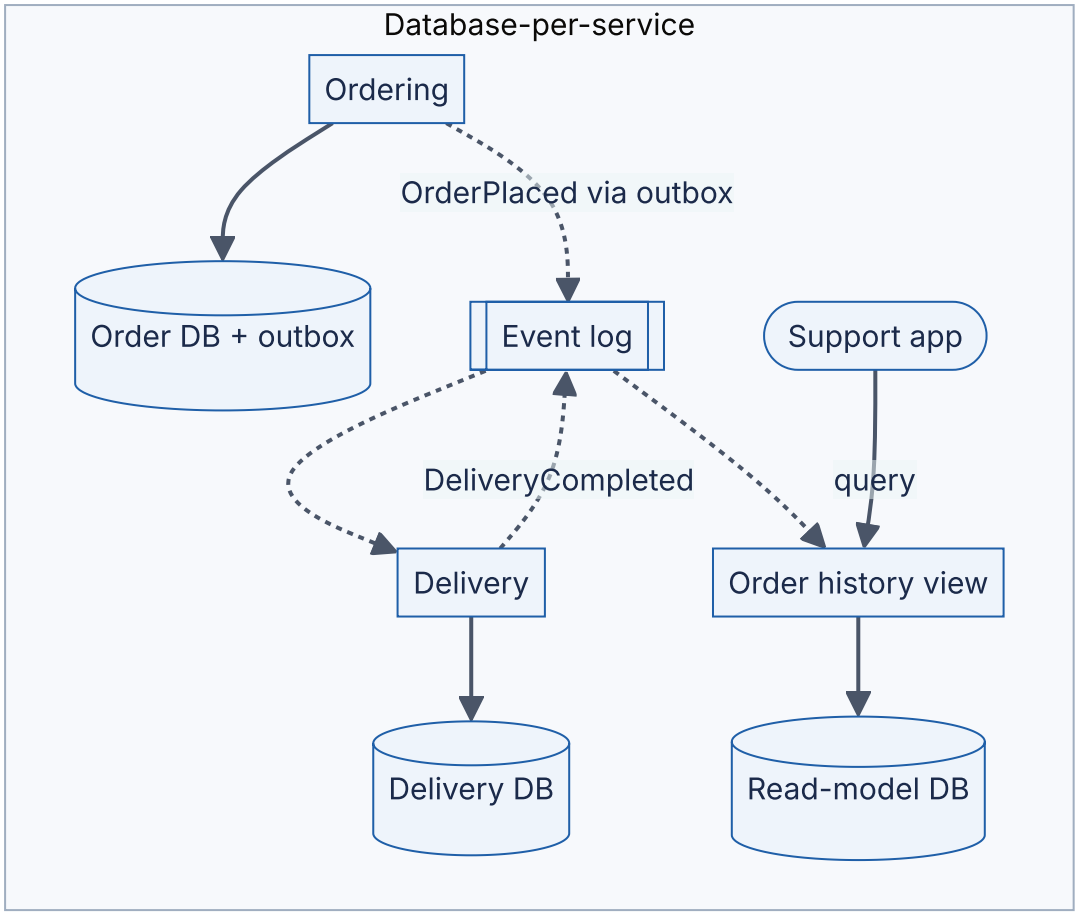
34.11.1 Database-per-service and the shared-database anti-pattern

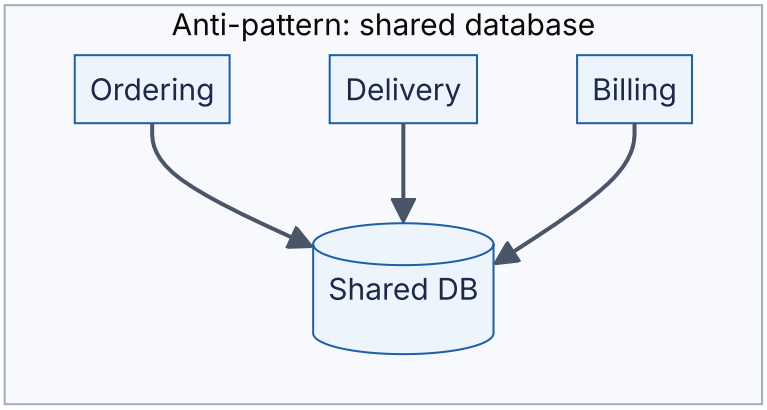
DEFINITION

Definition — Database-per-service. Each service’s persistent data is private to that service and reachable by others only through its API or published events. The service may use its own database server, its own schema on a shared server, or private tables, provided no other service reads or writes them [Richardson 2018].

The opposite is the **shared database**: several services read and write the same tables. It looks efficient, since joins are free and there is one source of truth, but it is content coupling (§34.3.2) at scale. Nobody can change a column without finding every service that uses it; one service’s heavy query slows the others; and invariants are enforced by whichever service wrote last. The schema becomes the real, unversioned API of the system.

Figure 34.12 — Shared database versus database-per-service with an event-fed read model.





Reading the diagram. On the left, three services share one database: there is one storage boundary for three owners, every table is a shared interface, and a lock or slow query from one service hurts all three. On the right, each service writes only its own database. Ordering commits an order and an outbox row in one local transaction, and a relay publishes `OrderPlaced` to the event log asynchronously (dotted). Delivery keeps the order fields it needs in its own database. An **order history view** service consumes events from both Ordering and Delivery into a denormalized read model that the support app queries synchronously. Failure points: if the event log or relay stops, copies go stale but nothing fails outright; consumers must be idempotent because delivery is at least once (§32.10).

Scaling: each database is sized for its own load, and the read model can be rebuilt by replaying the log.

34.11.2 Replicating data with events

When Delivery needs the customer's address and the restaurant's location, it does not call Ordering for every courier assignment. It keeps a local copy, updated from events. Rules for doing so safely:

1. **One owner per fact.** Ordering owns the order address; Delivery's copy is a cache that it never edits.
2. **Publish reliably.** Use the transactional outbox or change data capture (§32.5–§32.6) so the database and the event log cannot disagree.
3. **Consume idempotently and in order per key.** Partition events by aggregate ID so all events for one order arrive in order (§31.5), and ignore events whose version is not newer than the copy's.
4. **Carry enough state.** "Event-carried state transfer" puts the changed fields in the event so consumers need not call back.

Cross-service invariants then become **sagas**: a sequence of local transactions with compensations (refund the payment if no courier can be found), coordinated by choreography or an orchestrator. Chapter 32 owns that topic (§32.7–§32.8).

34.11.3 Querying across services

A support agent wants "all orders for customer X in the last month, with delivery times and refund status": data owned by three services. Two patterns exist [Richardson 2018]:

- **API composition.** A composer (a BFF or query service) calls each owner and joins in memory. Simple and always fresh, but its latency is that of the slowest owner, its availability is the product of the owners' (§34.14.3), and large joins (all orders with any refund) need inefficient fan-out.
- **CQRS view.** A dedicated read model, fed by events from the owners, stores the pre-joined answer (Figure 34.12). Queries are fast and independent of the owners' availability, at the cost of replication lag (typically under a second to seconds) and another datastore to run (§32.4).

Table 34.6 — Querying across services.

	API composition	CQRS view
Freshness	Current	Lags by the replication delay
Latency	Slowest owner plus composition	One local query
Availability	Product of owners' availability	Independent of owners at read time
Complexity	Low	Event handling, idempotency, rebuilds
Choose when	Few owners, small result sets	Frequent queries, joins across many owners, search

COMMON MISTAKE

Common misconception — "Database-per-service means one database server per service." It means private *ownership*. Several services may share a managed database cluster with separate schemas and credentials, which is often the cost-effective start, as long as no service can read another's schema. Enforce the boundary with database permissions, not with good intentions.

34.12 Deployment strategies

The defining property of a microservice is that it can be deployed alone. Chapter 43 covers rolling, blue–green and canary deployments and feature flags in depth (§43.4–§43.7); this section lists what microservices add.

1. **One pipeline per service.** Each service builds, tests (including contract verification, §34.8.5) and deploys from its own pipeline, without waiting for other services.
2. **Backward and forward compatibility at every step.** During a rolling deploy, old and new versions of a service run side by side, and consumers on either side may be old or new. Every API, event and schema change therefore uses expand and contract (§34.8.4); database changes too (§43.13).
3. **Progressive delivery.** Shift a small share of traffic to the new version (with a mesh, by weight, §34.10.2), compare its error rate and latency with the old version, and roll forward or back automatically.
4. **Decouple deploy from release.** Ship code dark behind a feature flag, then enable it gradually.

WARNING / TRADE-OFF

Warning — The lockstep release is a symptom. If a release plan says "deploy Payment v42, then Ordering v118, then Billing v77 within the same hour", the services are not independently deployable. Find the incompatible change and split it into compatible steps.

34.13 Migration from a monolith

34.13.1 The strangler fig pattern

> DEFINITION
>
> **Definition — Strangler fig application.** A migration strategy in which a new system is grown around the edges of an old one, taking over one capability at a time while the old system keeps running, until the old system can be retired. Fowler named it after strangler fig vines, which grow around a host tree until they stand on their own [Fowler 2004].

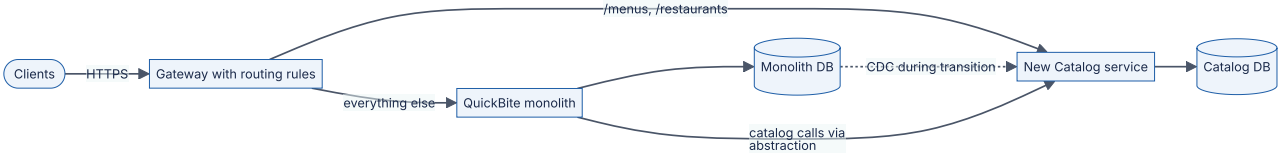
Why does this exist?

The alternative, a “big bang” rewrite, stops feature delivery for months or years, must reproduce every undocumented behavior of the old system, and delivers no value until the end. Incremental migration delivers value early, can be paused at any point, and keeps the old system as a fallback.

How it works internally

1. **Put a routing layer in front** of the monolith (a reverse proxy or the API gateway); initially it sends everything to the monolith.
2. **Pick a capability** with low change coupling to the rest (§34.3.2), clear data ownership and real value from extraction.
3. **Build it as a service**, with its own data. Synchronize data during the transition, for example with change data capture from the monolith’s tables.
4. **Redirect traffic** for that capability’s routes to the new service, gradually (by percentage or by customer), with the ability to switch back.
5. **Remove the dead code** from the monolith, then repeat.

Figure 34.13 — Strangler fig: extracting Catalog from the QuickBite monolith.



Reading the diagram. All clients reach the gateway over HTTPS; routing rules send catalog paths to the new Catalog service and everything else to the monolith (synchronous). During the transition, change data capture streams menu changes still written by old monolith screens into Catalog’s database (dotted, asynchronous), and monolith code that needs menu data calls Catalog through an internal abstraction instead of its own tables. Two storage boundaries now exist, and for a period the monolith database remains the

source of truth for some fields, so ownership must be explicit per field. Failure points: the routing layer (must be redundant), the CDC pipeline (lag shows stale menus) and divergent behavior between old and new code. Scaling: Catalog now scales independently with read traffic.

34.13.2 Branch by abstraction and parallel run

Routing works at the edge. Functionality deep inside the monolith, called by other monolith code, needs **branch by abstraction**: introduce an interface in front of the existing implementation, move all callers to the interface, build the new implementation (a client to the new service) behind it, switch with a flag, then delete the old implementation [Fowler 2014: BranchByAbstraction; Newman 2019]. All of this happens on the main branch with no long-lived feature branch.

For risky logic (pricing, payments), use a **parallel run**: call both old and new implementations, return the old result to the user, and compare the results, logging any differences. GitHub's Scientist library automates this for code paths inside an application [GitHub Scientist]. Only when differences are rare and understood do you switch to the new implementation as the source of truth. Make sure only one side has side effects (only one sends the email or charges the card).

34.13.3 A worked migration plan

Table 34.7 — Migrating QuickBite's monolith over about four quarters (illustrative).

Phase	Step	Exit criterion
0	Gateway in front of monolith; tracing and per-route metrics; modularize code by context	All traffic via gateway; module dependencies mapped
1	Extract Notification (async, low coupling) via `OrderPlaced` events from an outbox	Monolith no longer sends messages
2	Extract Catalog with CDC sync and route-by-route redirection	Catalog DB is source of truth; monolith reads via API
3	Extract Delivery; parallel-run courier assignment for two weeks	Assignment differences below 0.1%, all explained
4	Extract Payment behind branch by abstraction; ACL for provider	Payment tables removed from monolith DB
5	Remaining Ordering core stays a well-modularized service	Decide on evidence whether to split further

The order follows the change-coupling data: the least coupled, lowest-risk capabilities first, so the team learns the platform (pipelines, discovery, tracing) on cheap mistakes.

Payment comes late because it has high coupling with Ordering ($C = 0.43$ in §34.3.2). Phase 5 is a legitimate end state: nothing requires the core to be split.

INDUSTRY EXAMPLE

Shopify's modular monolith. Shopify chose not to split its large Ruby on Rails monolith into microservices, and instead enforced component boundaries inside it, with tooling that detects violations of the declared dependencies between components [Westeinde 2019]. This captures much of the boundary benefit without the network. *Evidence: Primary* — [Westeinde 2019]

34.14 Anti-patterns

34.14.1 The distributed monolith

DEFINITION

Definition — Distributed monolith. A system deployed as multiple services that cannot be changed, deployed or operated independently: services share databases, must be released together, or call each other synchronously so tightly that one failure stops all of them. It has the costs of distribution and the coupling of a monolith [Newman 2021].

Symptoms: coordinated releases (§34.12), a shared database (§34.11), long synchronous call chains, and a single change touching many repositories. The cause is almost always boundaries drawn without regard to cohesion, often by technical layer (Figure 34.1) or by noun ("Customer service", "Product service") instead of by capability.

34.14.2 Nanoservices and shared-library coupling

Nanoservices are services so fine-grained that the network and operational overhead outweighs their function: a service per database table, or per function. Each adds a pipeline, an on-call surface, a versioned API and network hops.

Shared-library coupling occurs when services share a library containing domain model classes or business logic. Updating the library forces every service to rebuild and redeploy, often in lockstep, and the library's model becomes a hidden shared kernel. Sharing infrastructure libraries (logging, tracing, an RPC client) is fine if versions can differ between services; sharing domain models is not.

34.14.3 Synchronous call chains

FORMULA

Availability and latency of a synchronous call chain

$$A_{\text{chain}} = \prod_{i=1}^{n} A_i = A^n \ \text{(equal services)} \qquad L_{\text{chain}} = \sum_{i=1}^{n} (R_i + s_i)$$

Symbol	Meaning	Units
n	Number of services that must all succeed for the request	count
A_i	Availability of service i (independent failures assumed)	dimensionless
A_{chain}	Availability of the request path	dimensionless
R_i, s_i	Round-trip and processing time of hop i	ms
L_{chain}	End-to-end latency of the chain	ms

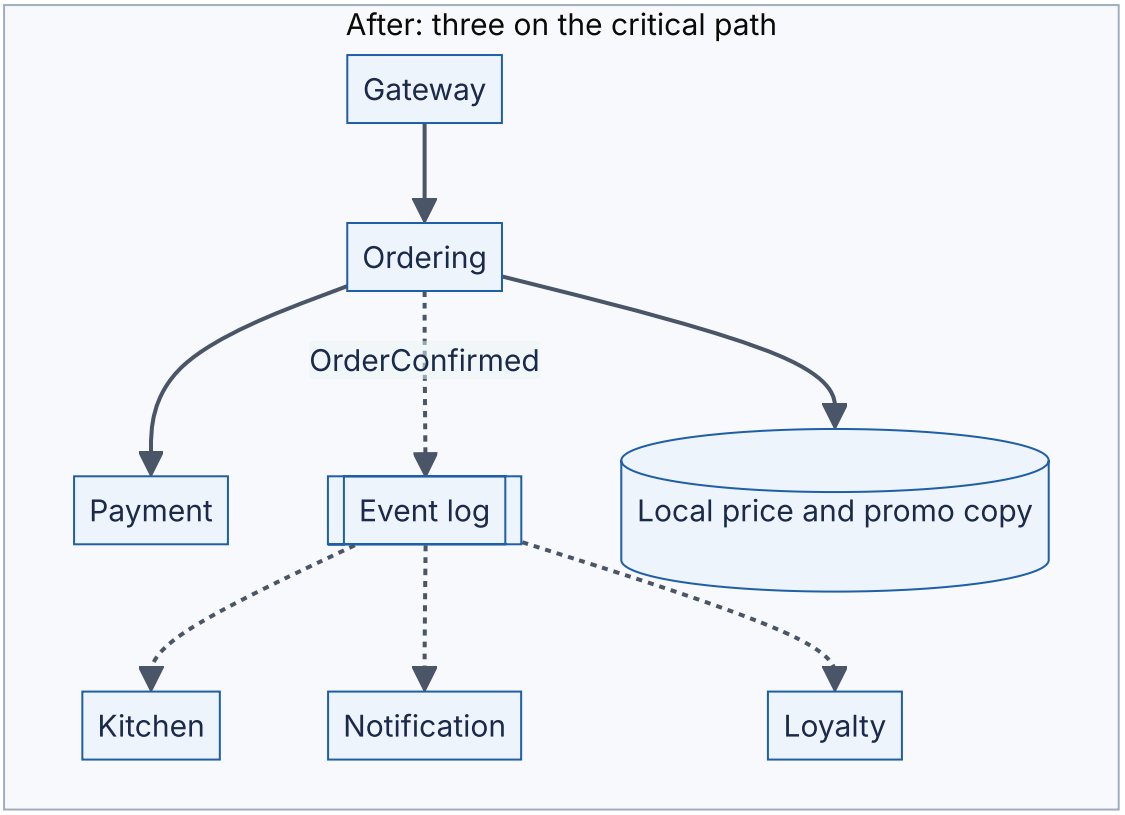
WORKED EXAMPLE

Worked example — QuickBite checkout as a chain. Each service is 99.9% available. A distributed-monolith checkout calls gateway → BFF → Ordering → Pricing → Payment, five in sequence. Over a 30-day month (720 hours):

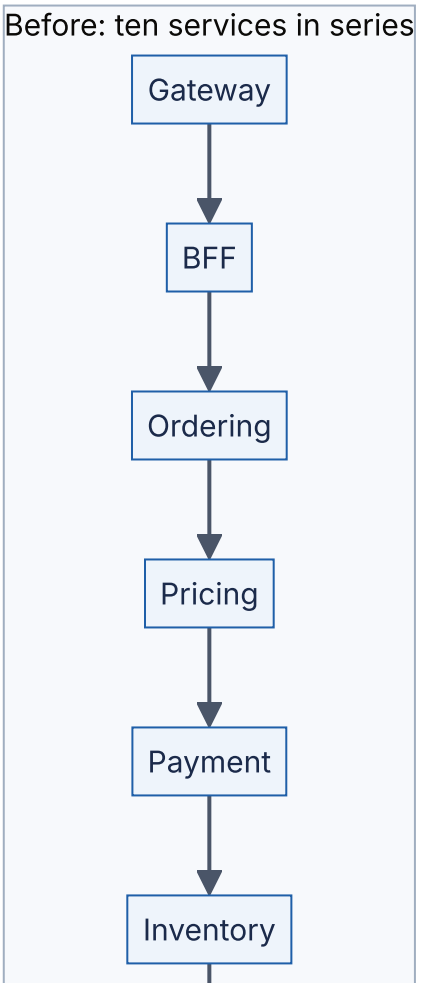
1. Five in series: $A = 0.999^5 = 0.99501$; unavailability $0.00499 \times 720 = 3.59$ hours/month.
2. Ten in series (add Inventory, Promotions, Kitchen, Notification, Loyalty synchronously): $A = 0.999^{10} = 0.99004$; $0.00996 \times 720 = 7.17$ hours/month.
3. Redesign with three services on the critical path (gateway, Ordering, Payment) and the rest asynchronous: $A = 0.999^3 = 0.99700$; 2.16 hours/month.
4. Latency at 0.5 ms network, 0.25 ms mesh and 10 ms processing per hop: ten hops cost $10 \times 10.75 = 107.5$ ms; three cost 32.25 ms.

Interpretation. Every synchronous dependency multiplies in its unavailability: ten 99.9% services give barely two nines. Retries help only against transient faults, and correlated failures (a shared database or cluster) make reality worse than the independence assumption. **Engineering implication.** Count the services on each critical path and keep it short; move non-essential work to events; and for remaining synchronous calls use timeouts, fallbacks and circuit breakers (Chapter 22) so a non-essential dependency degrades the response instead of failing it.

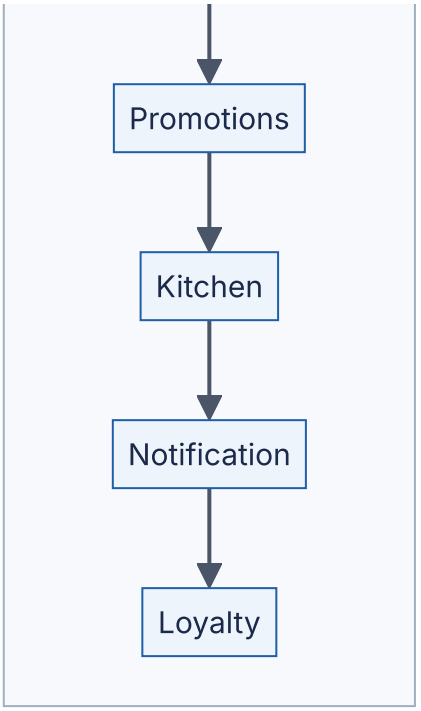
Figure 34.14 — Shortening the critical path.



After: three on the critical path
Gateway
Ordering
OrderConfirmed
Payment
Event log
Local price and promo copy
Kitchen
Notification
Loyalty



Before: ten services in series
Gateway
BFF
Ordering
Pricing
Payment
Inventory



Reading the diagram. Before, ten synchronous calls must all succeed in order; any failure fails checkout, and latency is the sum of all hops. After, only the gateway, Ordering and Payment are on the synchronous path. Pricing and promotion rules are replicated into a local copy that Ordering reads (a storage boundary inside Ordering, fed by events). Kitchen, Notification and Loyalty consume `OrderConfirmed` asynchronously from the event log. Inventory is checked from a local, event-fed availability copy (not shown). Failure points shrink to three services plus the outbox relay, whose failure delays but does not lose events. Scaling: asynchronous consumers scale on backlog.

INDUSTRY EXAMPLE

Two public reversals. Segment described consolidating more than a hundred destination microservices back into a single service after the operational cost of many tiny services, shared-library versions and per-service queues outgrew the benefit [Noonan 2018]. Amazon Prime Video's monitoring team reported cutting infrastructure cost by about 90% by moving an audio/video quality-inspection workload from distributed serverless components to a single process, because passing frames between components dominated the cost [Kolny 2023]. Neither is an argument against services in general; both show granularity chosen without regard to the data flow. *Evidence: Primary* — [Noonan 2018; Kolny 2023]

Table 34.8 — Anti-patterns at a glance.

Anti-pattern	Symptom	Fix
Distributed monolith	Lockstep releases	Re-cut boundaries by capability and change coupling; expand and contract
Shared database	Schema changes need many teams	Database-per-service; events; CQRS views
Nanoservices	More services than engineers	Merge into capability-sized services
Shared domain library	Library bump forces fleet redeploy	Share only infrastructure; each context owns its model
Long synchronous chains	A^n availability; summed latency	Events, local copies, fewer hops
Gateway with business logic	Every change goes through the platform team	Move logic into services or BFFs

34.15 Summary and revision notes

SUMMARY

- A microservice is built around one business capability, owned by one team, independently deployable and the sole owner of its data. Its main benefit is independent change; its main cost is distribution.
- Choose boundaries by cohesion and change coupling ($C = n_{AB}/(n_A + n_B - n_{AB})$ from version history), team ownership and transaction boundaries, not by technical layer or size.
- DDD supplies the model: ubiquitous language, entities, value objects, small aggregates (one transaction, one aggregate; conflict probability $1 - e^{-\lambda w}$) and domain events.
- Bounded contexts are the best first service boundaries. Context maps make relationships explicit; an anticorruption layer keeps foreign models out. Event storming finds the boundaries.
- An API gateway handles edge concerns; BFFs shape APIs per client and save expensive round trips. Keep business logic out of both.
- Service discovery combines a registry, health checks and client-side or server-side lookup. Stale entries persist for about $k \cdot h + t_{\text{prop}} + t_{\text{cache}}$, so add passive ejection and retries.
- Prefer one synchronous call on the critical path and events elsewhere; batch chatty calls; fan-out exposes you to p^N tails; version with expand and contract; verify compatibility with consumer-driven contracts.
- Tracing links spans across services by propagating trace context; Chapter 40 goes deeper.
- A service mesh moves mTLS, retries and telemetry into proxies; sidecars add roughly 0.2–0.25 ms per hop and per-pod memory; Istio’s ambient mode (GA in 1.24) uses per-node ztunnels and optional waypoints.
- Database-per-service is mandatory; share data by events, query with API composition or CQRS views, and keep invariants inside one service or use sagas.
- Migrate with the strangler fig, branch by abstraction and parallel run, least-coupled capabilities first.
- The distributed monolith is the main failure mode; synchronous chains have availability A^n.

34.16 Knowledge checkpoint

1. State four properties of a microservice.
2. Modules A and B were touched by 50 and 40 commits, 30 of them shared. Compute $C(A, B)$ and interpret it.

3. Why is content coupling worse than domain coupling?
4. Distinguish an entity from a value object, with one QuickBite example of each.
5. An aggregate receives 5 writes/s from others and each write takes 40 ms. What is the conflict probability?
6. What is the difference between a conformist relationship and an anticorruption layer?
7. Why should an unknown payment status raise an error in an ACL while an unknown decline code may map to a default?
8. A mobile screen needs 5 sequential calls, mobile RTT 80 ms, service time 10 ms, datacenter RTT 1 ms. Compare direct calls with a BFF calling sequentially.
9. Why does Eureka keep possibly stale instances during a heartbeat drop?
10. Health checks every 5 s, 3 misses, 1 s propagation, 10 s client cache: what is the stale window?
11. What does a consumer-driven contract check, and what does it not check?
12. What does the `traceparent` header carry?
13. Name the two layers of Istio ambient mode and what each handles.
14. With 300 pods, 60 MB per sidecar and 15,000 internal requests/s at 0.2 vCPU per 1,000 requests/s per proxy, estimate sidecar memory and CPU.
15. When would you choose a CQRS view over API composition?
16. What is the availability of eight services in series at 99.95% each, and the monthly downtime?

Answers

1. Built around one business capability; owned by one team; independently deployable; sole owner of its data.
2. $30/(50 + 40 - 30) = 0.5$: half of all changes to either touch both; they probably belong together or need a better interface.
3. Content coupling lets another service change your internal state directly, so you can no longer enforce invariants or change your schema; domain coupling only uses your published API.
4. An entity has identity over time (an `Order`); a value object is defined by its attributes and immutable (`Money`).
5. $1 - e^{-5 \times 0.04} = 1 - e^{-0.2} = 0.181$.
6. A conformist adopts the upstream model unchanged; an ACL translates it into the downstream's own model.
7. Mapping an unknown decline code to `OTHER` still declines the order safely; guessing whether an unknown status means money moved could ship unpaid orders or double-charge.
8. Direct: $5 \times 90 = 450$ ms. BFF: $80 + 5 \times 11 = 135$ ms.
9. A sudden drop in heartbeats is more likely a network problem than mass failure; a stale list is better than none (availability over consistency).
10. $3 \times 5 + 1 + 10 = 26$ s.

11. It checks that the provider still satisfies the request and response shapes the consumer relies on; it does not check business correctness.
12. A version, the trace ID, the parent span ID and trace flags such as sampled.
13. ztunnel, a per-node L4 proxy for mTLS, identity and L4 policy; waypoint proxies for L7 routing, retries and policy where needed.
14. Memory $300 \times 60 = 18,000$ MB $= 18$ GB; CPU $(15,000 \times 2/1,000) \times 0.2 = 6$ vCPU.
15. When the query is frequent, joins many owners or needs search or aggregation, and seconds of staleness are acceptable.
16. $0.9995^8 = 0.99601$; about $0.004 \times 720 = 2.87$ hours per month.

34.17 Interview questions

Basic

Q1. How do you decide service boundaries? Answer. Start from business capabilities and bounded contexts, found with event storming. Check that each candidate has one owning team, keeps its invariants inside one transaction and has low change coupling with its neighbors (measured from history). Prefer coarse services first and split on evidence such as different scaling or release needs.

Q2. What does an API gateway do, and what should it not do? Answer. It is the single entry point: TLS termination, authentication, rate limiting, routing, observability and sometimes aggregation. It should not contain business logic, which would make it a shared monolith that every team must change.

Intermediate

Q3. Orders, payments and inventory each have their own database. How do you place an order consistently? Answer. Keep payment authorization synchronous if the customer needs the result, and make the overall flow a saga: each service commits locally and publishes events through an outbox; failures trigger compensations (release stock, refund). Consumers are idempotent. Explain the accepted intermediate states and how the UI shows them.

Q4. How do you prevent a provider change from breaking consumers without end-to-end test environments? Answer. Consumer-driven contracts: consumers generate contracts from their tests and publish them to a broker; the provider verifies all of them in CI using provider states; deployment is gated on verification against the versions in the target environment. Combine with additive changes, tolerant readers and expand and contract.

Advanced

Q5. Should we adopt a service mesh? Answer. Identify the problem: uniform mTLS and identity-based policy, polyglot telemetry and traffic shifting are good reasons. Quantify cost: about 0.2–0.25 ms per hop at p99 for two proxies, CPU proportional to internal traffic, memory per pod for sidecars. Consider ambient mode to cut per-pod cost, and plan for control-plane operations, upgrades and retry duplication with libraries.

Q6. A company has 120 services, releases need coordination and incidents cascade. Diagnose and plan. Answer. Likely a distributed monolith. Measure change coupling between services, map synchronous critical paths and compute their A^n, and find shared databases and shared domain libraries. Merge strongly coupled services, move non-essential calls to events with local copies, introduce contract testing and expand-and-contract, and set ownership so each service has one team. Track deploy independence and critical-path length as metrics.

34.18 Practical exercises

1. Compute change coupling for every pair of top-level directories in a repository you know, using `git log --name-only`; list the five most coupled pairs.
2. Extend the ACL of §34.5.3 with a refund response and outbound translation of a `ChargeRequest`; add tests.
3. Extend the contract library of §34.8.5 with an array matcher (`each_like`) and a message (event) contract.
4. Simulate the stale-endpoint window of §34.7.3 with 20 instances, one crash and passive ejection after 5 errors; compare failures with and without retries.
5. Draw QuickBite's context map for a new "group ordering" feature and state each relationship pattern.

34.19 Design challenges

1. **Ride-hailing decomposition.** Propose bounded contexts, a context map and the synchronous critical path for "request a ride"; compute its availability at 99.9% per service.
2. **Strangling a billing monolith.** Plan a four-phase migration of invoicing out of a 15-year-old ERP, with ACLs, CDC and a parallel run; define exit criteria per phase.
3. **Mesh or library.** A trading platform has a 2 ms internal latency budget across 3 hops and 40,000 requests/s. Decide between sidecars, ambient mode and an RPC library, with numbers.

Chapter 35 — Object-Oriented Design

> **Level:** 1–2 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

The high-level design decides which services exist and how they talk (§1.5); the low-level design decides what happens *inside* one service. Object-oriented design is the most common vocabulary for that inside view. It answers a practical question: how do you arrange thousands of lines of code so that a rule lives in one place, a change touches few files, and a mistake is caught where it happens?

This chapter builds that vocabulary from variables, functions and loops alone, using one running example: the checkout of a small online shop. You start with a product and a cart, protect the cart's rules, add kinds of products, discount rules and payment methods, untangle a hierarchy that grows out of control, write down each class's promises, and measure how well the pieces fit. Every idea is shown in Python and Java side by side; all programs were run (Python 3.13, Java 21).

35.1 Learning objectives

After this chapter you should be able to:

- Write classes whose constructors reject invalid state, and distinguish identity from equality.
- Protect invariants with encapsulation, avoid setter-driven designs, and apply "tell, don't ask".
- Use inheritance and overriding, and demonstrate the fragile base class problem.
- Explain dynamic dispatch, duck typing and simple generics.
- Choose between an abstract class and an interface.
- Refactor an inheritance hierarchy into composition and quantify the saving.
- Write preconditions, postconditions and invariants, and explain why a subclass may not strengthen a precondition.
- Classify coupling and cohesion, compute LCOM1, and apply the Law of Demeter.
- Recognize the anemic domain model, the god class and deep hierarchies.

35.2 Prerequisites

- Basic programming: variables, functions, `if`, loops, lists and dictionaries.

- High-level vs low-level design — §1.5 (this chapter is the toolbox for low-level design).

SOLID is Ch 36, design patterns Ch 37, and UML notation and full low-level design exercises Ch 38. The class diagrams here use a few Mermaid symbols, explained as they appear.

35.3 Classes and objects

35.3.1 State plus behavior

DEFINITION

Definition — Object. A value in a running program that bundles **state** (data, stored in **attributes** or **fields**) with **behavior** (functions that operate on that data, called **methods**). Each object has its own copy of the state.

DEFINITION

Definition — Class. A template that describes the attributes and methods every object of a kind will have. Creating an object from a class is called **instantiation**; the object is an **instance** of the class.

First-principles explanation

A blank paper order form is printed once; every filled-in copy is separate. A class is the blank form; an object is a filled-in copy that also carries the instructions for working with its contents: a cart object knows how to add an item and total itself.

Without objects, you keep data in a dictionary and write free-standing functions such as `cart_add(cart_dict, product, 2)`. That works until another team writes `cart_dict["items"].append(...)` directly, skipping the rules. Objects put the data and the sanctioned ways of changing it in one place.

Why does this exist?

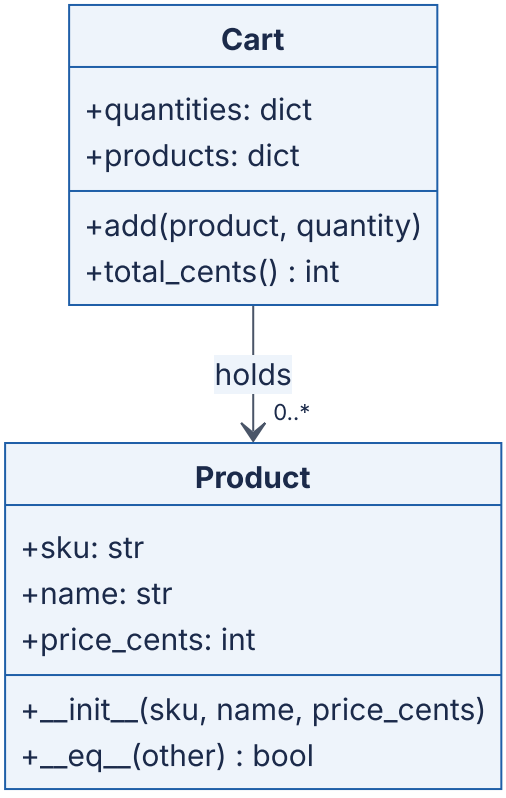
Programs model things that have data and rules: a cart has lines, and quantities must be positive. When data and rules live in different files, someone eventually changes the data without the rules. Classes (Simula 67, then Smalltalk, C++, Java, Python) keep them together.

How it works internally

1. The class definition is loaded once and holds the method code shared by all instances.
2. Calling the class (`Product(...)`, Java `new Product(...)`) allocates memory for a new object.
3. The **constructor** (`__init__`, or Java's method named after the class) puts the object into a valid starting state, or refuses by raising an exception.
4. `obj.method(args)` runs the method with `obj` passed implicitly (`self` in Python, `this` in Java), so it works on *that* object's state.
5. When nothing refers to the object any more, the garbage collector reclaims it.

Architecture diagram

Figure 35.1 — The first shop model: products in a cart.



Reading the diagram.

- **Components.** Each box is a class: name, then attributes (state), then methods (behavior). `+` means public.
- **Direction.** `Cart` refers to zero or more (`0..*`) products; a product knows nothing about carts.
- **Sync/async and storage.** Synchronous in-process calls; objects live in memory only.

- **Failure points.** Every attribute is public, so any code can set `price_cents` to −5 after construction. The constructor protects only the moment of creation; §35.4 fixes this.
- **Scaling.** A new field is added in one class and every instance gets it.

Code example

Prices are stored as integer cents, never floating point, because `0.1 + 0.2` is not exactly `0.3` in binary floating point and money must add up exactly.

```
        class Product:
            """Something the shop sells. Two products are equal if their SKUs match."""

            def __init__(self, sku, name, price_cents):
                if not sku:
                    raise ValueError("sku must be non-empty")
                if price_cents < 0:
                    raise ValueError("price_cents must be >= 0")
                self.sku = sku                  # state: three attributes
                self.name = name
                self.price_cents = price_cents

            def __eq__(self, other):            # equality: "same SKU"
                return isinstance(other, Product) and self.sku == other.sku

            def __hash__(self):                 # equal objects must hash equally
                return hash(self.sku)

        class Cart:
            """A shopping cart. Each cart is a distinct thing, even if two hold the same
items."""

            def __init__(self):
                self.quantities = {}            # sku -> quantity
                self.products = {}              # sku -> Product

            def add(self, product, quantity=1): # behavior
                self.products[product.sku] = product
                self.quantities[product.sku] = self.quantities.get(product.sku, 0) +
quantity

            def total_cents(self):
                return sum(self.products[s].price_cents * q for s, q in
self.quantities.items())

        mug_a = Product("SKU-MUG", "Mug", 1299)
        mug_b = Product("SKU-MUG", "Mug", 1299)
        print(mug_a == mug_b, mug_a is mug_b)        # True False

        cart1, cart2 = Cart(), Cart()
        cart1.add(mug_a, 2)
        cart2.add(mug_b, 2)
        print(cart1.total_cents())                   # 2598
        print(cart1 == cart2, cart1 is cart2)        # False False

        try:
            Product("SKU-BAD", "Broken", -5)
        except ValueError as e:
            print("rejected:", e)                    # rejected: price_cents must be >=
0
```

```
        import java.util.LinkedHashMap;
        import java.util.Map;

        final class Product {
            final String sku;                          // state: three fields
            final String name;
            final long priceCents;

            Product(String sku, String name, long priceCents) {   // constructor
                if (sku == null || sku.isEmpty())
                    throw new IllegalArgumentException("sku must be non-empty");
                if (priceCents < 0)
                    throw new IllegalArgumentException("priceCents must be >= 0");
                this.sku = sku;
                this.name = name;
                this.priceCents = priceCents;
            }

            @Override public boolean equals(Object o) {          // equality: "same SKU"
                return o instanceof Product other && sku.equals(other.sku);
            }

            @Override public int hashCode() {                    // equal objects, equal
hashes
                return sku.hashCode();
            }
        }

        class Cart {
            final Map<String, Integer> quantities = new LinkedHashMap<>();
            final Map<String, Product> products = new LinkedHashMap<>();

            void add(Product product, int quantity) {            // behavior
                products.put(product.sku, product);
                quantities.merge(product.sku, quantity, Integer::sum);
            }

            long totalCents() {
                long total = 0;
                for (var e : quantities.entrySet())
                    total += products.get(e.getKey()).priceCents * e.getValue();
                return total;
            }
        }

        class Main {
            public static void main(String[] args) {
                Product mugA = new Product("SKU-MUG", "Mug", 1299);
                Product mugB = new Product("SKU-MUG", "Mug", 1299);
                System.out.println(mugA.equals(mugB) + " " + (mugA == mugB));     //
true false

                Cart cart1 = new Cart(), cart2 = new Cart();
                cart1.add(mugA, 2);
                cart2.add(mugB, 2);
                System.out.println(cart1.totalCents());                           //
```

```
2598
                System.out.println(cart1.equals(cart2) + " " + (cart1 == cart2)); //
false false

                try {
                    new Product("SKU-BAD", "Broken", -5);
                } catch (IllegalArgumentException e) {
                    System.out.println("rejected: " + e.getMessage());
                }
            }
        }
```

What to notice:

- The constructor is the gatekeeper: an invalid `Product` is never created.
- Python creates attributes on first assignment; Java declares typed fields up front, and `final` means "assigned once".
- `mug_a == mug_b` is `True` because `Product` defines equality by SKU. `cart1 == cart2` is `False` even though both carts hold the same items, because `Cart` does not define equality and falls back to identity.

35.3.2 Identity versus equality

DEFINITION

Definition — Identity and equality. Identity asks "are these the same object in memory?" (Python `is`, Java `==` on references). **Equality** asks "do these objects represent the same value by a rule the class defines?" (Python `==` via `__eq__`, Java `equals`). Unless a class overrides equality, both languages default to identity.

Two copies of the same banknote are interchangeable; two customers named "Ada Lopez" are not. A **value object** (a price, an address) is defined by its attributes, so equality compares attributes and the object is usually immutable. An **entity** (a customer, an order, a cart) has an identity that persists while its attributes change; two carts with the same contents are still two carts.

Table 35.1 — Identity and equality in Python and Java.

Question	Python	Java	Default if not overridden
Same object?	`a is b`	`a == b` (references)	—
Same value?	`a == b` → `__eq__`	`a.equals(b)`	Identity
Hash consistent with equality	`__hash__`	`hashCode()`	Identity-based
Typical value object	`@dataclass(frozen=True)`	`record`	—

The rule that trips people up: **equal objects must have equal hashes**. Hash tables find a bucket by hash, then compare with equality. Override `equals` without `hashCode` in Java and a `HashSet` can hold "duplicates" [Bloch 2018, Items 10–11]. Python defining `__eq__` without `__hash__` makes instances unhashable, a loud `TypeError` instead of a silent duplicate.

Failure scenarios

Table 35.2 — Failure scenarios for classes, constructors and equality.

What goes wrong	Why	Detection	Recovery	Prevention
Duplicate products in a set	`equals` overridden, `hashCode` not	Set size larger than expected	Add `hashCode` from the same fields	Records/dataclasses generate both
Object found then "lost" in a map	Mutable field used in the hash changed after insertion	Lookups return `None` for present keys	Remove and reinsert	Hash only immutable fields
Invalid object deep in the system	Constructor accepted bad input	Errors far from the cause	Fix the creating code	Validate in the constructor

COMMON MISTAKE

Misconception — "Objects are just dictionaries with functions attached." Mechanically, a Python object nearly is one. The design point is different: a class decides *which* changes to its state are allowed. A dictionary allows every change, which is why the rules end up scattered across the code that uses it.

35.4 Encapsulation

35.4.1 Invariants and information hiding

DEFINITION

Definition — Encapsulation. Keeping an object's state private and allowing it to change only through the object's own methods, so the object can guarantee its own rules. **Information hiding** [Parnas 1972] is the broader design principle behind it: each module hides a design decision that is likely to change (a data layout, an algorithm) behind an interface that is not.

> DEFINITION
>
> **Definition — Class invariant.** A condition on an object's state that is true whenever no method of the object is running: after the constructor finishes and after every public method returns.

First-principles explanation

You cannot walk into a bank vault; you ask the teller, who checks your balance first. The counter is encapsulation, and "no account goes below zero" holds precisely because every withdrawal goes through the teller. One side door into the vault, and the rule becomes something every visitor must remember.

In Figure 35.1, any code can write `cart.quantities["SKU-MUG"] = -3`. The cart can promise nothing about its contents, so every reader must defend itself, and the one that forgets causes the bug.

Why does this exist?

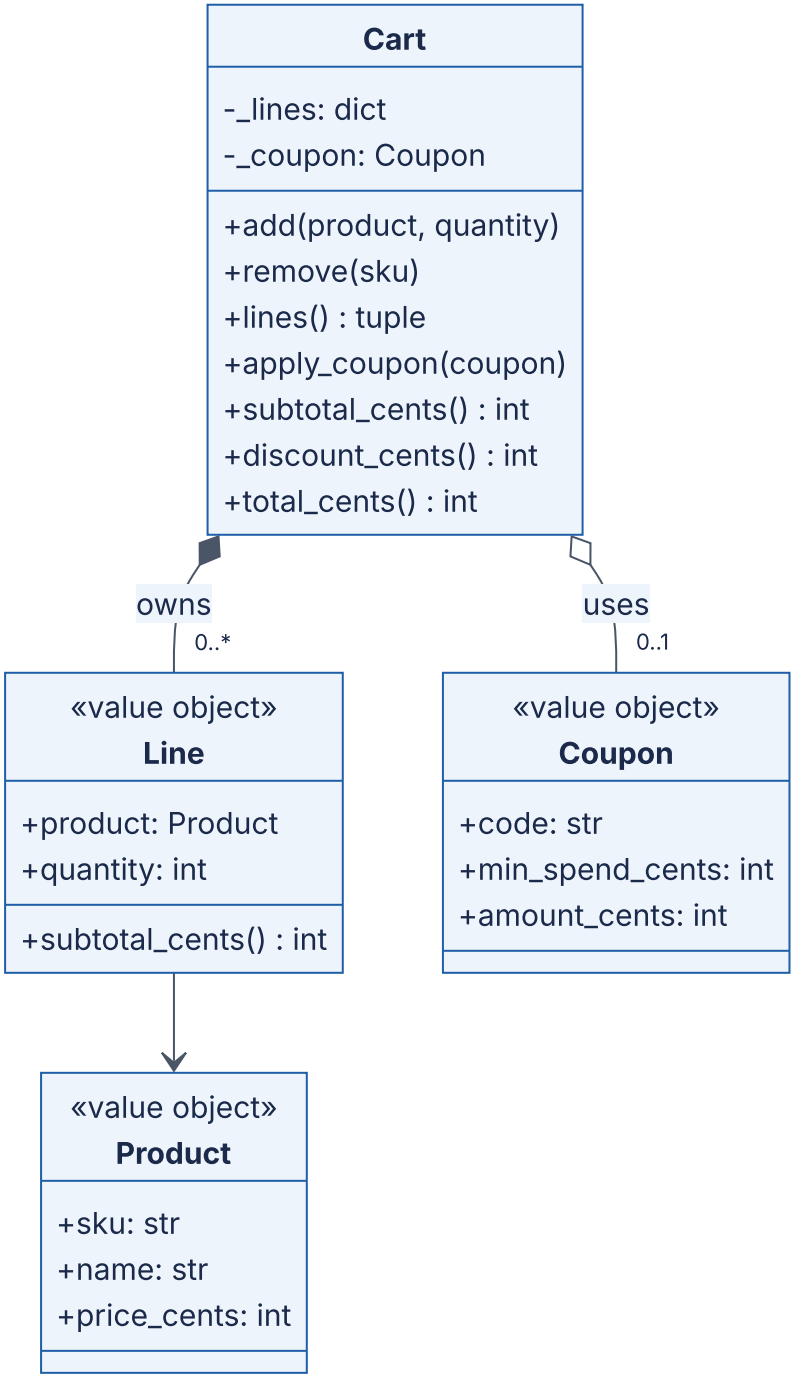
1. **Correctness.** If the only way to change quantities is `add` and `remove`, checking the rule in those two methods proves it for the whole program.
2. **Change.** If callers read `cart.quantities` directly, you cannot change how quantities are stored without editing every caller. Parnas's 1972 argument was exactly this: decompose by the decisions likely to change, and hide each one.

How it works internally

- **Java** enforces access in the compiler: `private` (class only), package-private (no modifier), `protected` (subclasses and package), `public`.
- **Python** has no enforced privacy. A leading underscore (`_lines`) is a convention meaning "internal"; a double underscore triggers **name mangling** (`_Cart__lines`), which avoids clashes in subclasses but stops nobody determined.
- The stronger tool in both is **immutability**: Python's `@dataclass(frozen=True)` and Java's `record` produce objects whose state cannot change after construction.
- Return a **copy** or **read-only view** of internal data, never the internal collection.

Architecture diagram

Figure 35.2 — The encapsulated cart.



Reading the diagram.

- **Components.** `Cart` is the entity that enforces the rules; `Line`, `Coupon` and `Product` are immutable value objects (`<<value object>>` is a free-text label). `-` marks private members: the only doors into `Cart` are its public methods.
- **Relationships.** The filled diamond (`*--`) means the cart *owns* its lines; the hollow diamond (`o--`) means it *uses* a coupon that exists independently (Ch 38 covers the notation).
- **Sync/async and storage.** Synchronous, in memory.

- **Failure points.** Only a bug inside `Cart` can break the invariants, and `lines()` returns an immutable snapshot, not a side door.
- **Scaling.** The dictionary could become a database-backed store without changing any caller.

Code example

```
        from dataclasses import dataclass

        MAX_QTY_PER_LINE = 10

        @dataclass(frozen=True)
        class Product:
            sku: str
            name: str
            price_cents: int

        @dataclass(frozen=True)
        class Line:                                 # immutable: safe to hand out
            product: Product
            quantity: int

            def subtotal_cents(self):
                return self.product.price_cents * self.quantity

        @dataclass(frozen=True)
        class Coupon:
            code: str
            min_spend_cents: int
            amount_cents: int

        class Cart:
            """Invariants:
            1. every line has 1 <= quantity <= MAX_QTY_PER_LINE
            2. 0 <= total_cents() <= subtotal_cents()
            """

            def __init__(self):
                self._lines = {}                    # sku -> Line; underscore = "private,
keep out"
                self._coupon = None

            def add(self, product, quantity=1):
                if quantity < 1:
                    raise ValueError("quantity must be >= 1")
                current = self._lines.get(product.sku)
                new_qty = quantity + (current.quantity if current else 0)
                if new_qty > MAX_QTY_PER_LINE:

            }

            long totalCents() { return subtotalCents() - discountCents(); }
        }

        class Main {
            public static void main(String[] args) {
                Product mug = new Product("SKU-MUG", "Mug", 1299);
```

```
                Product tea = new Product("SKU-TEA", "Green tea", 2450);
                Cart cart = new Cart();
                cart.add(mug, 2);
                cart.add(tea, 1);
                cart.applyCoupon(new Coupon("SAVE5", 5000, 500));
                System.out.println(cart.subtotalCents() + " " + cart.discountCents() + "
" + cart.totalCents());
                cart.remove("SKU-TEA");
                System.out.println(cart.subtotalCents() + " " + cart.discountCents() + "
" + cart.totalCents());
                try {
                    cart.add(mug, 9);
                } catch (IllegalArgumentException e) {
                    System.out.println("rejected: " + e.getMessage());
                }
                try {
                    cart.lines().clear();
                } catch (UnsupportedOperationException e) {
                    System.out.println("rejected: " + e.getClass().getSimpleName());
                }
            }
        }
```

What to notice:

- The cart stores no `total` field. The total is *derived* from the lines and the coupon each time it is asked for, so it can never disagree with them. When the tea is removed, the subtotal falls to 2,598 cents, below the 5,000-cent minimum, and the discount disappears automatically. A stored total updated through a setter would have kept the stale 500-cent discount.
- Both invariants are enforced in one place: adding 9 mugs to a line of 2 is refused because 11 > 10.
- `lines()` returns frozen dataclasses or records in an immutable collection: callers can read everything and change nothing.

35.4.2 Getters and setters: the pitfalls

A **getter** returns a field (`get_price()`), a **setter** assigns one (`set_price(x)`). Generating both for every private field satisfies the letter of encapsulation and defeats its purpose: a setter for every field is a public field with extra typing.

1. **Setters bypass invariants.** `line.set_quantity(-3)` creates a state no business rule permits. Expose operations named after the business action (`apply_coupon`, `remove`), which can check the rule.
2. **Getters leak representation.** `get_lines()` returning the internal mutable list is a side door: `cart.get_lines().clear()` empties the cart without going through any method. Bloch's example is a `Period` class whose start and end are mutable `java.util.Date` objects: a caller who keeps a reference can move the end before the

start. His remedy is **defensive copying** of mutable inputs and outputs [Bloch 2018, Item 50].

3. **Getters invite logic to move outside.** Callers that can read `quantity`, `price` and `coupon` start computing totals themselves, and the discount rule is copied into the checkout page, the email and the invoice.

Read-only access to immutable values (`product.sku`) is harmless and needed for display. The test is whether the caller then *makes a decision* the object should have made.

35.4.3 Tell, don't ask

> KEY CONCEPT
>
> **Tell, don't ask.** Rather than asking an object for its data and deciding what to do with it, tell the object what you want and let it decide [Fowler 2013, "TellDontAsk"]. The rule that uses the data then lives with the data.

```
        # Asking: the caller pulls data out and makes the decision.   # illustrative
        if cart.subtotal_cents() >= 5000:
            cart.discount_cents = 500          # requires a writable field; the rule is
now out here

        # Telling: the cart owns the rule.
        cart.apply_coupon(Coupon("SAVE5", min_spend_cents=5000, amount_cents=500))
```

```
        // Asking (illustrative): the rule lives in the caller and needs a setter.
        if (cart.subtotalCents() >= 5000) cart.setDiscountCents(500);

        // Telling: the cart owns the rule.
        cart.applyCoupon(new Coupon("SAVE5", 5000, 500));
```

The asking version needs a writable discount field, and when the tea is removed nobody re-checks the minimum spend. The telling version re-evaluates the rule every time because it lives inside the cart.

Real-world industry applications

INDUSTRY EXAMPLE

`java.util.Date` versus `java.time`. `java.util.Date` is mutable: a class that stores a `Date` passed by a caller, or returns its own `Date` from a getter, can have its state changed from outside, which is why *Effective Java* uses it as the example for defensive copying. The `java.time` API introduced in Java 8 (JSR 310) made its date and time classes immutable and documents them as thread-safe, which removes the need for defensive copies entirely. *Evidence: Primary* — [Bloch 2018, Items 17 and 50]; [Oracle: java.time package documentation]

Advantages and disadvantages

- **Advantages.** Invariants checked in one place; representation can change freely; immutable values can be shared, even across threads.
- **Disadvantages.** More methods to design; immutability means a new object per change (costly for large, often-updated collections); Python's privacy depends on discipline.

Failure scenarios

Table 35.3 — Failure scenarios for encapsulation.

What goes wrong	Why	Detection	Recovery	Prevention
Negative quantity reaches the invoice	Public field or setter	Data-quality checks, customer complaint	Correct data, add the check	Business-named methods with validation
Cart emptied by a report job	Getter returned the internal list	Hard to trace "spooky" changes	Return a copy	Copies or read-only views
Stale discount after item removal	Derived value stored and set from outside	Totals disagree with lines	Recompute	Derive, don't store

COMMON MISTAKE

Misconception — "Private fields plus getters and setters equals encapsulation." Encapsulation is about who may make which state changes. Ask which *operations* the business allows on the object, and expose those.

35.5 Inheritance

35.5.1 Is-a relationships and method overriding

> DEFINITION
>
> **Definition — Inheritance.** A mechanism by which a class (the **subclass**, **child** or **derived class**) is defined as an extension of another (the **superclass**, **parent** or **base class**). The subclass automatically has the parent's attributes and methods, may add new ones, and may **override** inherited methods by providing its own version with the same name and parameters.

First-principles explanation

The shop now sells a mug (physical: it has a weight and costs money to ship) and an e-book (digital: a download link, free shipping). Both have a SKU, name and price. Copying `Product` twice means every fix is made twice. Inheritance says "a physical product *is a* product, plus a weight and its own shipping rule": shared code is written once in the parent, and each child states only what differs.

The **is-a** test applies to *behavior*, not everyday language: everything the code does with a product must make sense for a physical product. §35.9 makes this precise.

Why does this exist?

It provides **reuse** (shared code in the parent) and, more importantly, **substitutability**: code written for `Product` works unchanged for every subclass, including ones written years later. That makes polymorphism (§35.6) possible. The GoF call inheritance-for-reuse **white-box reuse**, because the subclass sees the parent's internals, and warn that "inheritance breaks encapsulation" [Gamma et al. 1994, ch. 1]. §35.5.2 shows how.

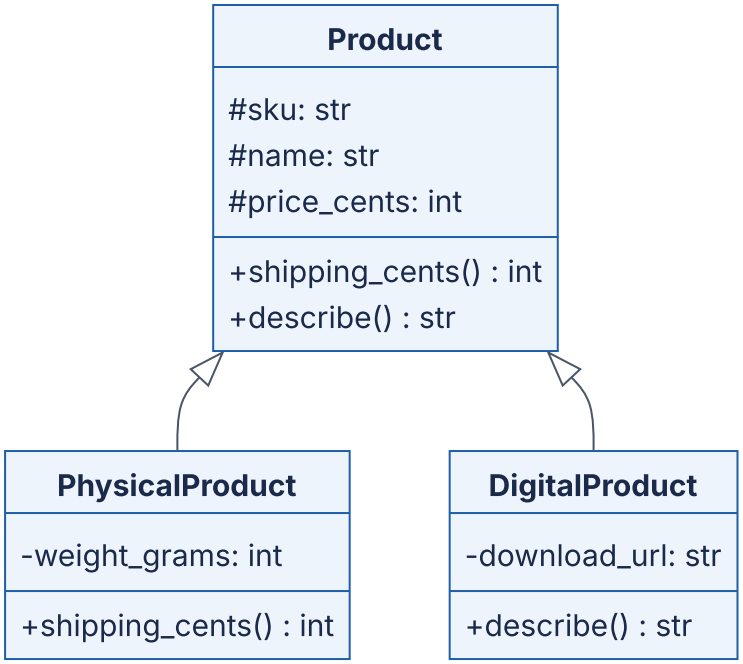
How it works internally

1. The subclass names its parent: `class PhysicalProduct(Product)` or `extends Product`. Java allows one parent class; Python allows several, resolved by the method resolution order.
2. The subclass constructor initializes the parent's part first with `super().__init__(...)` or `super(...)`.
3. A call `p.shipping_cents()` looks for the method in the object's actual class, then its parent, up the chain; the first match runs. That is how an override replaces inherited behavior.
4. An override can call the parent's version with `super` to extend rather than replace it.

5. Java's `@Override` makes the compiler confirm a parent method exists, catching typos that would silently create a new method.

Architecture diagram

Figure 35.3 — Products by inheritance.



Reading the diagram.

- **Components.** `PhysicalProduct` adds a weight and overrides `shipping_cents`; `DigitalProduct` adds a URL and overrides `describe`. `#` means protected (visible to subclasses): the white-box coupling.
- **Direction.** The hollow triangle (`<|--`) points from child to parent and reads "is a"; the parent does not know its children.
- **Sync/async and storage.** Synchronous in-process calls; no storage.
- **Failure points.** Every change to `Product` reaches both children; a parent method assuming every product has a weight breaks `DigitalProduct`.
- **Scaling.** A third kind of product is one subclass; a *second* axis of variation is a different story (§35.8).

Code example

Shipping is 399 cents plus 50 cents per started 100 g. The mug weighs 350 g, which starts 4 blocks of 100 g, so shipping is $399 + 4 \times 50 = 599$ cents.

```
        class Product:
            def __init__(self, sku, name, price_cents):
                self.sku = sku
                self.name = name
                self.price_cents = price_cents

            def shipping_cents(self):
                return 0                                  # default: nothing to ship

            def describe(self):
                return f"{self.name} ({self.price_cents / 100:.2f})"

        class PhysicalProduct(Product):                   # PhysicalProduct IS-A Product
            BASE_CENTS = 399
            CENTS_PER_100G = 50

            def __init__(self, sku, name, price_cents, weight_grams):
                super().__init__(sku, name, price_cents)  # let the parent set up its
part
                self.weight_grams = weight_grams

            def shipping_cents(self):                     # override
                hundreds = -(-self.weight_grams // 100)   # ceiling division
                return self.BASE_CENTS + self.CENTS_PER_100G * hundreds

        class DigitalProduct(Product):
            def __init__(self, sku, name, price_cents, download_url):
                super().__init__(sku, name, price_cents)
                self.download_url = download_url

            def describe(self):                           # override and extend
                return super().describe() + " [download]"

        items = [PhysicalProduct("SKU-MUG", "Mug", 1299, weight_grams=350),
                 DigitalProduct("SKU-EBOOK", "Tea guide", 899,
"https://example.com/dl/42")]
        for p in items:
            print(p.describe(), p.shipping_cents())
        # Mug (12.99) 599
        # Tea guide (8.99) [download] 0
```

```
        import java.util.List;

        class Product {
            protected final String sku;
            protected final String name;
            protected final long priceCents;

            Product(String sku, String name, long priceCents) {
                this.sku = sku;
                this.name = name;
                this.priceCents = priceCents;
            }

            long shippingCents() { return 0; }                      // default

            String describe() {
                return String.format("%s (%.2f)", name, priceCents / 100.0);
            }
        }

        class PhysicalProduct extends Product {                      // IS-A Product
            static final long BASE_CENTS = 399, CENTS_PER_100G = 50;
            private final int weightGrams;

            PhysicalProduct(String sku, String name, long priceCents, int weightGrams) {
                super(sku, name, priceCents);                        // parent's con-
structor first
                this.weightGrams = weightGrams;
            }

            @Override long shippingCents() {                         // override
                long hundreds = (weightGrams + 99) / 100;            // ceiling divi-
sion
                return BASE_CENTS + CENTS_PER_100G * hundreds;
            }
        }

        class DigitalProduct extends Product {
            private final String downloadUrl;

            DigitalProduct(String sku, String name, long priceCents, String download-
Url) {
                super(sku, name, priceCents);
                this.downloadUrl = downloadUrl;
            }

            @Override String describe() { return super.describe() + " [download]"; }
        }

        class Main {
            public static void main(String[] args) {
                List<Product> items = List.of(
                    new PhysicalProduct("SKU-MUG", "Mug", 1299, 350),
                    new DigitalProduct("SKU-EBOOK", "Tea guide", 899,
"https://example.com/dl/42"));
                for (Product p : items)
```

```
                System.out.println(p.describe() + " " + p.shippingCents());
            }
        }
```

What to notice:

- The loop never checks which kind of product it has; each object answers `shipping_cents()` its own way.
- The parent's default `shipping_cents` returns 0, so a future physical subclass that forgets to override ships free. §35.7 turns that silent bug into an error with an abstract method.

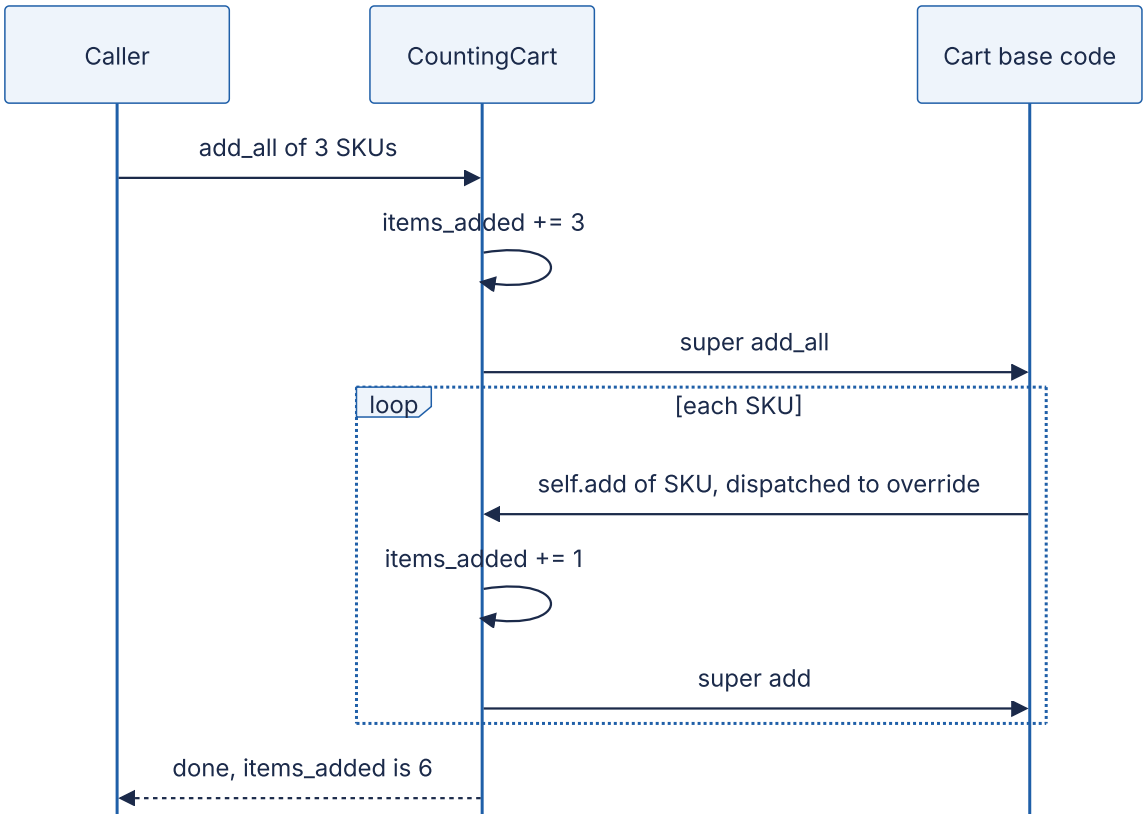
35.5.2 The fragile base class problem

> DEFINITION
>
> **Definition — Fragile base class problem.** A change to a base class that is correct on its own breaks subclasses, because the subclasses depend on implementation details of the base (which methods call which) that were never part of its documented interface.

First-principles explanation

The analytics team subclasses `Cart` to count every item ever added, overriding both `add` and `add_all`. Nobody told them that `add_all` calls `add` once per item, so the count doubles. This is the shop version of Bloch's `InstrumentedHashSet`, which reports 6 additions after adding 3 elements [Bloch 2018, Item 18].

Figure 35.4 — How self-use double-counts in the subclass.



Reading the diagram.

- **Components.** One object, two layers of code: the `CountingCart` overrides and the inherited `Cart` methods.
- **Direction and sync.** Every arrow is a synchronous call on the *same* object. In `Base->>CC`, base code calls `self.add` and dynamic dispatch (§35.6) sends it to the override.
- **Storage.** None; the counter is an in-memory field.
- **Failure point.** The undocumented internal call from `add_all` to `add` is the hidden dependency.
- **Scaling.** Every subclass of `Cart` shares this exposure; the more there are, the harder `Cart` is to change.

```
        class Cart:
            def __init__(self):
                self._quantities = {}

            def add(self, sku, quantity=1):
                self._quantities[sku] = self._quantities.get(sku, 0) + quantity

            def add_all(self, skus):
                for sku in skus:
                    self.add(sku)            # self-use: add_all is built on add (undoc-
umented)

        class CountingCart(Cart):
            """Counts every item a shopper ever puts in the cart, for analytics."""

            def __init__(self):
                super().__init__()
                self.items_added = 0

            def add(self, sku, quantity=1):
                self.items_added += quantity
                super().add(sku, quantity)

            def add_all(self, skus):
                self.items_added += len(skus)
                super().add_all(skus)        # ...which calls self.add, which counts
again

        cart = CountingCart()
        cart.add_all(["SKU-MUG", "SKU-TEA", "SKU-PEN"])
        print(cart.items_added)              # 6, not 3
```

```java
import java.util.HashMap;
import java.util.List;
import java.util.Map;

class Cart {
    private final Map<String, Integer> quantities = new HashMap<>();

    void add(String sku, int quantity) {
        quantities.merge(sku, quantity, Integer::sum);
    }

    void addAll(List<String> skus) {
        for (String sku : skus) add(sku, 1);       // self-use (undocumented)
    }
}

class CountingCart extends Cart {
    int itemsAdded = 0;

    @Override void add(String sku, int quantity) {
        itemsAdded += quantity;
        super.add(sku, quantity);
    }

    @Override void addAll(List<String> skus) {
        itemsAdded += skus.size();
        super.addAll(skus);                        // calls this.add(...) again
    }
}

class Main {
    public static void main(String[] args) {
        CountingCart cart = new CountingCart();
        cart.addAll(List.of("SKU-MUG", "SKU-TEA", "SKU-PEN"));
        System.out.println(cart.itemsAdded);       // 6, not 3
    }
}
```

Removing the `add_all` override fixes the count *today*. If the cart team later rewrites `add_all` to update the dictionary directly, a change that passes all of `Cart`'s tests, `CountingCart` silently *under*counts. Either way the subclass depends on a private choice in the parent. The fix, composition with forwarding, is in §35.8. Bloch's rule: "design and document for inheritance or else prohibit it" [Bloch 2018, Item 19], by documenting self-use or declaring the class `final` (Python's `typing.final` lets type checkers flag subclassing).

Real-world industry applications

INDUSTRY EXAMPLE

`java.util.Stack` and `java.util.Properties`. `Stack` extends `Vector`, so every stack exposes methods for inserting at arbitrary positions, breaking last-in, first-out. `Properties` extends `Hashtable`, whose inherited `put` accepts non-string objects. Bloch cites both as is-a violations that cannot be fixed without breaking compatibility; the `Stack` documentation now recommends `Deque` instead. *Evidence: Primary* — [Bloch 2018, Item 18]; [Oracle: java.util.Stack API documentation]

Advantages and disadvantages

- **Advantages.** Little code for genuine is-a variations; substitutability enables polymorphism.
- **Disadvantages.** White-box coupling to the parent; fixed at compile time; one parent in Java; deep hierarchies hide which method runs.

Failure scenarios

Table 35.4 — Failure scenarios for inheritance.

What goes wrong	Why	Detection	Recovery	Prevention
Counts doubled or missing	Fragile base class self-use	Metrics disagree with source data	Switch subclass to composition	Document self-use or make classes `final`
Subclass exposes forbidden operations	Inherited methods break child's rules (Stack/Vector)	Misuse in code review or production	Hide behind a wrapper	Apply the behavioral is-a test
New physical product ships free	Default implementation inherited silently	Revenue leak in reports	Add override	Abstract method instead of default

COMMON MISTAKE

Misconception — "Inheritance is mainly for code reuse." A helper object gives the same reuse without the coupling. Inherit when callers treat the child *as* the parent and the child keeps every promise the parent makes (§35.9).

35.6 Polymorphism

35.6.1 Subtype polymorphism and dynamic dispatch

DEFINITION

Definition — Polymorphism. The ability of one piece of code to work with values of different types. **Subtype polymorphism** means code written against a type also works with any of its subtypes, and each object responds to a method call with its own implementation. **Dynamic dispatch** is the run-time mechanism that picks which implementation runs, based on the object's actual class rather than the declared type of the variable.

First-principles explanation

A cashier says "Please pay" to everyone in the queue; one taps a card, one hands over cash, one scans a phone. The instruction never changes, even when a new payment method appears.

Marketing invents discount rules monthly: 10% off, 5 off orders over 50, buy two mugs get one free. Without polymorphism the checkout grows an `if rule.kind == "percent" ... elif ...` chain that must be edited and retested for every rule. With it, each rule is an object with a `discount_cents(lines)` method, and the checkout just calls it.

Why does this exist?

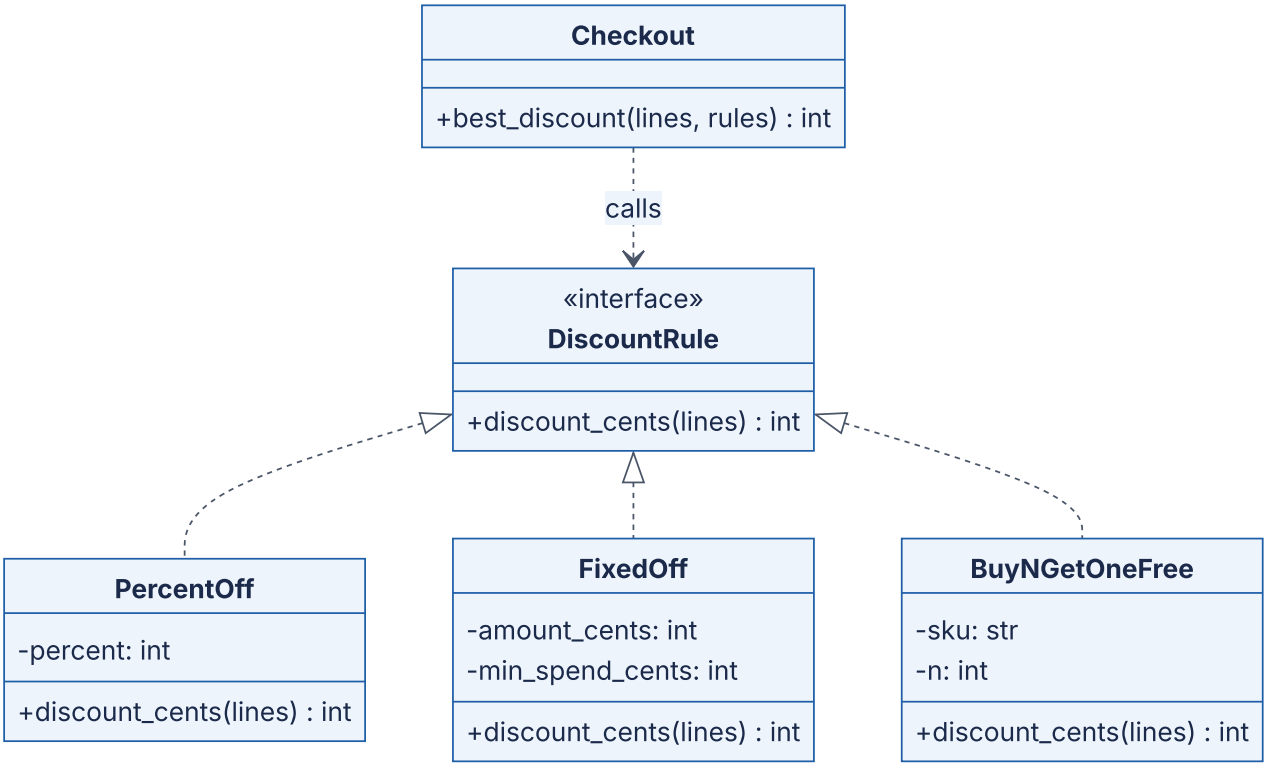
To let variations grow without editing the code that uses them: the Open/Closed Principle of §36.4, of which polymorphism is the mechanism.

How it works internally

1. **Java.** Each class has a **method table** (vtable) of pointers to its overridable methods, and every object points to its class. `rule.discountCents(lines)` becomes "load the class, load the table entry, jump": a couple of memory loads and an indirect jump. Just-in-time compilers inline the one or two classes a call site usually sees, so the overhead is usually negligible.
2. **Python.** `rule.discount_cents` is looked up by name at run time, in the object, then its class and parents. The classes need not share a parent.
3. **Static versus dynamic type.** In `DiscountRule rule = new PercentOff(10);` the compiler checks against `DiscountRule` (static type); the runtime runs `PercentOff`'s code (dynamic type).

Architecture diagram

Figure 35.5 — Discount rules behind one interface.



Reading the diagram.

- **Components.** `DiscountRule` is an interface (methods without implementation), implemented by three classes (`<|..`). `Checkout` depends (`..>`) only on the interface.
- **Direction and sync.** `Checkout` calls whichever rules it is handed, synchronously, via dynamic dispatch.
- **Storage.** In production the rule parameters come from a database or configuration, and a factory builds the objects (Ch 37).
- **Failure points.** A rule returning more than the subtotal would corrupt totals; the cart's invariant (§35.4) caps the discount.
- **Scaling.** A fourth rule is a new class; `Checkout` and its tests do not change.

Code example

The cart has 3 mugs at 1,299 and 1 tea at 2,450: subtotal $3 \times 1299 + 2450 = 6,347$ cents. Ten percent is 634 cents (integer division rounds down), the fixed rule gives 500, and "buy 2, get 1 free" on mugs gives one free mug, 1,299. The best is 1,299.

            }
        }

        final class FixedOff implements DiscountRule {
            private final long amountCents, minSpendCents;
            FixedOff(long amountCents, long minSpendCents) {
                this.amountCents = amountCents;
                this.minSpendCents = minSpendCents;
            }

            @Override public long discountCents(List<Line> lines) {
                long subtotal = 0;
                for (Line l : lines) subtotal += l.unitCents() * l.quantity();
                return subtotal >= minSpendCents ? amountCents : 0;
            }
        }

        final class BuyNGetOneFree implements DiscountRule {
            private final String sku;
            private final int n;
            BuyNGetOneFree(String sku, int n) { this.sku = sku; this.n = n; }

            @Override public long discountCents(List<Line> lines) {
                long free = 0;
                for (Line l : lines)
                    if (l.sku().equals(sku)) free += (l.quantity() / (n + 1)) * l.unit-
Cents();
                return free;
            }
        }

        class Main {
            static long bestDiscount(List<Line> lines, List<DiscountRule> rules) {
                long best = 0;
                for (DiscountRule rule : rules)                    // dynamic dispatch
here
                    best = Math.max(best, rule.discountCents(lines));
                return best;
            }
```

```
            public static void main(String[] args) {
                List<Line> lines = List.of(new Line("SKU-MUG", 1299, 3), new Line("SKU-
TEA", 2450, 1));
                List<DiscountRule> rules = List.of(
                    new PercentOff(10), new FixedOff(500, 5000), new
BuyNGetOneFree("SKU-MUG", 2));
                for (DiscountRule r : rules)
                    System.out.println(r.getClass().getSimpleName() + " " +
r.discountCents(lines));
                System.out.println("best: " + bestDiscount(lines, rules));
            }
        }
```

What to notice:

- `best_discount` contains no `if` on the rule's kind.
- In Python the classes share no parent; each simply *has* `discount_cents` (duck typing, §35.6.2). In Java each must declare `implements DiscountRule`.

35.6.2 Duck typing

> DEFINITION
>
> **Definition — Duck typing.** A style of polymorphism in which an object is acceptable wherever it supports the operations actually used, regardless of its declared class ("if it walks like a duck and quacks like a duck"). Checking happens when the method is called. **Structural typing** is the static version: a type checker accepts an object if its shape matches a declared protocol.

Duck typing is short and flexible: any object with `discount_cents(lines)` is a discount rule, including a three-line test double. The price is late errors: a missing method raises `AttributeError` only when the line runs, perhaps in production. `typing.Protocol` [PEP 544] recovers much of the safety: a static checker such as mypy verifies the shape before the program runs, without inheritance. Java's default is **nominal typing**: a class is a `DiscountRule` only if it says so.

35.6.3 Parametric polymorphism (generics), briefly

"Return the cheapest item in a list" is the same code for products or shipping options. **Parametric polymorphism** (**generics**) writes it once with a type parameter `T`, and the type checker still knows a list of products gives back a product.

```
        from typing import Protocol, TypeVar

        class Priced(Protocol):
            @property
            def price_cents(self) -> int: ...

        T = TypeVar("T", bound=Priced)

        def cheapest(items: list[T]) -> T:
            """Works for a list of any priced type and returns that same type."""
            if not items:
                raise ValueError("items must be non-empty")
            return min(items, key=lambda item: item.price_cents)

        class Product:
            def __init__(self, sku, price_cents):
                self.sku, self.price_cents = sku, price_cents

        class ShippingOption:
            def __init__(self, carrier, price_cents):
                self.carrier, self.price_cents = carrier, price_cents

        print(cheapest([Product("SKU-MUG", 1299), Product("SKU-PEN", 250)]).sku)       #
SKU-PEN
        print(cheapest([ShippingOption("PostCo", 599), ShippingOption("FastCo",
999)]).carrier)  # PostCo
```

```
        import java.util.List;

        interface Priced { long priceCents(); }

        record Product(String sku, long priceCents) implements Priced {}
        record ShippingOption(String carrier, long priceCents) implements Priced {}

        class Main {
            // <T extends Priced>: any type T, as long as it is Priced. Returns that
same T.
            static <T extends Priced> T cheapest(List<T> items) {
                if (items.isEmpty()) throw new IllegalArgumentException("items must be
non-empty");
                T best = items.get(0);
                for (T item : items)
                    if (item.priceCents() < best.priceCents()) best = item;
                return best;
            }

            public static void main(String[] args) {
                Product p = cheapest(List.of(new Product("SKU-MUG", 1299), new
Product("SKU-PEN", 250)));
                ShippingOption s = cheapest(List.of(new ShippingOption("PostCo", 599),
                                                    new ShippingOption("FastCo", 999)));
                System.out.println(p.sku() + " " + s.carrier());   // no casts needed
            }
        }
```

What to notice: the **bound** (`bound=Priced`, `T extends Priced`) restricts `T` to priced types. Java checks generics at compile time; Python's hints are checked only by external tools.

Table 35.5 — Kinds of polymorphism.

Kind	What varies	Mechanism	Checked	Example in this chapter
Subtype	Behavior per subclass	Overriding + dynamic dispatch	Compile time (Java)	`DiscountRule` implementations
Duck / structural	Any object with the right methods	Run-time lookup; `Protocol` for static check	Run time (Python), optional static	Python discount rules
Parametric (generics)	Element type	Type parameters	Compile time / type checker	`cheapest(List<T>)`
Ad hoc (overloading)	Argument types	Same name, different parameter lists	Compile time (Java)	Not used; mention only

The classification follows Cardelli and Wegner [Cardelli & Wegner 1985], who distinguish *universal* polymorphism (parametric and subtype) from *ad hoc* polymorphism (overloading and coercion).

Advantages and disadvantages

- **Advantages.** New variants without editing callers; easy fakes in tests; behavior chosen at run time.
- **Disadvantages.** A call site no longer shows which code runs; tiny classes for variations that never change are over-engineering; duck typing defers errors.

Alternatives and trade-offs

If new *kinds* arrive often, use polymorphism. If the kinds are fixed (say, order states) but new *operations* arrive often, a `switch` over a sealed set of types, which Java 21 checks for exhaustiveness, can be clearer.

COMMON MISTAKE

Misconception — "Polymorphism means using inheritance." It needs a shared *type*: a Java interface with no inherited code, or in Python nothing declared at all.

35.7 Abstraction

35.7.1 Abstract classes and interfaces

DEFINITION

Definition — Abstraction. Representing something by the operations that matter to its users while leaving out the details of how they are carried out. In code, an **abstract class** is a class that cannot be instantiated and may contain both implemented methods and **abstract methods** (declared, with no body) that subclasses must implement. An **interface** declares a set of methods a type promises to provide; in Java it has no instance state, and since Java 8 it may include `default` method bodies built only on its other methods.

First-principles explanation

You drive a petrol car and an electric car with the same pedals. Checkout code wants the same for payments: "charge 25.98 to this method" and get a receipt, without seeing card processors or gift-card balances.

Payment methods share two kinds of things. *Common work*: every payment checks the amount against a limit and records what was charged. *Capabilities* only some have: cards can be refunded, gift cards here cannot. Common work with one varying step fits an abstract class; a capability across unrelated classes fits an interface.

Why does this exist?

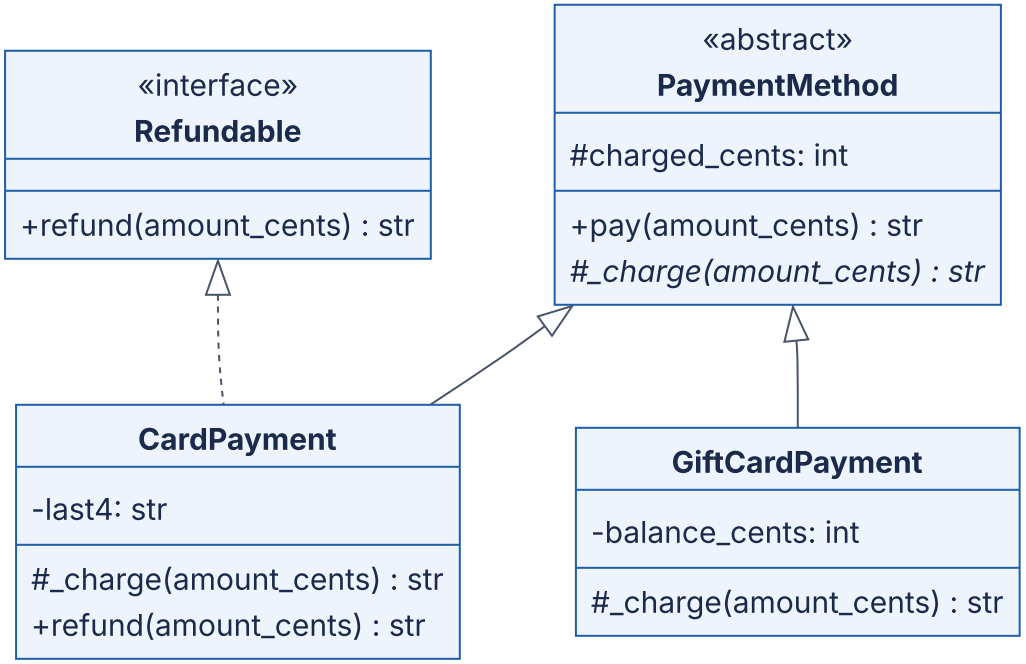
- To **force** subclasses to supply the varying part, turning the free-shipping bug of §35.5.1 into a compile error (Java) or instantiation error (Python).
- To let callers depend on a **small, stable surface**: "Program to an interface, not an implementation" [Gamma et al. 1994, ch. 1].
- To let one class play **several roles** (one parent class, many interfaces in Java).

How it works internally

- **Python.** Inherit from `abc.ABC` and mark methods `@abstractmethod`; instantiating raises `TypeError` while any remain unimplemented. A Python "interface" is an all-abstract ABC or a `typing.Protocol`.
- **Java.** An `abstract class` cannot be instantiated; `interface` methods are public and abstract unless `default` or `static`.
- A parent that fixes the steps in a `final` method and leaves one abstract is the Template Method pattern (§37.15).

Architecture diagram

Figure 35.6 — Payment methods: an abstract class plus a capability interface.



Reading the diagram.

- **Components.** `PaymentMethod` is abstract (`*` marks the abstract `_charge`); `Refundable` is an interface. `CardPayment` is both; `GiftCardPayment` only a payment method. Solid triangles are class inheritance, dotted ones interface implementation.

- **Direction and sync.** Checkout calls `pay`, which calls the subclass's `_charge`, synchronously; in production `_charge` is a slow, failure-prone network call to a provider.
- **Storage.** Balances are in memory here; really in a database or at the provider.
- **Failure points.** `charged_cents` changes only after `_charge` succeeds. "Charged but response lost" needs idempotency keys (§22.15).
- **Scaling.** A new method is one subclass; a new capability is one interface.

Code example

```
        from abc import ABC, abstractmethod

        class Refundable(ABC):
            """Interface: a pure promise, no state."""
            @abstractmethod
            def refund(self, amount_cents): ...

        class PaymentMethod(ABC):
            """Abstract class: shared state and shared steps, one step left open."""
            MAX_CHARGE_CENTS = 500_000

            def __init__(self):
                self.charged_cents = 0                      # shared state

            def pay(self, amount_cents):                    # shared, fixed algorithm
                if not 0 < amount_cents <= self.MAX_CHARGE_CENTS:
                    raise ValueError("amount out of range")
                receipt = self._charge(amount_cents)        # the varying step
                self.charged_cents += amount_cents
                return receipt

            @abstractmethod
            def _charge(self, amount_cents): ...            # subclasses must supply
this

        class CardPayment(PaymentMethod, Refundable):
            def __init__(self, last4):
                super().__init__()
                self.last4 = last4

            def _charge(self, amount_cents):
                return f"card ...{self.last4} charged {amount_cents}"

            def refund(self, amount_cents):
                if amount_cents > self.charged_cents:
                    raise ValueError("cannot refund more than was charged")
                self.charged_cents -= amount_cents
                return f"card ...{self.last4} refunded {amount_cents}"

        class GiftCardPayment(PaymentMethod):               # not Refundable in this shop
            def __init__(self, balance_cents):
                super().__init__()
                self.balance_cents = balance_cents

            def _charge(self, amount_cents):
                if amount_cents > self.balance_cents:
                    raise ValueError("insufficient gift-card balance")
                self.balance_cents -= amount_cents
                return f"gift card charged {amount_cents}, {self.balance_cents} left"
```

```
        for method in (CardPayment("4242"), GiftCardPayment(3000)):
            print(method.pay(2598))
            if isinstance(method, Refundable):
                print(method.refund(1299))

        try:
            PaymentMethod()
        except TypeError as e:
            print("TypeError:", e)
        # card ...4242 charged 2598
        # card ...4242 refunded 1299
        # gift card charged 2598, 402 left
        # TypeError: Can't instantiate abstract class PaymentMethod without an implemen-
tation
        #            for abstract method '_charge'
```

```
        interface Refundable {                                  // pure promise, no
state
            String refund(long amountCents);
        }

        abstract class PaymentMethod {                          // shared state + steps
            static final long MAX_CHARGE_CENTS = 500_000;
            protected long chargedCents = 0;

            final String pay(long amountCents) {                // final: subclasses
can't change it
                if (amountCents <= 0 || amountCents > MAX_CHARGE_CENTS)
                    throw new IllegalArgumentException("amount out of range");
                String receipt = charge(amountCents);           // the varying step
                chargedCents += amountCents;
                return receipt;
            }

            protected abstract String charge(long amountCents);  // subclasses must sup-
ply this
        }

        final class CardPayment extends PaymentMethod implements Refundable {
            private final String last4;
            CardPayment(String last4) { this.last4 = last4; }

            @Override protected String charge(long amountCents) {
                return "card ..." + last4 + " charged " + amountCents;
            }

            @Override public String refund(long amountCents) {
                if (amountCents > chargedCents)
                    throw new IllegalArgumentException("cannot refund more than was
charged");
                chargedCents -= amountCents;
                return "card ..." + last4 + " refunded " + amountCents;
            }
        }

        final class GiftCardPayment extends PaymentMethod {
            private long balanceCents;
            GiftCardPayment(long balanceCents) { this.balanceCents = balanceCents; }

            @Override protected String charge(long amountCents) {
                if (amountCents > balanceCents)
                    throw new IllegalArgumentException("insufficient gift-card bal-
ance");
                balanceCents -= amountCents;
                return "gift card charged " + amountCents + ", " + balanceCents + "
left";
            }
        }

        class Main {
            public static void main(String[] args) {
                PaymentMethod[] methods = { new CardPayment("4242"), new
```

```
        GiftCardPayment(3000) };
                for (PaymentMethod m : methods) {
                    System.out.println(m.pay(2598));
                    if (m instanceof Refundable r) System.out.println(r.refund(1299));
                }
                // new PaymentMethod();  // compile error: PaymentMethod is abstract
            }
        }
```

What to notice:

- `pay` is `final` in Java, so no subclass can skip the amount check; Python relies on convention.
- The `Refundable` check asks about a *capability*, not a concrete class, so new refundable methods need no edits.
- The abstract class carries shared *state*, which a Java interface cannot.

Table 35.6 — Abstract class versus interface.

Aspect	Abstract class	Interface
What it is	Partially implemented parent	A named set of operations
How it works	`extends` / inherit; abstract methods filled in by children	`implements` (Java); ABC or `Protocol` (Python)
Instance state	Yes	No (Java); by convention none (Python)
How many per class	One (Java); several (Python)	Many
Advantages	Shares code and state; can fix the algorithm with `final`	Loose coupling; unrelated classes can share a role; easy to fake in tests
Disadvantages	Couples children to parent internals; uses the single parent slot (Java)	Cannot hold state; adding a method breaks implementers unless it has a `default`
Choose when	Closely related variants share real work and state	You need a role or capability, or you are defining a boundary between modules

Bloch's advice combines the two: define the type as an interface, and optionally provide an abstract **skeletal implementation** class that implementers may extend for convenience [Bloch 2018, Item 20]. The Java collections follow this design.

Real-world industry applications

INDUSTRY EXAMPLE

Java collections and Python's `collections.abc`. Java defines collection types as interfaces (`List`, `Map`) with skeletal abstract classes (`AbstractList`, `AbstractMap`), so a new implementation writes only a few primitive methods. In Python, a subclass of `collections.abc.Sequence` that implements `__getitem__` and `__len__` receives `__contains__`, `__iter__`, `index` and `count` as mixin methods. *Evidence: Primary* — [Bloch 2018, Item 20]; [Python docs: collections.abc]

COMMON MISTAKE

Misconception — "Abstraction means adding interfaces everywhere." An interface with one implementation and no test fake is cost without benefit. Abstract where variation is real (payment providers, discount rules, storage).

35.8 Composition over inheritance

35.8.1 Has-a relationships and delegation

DEFINITION

Definition — Composition and delegation. Composition builds an object out of other objects that it holds in its fields (a **has-a** relationship). **Delegation** is the object forwarding part of its work to one of those parts by calling the part's methods. "Favor object composition over class inheritance" is the second principle stated in the GoF introduction [Gamma et al. 1994, ch. 1].

First-principles explanation

A computer *has* a keyboard plugged in through a standard socket; you can swap it without rebuilding the computer. Inheritance is like casting the keyboard into the case.

Orders now vary two independent ways: shipping (standard: free over 50, else 4.99; express: 12.99) and packaging (plain box, or gift wrap at 3.50). With inheritance every *combination* is a subclass (`StandardPlainOrder`, `ExpressGiftOrder`, ...), each new option multiplies the grid, and a customer who upgrades to express cannot change an existing object's class.

Why does this exist?

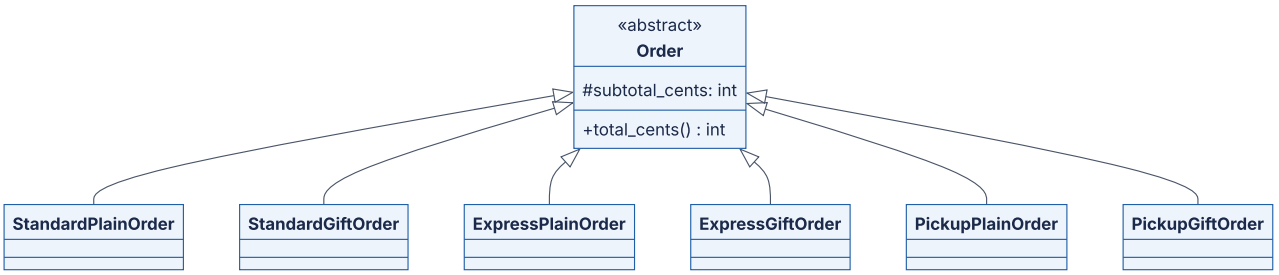
Inheritance is compile-time, single-axis and white-box. Requirements vary along several axes, change at run time, and come from teams who should not read each other's internals. Composition makes each axis a part behind a small interface, replaceable at run time and known only through its public methods (**black-box reuse**).

How it works internally

1. Identify each independent axis of variation (shipping, packaging).
2. For each axis, define a small interface (`ShippingPolicy.cost_cents(subtotal)` , `Packaging.cost_cents()`) and one class per variant.
3. Give the whole (`Order`) one field per axis, set in the constructor.
4. Implement the whole's methods by **delegating** to the parts.
5. To change behavior at run time, replace a part (`order.upgrade_shipping(ExpressShipping())`).

Architecture diagram

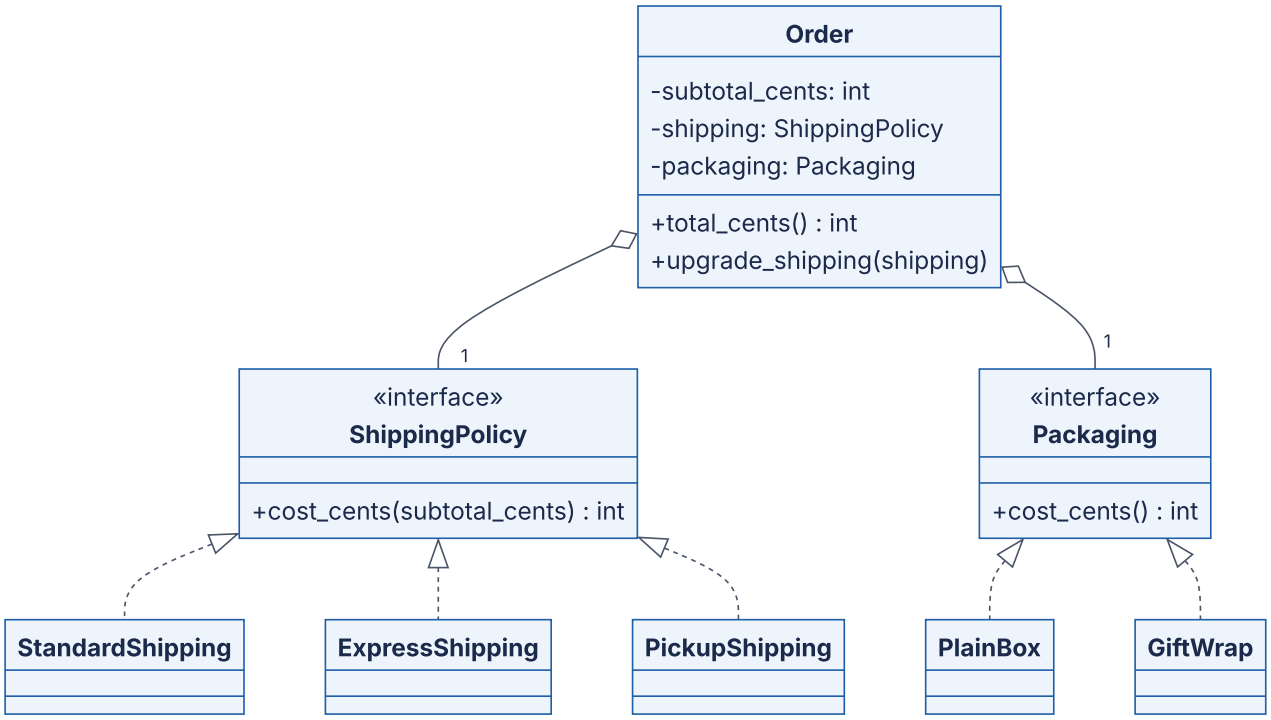
Figure 35.7 — Before: one subclass per combination.



Reading the diagram.

- **Components and direction.** One abstract `Order` and six subclasses, one per (shipping, packaging) pair for 3 × 2 options; all arrows are inheritance.
- **Sync/async and storage.** In-process only.
- **Failure points.** The gift-wrap price is duplicated in three subclasses; missing one in a price change gives inconsistent totals. Orders cannot switch shipping.
- **Scaling.** Classes grow as the *product* of options per axis: the "class explosion".

Figure 35.8 — After: an order composed of a shipping policy and a packaging.



Reading the diagram.

- **Components.** `Order` has (`o--`) one `ShippingPolicy` and one `Packaging`, each an interface with its own family of classes.
- **Direction and sync.** `total_cents()` synchronously calls both parts and adds the results: delegation.
- **Storage.** A database row would store the chosen *codes*; a factory rebuilds the objects (Ch 37).
- **Failure points.** Each price rule exists once; a missing part should be rejected by the constructor.
- **Scaling.** A new option is one class; classes grow as the *sum* of options.

Mathematical foundations

FORMULA

Class count: inheritance per combination versus composition per axis

$$N_{\text{inherit}} = \prod_{i=1}^{a} k_i \qquad N_{\text{compose}} = 1 + \sum_{i=1}^{a} k_i$$

Symbol	Meaning	Units
a	Number of independent axes of variation	count
k_i	Number of options on axis i	count
N_{inherit}	Concrete subclasses needed to cover every combination	classes
N_{compose}	Classes needed with composition: one whole plus one class per option	classes

WORKED EXAMPLE

Worked example — Adding payment timing as a third axis.

1. Current axes: shipping has $k_1 = 3$ options (standard, express, pickup), packaging $k_2 = 2$ (plain, gift).
2. Inheritance: $3 \times 2 = 6$ subclasses. Composition: $1 + 3 + 2 = 6$ classes. Equal counts, but composition already wins on duplication and run-time change.
3. Add payment timing, $k_3 = 3$ (now, on delivery, installments), and an eco box, so $k_2 = 3$.
4. Inheritance: $N = 3 \times 3 \times 3 = 27$ subclasses. Composition: $N = 1 + 3 + 3 + 3 = 10$ classes.
5. One more shipping option ($k_1 = 4$): inheritance needs $4 \times 3 \times 3 = 36$, that is 9 *new* classes; composition needs 11, that is 1 new class.

Interpretation. Each additional axis multiplies the inheritance count but only adds to the composition count.

Engineering implication. At the second independent axis, stop subclassing along it, while N_{inherit} is still small.

Code example

The code also fixes §35.5.2's `CountingCart`: instead of *being* a cart it *has* one and forwards to it, a **wrapper class** [Bloch 2018, Item 18]. The inner cart's `add_all` calls the inner `add`, never the wrapper's, so the count is right whatever the cart team changes.

```
        # --- Parts: each varies independently ------------------------------------
        class StandardShipping:
            def cost_cents(self, subtotal_cents):
                return 0 if subtotal_cents >= 5000 else 499

        class ExpressShipping:
            def cost_cents(self, subtotal_cents):
                return 1299

        class PlainBox:
            def cost_cents(self):
                return 0

        class GiftWrap:

            public int quantityOf(String sku) { return quantities.getOrDefault(sku, 0);
}
        }
```

```
        final class CountingCart implements CartOps {      // HAS-A CartOps
            private final CartOps inner;
            int itemsAdded = 0;
            CountingCart(CartOps inner) { this.inner = inner; }

            public void add(String sku, int quantity) { itemsAdded += quantity;
inner.add(sku, quantity); }
            public void addAll(List<String> skus) { itemsAdded += skus.size();
inner.addAll(skus); }
            public int quantityOf(String sku) { return inner.quantityOf(sku); }
        }

        class Main {
            public static void main(String[] args) {
                Order order = new Order(4200, new StandardShipping(), new
GiftWrap("Happy birthday!"));
                System.out.println(order.totalCents());          // 5049
                order.upgradeShipping(new ExpressShipping());
                System.out.println(order.totalCents());          // 5849

                CountingCart cart = new CountingCart(new Cart());
                cart.addAll(List.of("SKU-MUG", "SKU-TEA", "SKU-PEN"));
                System.out.println(cart.itemsAdded);             // 3
                System.out.println(new Order(6000, new StandardShipping(), new
PlainBox()).totalCents()); // 6000
            }
        }
```

What to notice:

- `upgrade_shipping` changes an existing order's behavior; inheritance would need a new object of another class.
- The wrapper implements `CartOps` like `Cart`, so it is substitutable without inheriting code, at the cost of one forwarding method per interface method.

Table 35.7 — Inheritance versus composition.

Aspect	Inheritance (is-a)	Composition (has-a)
What it is	Child class extends parent	Object holds parts and delegates
How it works	Method lookup up the class chain	Explicit calls to fields
Advantages	Little code for true subtypes; substitutability	Independent axes; run-time change; black-box reuse
Disadvantages	White-box coupling; fixed at compile time; class explosion	Forwarding boilerplate; more objects to wire together
Performance	One dispatch	One extra call per delegation (usually inlined by the JIT)
Operational complexity	Low at first, rises with depth	Moderate and stays flat
Choose when	Child keeps every promise of the parent and there is one axis	Several axes, run-time choice, or reuse across team boundaries

Real-world industry applications

INDUSTRY EXAMPLE

Java collection wrappers. `Collections.unmodifiableList`, `synchronizedList` and `checkedList` return wrappers that hold the original list and forward calls, adding read-only behavior, locking or type checks. Because they compose, each works with *any* `List` and they can be stacked, which subclassing `ArrayList` could not achieve. *Evidence: Primary* — [Oracle: java.util.Collections API documentation]; [Bloch 2018, Item 18]

INDUSTRY EXAMPLE

Shop order variants. The refactor from six combination subclasses to a composed order is a teaching example, not any company's system. *Evidence: Illustrative* — hypothetical design.

Failure scenarios

Table 35.8 — Failure scenarios when moving to composition.

What goes wrong	Why	Detection	Recovery	Prevention
`None` / `null` part causes crash at checkout	Part not supplied	Error on first total	Supply a default part	Validate parts in the constructor
Wrapper forgets a newly added method	Interface grew, wrapper not updated	Compile error (Java); `AttributeError` (Python)	Add the forwarder	Keep interfaces small; tests on wrappers
Too many tiny objects	Composition applied where nothing varies	Hard-to-follow wiring code	Inline unused parts	Compose along *real* axes only

COMMON MISTAKE

Misconception — "Composition over inheritance means never inherit." The GoF say *favor*. Implementing interfaces, extending classes designed for extension, and true single-axis subtypes are fine; composition is the default when unsure.

35.9 Interfaces and contracts

35.9.1 Design by contract

DEFINITION

Definition — Design by contract. A method of specifying software in which each routine states a **precondition** (what must be true when it is called: the caller's obligation), a **postcondition** (what it guarantees when it returns: the supplier's obligation), and each class states an **invariant** (what is true of every instance between calls). The approach, and the term, come from Bertrand Meyer and the Eiffel language [Meyer 1997].

First-principles explanation

A courier promises: "If the parcel weighs at most 30 kg and is properly addressed, we deliver within two days." The first half is your obligation (precondition), the second the courier's promise (postcondition). Send 40 kg and the courier owes you nothing.

`reserve(sku: str, quantity: int)` gives types but not that `quantity` must be positive and at most what is available, or that availability drops by exactly `quantity`. A contract makes those rules part of the interface.

Why does this exist?

Without contracts, either nobody checks (bad input corrupts state far from the cause) or every layer checks differently, bloating code and still leaving gaps [Meyer 1997]. A contract assigns each check to one side. It also defines correct inheritance: a subclass must honor its parent's contract, formalized as **behavioral subtyping** [Liskov & Wing 1994] and developed in §36.5.

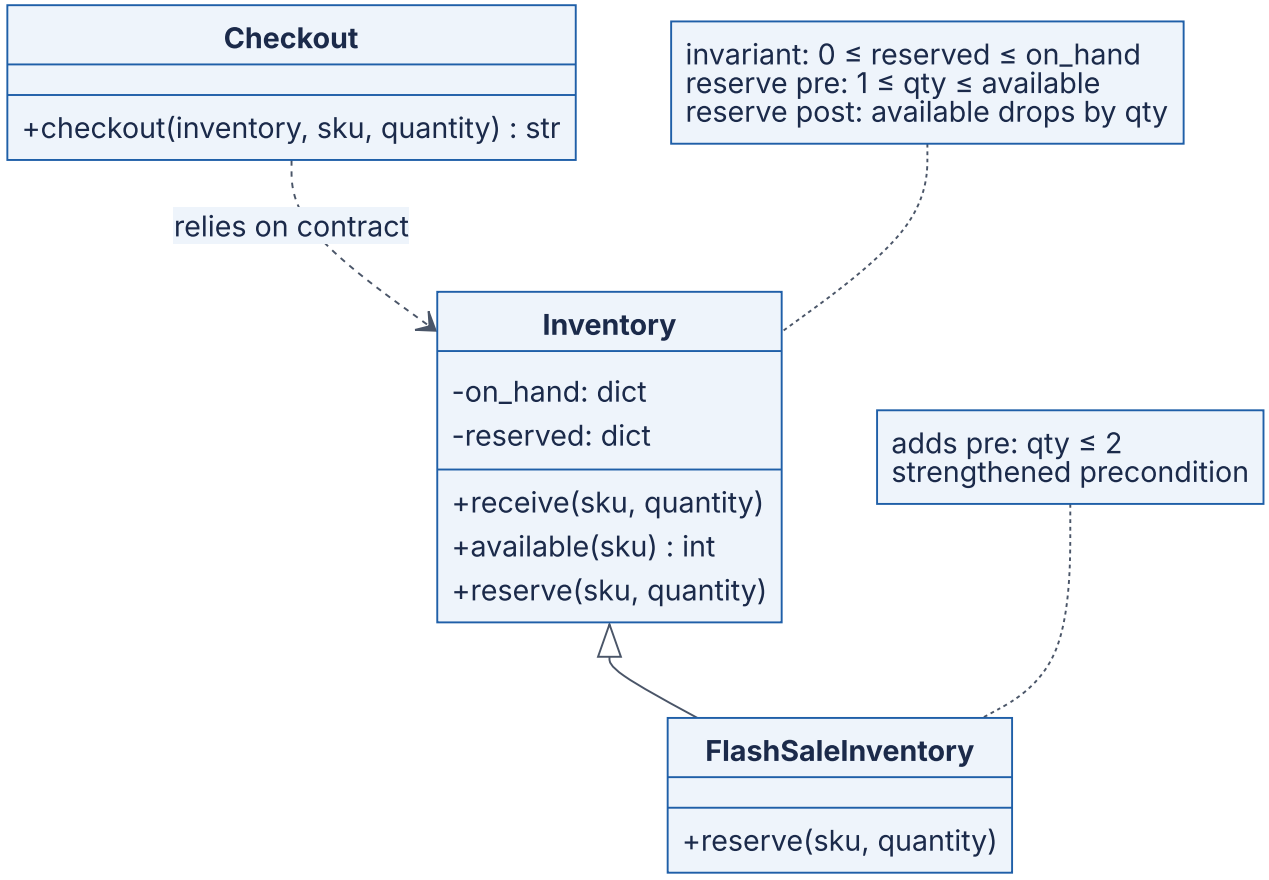
How it works internally

1. **Preconditions** are checked on entry; public APIs fail fast with `ValueError` or `IllegalArgumentException` [Bloch 2018, Item 49].
2. **Postconditions** relate the result to the inputs and the *old* state: save the old value, assert afterwards.
3. **Invariants** are checked at the end of the constructor and every state-changing public method.
4. **Assertions** can be switched off (`python -O`; Java without `-ea`), so never validate user input with `assert`.
5. **Meyer's rule.** A subclass may **weaken** the precondition and **strengthen** the postcondition, never the reverse, and must keep the invariant. Eiffel enforces this with

`require else` and `ensure then`.

Architecture diagram

Figure 35.9 — The inventory contract and a subclass that breaks it.



Reading the diagram.

- **Components.** `Inventory` tracks stock on hand and reserved; the notes record its contract and the subclass's extra condition. `Checkout` is client code.
- **Direction and sync.** `Checkout` calls `available` then `reserve` synchronously, written against `Inventory`'s contract but handed a `FlashSaleInventory`.
- **Storage.** In production "check then reserve" must be atomic in the database, for example one `UPDATE ... WHERE available >= qty` (Ch 11), or concurrent checkouts both pass.
- **Failure point.** The subclass rejects a call the parent allows; `Checkout` has no handling for an "impossible" failure.
- **Scaling.** Every new caller and subclass is checked against the same written rules.

Code example

```
        class Inventory:
            """Stock for each SKU.
            Class invariant: for every SKU, 0 <= reserved <= on_hand.
            """

            def __init__(self):
                self._on_hand = {}
                self._reserved = {}

            def receive(self, sku, quantity):
                # Precondition (caller's duty): quantity >= 1
                if quantity < 1:
                    raise ValueError("precondition: quantity >= 1")
                self._on_hand[sku] = self._on_hand.get(sku, 0) + quantity
                self._reserved.setdefault(sku, 0)
                self._check_invariant(sku)

            def available(self, sku):
                return self._on_hand.get(sku, 0) - self._reserved.get(sku, 0)

            def reserve(self, sku, quantity):
                # Preconditions (caller's duty)
                if quantity < 1:
                    raise ValueError("precondition: quantity >= 1")
                if quantity > self.available(sku):
                    raise ValueError("precondition: quantity <= available(sku)")
                old_available = self.available(sku)

                self._reserved[sku] += quantity

                # Postcondition (supplier's promise) and invariant
                assert self.available(sku) == old_available - quantity, "postcondition"
                self._check_invariant(sku)

            def _check_invariant(self, sku):
                assert 0 <= self._reserved.get(sku, 0) <= self._on_hand.get(sku, 0),
"invariant"

        inv = Inventory()
        inv.receive("SKU-MUG", 5)
        inv.reserve("SKU-MUG", 3)
        print(inv.available("SKU-MUG"))           # 2
        try:
            inv.reserve("SKU-MUG", 3)             # caller broke the precondition
        except ValueError as e:
            print("refused:", e)

        class FlashSaleInventory(Inventory):
            """BAD subclass: strengthens the precondition (max 2 per reservation)."""
            def reserve(self, sku, quantity):
                if quantity > 2:
                    raise ValueError("flash sale: at most 2 per reservation")
```

```
            super().reserve(sku, quantity)

    def checkout(inventory, sku, quantity):  # written against Inventory's contract
        if quantity <= inventory.available(sku):
            inventory.reserve(sku, quantity)  # contract says this cannot fail
            return "reserved"
        return "out of stock"

    for cls in (Inventory, FlashSaleInventory):
        store = cls()
        store.receive("SKU-TEA", 10)

    # 2
    # refused: precondition: quantity <= available(sku)
    # Inventory reserved
    # FlashSaleInventory surprise: flash sale: at most 2 per reservation
```

```
        import java.util.HashMap;
        import java.util.Map;

        /** Class invariant: for every SKU, 0 <= reserved <= onHand. */
        class Inventory {
            private final Map<String, Integer> onHand = new HashMap<>();
            private final Map<String, Integer> reserved = new HashMap<>();

            /** @pre quantity >= 1 */
            void receive(String sku, int quantity) {
                if (quantity < 1) throw new IllegalArgumentException("precondition:
quantity >= 1");
                onHand.merge(sku, quantity, Integer::sum);
                reserved.putIfAbsent(sku, 0);
                assert invariantHolds(sku) : "invariant";
            }

            int available(String sku) {
                return onHand.getOrDefault(sku, 0) - reserved.getOrDefault(sku, 0);
            }

            /** @pre 1 <= quantity <= available(sku)
             *  @post available(sku) == old available(sku) - quantity */
            void reserve(String sku, int quantity) {
                if (quantity < 1)
                    throw new IllegalArgumentException("precondition: quantity >= 1");
                if (quantity > available(sku))
                    throw new IllegalArgumentException("precondition: quantity <=
available(sku)");
                int oldAvailable = available(sku);

                reserved.merge(sku, quantity, Integer::sum);

                assert available(sku) == oldAvailable - quantity : "postcondition";
                assert invariantHolds(sku) : "invariant";
            }

            private boolean invariantHolds(String sku) {
                int r = reserved.getOrDefault(sku, 0);
                return 0 <= r && r <= onHand.getOrDefault(sku, 0);
            }
        }

        /** BAD subclass: strengthens the precondition. */
        class FlashSaleInventory extends Inventory {
            @Override void reserve(String sku, int quantity) {
                if (quantity > 2) throw new IllegalArgumentException("flash sale: at
most 2 per reservation");
                super.reserve(sku, quantity);
            }
        }

        class Main {
            static String checkout(Inventory inventory, String sku, int quantity) {
                if (quantity <= inventory.available(sku)) {
                    inventory.reserve(sku, quantity);     // the contract says this can-
```

```
not fail
                    return "reserved";
                }
                return "out of stock";
            }

            public static void main(String[] args) {
                Inventory inv = new Inventory();
                inv.receive("SKU-MUG", 5);
                inv.reserve("SKU-MUG", 3);
                System.out.println(inv.available("SKU-MUG"));                  // 2
                try {
                    inv.reserve("SKU-MUG", 3);
                } catch (IllegalArgumentException e) {
                    System.out.println("refused: " + e.getMessage());
                }
                for (Inventory store : new Inventory[] { new Inventory(), new
FlashSaleInventory() }) {
                    store.receive("SKU-TEA", 10);
                    String name = store.getClass().getSimpleName();
                    try {
                        System.out.println(name + " " + checkout(store, "SKU-TEA", 4));
                    } catch (IllegalArgumentException e) {
                        System.out.println(name + " surprise: " + e.getMessage());
                    }
                }
            }
        }
```

What to notice:

- Preconditions always run; postconditions and invariants use `assert` (Java was run with `-ea`). Eiffel's `old` keyword is a local variable here.
- `FlashSaleInventory` compiles and passes its own tests yet breaks `checkout`: types check *signatures*, only contracts catch *behavior*. Put the limit in the base contract instead (a queryable `max_per_reservation(sku)`).

Real-world industry applications

INDUSTRY EXAMPLE

Eiffel and mainstream languages. Eiffel has `require`, `ensure` (with `old`) and `invariant` clauses, monitored at run time per a compilation setting and inherited by subclasses. Java approximates this with Javadoc, exceptions, `Objects.requireNonNull`, and `assert` (off by default). *Evidence: Primary* — [Meyer 1997]; [Bloch 2018, Item 49]

Failure scenarios

Table 35.9 — Failure scenarios for contracts.

What goes wrong	Why	Detection	Recovery	Prevention
Subclass rejects valid calls	Strengthened precondition	Unhandled exception in client code	Move rule into the base contract	Meyer's rule; contract tests run against every subclass
Input validation silently off in production	Validation written with `assert`	Bad data in production	Replace with explicit checks	`assert` only for internal conditions
Overselling under load	Check-then-act across two calls, not atomic	Negative stock in reports	Compensate (cancel, refund)	Atomic conditional update in the store
Each layer re-validates differently	No written contract	Conflicting error messages	Document and centralize	One owner per check

COMMON MISTAKE

Misconception — "A subclass that adds a safety check is always safer." Extra demands on *inputs* break callers that obey the parent's contract; extra guarantees on *outputs* are safe.

35.10 Cohesion and coupling

35.10.1 Two measures of a good module

DEFINITION

Definition — Cohesion and coupling. Cohesion is how strongly the elements inside one module (here, one class) belong together: whether they serve a single purpose. **Coupling** is how strongly one module depends on others: how much it must know about them, and how likely a change in one is to force a change in the other. Good designs have **high cohesion and low coupling**. Both terms come from structured design [Stevens, Myers & Constantine 1974].

First-principles explanation

A well-run kitchen has stations: one cook does sauces, another grills. Everything at the sauce station is about sauces (high cohesion). The grill cook needs only "two portions of pepper sauce, please", not the recipe (low coupling). Now imagine one cook who does sauces, the accounts and the window cleaning, and a grill cook who walks over and adjusts the sauce burner directly. Any change to either person's routine breaks the other.

Every principle in this chapter so far is a way to get one or both properties. Encapsulation lowers coupling (callers know only methods). Tell, don't ask raises cohesion (rules sit with

their data). Composition lowers coupling (black-box parts). Contracts make the remaining coupling explicit.

Why does this exist?

Stevens, Myers and Constantine observed in 1974 that the cost of changing a program depends on how far a change spreads. If modules are cohesive, a change in requirements maps to a change in one module. If they are loosely coupled, the change stops there. Their paper and the later book by Yourdon and Constantine [Yourdon & Constantine 1979] ranked kinds of coupling and cohesion from worst to best, and these rankings are still the standard vocabulary.

How it works internally: kinds of coupling

Table 35.10 — Kinds of coupling, from tightest (worst) to loosest (best), with shop examples.

Kind	What it means	Shop example	Fix
Content	One module reads or changes another's internals	Report job edits `cart._lines` directly	Encapsulate (§35.4)
Common	Modules share global mutable data	Every module reads a global `CURRENT_DISCOUNT`	Pass values; one owner
External	Modules share an externally imposed format or device	Two classes parse the same payment-provider file layout	One adapter owns the format
Control	One module passes a flag that steers the other's logic	`total(cart, mode="gift")` with branches inside	Polymorphism or separate methods
Stamp	A whole structure is passed when only part is used	`shipping_cost(order)` reads only the weight	Pass what is needed
Data	Only needed elementary data passed as parameters	`shipping_cost(weight_grams)`	—
Message	Modules interact only by calling public methods	`order.settle()`	— (object-oriented ideal)

Message coupling is not in the 1974 paper; it is commonly added at the loose end for object-oriented systems. **Inheritance** is another strong form of coupling not in the original list: a subclass depends on its parent's implementation (§35.5.2). Coupling is not bad in itself: a system with no coupling does nothing. The goal is that each dependency is *necessary*, *narrow* and *visible*.

How it works internally: kinds of cohesion

Table 35.11 — Kinds of cohesion, from weakest to strongest.

Kind	Elements are grouped because…	Shop example
Coincidental	No real reason	`ShopUtils` with `format_price`, `send_sms`, `parse_csv`
Logical	They do the same *kind* of thing	`Validators` for carts, emails and addresses
Temporal	They run at the same time	`on_startup()` that loads config, warms cache, opens logs
Procedural	They run in a fixed sequence	`checkout_steps()` mixing pricing, stock and email
Communicational	They work on the same data	Methods that all read the order record
Sequential	The output of one is the input of the next	Price → apply discount → add tax
Functional	All contribute to one well-defined task	`Cart`: manage lines and compute totals

Mathematical foundations: the LCOM intuition

You can approximate cohesion mechanically. If the methods of a class use disjoint sets of fields, the class is probably several classes glued together. Chidamber and Kemerer turned this into a metric, **Lack of Cohesion in Methods** [Chidamber & Kemerer 1994].

FORMULA

LCOM1 (Chidamber–Kemerer lack of cohesion in methods)

$$\text{LCOM} = \begin{cases} |P| - |Q| & \text{if } |P| > |Q| \\ 0 & \text{otherwise} \end{cases}$$

Symbol	Meaning	Units
m	Number of methods in the class	count
I_j	Set of instance fields used by method j	set of fields
P	Pairs of methods (j, k) with $I_j \cap I_k = \varnothing$ (share no field)	pairs
Q	Pairs of methods with $I_j \cap I_k \neq \varnothing$ (share at least one field)	pairs
$\|P\| + \|Q\|$	Total method pairs, $m(m-1)/2$	pairs
LCOM	Lack of cohesion; 0 is best, larger is worse	pairs

A related variant, often called **LCOM4** (attributed to Hitz and Montazeri), counts the **connected components** of the graph in which methods are linked when they share a field. One component means one responsibility; three components suggest three classes.

WORKED EXAMPLE

Worked example — A `CheckoutManager` god class.

The class has six methods with these field uses: `add_item` {lines}; `subtotal` {lines}; `apply_coupon` {coupon, lines}; `send_receipt` {smtp, email_template}; `render_invoice` {pdf_engine, email_template}; `log_event` {logger}.

1. Total pairs: $m(m-1)/2 = 6 \times 5/2 = 15$.
2. Pairs that share a field (Q): add_item–subtotal, add_item–apply_coupon, subtotal–apply_coupon (all share `lines`), send_receipt–render_invoice (share `email_template`). $|Q| = 4$.
3. Pairs that share nothing: $|P| = 15 - 4 = 11$.
4. LCOM = $11 - 4 = 7$.
5. Connected components: {add_item, subtotal, apply_coupon}, {send_receipt, render_invoice}, {log_event}: three.
6. After splitting out the cart methods into `Cart`: 3 methods, 3 pairs, all sharing `lines`, so $|P| = 0$, $|Q| = 3$ and LCOM = 0.

Interpretation. An LCOM of 7 on a six-method class means most pairs of methods have nothing to do with each other; the three components name the classes hiding inside: `Cart`, a receipt/invoice sender, and a logger that should be injected rather than owned.

Engineering implication. Use LCOM as a *pointer* to classes worth reading, not as a target to optimize. It ignores methods that call each other, treats getters as tiny methods that inflate P, and varies between tools that use different LCOM definitions. A high value plus a vague class name (`Manager`, `Helper`, `Utils`) is a strong signal.

The calculation is mechanical, so here it is as a short script (Python only, since it is a measuring tool rather than an object-oriented construct):

```
        from itertools import combinations

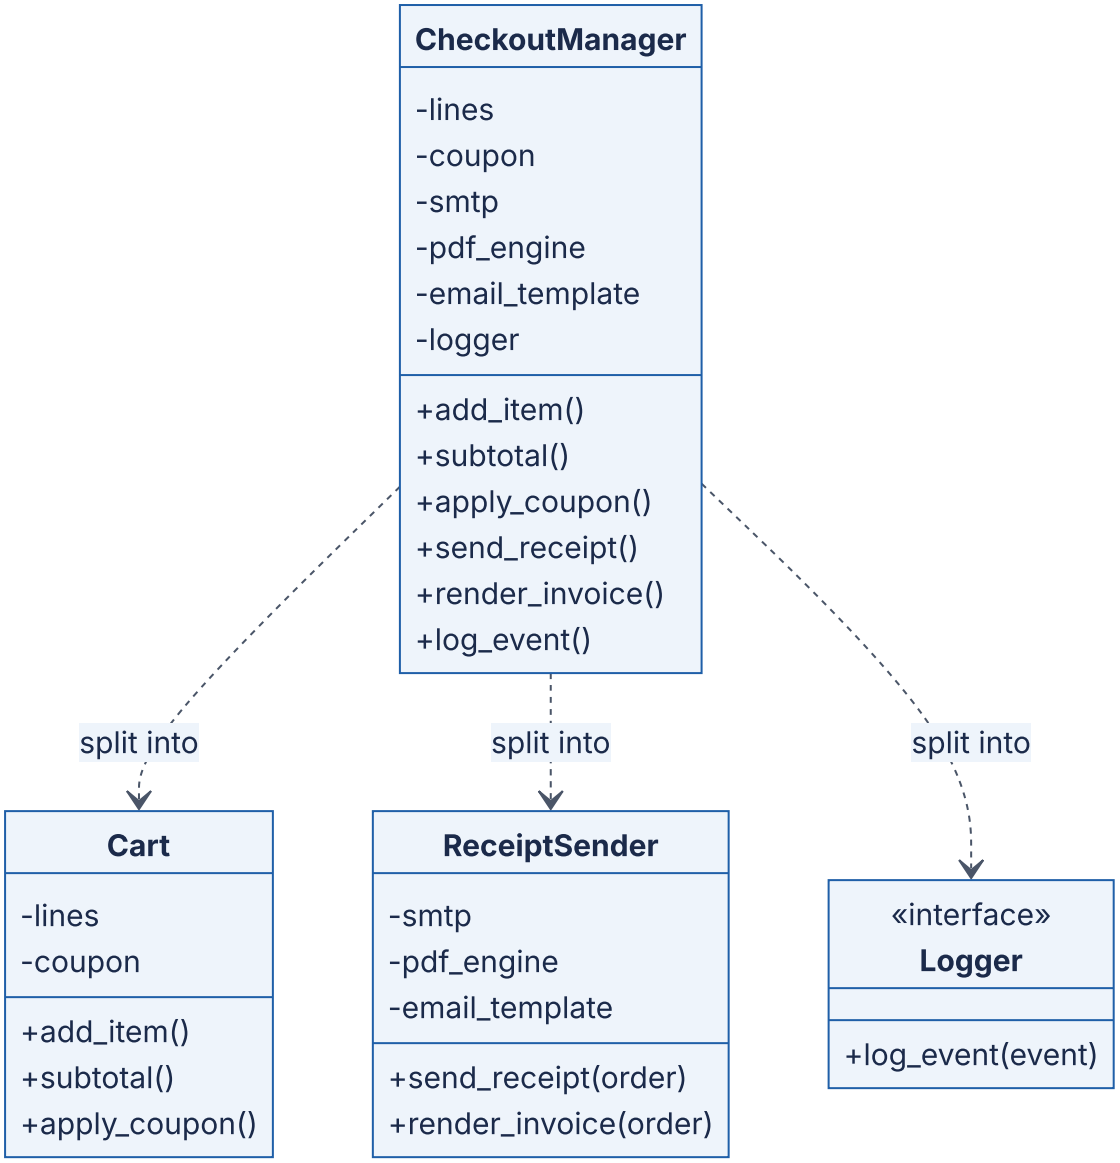
        def lcom1(uses):
            """Chidamber-Kemerer LCOM: uses maps method name -> set of attributes it
touches."""
            p = q = 0
            for a, b in combinations(uses, 2):
                if uses[a] & uses[b]:
                    q += 1                      # pair shares at least one attribute
                else:
                    p += 1                      # pair shares nothing
            return max(p - q, 0), p, q

        def components(uses):
            """Groups of methods linked by shared attributes (the LCOM4 intuition)."""
            groups = []
            for method, attrs in uses.items():
                merged = [g for g in groups if g[1] & attrs]
                names, fields = {method}, set(attrs)
                for g in merged:
                    names |= g[0]
                    fields |= g[1]
                    groups.remove(g)
                groups.append((names, fields))
            return [sorted(g[0]) for g in groups]

        checkout_manager = {
            "add_item":       {"lines"},
            "subtotal":       {"lines"},
            "apply_coupon":   {"coupon", "lines"},
            "send_receipt":   {"smtp", "email_template"},
            "render_invoice": {"pdf_engine", "email_template"},
            "log_event":      {"logger"},
        }
        print(lcom1(checkout_manager))          # (7, 11, 4)
        for group in components(checkout_manager):
            print(group)
        # ['add_item', 'apply_coupon', 'subtotal']
        # ['render_invoice', 'send_receipt']
        # ['log_event']

        cart = {k: v for k, v in checkout_manager.items() if k in ("add_item", "subto-
tal", "apply_coupon")}
        print(lcom1(cart))                      # (0, 0, 3)
```

Figure 35.10 — Splitting a low-cohesion class along its LCOM components.



Reading the diagram.

- **Components.** Left: the original god class with six fields and six unrelated methods. Right: three classes, one per connected component found by the script.
- **Relationships.** The dotted “split into” arrows show the refactoring, not run-time calls. After the split, an order-placement service would call `Cart` for totals and `ReceiptSender` after payment, and receive a `Logger` from outside.
- **Sync/async.** Sending a receipt is a natural candidate for asynchronous processing via a queue (Ch 30), which is only easy once it is its own class.
- **Storage.** `Cart` state goes to the cart store; `ReceiptSender` is stateless apart from its configuration.
- **Failure points.** In the god class, an SMTP outage can fail a method that also holds cart state; after the split, a receipt failure cannot corrupt the cart.
- **Scaling.** Each new class can change, be tested and, in a service architecture, be deployed independently.

35.10.2 The Law of Demeter

DEFINITION

Definition — Law of Demeter (object form). A method `M` of an object `O` should call methods only on: `O` itself; `M`'s parameters; objects `M` creates; and `O`'s own fields (its direct parts) [Lieberherr & Holland 1989]. Informally: "talk only to your immediate friends", or "use only one dot" (excluding fluent builders and value-object chains).

First-principles explanation

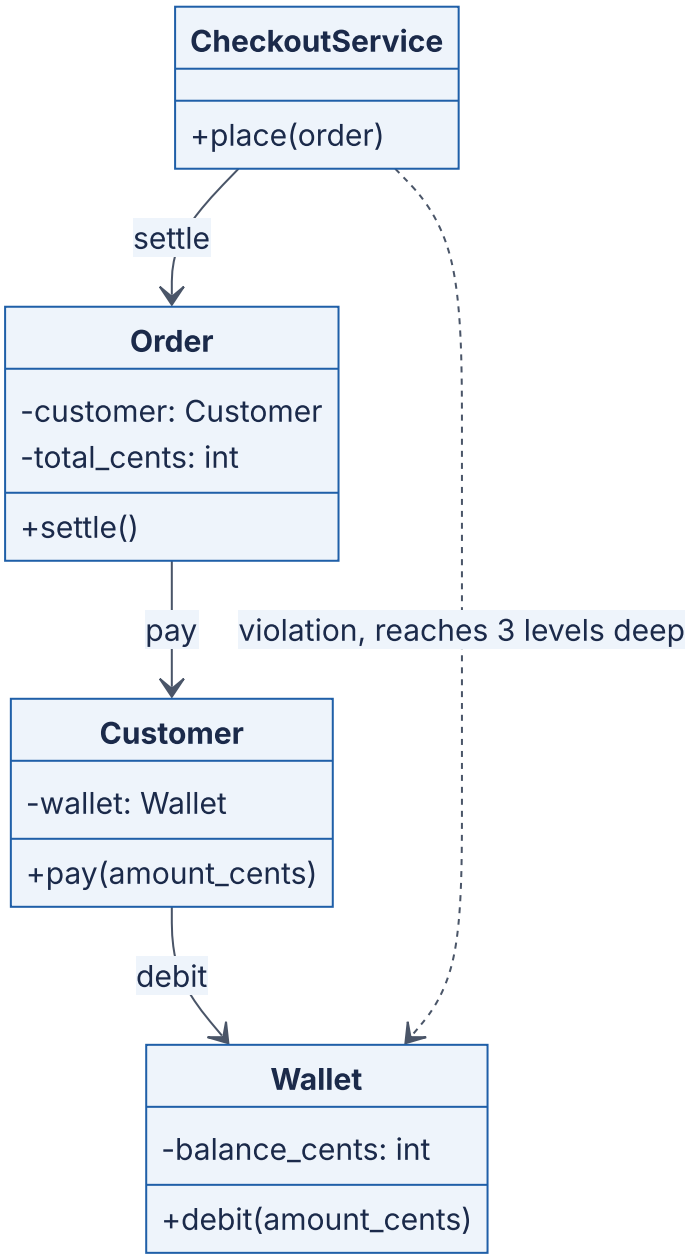
When you pay in a shop, the cashier asks you to pay. The cashier does not reach into your bag, open your wallet, take out a card and swipe it. If you change wallets, or pay by phone, the cashier's procedure does not change. Code like `order.customer.wallet.balance_cents -= total` is the cashier rummaging in your bag: the checkout now depends on `Order` having a customer, the customer having a wallet, and the wallet storing its balance in a field called `balance_cents`. Three classes' internals, one line. Martin calls such chains **train wrecks** [Martin 2008, ch. 6].

Why does this exist?

The Law of Demeter was formulated in the late 1980s by Karl Lieberherr's Demeter project at Northeastern University as a style rule that limits how much of the object structure any one method knows. Each method that obeys it depends only on its immediate neighbors, so a change to one class's structure affects only that class's neighbors. It is the object-level form of low coupling, and it pushes you towards tell, don't ask: instead of reaching through objects, you add a method to the nearest one.

Architecture diagram

Figure 35.11 — Reaching through objects versus talking to neighbors.



Reading the diagram.

- **Components.** A checkout service, an order, the customer who placed it and the customer's wallet.
- **Direction and sync.** Solid arrows are the compliant path: each object calls only its direct part, synchronously. The dotted arrow is the train-wreck dependency that compliant code removes.
- **Storage.** The wallet balance would be persisted by the payment component; only `Wallet` knows its representation.
- **Failure points.** With the violation, a change to `Wallet` (say, balances move to an external provider) breaks `CheckoutService`. With the compliant design, only `Customer` might change.

- **Scaling.** Adding a second way to pay (a company account) changes `Customer.pay`, not every caller.

Code example

```
        class Wallet:
            def __init__(self, balance_cents):
                self._balance_cents = balance_cents

            def debit(self, amount_cents):
                if amount_cents > self._balance_cents:
                    raise ValueError("insufficient funds")
                self._balance_cents -= amount_cents

            def balance_cents(self):
                return self._balance_cents

        class Customer:
            def __init__(self, name, wallet):
                self.name = name
                self._wallet = wallet

            def pay(self, amount_cents):                  # Customer talks to its own
part
                self._wallet.debit(amount_cents)

        class Order:
            def __init__(self, customer, total_cents):
                self._customer = customer
                self._total_cents = total_cents
                self.paid = False

            def settle(self):                             # Order talks to its own part
                self._customer.pay(self._total_cents)
                self.paid = True

        # Violates the Law of Demeter: the checkout reaches through three objects.
        #   order.customer.wallet.balance_cents -= order.total_cents
        # Follows it: the checkout talks only to the order.
        wallet = Wallet(10_000)
        order = Order(Customer("Ada", wallet), 4548)
        order.settle()
        print(order.paid, wallet.balance_cents())         # True 5452
```

```
        final class Wallet {
            private long balanceCents;
            Wallet(long balanceCents) { this.balanceCents = balanceCents; }

            void debit(long amountCents) {
                if (amountCents > balanceCents) throw new IllegalStateException("insuf-
ficient funds");
                balanceCents -= amountCents;
            }
            long balanceCents() { return balanceCents; }
        }

        final class Customer {
            private final String name;
            private final Wallet wallet;
            Customer(String name, Wallet wallet) { this.name = name; this.wallet = wal-
let; }

            String name() { return name; }
            void pay(long amountCents) { wallet.debit(amountCents); }   // talks to its
own field
        }

        final class Order {
            private final Customer customer;
            private final long totalCents;
            private boolean paid = false;
            Order(Customer customer, long totalCents) { this.customer = customer;
this.totalCents = totalCents; }

            void settle() { customer.pay(totalCents); paid = true; }    // talks to its
own field
            boolean isPaid() { return paid; }
        }

        class Main {
            public static void main(String[] args) {
                // Violation (would need getters all the way down):
                //   order.getCustomer().getWallet().debit(order.getTotalCents());
                Wallet wallet = new Wallet(10_000);
                Order order = new Order(new Customer("Ada", wallet), 4548);
                order.settle();
                System.out.println(order.isPaid() + " " + wallet.balanceCents());   //
true 5452
            }
        }
```

What to notice:

- Each method calls only its own fields: `Order.settle` → `customer.pay`; `Customer.pay` → `wallet.debit`. No class knows the structure two levels away.
- The cost is small **wrapper methods** (`Customer.pay`). If a class accumulates dozens of pass-through methods, that is a sign the caller needs a different object, not that

the law should be broken.
- The law is about *objects with behavior*. Chaining over data or fluent APIs (`text.strip().lower()`, a stream pipeline) returns new values rather than reaching into structure, and is not a violation in spirit.

Real-world industry applications

INDUSTRY EXAMPLE

Demeter project. The Law of Demeter was developed in the Demeter project on adaptive software at Northeastern University and published as a style rule with a formal statement and examples of mechanically transforming non-compliant programs into compliant ones. The authors present it as a heuristic that limits the spread of change, not an absolute law, and discuss the trade-off of extra wrapper methods. *Evidence: Primary* — [Lieberherr & Holland 1989]

Failure scenarios

Table 35.12 — Failure scenarios from poor cohesion and coupling.

What goes wrong	Why	Detection	Recovery	Prevention
Small change touches 15 files	High coupling (content, common, control)	Large diffs for small features; merge conflicts	Introduce interfaces and owners	Message/data coupling; Law of Demeter
SMTP outage blocks cart updates	Low cohesion: unrelated duties in one class	Incident shows unrelated failure	Split class	Review LCOM components and class names
Refactoring `Wallet` breaks checkout	Train-wreck chains	Compile errors far away	Add delegating methods	One-dot rule for behavior objects
Global discount flag changed by a test leaks into others	Common coupling	Flaky tests	Pass configuration explicitly	No global mutable state

COMMON MISTAKE

Misconception — "Low coupling means fewer classes." Merging classes reduces the number of dependencies *between classes* by hiding them inside one class, where they become low cohesion instead. The goal is the right boundaries: each class cohesive, each dependency narrow.

35.11 Common mistakes

The previous sections each ended with a misconception about one idea. Three mistakes combine several ideas and are the ones reviewers and interviewers look for first.

COMMON MISTAKE

Anemic domain model. Classes such as `Order`, `Cart` and `Customer` hold only fields with getters and setters, and all the rules live in "service" classes (`OrderService.calculateTotal(order)`, `CartService.applyCoupon(cart, coupon)`). It looks object-oriented but is procedural code with data structures: every invariant is enforced, or not, by whichever service touches the data, and the same rule is reimplemented in several services. Fowler named it an anti-pattern because it pays the cost of a domain model without the benefit [Fowler 2003]. **Fix:** move each rule next to the data it governs (tell, don't ask, §35.4.3); keep services for coordinating several objects and for infrastructure such as transactions. **Caveat:** for simple create-read-update-delete screens with almost no rules, plain data records and a thin service are a reasonable, honest choice.

COMMON MISTAKE

God class. One class, often named `Manager`, `Processor`, `Helper` or after the whole application, accumulates most of the system's behavior and data: thousands of lines, dozens of fields, and imports from every package. Riel's design heuristics warn against such classes and recommend distributing system intelligence evenly across top-level classes [Riel 1996]. Symptoms: high LCOM with several connected components (§35.10.1), most commits touch it, and its tests are slow and brittle. **Fix:** split along the components that LCOM reveals, starting with the least coupled group; move behavior to the classes whose data it uses.

COMMON MISTAKE

Deep inheritance hierarchies. `Product → ShippableProduct → FragileShippableProduct → FragileShippableImportedProduct → ...`. Each level adds coupling to every level above it (§35.5.2), a reader must open five files to know what one method does, and new requirements that cut across the hierarchy ("imported but not fragile") cause the class explosion of §35.8. Chidamber and Kemerer's depth-of-inheritance-tree metric was proposed partly because deeper classes are harder to predict [Chidamber & Kemerer 1994]. **Fix:** keep hierarchies shallow (one or two levels below an interface or abstract class is typical), turn independent axes into composed parts, and use interfaces for capabilities.

Table 35.13 — Common mistakes at a glance.

Mistake	Quick test	First fix
Anemic domain model	Do the entity classes have any methods besides getters and setters?	Move one rule into its entity
God class	Can you describe the class in one sentence without “and”?	Split along LCOM components
Deep hierarchy	More than two or three levels of concrete classes?	Extract an axis into a composed part
Setter for every field	Can a caller break an invariant with one call?	Replace setters with business operations
Inheritance for reuse only	Would callers ever use the child *as* the parent?	Delegate to a helper object

35.12 Summary and revision notes

SUMMARY

- **Objects** bundle state and behavior; a **class** is their template. Constructors must leave objects valid or refuse to create them. **Identity** (`is` , Java `==`) differs from **equality** (`==` / `__eq__` , `equals`); override equality and hashing together, value equality for value objects, identity for entities.
- **Encapsulation** protects **invariants** and hides decisions likely to change [Parnas 1972]. Expose business operations, not setters; return copies or immutable views; derive values instead of storing them; **tell, don't ask**.
- **Inheritance** models behavioral is-a and enables substitutability, but is white-box reuse: the **fragile base class problem** means subclasses depend on parent internals (`CountingCart` counted 6 instead of 3). Design and document for inheritance, or prohibit it.
- **Polymorphism**: one call, many behaviors. Subtype polymorphism uses **dynamic dispatch**; Python also allows **duck typing**, checkable with `Protocol` ; **generics** abstract over element types.
- **Abstraction**: abstract classes share state and steps and force subclasses to fill gaps; interfaces declare roles and allow many per class. Program to an interface.
- **Composition over inheritance**: one composed part per axis of variation turns $\prod k_i$ subclasses into $1 + \sum k_i$ classes (27 vs 10 for three axes of three) and allows run-time change. Wrappers with forwarding fix fragile subclasses.
- **Design by contract**: preconditions (caller's duty), postconditions (supplier's promise), invariants. Subclasses may weaken preconditions and strengthen postconditions, never the reverse (preview of §36.5).
- **High cohesion, low coupling**. Prefer data and message coupling; LCOM1 $= \max(|P| - |Q|, 0)$ and connected components point at classes to split. **Law of Demeter**: talk only to your immediate friends.
- Watch for the **anemic domain model**, the **god class** and **deep hierarchies**.

35.13 Knowledge checkpoint

1. What is the difference between a class and an object?
2. Two `Product` objects have the same SKU. Under the design of §35.3, what do `a == b` and `a is b` return, and why?
3. Why must `hashCode` change whenever you override `equals` in Java?
4. Name two ways a getter can break encapsulation.
5. In §35.4, why does the cart not store a `total` field?

6. What exactly goes wrong in the `CountingCart` subclass, and why is removing its `add_all` override not a real fix?
7. What is dynamic dispatch? What decides which method runs?
8. How does duck typing differ from Java's interfaces, and what does `typing.Protocol` add?
9. Give one thing an abstract class can do that a Java interface cannot, and one thing an interface can do that an abstract class cannot.
10. A design has 4 shipping options, 3 packagings and 2 payment timings. How many classes does inheritance-per-combination need, and how many does composition need?
11. State Meyer's rule for preconditions and postconditions in a subclass.
12. Why should user-input validation not be written with `assert`?
13. Rank data, control and content coupling from best to worst.
14. Compute LCOM1 for a class with 4 methods in which exactly one pair shares a field.
15. Rewrite `order.get_customer().get_address().get_city()` used to compute shipping so that it obeys the Law of Demeter.

Answers

1. A class is the template (fields and methods); an object is one instance with its own state, created from the class.
2. `a == b` is `True` because `Product.__eq__` compares SKUs; `a is b` is `False` because they are two distinct objects in memory.
3. Hash-based collections find a bucket by hash first; equal objects with different hashes land in different buckets, so lookups fail and sets hold duplicates.
4. Returning an internal mutable collection (callers can modify it), and exposing data that lets callers make decisions the object should make (logic leaks out).
5. The total is derived from lines and coupon; storing it would let it disagree with them, for example keeping a discount after an item removal drops the subtotal below the minimum.
6. `add_all` counts 3, then the base `add_all` calls the overridden `add` 3 times, counting 3 more: 6. Removing the override relies on the base still calling `add`; if the base changes, the count becomes wrong again.
7. Choosing the method implementation at run time from the object's actual class, not the variable's declared type.
8. Duck typing accepts any object that has the methods used, checked when called; Java requires an explicit `implements`. `Protocol` lets a static checker verify the shape before running, without inheritance.
9. Abstract class: hold instance state (or a `final` template method using it). Interface: be implemented by a class that already extends another class (many interfaces per class).
10. Inheritance: $4 \times 3 \times 2 = 24$. Composition: $1 + 4 + 3 + 2 = 10$.

11. A redefinition may only weaken the precondition and only strengthen the postcondition, and must keep the class invariant.
12. Assertions can be disabled (`python -O` , Java without `-ea`), so the check would silently disappear in production.
13. Data (best), control, content (worst).
14. 6 pairs; $|Q| = 1$, $|P| = 5$; LCOM $= 5 - 1 = 4$.
15. Add `order.shipping_city()` (which asks `customer.shipping_city()` , which asks its address), or better, tell: `order.shipping_cost(rate_table)` .

35.14 Interview questions

Basic

Q1. What are the four pillars of object-oriented programming, and how do they relate? Answer. Encapsulation (an object guards its state and invariants), abstraction (callers see what an object does, not how), inheritance (a class extends another, sharing code and type), and polymorphism (one call, behavior chosen by the object). Encapsulation and abstraction create boundaries; polymorphism lets you vary what is behind a boundary; inheritance is one way, and often not the best way, to get polymorphism. Mention that composition and interfaces deliver polymorphism with less coupling.

Q2. When would you use an abstract class rather than an interface? Answer. An abstract class when closely related variants share real state and an algorithm whose order must be fixed, such as `PaymentMethod.pay` validating, charging and recording. An interface for a role or capability that unrelated classes can play (`Refundable`), for module boundaries, and whenever a class may need several roles. A common combination is an interface for the type plus an optional skeletal abstract class.

Q3. Why are public setters for every field considered poor design? Answer. They let any caller put the object in a state the business rules forbid and spread the rules across callers. Replace them with operations named after business actions that check invariants (`apply_coupon` , `remove`), keep immutable values immutable, and derive computed values.

Intermediate

Q4. “Favor composition over inheritance.” When is inheritance still the right choice? Answer. When the child is a behavioral subtype (keeps every promise of the parent), there is a single axis of variation, the parent was designed and documented for extension, and both are maintained together. Implementing an interface is always fine. Otherwise, compose: separate axes into parts, delegate, and swap parts at run time. Quantify: $\prod k_i$ versus $1 + \sum k_i$ classes.

Q5. Explain the fragile base class problem with an example and two remedies. Answer. A subclass overrides `add` and `add_all` to count items; the base `add_all` internally calls `add`, so items are counted twice. Change the base and the subclass breaks the other way. Remedies: wrap instead of extend (forwarding wrapper implementing the same interface), or have the base class document its self-use or be declared `final`.

Q6. Implement `equals` for a `Money(amount_cents, currency)` value object. What must you remember? Answer. Compare both fields; handle `null` and other types; override `hashCode` with the same fields; make the class immutable so the hash cannot change while it is in a set; keep equality reflexive, symmetric and transitive (be careful with subclasses adding fields, which is why value classes are usually `final` or records).

Advanced

Q7. Design the classes for a shop checkout that supports multiple discount rules, payment methods and shipping options. Answer. `Cart` (entity) owns immutable `Line`s and enforces quantity invariants; `Product` and `Money` are value objects. `DiscountRule` interface with one class per rule; a pricing component picks or stacks rules with a cap at the subtotal. `ShippingPolicy` and `Packaging` as composed parts of `Order`. `PaymentMethod` abstract class with a fixed `pay` template and a `Refundable` capability interface. `Inventory` with a written contract for `reserve`, implemented atomically in storage. Walk through one checkout with a sequence of calls, then discuss extension (new rule = new class), testing (fakes for payment) and failure handling (payment timeouts need idempotency, §22.15).

Q8. Is a `Square` a `Rectangle`? Answer. Mathematically yes; behaviorally only if rectangles are immutable. If `Rectangle` has `set_width` with the postcondition “width changes, height unchanged”, a `Square` must change both, which weakens the postcondition, so code written for rectangles breaks. Options: make shapes immutable, give them a common `Shape` interface without setters, or do not relate them. This is the behavioral subtyping idea of Liskov and Wing, developed in §36.5.

Q9. You inherit a 6,000-line `OrderManager`. How do you approach it? Answer. Add characterization tests around current behavior first. Map which methods use which fields (LCOM components) and which callers use which methods. Extract the most independent component first behind an interface, delegate from the old class so callers keep working, and repeat. Move rules into the entities they govern. Track size, coupling and change frequency to show progress, and avoid a big-bang rewrite.

35.15 Practical exercises

1. **Money value object.** Write `Money(amount_cents, currency)` in Python (frozen dataclass) and Java (record) with addition that refuses mixed currencies. Show that

equal values hash equally and work as set elements.

2. **Break and fix encapsulation.** Change §35.4's `lines()` to return the internal dictionary, write a caller that breaks invariant 1, then restore the snapshot and show the caller now fails.
3. **Fragile base, other direction.** Remove `add_all` from `CountingCart` (§35.5.2), confirm the count is 3, then rewrite the base `add_all` to update the dictionary directly and show the count becomes 0 for `add_all`. Then switch to the wrapper of §35.8 and repeat.
4. **A fourth discount.** Add `CategoryPercentOff` to §35.6 without editing `best_discount`. Then add a rule that stacks discounts but caps the total at the subtotal.
5. **Contract tests.** Write one test function that takes any `Inventory` and checks the `reserve` contract; run it against both classes of §35.9.
6. **Measure cohesion.** Run the LCOM script on a class from a codebase you know, by listing methods and the fields each uses. Do the components suggest a split?

35.16 Design challenges

1. **Library loans.** Design classes for a library that lends books, e-books and DVDs with different loan periods and late fees, and members with different borrowing limits. Identify axes of variation, decide inheritance versus composition, write the contract of `lend(item, member)`, and draw a class diagram.
2. **Notification system.** Orders must notify customers by email, SMS or push, in several languages, with immediate or daily-digest timing. Show the class explosion an inheritance design would cause, compute it, and give a composed design.
3. **Refactor a god class.** Given a `CheckoutManager` with pricing, stock reservation, payment, receipts and analytics, propose the target classes, the order of extraction, how callers keep working during the change, and how you would measure that cohesion improved.

Chapter 36 — SOLID Principles

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 4 h

Chapter 35 gave you the raw materials of object-oriented design: classes, encapsulation, inheritance, polymorphism, interfaces, cohesion and coupling. Those tools say what you *can* build. They do not say which of the many possible arrangements will still be pleasant to change in two years, when the tax rules have changed three times, marketing has rewritten every email, and the payment provider has been replaced. **SOLID** is a set of five design principles that answer that question at the level of classes and modules. Robert C. Martin collected and named them in the late 1990s and early 2000s [Martin 2002]; the acronym itself came later.

Table 36.1 — The five SOLID principles at a glance.

Letter	Principle	One-line test
S	Single Responsibility	Does this module answer to exactly one group of people?
O	Open/Closed	Can I add the next expected variant without editing working code?
L	Liskov Substitution	Can every subtype be used wherever its base type is expected, without surprises?
I	Interface Segregation	Does each client depend only on the methods it calls?
D	Dependency Inversion	Does policy code depend on abstractions that it owns, not on concrete details?

All five serve one goal: to **limit how far a change spreads**. A design in which one business decision touches one module, which is recompiled, retested and redeployed alone, is cheap to change. A design in which every change ripples through ten files owned by four teams is expensive, slow and fragile. SOLID gives you five specific ways to stop the ripple.

The chapter uses one running example throughout: the **order billing and notification module** of an online shop. When a customer places an order, the module computes an invoice (merchandise, gift-wrap fees, sales tax), stores the order, charges the customer's card and tells the customer, by email, SMS, push notification or webhook. For each principle you will see a violating version, the pain it causes, and the refactor in Python and

Java. The final section lifts the principles to components and services, and shows when they do more harm than good.

36.1 Learning objectives

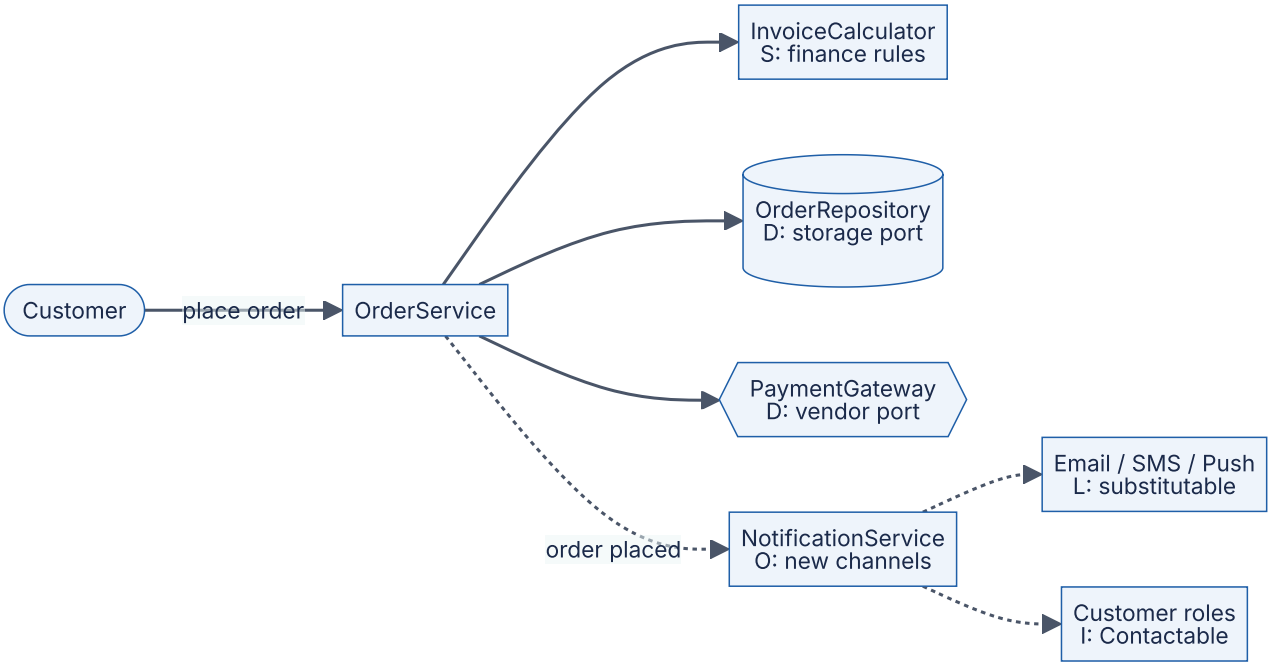
After this chapter you should be able to:

- State each SOLID principle precisely, including its original source, and explain the problem it solves in terms of change and dependency.
- Identify the **actors** behind a class and split it so that each module answers to one actor.
- Distinguish Meyer’s inheritance-based open–closed principle from Martin’s abstraction-based version, and use strategy-style polymorphism to add variants without editing existing code.
- Apply the Liskov–Wing rules (preconditions may be weakened, postconditions strengthened, invariants and history preserved) to decide whether a subtype is safe, and write a reusable contract test.
- Split a fat interface into role interfaces and explain the effect on coupling, rebuilds and stubs.
- Explain dependency inversion, dependency injection and inversion of control as three different ideas, and use fakes to test policy code without networks or databases.
- Map SOLID to component and service boundaries, compute Martin’s instability and abstractness metrics, and recognize when an abstraction is needless.
- Discuss SOLID trade-offs fluently in a low-level design interview.

36.2 Prerequisites

- Classes, encapsulation and interfaces — §35.3, §35.4, §35.9 (every principle is about how classes and interfaces are arranged).
- Inheritance and polymorphism — §35.5, §35.6 (open/closed and Liskov substitution are rules for using them safely).
- Composition over inheritance — §35.8 (most refactors in this chapter replace inheritance with composition).
- Design by contract — §35.9.1 (preconditions and postconditions are the language of Liskov substitution).
- Cohesion and coupling — §35.10 (single responsibility sharpens cohesion; dependency inversion manages coupling).
- Optional: layered and hexagonal architecture — §33.3, §33.10 (needed only for §36.8).

Figure 36.1 — The running example and where each principle acts.



Reading the diagram. The customer (stadium) places an order through `OrderService`, the coordinating class. Solid arrows are synchronous calls made while the customer waits: computing the invoice, storing the order (cylinder, the storage boundary) and charging the card through an external payment provider (hexagon, the main failure point outside your control). Dotted arrows are asynchronous: notification happens after the order is committed, so a slow SMS provider cannot block checkout. Each box is labeled with the principle that shapes it (S, O, L, I or D); the dependency-inverted ports are also what let storage and payments be scaled or replaced independently.

36.3 Single Responsibility Principle

36.3.1 Definition: one reason to change means one actor

> DEFINITION
>
> **Definition — Single Responsibility Principle (SRP).** A module should be responsible to one, and only one, **actor**, where an actor is a group of people (a role, a team, a stakeholder) who request changes to the module for the same reasons [Martin 2017]. The earlier formulation is “a class should have only one reason to change” [Martin 2002].

The name misleads almost everyone. “Single responsibility” sounds like “a class should do one thing”, which is a different and older rule about functions. A class can do many things (validate, compute, round, format a number) and still have one responsibility, because all of those things change for the same reason. Martin made this explicit in a 2014

essay: the principle is about *people*, and its practical form is “gather together the things that change for the same reasons; separate those things that change for different reasons” [Martin 2014].

First-principles explanation

Think of a shared kitchen notice board. If the cleaning rota, the menu and the fire-safety instructions are written on one sheet of paper, then every time the chef reprints the menu there is a chance the fire-safety section is lost or garbled, and the safety officer never asked for anything to change. Three people with unrelated concerns edit one artifact. Give each concern its own sheet and each person can change their sheet without touching anyone else’s.

Code behaves the same way. Each line in a source file was written to satisfy someone. When two groups of people with different priorities edit the same class, three things go wrong. Their changes **collide** (merge conflicts, contested reviews). One group’s change **breaks** behavior the other group relies on, often through shared helper code. And every change to the class forces **retesting and redeployment** of behavior that did not change.

Why does this exist?

The idea predates the name. Parnas argued in 1972 that a system should be split into modules so that each hides one design decision likely to change, rather than one step in a processing flowchart [Parnas 1972]. Cohesion (§35.10) captured “things in this module belong together”. SRP sharpens cohesion by giving a test you can actually apply: *list the people who would ask for this code to change*. If the list has more than one entry with different motives, the module has more than one responsibility.

How it works internally

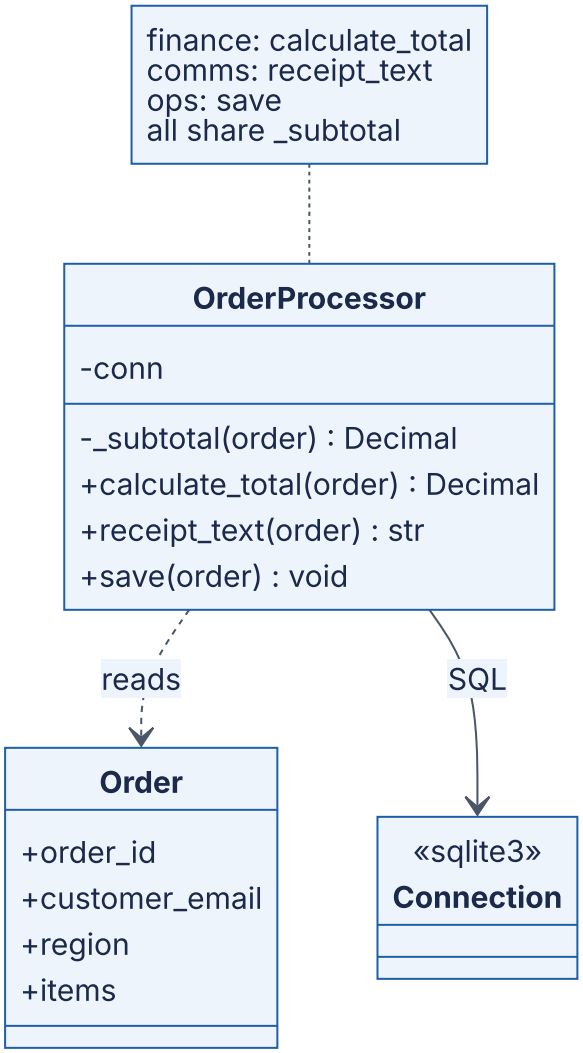
Applying SRP is a four-step procedure:

1. **List the operations** of the class.
2. **Name the actor** for each operation: who would file the ticket that changes it? Use roles (finance, customer communications, operations), not individuals.
3. **Look for shared code** used by operations with different actors. That is where accidental coupling hides.
4. **Split by actor**, give each part its own data or value objects, and, if callers want a single entry point, add a thin **facade** that sequences the parts but contains no business rule.

36.3.2 The violation: one class, three actors

Here is the first version of the billing module. One class computes the total, writes the receipt and saves the order.

Figure 36.2 — Before SRP: one class answers to three actors.



Reading the diagram. One class, `OrderProcessor`, holds a database connection and depends on the `Order` data class (dashed arrow, a usage dependency) and on a SQL connection (solid arrow, an association). Calls are synchronous, in-process method calls. The note lists which actor owns which method. The failure point is the private helper `_subtotal`, which all three public methods use: it is the one place where finance, communications and operations code meet. The storage boundary (the SQL connection) is inside the same class as the tax rules, so a schema change and a tax change produce edits to the same file. This class can only scale by deploying everything together.

```
        from dataclasses import dataclass, field
        from decimal import Decimal, ROUND_HALF_UP
        import sqlite3

        @dataclass
        class LineItem:
            sku: str
            unit_price: Decimal
            quantity: int
            gift_wrap: bool = False

        @dataclass
        class Order:
            order_id: str
            customer_email: str
            region: str
            items: list[LineItem] = field(default_factory=list)

        TAX_RATES = {"CA": Decimal("0.0725"), "NY": Decimal("0.04")}
        GIFT_WRAP_FEE = Decimal("4.00")

        class OrderProcessor:
            """Before SRP: finance, customer comms and operations all edit this
class."""

            def __init__(self, conn: sqlite3.Connection):
                self.conn = conn
                conn.execute("CREATE TABLE IF NOT EXISTS orders "
                             "(id TEXT PRIMARY KEY, email TEXT, total TEXT)")

            def _subtotal(self, order: Order) -> Decimal:      # shared helper
                total = Decimal("0")
                for item in order.items:
                    total += item.unit_price * item.quantity
                    if item.gift_wrap:
                        total += GIFT_WRAP_FEE
                return total

            # Actor 1 -- finance: tax and fee policy
            def calculate_total(self, order: Order) -> Decimal:
                sub = self._subtotal(order)
                tax = (sub * TAX_RATES[order.region]).quantize(Decimal("0.01"),
ROUND_HALF_UP)
                return sub + tax

            # Actor 2 -- customer communications: receipt wording and layout
            def receipt_text(self, order: Order) -> str:
                return (f"Order {order.order_id}: items {self._subtotal(order):.2f}, "
                        f"total due {self.calculate_total(order):.2f}")

            # Actor 3 -- operations: schema and storage
            def save(self, order: Order) -> None:
                self.conn.execute("INSERT INTO orders VALUES (?, ?, ?)",
                                  (order.order_id, order.customer_email,
                                   str(self.calculate_total(order))))
```

```
        if __name__ == "__main__":
            order = Order("A-1001", "ana@example.com", "CA",
                          [LineItem("MUG", Decimal("20.00"), 2, gift_wrap=True)])
            processor = OrderProcessor(sqlite3.connect(":memory:"))
            processor.save(order)
            print(processor.receipt_text(order))
            # Order A-1001: items 44.00, total due 47.19
```

What to notice:

- `_subtotal` mixes two concepts: the merchandise value and the gift-wrap fee. Both the tax computation and the receipt rely on it.
- The receipt calls `calculate_total`, so receipt wording now depends on tax policy.
- The class creates its own table. A database migration and a tax change land in the same file and the same deployment.

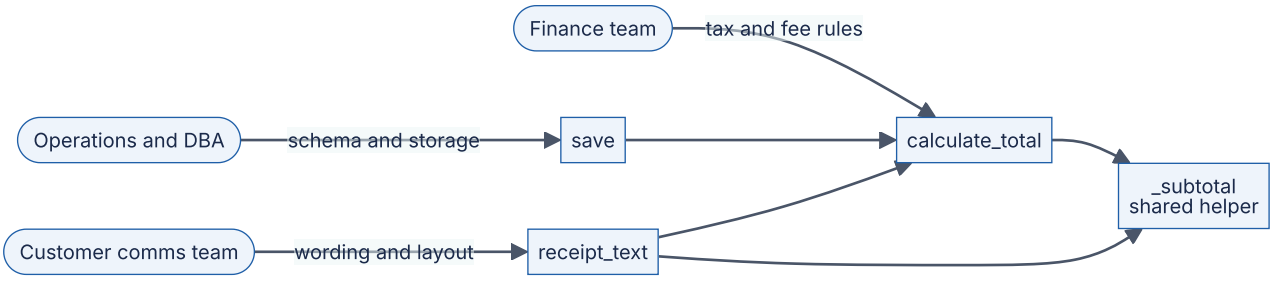
WORKED EXAMPLE

Worked example — How a finance change breaks the receipt. Finance learns that in its main state gift wrapping should not be taxed. A developer on the finance team edits `_subtotal` to return only merchandise, and adds the wrap fee after tax in `calculate_total`. For order A-1001 (two mugs at $20.00, one gift-wrapped line, California rate 7.25%):

1. Before the change: subtotal = 2 × 20.00 + 4.00 = 44.00; tax = 44.00 × 0.0725 = 3.19; total = 47.19. Receipt: “items 44.00, total due 47.19”. The $3.19 difference is tax, as the customer expects.
2. After the change: `_subtotal` = 40.00; tax = 40.00 × 0.0725 = 2.90; total = 40.00 + 2.90 + 4.00 = 46.90. Receipt: “items 40.00, total due 46.90”.
3. The customer now sees $6.90 between “items” and “total” with no explanation of the $4.00 wrap fee. Nobody on the communications team changed anything; their tests (if they exist) assert wording, not arithmetic.

Interpretation. The finance change was correct for finance, and the defect landed in another actor’s output through a shared helper. **Engineering implication.** Shared code between actors is not reuse; it is accidental coupling. Two pieces of code that look identical today but change for different reasons should be allowed to diverge.

Figure 36.3 — Actors map to methods; shared code couples them.

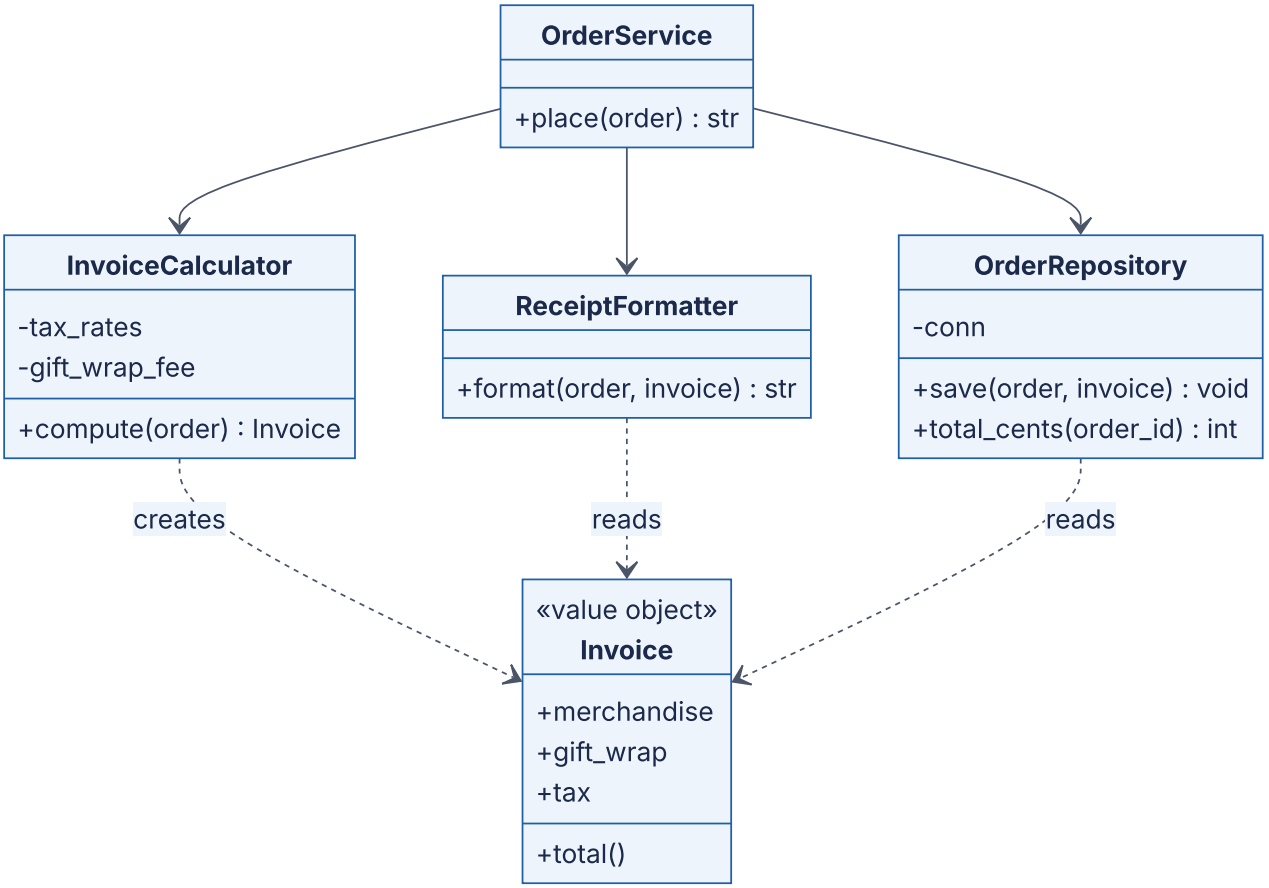


Reading the diagram. Stadium shapes are the three actors; rectangles are methods of the single class. Arrows from actors are change requests; arrows between methods are synchronous in-process calls. Follow them into `_subtotal`: a finance change reaches the receipt and the stored total. That convergence is the failure point SRP targets. Splitting into smaller methods does not help; the methods are already small, and what matters is that their *change paths* converge. No storage boundary is shown because the problem is code ownership.

36.3.3 The refactor: split by actor

The refactor creates one class per actor and a value object, `Invoice`, that carries finance's result to the others so nobody recomputes it.

Figure 36.4 — After SRP: one class per actor, coordinated by a facade.



Reading the diagram. `OrderService` is a facade: it holds references (solid arrows) to three collaborators and calls them synchronously in sequence. Each collaborator answers to one actor: `InvoiceCalculator` to finance, `ReceiptFormatter` to communications, `OrderRepository` to operations. The immutable `Invoice` value object (dashed arrows, usage) is created only by the calculator and read by the others, so the arithmetic exists in exactly one place. The storage boundary is now confined to `OrderRepository`; a schema migration touches only that class. Failure points are isolated too: a formatting bug cannot change a stored total.

Code example

```
        from dataclasses import dataclass
        from decimal import Decimal, ROUND_HALF_UP
        import sqlite3

                          (LineItem("MUG", Decimal("20.00"), 2, gift_wrap=True),))
            rates = {"CA": Decimal("0.0725"), "NY": Decimal("0.04")}
            for tax_wrap in (True, False):           # finance flips one policy flag
                repo = OrderRepository(sqlite3.connect(":memory:"))
                service = OrderService(InvoiceCalculator(rates, Decimal("4.00"),
tax_wrap),
                                       ReceiptFormatter(), repo)
                print(f"tax_gift_wrap={tax_wrap}")
                print(service.place(order))
                print("  stored cents:", repo.total_cents("A-1001"))
        # Output (abridged): Tax 3.19, Total 47.19, stored 4719; then Tax 2.90, Total
46.90, stored 4690
```

What to notice:

- Finance’s policy change is now one constructor argument in one class. The receipt shows a separate gift-wrap line, so it reconciles in both cases (40.00 + 4.00 + 2.90 = 46.90).
- `Invoice` is frozen. Communications and operations read finance’s numbers; they cannot alter them.
- The repository stores integer cents, an operations decision invisible to the other two classes.
- `OrderService` contains no `if`, no arithmetic and no SQL. A facade that starts accumulating rules is a sign that a fourth actor has appeared.

The same design in Java (compiled and run with `javac` / `java` 21):

```
        // File: SrpAfter.java  (Java 17+)
        import java.math.BigDecimal;
        import java.math.RoundingMode;
        import java.util.HashMap;
        import java.util.List;
        import java.util.Map;

        public class SrpAfter {
            record LineItem(String sku, BigDecimal unitPrice, int quantity, boolean
giftWrap) {}
            record Order(String orderId, String customerEmail, String region,
List<LineItem> items) {}
            record Invoice(BigDecimal merchandise, BigDecimal giftWrap, BigDecimal tax)
{
                BigDecimal total() { return merchandise.add(giftWrap).add(tax); }
            }

            /** Answers to finance. */
            static final class InvoiceCalculator {
                private final Map<String, BigDecimal> taxRates;
                private final BigDecimal giftWrapFee;
                private final boolean taxGiftWrap;
                InvoiceCalculator(Map<String, BigDecimal> taxRates, BigDecimal
giftWrapFee, boolean taxGiftWrap) {
                    this.taxRates = taxRates; this.giftWrapFee = giftWrapFee;
this.taxGiftWrap = taxGiftWrap;
                }
                Invoice compute(Order order) {
                    BigDecimal merchandise = BigDecimal.ZERO, wraps = BigDecimal.ZERO;
                    for (LineItem i : order.items()) {
                        merchandise =
merchandise.add(i.unitPrice().multiply(BigDecimal.valueOf(i.quantity())));
                        if (i.giftWrap()) wraps = wraps.add(giftWrapFee);
                    }
                    BigDecimal taxable = taxGiftWrap ? merchandise.add(wraps) : merchan-
dise;
                    BigDecimal tax = taxable.multiply(taxRates.get(order.region()))
                                            .setScale(2, RoundingMode.HALF_UP);
                    return new Invoice(merchandise, wraps, tax);
                }
            }

            /** Answers to customer communications. */
            static final class ReceiptFormatter {
                String format(Order order, Invoice inv) {
                    StringBuilder sb = new StringBuilder("Order " + order.orderId() +
"\n");
                    sb.append(String.format("  Merchandise %8.2f%n", inv.merchan-
dise()));
                    if (inv.giftWrap().signum() > 0) sb.append(String.format("  Gift
wrap   %8.2f%n", inv.giftWrap()));
                    sb.append(String.format("  Tax         %8.2f%n", inv.tax()));
                    sb.append(String.format("  Total       %8.2f", inv.total()));
                    return sb.toString();
                }
            }
```

```
            /** Answers to operations. An in-memory map stands in for the database. */
            static final class OrderRepository {
                private final Map<String, Long> totalCents = new HashMap<>();
                void save(Order order, Invoice inv) {
                    totalCents.put(order.orderId(), inv.total().movePointRight(2).long-
ValueExact());
                }
                long totalCents(String orderId) { return totalCents.get(orderId); }
            }

            /** Facade: sequences the parts, owns no rule. */
            static final class OrderService {
                private final InvoiceCalculator calculator;
                private final ReceiptFormatter formatter;
                private final OrderRepository repository;
                OrderService(InvoiceCalculator c, ReceiptFormatter f, OrderRepository
r) {
                    calculator = c; formatter = f; repository = r;
                }
                String place(Order order) {
                    Invoice invoice = calculator.compute(order);
                    repository.save(order, invoice);
                    return formatter.format(order, invoice);
                }
            }

            public static void main(String[] args) {
                Order order = new Order("A-1001", "ana@example.com", "CA",
                        List.of(new LineItem("MUG", new BigDecimal("20.00"), 2, true)));
                Map<String, BigDecimal> rates = Map.of("CA", new BigDecimal("0.0725"),
"NY", new BigDecimal("0.04"));
                for (boolean taxWrap : new boolean[] {true, false}) {
                    OrderRepository repo = new OrderRepository();
                    OrderService service = new OrderService(
                            new InvoiceCalculator(rates, new BigDecimal("4.00"),
taxWrap), new ReceiptFormatter(), repo);
                    System.out.println("taxGiftWrap=" + taxWrap + "\n" +
service.place(order));
                    System.out.println("  stored cents: " + repo.totalCents("A-1001"));
                }
            }
        }
```

What to notice:

- Records give immutable value objects for free; `BigDecimal` with an explicit `RoundingMode` avoids binary floating-point error in money (never use `double` for currency).
- `movePointRight(2).longValueExact()` throws if the total somehow had fractions of a cent, turning a silent rounding bug into a loud failure at the storage boundary.

Real-world industry applications

INDUSTRY EXAMPLE

`java.util.Date` and its successors. Java 1.0's `Date` combined three responsibilities: representing an instant, interpreting it as calendar fields (year, month, day) and parsing strings. JDK 1.1 deprecated the calendar-field and parsing methods in favor of `Calendar` and `DateFormat`, and Java 8's `java.time` package (JSR 310) separated the concepts further into `Instant`, `LocalDate`, `ZonedDateTime` and `DateTimeFormatter`. Each type now changes for one kind of reason: time-zone rules, calendar arithmetic or text formats. The cost was a long migration and two generations of deprecated API. *Evidence: Primary* — [Oracle Java SE API: java.util.Date; java.time]

Advantages and disadvantages

The benefits are fewer merge conflicts between teams, defects that stay inside one actor's code, smaller test surfaces and the freedom to deploy one part without the others. The costs are more classes, more names to learn and a coordination layer (the facade) that newcomers must find. Guessing the actors wrong creates seams in the wrong places.

Table 36.2 — SRP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
One team's change breaks another's output	Shared helper across actors	Cross-team bug reports; tests in an unrelated area fail	Duplicate the helper per actor, then let copies diverge	Map actors before extracting "common" code
Constant merge conflicts on one file	Several teams edit one class	Version-control history: many authors, unrelated commits	Split by actor behind a facade	Review ownership in design reviews
Over-split code: one change touches six classes	Split by technical step, not by actor	Every feature ticket edits the same cluster of files	Merge classes that always change together	Split only along observed reasons to change

Common misconceptions

COMMON MISTAKE

"SRP means a class should do only one thing." That rule applies to functions. A class may do many related things. SRP asks *who* requests changes, and a 300-line class that only finance ever changes satisfies it better than five 60-line classes that every ticket touches together.

COMMON MISTAKE

“Duplicated code always violates DRY, so merge it.” Two blocks that look the same but answer to different actors are *accidental* duplicates. Merging them creates the coupling in the worked example above. Merge only when the code represents the same knowledge and will change for the same reason.

INTERVIEW TIP

SRP in LLD interviews. When you sketch classes for a parking lot or a billing system, name the actor behind each class out loud (“pricing changes when the business changes rates; the ticket printer changes when the hardware changes”). Interviewers listen for *reasons to change*, not class counts. If asked to “add a feature”, show that it lands in one class.

36.4 Open/Closed Principle

36.4.1 Definition: Meyer’s version and Martin’s version

DEFINITION

Definition — Open/Closed Principle (OCP). Software entities (classes, modules, functions) should be **open for extension** but **closed for modification**: you should be able to add new behavior by adding new code, without editing code that already works and is already depended upon [Martin 2002]. The principle was first stated by Bertrand Meyer [Meyer 1988].

The two halves sound contradictory until you see what each refers to. “Closed” refers to the existing source: its text, its tests, its users. “Open” refers to the set of behaviors the system can exhibit. The trick that reconciles them is an **abstraction** that stays fixed while the number of implementations behind it grows.

Meyer and Martin used different tricks, and interviewers sometimes ask about the difference.

Table 36.3 — Meyer’s and Martin’s open-closed principles.

Aspect	Meyer (1988, 1997)	Martin (1996, 2002)
Problem	A published library module must stay stable for its users, yet keep evolving	Client code must not be edited every time a new variant appears
“Closed” means	The module has a stable, well-defined interface and is available for use by other modules	The client’s source is not edited when variants are added
“Open” means	The module can still be extended, for example with new features or fields	New behavior can be added by writing new classes
Mechanism	Implementation inheritance: a subclass reuses and extends the frozen original	Abstract interfaces and polymorphism: clients depend on an interface; variants implement it
Typical risk	Deep, fragile inheritance trees	Speculative interfaces nobody extends

Meyer’s setting was library engineering: once a class is compiled, documented and used by others, you do not edit it; you inherit from it and add to the subclass [Meyer 1997]. Martin kept the goal but moved the mechanism to abstraction: the client depends on an interface, and new implementations plug in behind it. Martin’s version dominates, partly because implementation inheritance invites the substitution problems of §36.5. Larman later restated the same idea as **protected variations**: identify points of predicted variation and wrap a stable interface around them [Larman 2001].

First-principles explanation

A wall socket is open/closed. The socket (the interface) was fixed decades ago; lamps, chargers and kettles that did not exist when it was installed plug into it without anyone rewiring the house. The house is closed for modification and open for extension *along one axis*: things that use the standard plug. It is not open along other axes. A device needing three-phase power still requires an electrician. Every OCP design is like this: closed against the kinds of change you anticipated, and open only along those axes.

Why does this exist?

Editing working code is risky in proportion to how many things depend on it. Each edit can break existing behavior, forces re-review and retesting, and, in compiled languages, recompiles and redeploys every dependent module. When the same `if/elif` chain over a “type” field appears in five places, adding one new type means five coordinated edits; missing one is a production bug. OCP replaces “find every place that switches on type” with “add one class”.

How it works internally

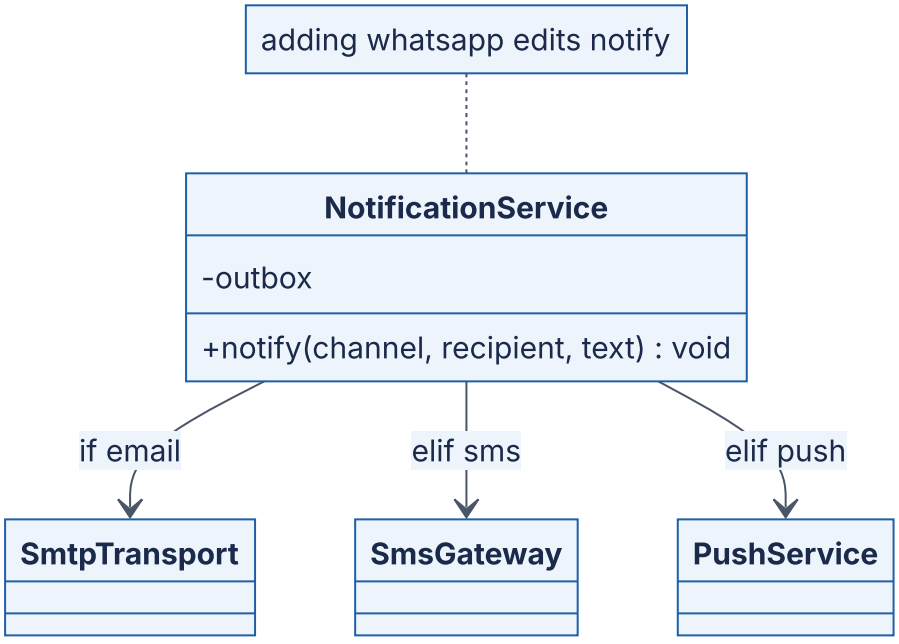
1. **Find the axis of variation**: the thing that keeps changing (channels, tax regimes, discount rules, file formats).
2. **Define an abstraction** that captures what clients need from every variant, in the client's vocabulary.
3. **Move each variant** into its own class implementing the abstraction (the Strategy pattern, §37.7).
4. **Make clients depend only on the abstraction**, and select variants in one place: a registry, a configuration file or a composition root.
5. **Add new variants as new classes**; existing code is untouched.

Martin calls the choice of axis **strategic closure**: no design is closed against every change, so you choose the changes you expect and close against those [Martin 2002].

36.4.2 The violation: a switch on channel

After the SRP refactor, the shop adds a notification step. The first version switches on a channel string.

Figure 36.5 — Before OCP: one method knows every channel.



Reading the diagram. A single class holds direct, synchronous references to three transports and chooses among them with a conditional; the edge labels show the branch that selects each one. Every transport is a failure point the service must know about, and every new transport adds an edge *and* an edit to `notify`. A change for WhatsApp re-runs and re-reviews email and SMS logic, and in a compiled language rebuilds every dependent.

```
        class NotificationService:
            """Before OCP: every new channel means editing this method."""

            def __init__(self, outbox: list):
                self.outbox = outbox                  # stands in for real transports

            def notify(self, channel: str, recipient: str, text: str) -> None:
                if channel == "email":
                    self.outbox.append(("smtp", recipient, f"Subject: Your
order\n\n{text}"))
                elif channel == "sms":
                    self.outbox.append(("sms-gateway", recipient, text[:160]))
                elif channel == "push":
                    self.outbox.append(("push", recipient, text[:100]))
                else:
                    raise ValueError(f"unknown channel: {channel}")

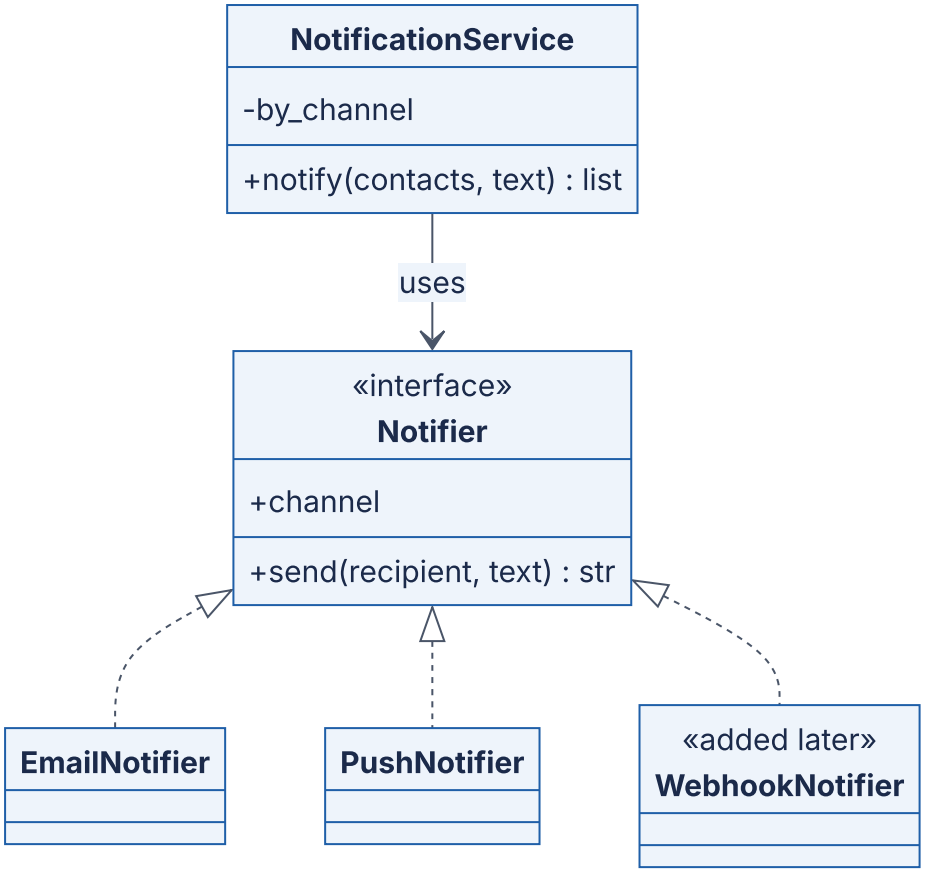
        if __name__ == "__main__":
            outbox = []
            service = NotificationService(outbox)
            service.notify("sms", "+15550100", "Order A-1001 shipped")
            try:
                service.notify("whatsapp", "+15550100", "Order A-1001 shipped")
            except ValueError as err:
                print("cannot extend without editing:", err)
```

What to notice:

- The only way to add a channel is to edit `notify`, a method every order flows through.
- `text[:160]` silently truncates SMS messages. Keep that line in mind; it returns as a Liskov violation in §36.5.

36.4.3 The refactor: depend on a Notifier abstraction

Figure 36.6 — After OCP: the service depends on an abstraction; channels plug in.



Reading the diagram. `NotificationService` holds a map from channel name to `Notifier` (solid arrow) and calls `send` synchronously through the interface. Three classes implement the interface (dashed arrows with hollow triangles, realization). `WebhookNotifier` was added months later in a new module; no arrow into or out of the service changed. Failure handling is now per implementation: a webhook timeout lives in `WebhookNotifier`. The service never imports a transport, so new channels do not rebuild or retest it. In production, `notify` would usually run asynchronously from a queue (Chapter 30), which Figure 36.1 shows as the dotted path.

Code example

```
        import itertools
        from typing import Protocol

        class Notifier(Protocol):
            """The stable abstraction. Contract: send() delivers the full text and
            returns a non-empty message id; it raises only for an invalid recipient."""
            channel: str
            def send(self, recipient: str, text: str) -> str: ...

        _ids = itertools.count(1)

        class EmailNotifier:
            channel = "email"
            def __init__(self, outbox: list):
                self.outbox = outbox
            def send(self, recipient: str, text: str) -> str:
                msg_id = f"em-{next(_ids)}"
                self.outbox.append((msg_id, recipient, f"Subject: Your
order\n\n{text}"))
                return msg_id

        class PushNotifier:
            channel = "push"
            def __init__(self, outbox: list):
                self.outbox = outbox
            def send(self, recipient: str, text: str) -> str:
                msg_id = f"pu-{next(_ids)}"
                self.outbox.append((msg_id, recipient, text))
                return msg_id

        class NotificationService:
            """Closed for modification: knows only the Notifier abstraction."""

            def __init__(self, notifiers: list[Notifier]):
                self._by_channel = {n.channel: n for n in notifiers}

            def notify(self, contacts: dict[str, str], text: str) -> list[str]:
                """contacts maps channel -> address, in the customer's preference or-
der."""
                sent = []
                for channel, address in contacts.items():
                    notifier = self._by_channel.get(channel)
                    if notifier is not None:          # unknown channels are skipped
                        sent.append(notifier.send(address, text))
                return sent

        # ---- Extension added months later, in a new module: no existing line edited --
--
        class WebhookNotifier:
            channel = "webhook"
            def __init__(self, outbox: list):
                self.outbox = outbox
            def send(self, recipient: str, text: str) -> str:
                msg_id = f"wh-{next(_ids)}"
```

```
                self.outbox.append((msg_id, recipient, {"event": "order.updated",
"text": text}))
                return msg_id

        if __name__ == "__main__":
            outbox: list = []
            service = NotificationService([EmailNotifier(outbox), PushNotifier(outbox),
                                           WebhookNotifier(outbox)])   # composition
root
            ids = service.notify({"email": "ana@example.com",
                                  "webhook": "https://erp.example.com/hooks/orders",
                                  "fax": "+15550199"}, "Order A-1001 shipped")
            print(ids)            # ['em-1', 'wh-2']  (no fax notifier registered)
```

What to notice:

- `typing.Protocol` gives **structural** typing: `WebhookNotifier` never names `Notifier`, yet a type checker accepts it because it has the right members [PEP 544].
- The docstring on `Notifier` states a **contract**, not just a signature. OCP only works if every implementation honors it, which is exactly the subject of §36.5.
- The constructor list is the single point where variants are chosen; moving it to configuration removes even that edit.

```
        // File: OcpAfter.java  (Java 17+)
        import java.util.ArrayList;
        import java.util.LinkedHashMap;
        import java.util.List;
        import java.util.Map;
        import java.util.function.Function;
        import java.util.stream.Collectors;

        public class OcpAfter {
            /** Stable abstraction: deliver the full text, return a non-empty message
id. */
            interface Notifier {
                String channel();
                String send(String recipient, String text);
            }

            static final List<String> OUTBOX = new ArrayList<>();   // stands in for
transports

            static final class EmailNotifier implements Notifier {
                public String channel() { return "email"; }
                public String send(String to, String text) {

                    contacts.forEach((channel, address) -> {
                        Notifier n = byChannel.get(channel);
                        if (n != null) ids.add(n.send(address, text));
                    });
                    return ids;
                }
            }

            // ---- Extension added later: a new class, no edits above this line ----
            static final class WebhookNotifier implements Notifier {
                public String channel() { return "webhook"; }
                public String send(String url, String text) {
```

```
                    OUTBOX.add("POST " + url + " |
{\"event\":\"order.updated\",\"text\":\"" + text + "\"}");
                    return "wh-" + OUTBOX.size();
                }
            }

            public static void main(String[] args) {
                NotificationService service = new NotificationService(
                        List.of(new EmailNotifier(), new PushNotifier(), new
WebhookNotifier()));
                Map<String, String> contacts = new LinkedHashMap<>();
                contacts.put("email", "ana@example.com");
                contacts.put("webhook", "https://erp.example.com/hooks/orders");
                contacts.put("fax", "+15550199");                    // no notifier:
skipped
                System.out.println(service.notify(contacts, "Order A-1001 shipped"));
// [em-1, wh-2]
            }
        }
```

What to notice: in Java the abstraction is nominal (`implements Notifier`), so the compiler rejects a class that forgets a method. A `LinkedHashMap` preserves the customer's preference order. In a real codebase, `java.util.ServiceLoader` can discover `Notifier` implementations on the class path, so even the composition root need not change.

Real-world industry applications

INDUSTRY EXAMPLE

Linux virtual file system. The Linux kernel's VFS layer calls file systems through tables of function pointers (`struct file_operations`, `struct inode_operations` and others). System-call code such as `read` and `write` dispatches through these tables and does not name ext4, XFS or NFS. A new file system is added by providing new operation tables and registering the file-system type, without editing the system-call layer. This is OCP in C, where an operations struct plays the role of an interface. *Evidence: Primary* — [Linux kernel docs: Overview of the Linux Virtual File System]

Advantages, disadvantages and alternatives

OCP cuts the cost of the *expected* change to "write one class and register it", keeps existing tests valid and allows separate teams to own variants. It costs indirection (a reader must find which implementation runs) and an up-front guess about the axis of change. A wrong guess is worse than no guess: the abstraction resists the change that actually arrives. Note too that polymorphism makes adding *types* cheap but adding *operations* expensive: a new method on `Notifier` must be implemented by every channel. If your system mostly gains operations over a fixed set of types, a `match` statement or the Visitor pattern can be the more open design. This tension is known as the expression problem.

Table 36.4 — OCP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
New variant needs edits in five places	Type switches duplicated across clients	Feature diffs touch many files with the same `if` chain	Replace the switch with polymorphism or a registry	One place selects variants
Abstraction cannot express the new variant	Wrong axis of closure	The new class needs flags or downcasts	Redesign the interface with the new knowledge	Close only after two or three real variants exist
Indirection without benefit	Interface added for a variant that never came	Interfaces with exactly one implementation for years	Inline the interface	Apply YAGNI (§36.8.3)

Common misconceptions

COMMON MISTAKE

"Closed for modification means never edit the class." Bug fixes, refactors and changes along an axis you did not anticipate are edited normally. OCP is about the *anticipated* kind of change being additive.

INTERVIEW TIP

OCP in LLD interviews. When the interviewer says "now add a new vehicle type / payment method / pricing rule", the answer they hope for is "that is one new class implementing `X`; nothing else changes". Design your first class diagram so that the obvious extension follows that path, and say which axis you have chosen to keep open.

36.5 Liskov Substitution Principle

36.5.1 Definition: behavioral subtyping

DEFINITION

Definition — Liskov Substitution Principle (LSP). Subtypes must be substitutable for their base types [Martin 2002]. More precisely, S is a **behavioral subtype** of T if every property you can prove about objects of type T, using T's specification, also holds for objects of type S [Liskov and Wing 1994].

Barbara Liskov introduced the idea in her 1987 OOPSLA keynote, "Data Abstraction and Hierarchy", as a substitution property: if for each object o1 of type S there is an object o2 of type T such that, for all programs P defined in terms of T, the behavior of P is un-

changed when o1 is substituted for o2, then S is a subtype of T [Liskov 1987]. Liskov and Wing's 1994 paper turned this into checkable rules for preconditions, postconditions, invariants and the history of an object [Liskov and Wing 1994]. Martin's one-line version is the one engineers quote.

First-principles explanation

A car-rental company promises "a mid-size car with an automatic gearbox". You are handed a different model from the one in the brochure, and that is fine: it is a substitute. It would not be fine to be handed a car that only starts if you phone the depot first (a stronger *precondition*), or one whose fuel gauge reads full when the tank is half empty (a weaker *postcondition*). Substitution is about the *promise*, not about what the thing looks like.

The compiler checks only the shape: method names and parameter types. LSP is about the behavior those signatures promise. A subclass that compiles can still break every caller.

Why does this exist?

Polymorphism is the engine of OCP: clients call `notifier.send(...)` without knowing which class runs. That only works if every implementation keeps the promises the client relies on. If one subtype behaves differently, the client must find out which type it holds (`isinstance` checks, `instanceof` casts, special cases) and OCP collapses, because each new subtype now needs a client edit. LSP is the condition that keeps polymorphism safe.

How it works internally: the Liskov–Wing rules

FORMULA

Behavioral subtyping rules for a method m of base type T overridden in subtype S

$$\text{Pre}_T(m) \Rightarrow \text{Pre}_S(m) \qquad \text{Post}_S(m) \Rightarrow \text{Post}_T(m) \qquad \text{Inv}_S \Rightarrow \text{Inv}_T$$

Symbol	Meaning	Units
$\text{Pre}_T(m)$	Precondition: what the caller must guarantee before calling m on a T	predicate (true/false)
$\text{Pre}_S(m)$	Precondition of the overriding method in S	predicate
$\text{Post}_T(m)$	Postcondition: what m guarantees on return, per T's specification	predicate
$\text{Post}_S(m)$	Postcondition of the overriding method in S	predicate
Inv_T, Inv_S	Invariants: properties true of every T (or S) object between calls	predicate
$\Rightarrow$	Logical implication: whenever the left side is true, the right side must be true	—

Read the rules as: a subtype may **accept more** (weaker precondition) and **promise more** (stronger postcondition), never accept less or promise less; it must keep the base type's invariants; and, the **history constraint**, it must not allow state changes that the base type's methods could not produce. A further rule follows from the postcondition rule: a subtype must not throw exceptions that the base contract does not allow, because an unexpected exception is a broken promise.

WORKED EXAMPLE

Worked example — Checking two SMS notifiers against the Notifier contract. The `Notifier` contract says: precondition, the text has 1 to 1,600 characters; postcondition, the full text is delivered and a non-empty id is returned. A single SMS holds at most 160 GSM-7 characters; a message split into concatenated parts holds 153 characters per part, because each part carries a small header that reassembles the message on the handset.

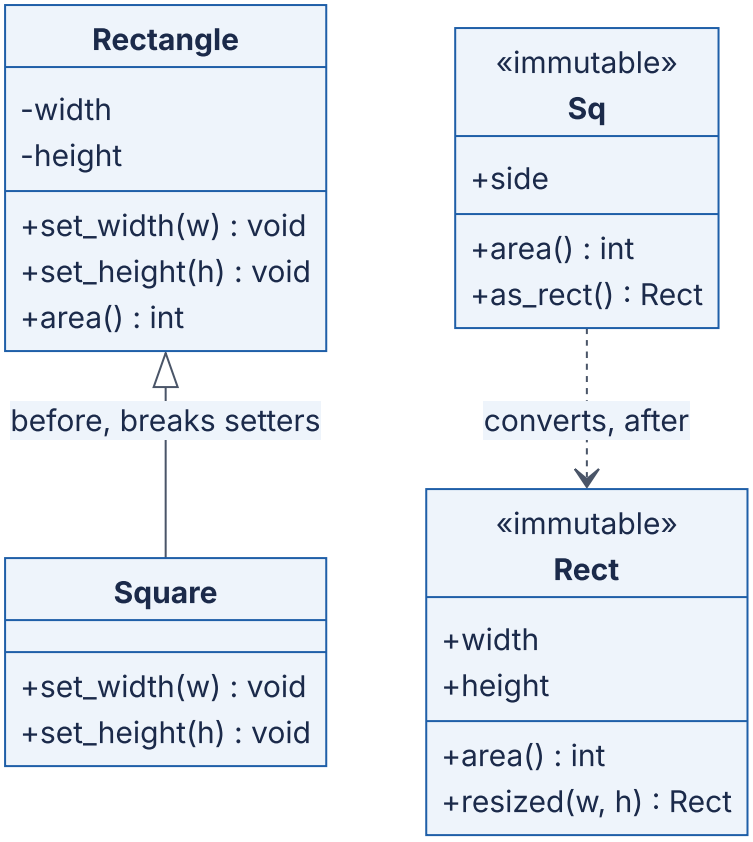
1. `StrictSmsNotifier` rejects text longer than 160. Take a 320-character receipt. Pre_T: $1 \le 320 \le 1{,}600$ is true. Pre_S: $320 \le 160$ is false. True ⇒ false is false, so the precondition rule fails: the subtype **strengthened** the precondition.
2. `TruncatingSmsNotifier` sends `text[:160]`. Preconditions match, but for 320 characters it delivers 160. Post_S ("first 160 characters delivered") does not imply Post_T ("all 320 delivered"), so the postcondition rule fails: the subtype **weakened** the postcondition.
3. `SegmentingSmsNotifier` splits long text into 153-character parts: $\lceil 320 / 153 \rceil = \lceil 2.09 \rceil = 3$ parts ($153 + 153 + 14 = 320$ characters). At the contract maximum, $\lceil 1{,}600 / 153 \rceil = \lceil 10.46 \rceil = 11$ parts. Both rules hold.

Interpretation. The strict notifier fails loudly at run time; the truncating one fails silently, which is worse, because customers receive half a receipt and no alert fires. **Engineering implication.** The base contract's limit of 1,600 characters is itself a design decision: a contract of 10,000 characters would force $\lceil 10{,}000 / 153 \rceil = 66$ SMS parts per message, which no business would pay for. Choose base-type preconditions that every reasonable implementation can honor.

36.5.2 The classic violation: Square extends Rectangle

Geometry says every square is a rectangle. Code says otherwise when `Rectangle` has independent setters.

Figure 36.7 — Rectangle and Square, before and after.



Reading the diagram. On the left, `Square` inherits from the mutable `Rectangle` (solid line, hollow triangle) and overrides both setters to keep its sides equal. That override breaks the base postcondition "`set_width` leaves the height unchanged", which is the failure point. On the right, the refactored types are immutable: no method mutates an object, so there is no setter whose postcondition a square could violate. `Sq` relates to `Rect` by conversion (dashed arrow), not inheritance; in Python an immutable `Square(Rectangle)` subclass is also safe, as the code shows. All calls are synchronous and in-memory; there is no storage boundary.

```
        class Rectangle:
            def __init__(self, width: int, height: int):
                self._w, self._h = width, height
            def set_width(self, w: int) -> None:
                self._w = w
            def set_height(self, h: int) -> None:
                self._h = h
            def area(self) -> int:
                return self._w * self._h

        class Square(Rectangle):
            """'A square is a rectangle' -- true in geometry, false for this con-
tract."""
            def __init__(self, side: int):
                super().__init__(side, side)
            def set_width(self, w: int) -> None:
                self._w = self._h = w             # keeps the square invariant ...
            def set_height(self, h: int) -> None:
                self._w = self._h = h             # ... by breaking Rectangle's postcon-
dition

        def resize_banner(r: Rectangle) -> int:
            """A client written against Rectangle's documented behavior."""
            r.set_width(5)
            r.set_height(4)
            assert r.area() == 20, f"expected area 20, got {r.area()}"
            return r.area()

        for shape in (Rectangle(1, 1), Square(1)):
            try:
                print(type(shape).__name__, "area", resize_banner(shape))
            except AssertionError as err:
                print(type(shape).__name__, "breaks the client:", err)
        # Rectangle area 20
        # Square breaks the client: expected area 20, got 16
```

The fix is to remove the operation that cannot be honored. With immutable values, a square really is a rectangle, because nothing can try to stretch it in place:

```
        from dataclasses import dataclass

        @dataclass(frozen=True)
        class Rectangle:
            width: int
            height: int
            def area(self) -> int:
                return self.width * self.height
            def resized(self, width: int, height: int) -> "Rectangle":
                """Postcondition: returns a Rectangle with exactly these sides."""
                return Rectangle(width, height)

        class Square(Rectangle):
            """Safe now: no operation lets a Square stop being square."""
            def __init__(self, side: int):
                super().__init__(side, side)
            @property
            def side(self) -> int:
                return self.width

        def resize_banner(r: Rectangle) -> int:
            resized = r.resized(5, 4)
            assert resized.area() == 20
            return resized.area()

        for shape in (Rectangle(1, 1), Square(1)):
            print(type(shape).__name__, "->", resize_banner(shape), "| original area",
shape.area())
        # Rectangle -> 20 | original area 1
        # Square -> 20 | original area 1
```

What to notice:

- The violation is not in `Square` alone or in `resize_banner` alone; it is in the *relationship*. LSP is a property of a subtype *with respect to a contract and its clients*.
- `resized` returns a plain `Rectangle`, so its postcondition ("a rectangle with these sides") holds for squares too.
- This is the history constraint at work: a mutable rectangle can reach states (width ≠ height) that a square must never reach, so a mutable square cannot be its subtype.

```
        // File: LspShapes.java  (Java 17+)
        public class LspShapes {
            // ----- Before: mutable Rectangle with a Square subclass -----
            static class Rectangle {
                protected int width, height;
                Rectangle(int w, int h) { width = w; height = h; }
                void setWidth(int w) { width = w; }     // postcondition: height un-
changed
                void setHeight(int h) { height = h; }   // postcondition: width un-
changed
                int area() { return width * height; }
            }
            static class Square extends Rectangle {
                Square(int side) { super(side, side); }
                @Override void setWidth(int w) { width = height = w; }
                @Override void setHeight(int h) { width = height = h; }
            }
            static int resizeBanner(Rectangle r) {
                r.setWidth(5);
                r.setHeight(4);
                return r.area();                        // the client expects 20
            }

            // ----- After: immutable value types; "resizing" returns a new Rectangle --
---
            record Rect(int width, int height) {
                int area() { return width * height; }
                Rect resized(int w, int h) { return new Rect(w, h); }
            }
            record Sq(int side) {
                int area() { return side * side; }
                Rect asRect() { return new Rect(side, side); }   // conversion, not sub-
typing
            }

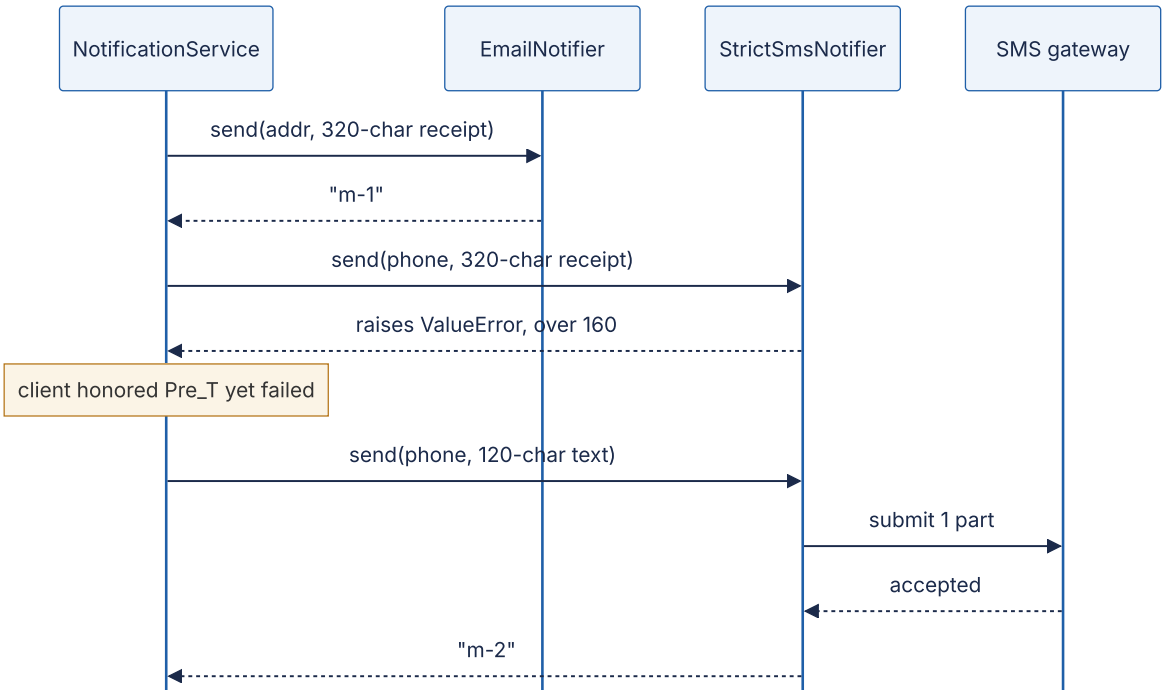
            public static void main(String[] args) {
                System.out.println("Rectangle: " + resizeBanner(new Rectangle(1, 1)));
// 20
                System.out.println("Square:    " + resizeBanner(new Square(1)) + "  <-
LSP violation");   // 16
                System.out.println("After, Rect: " + new Rect(1, 1).resized(5,
4).area());               // 20
                System.out.println("After, Sq:   " + new Sq(1).asRect().resized(5,
4).area());          // 20
            }
        }
```

What to notice: Java records are implicitly `final`, so the Java fix uses conversion (`asRect`) instead of inheritance. Both are valid; the point is that no type promises behavior it cannot keep.

36.5.3 The running example: substitutable notifiers and contract tests

The `text[:160]` line from §36.4.2 is a real LSP bug. Once channels become `Notifier` implementations, an SMS notifier that truncates or rejects long messages breaks the `NotificationService`, which was written against the contract “full text delivered”.

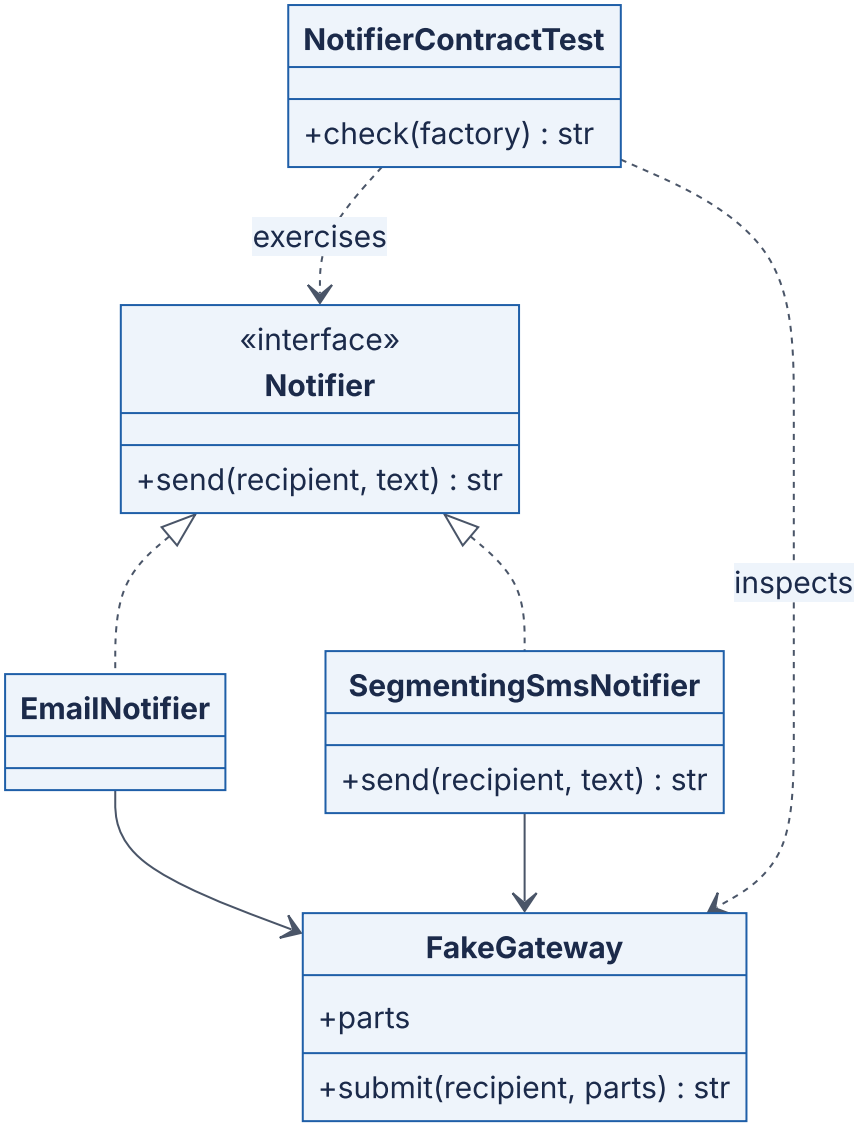
Figure 36.8 — A strengthened precondition fails at run time.



Reading the diagram. All calls are synchronous. The service sends the same valid 320-character receipt through two implementations of the same interface. The email notifier returns an id; the strict SMS notifier raises before contacting the external gateway, so the failure point is the subtype, not the network. The service did nothing wrong: it satisfied the base precondition. The only way the service could avoid this is to check the concrete type or the text length per channel, which reintroduces the switch that OCP removed. Short messages work, so such bugs pass casual testing and surface only with long receipts.

The defense is a **contract test**: one test function, written against the base type, run against every implementation. It turns LSP from a design-review opinion into a failing build.

Figure 36.9 — After LSP: every notifier passes one contract test.



Reading the diagram. Both notifiers realize `Notifier` and send through a gateway; in tests the gateway is a `FakeGateway` that records the parts submitted under each message id (the in-memory stand-in for the external SMS or SMTP provider). The contract test depends only on the interface and the fake (dashed arrows): it constructs each implementation through a factory, sends texts at the boundary lengths, and checks the postcondition by reassembling the parts. A new channel adds one line to the list under test, and the fake keeps the test fast and deterministic.

```
        import itertools
        from typing import Callable, Protocol

        MAX_TEXT = 1600          # Notifier contract: accept any text of 1..1,600 char-
acters
        SMS_SINGLE, SMS_SEGMENT = 160, 153   # GSM-7 limits: one SMS; one concatenated
part

        class FakeGateway:
            """Test double for a transport: records the parts sent under each message
id."""
            def __init__(self):
                self.parts: dict[str, list[str]] = {}
                self._ids = itertools.count(1)
            def submit(self, recipient: str, parts: list[str]) -> str:
                msg_id = f"m-{next(self._ids)}"
                self.parts[msg_id] = parts
                return msg_id

        class Notifier(Protocol):
            channel: str
            def send(self, recipient: str, text: str) -> str: ...

        class EmailNotifier:
            channel = "email"
            def __init__(self, gw: FakeGateway): self.gw = gw
            def send(self, recipient, text):
                return self.gw.submit(recipient, [text])

        class StrictSmsNotifier:                 # VIOLATION: strengthens the precondi-
tion
            channel = "sms"
            def __init__(self, gw: FakeGateway): self.gw = gw
            def send(self, recipient, text):
                if len(text) > SMS_SINGLE:
                    raise ValueError("SMS text limited to 160 characters")
                return self.gw.submit(recipient, [text])

        class TruncatingSmsNotifier:             # VIOLATION: weakens the postcondition
            channel = "sms"
            def __init__(self, gw: FakeGateway): self.gw = gw
            def send(self, recipient, text):
                return self.gw.submit(recipient, [text[:SMS_SINGLE]])

        class SegmentingSmsNotifier:             # honors the contract
            channel = "sms"
            def __init__(self, gw: FakeGateway): self.gw = gw
            def send(self, recipient, text):
                if len(text) <= SMS_SINGLE:
                    parts = [text]
                else:
                    parts = [text[i:i + SMS_SEGMENT] for i in range(0, len(text),
SMS_SEGMENT)]
                return self.gw.submit(recipient, parts)

        def check_notifier_contract(make: Callable[[FakeGateway], Notifier]) -> str:
```

```
            """One contract test, run against every implementation of Notifier."""
            gw = FakeGateway()
            notifier = make(gw)
            for length in (1, 160, 161, 320, MAX_TEXT):
                text = ("Order A-1001 update. " * 80)[:length]
                try:
                    msg_id = notifier.send("+15550100", text)
                except Exception as err:
                    return f"FAIL len={length}: raised {err!r}"
                if not msg_id:
                    return f"FAIL len={length}: empty message id"
                if "".join(gw.parts[msg_id]) != text:
                    return f"FAIL len={length}: text altered in transit"
            return "PASS"

        for cls in (EmailNotifier, StrictSmsNotifier, TruncatingSmsNotifier,
SegmentingSmsNotifier):
            print(f"{cls.__name__:<22} {check_notifier_contract(cls)}")

        gw = FakeGateway()
        mid = SegmentingSmsNotifier(gw).send("+15550100", "x" * 320)
        print("320 chars ->", len(gw.parts[mid]), "segments")
        # EmailNotifier          PASS
        # StrictSmsNotifier      FAIL len=161: raised ValueError('SMS text limited to
160 characters')
        # TruncatingSmsNotifier  FAIL len=161: text altered in transit
        # SegmentingSmsNotifier  PASS
        # 320 chars -> 3 segments
```

What to notice:

- The test probes the **boundaries** of the precondition (1, 160, 161 and 1,600 characters), where subtypes usually diverge.
- The postcondition is checked through the fake gateway, not by trusting the return value.
- In practice, write it as a parametrized pytest or an abstract JUnit class extended per implementation.

```
        // File: LspNotifiers.java  (Java 17+)
        import java.util.ArrayList;
        import java.util.HashMap;
        import java.util.List;
        import java.util.Map;
        import java.util.function.Function;

        public class LspNotifiers {
            static final int MAX_TEXT = 1600, SMS_SINGLE = 160, SMS_SEGMENT = 153;

            /** Test double for a transport: records the parts sent per message id. */
            static final class FakeGateway {
                final Map<String, List<String>> parts = new HashMap<>();
                String submit(String recipient, List<String> p) {
                    String id = "m-" + (parts.size() + 1);
                    parts.put(id, p);
                    return id;
                }
            }

            /** Contract: for 1 <= text.length() <= 1600, delivers the full text and
             *  returns a non-empty id. Throws only for an invalid recipient. */
            interface Notifier { String send(String recipient, String text); }

            record StrictSms(FakeGateway gw) implements Notifier {       // strengthens
precondition
                public String send(String to, String text) {
                    if (text.length() > SMS_SINGLE) throw new
IllegalArgumentException("SMS limited to 160 chars");
                    return gw.submit(to, List.of(text));
                }
            }
            record TruncatingSms(FakeGateway gw) implements Notifier {   // weakens
postcondition
                public String send(String to, String text) {
                    return gw.submit(to, List.of(text.substring(0,
Math.min(text.length(), SMS_SINGLE))));
                }
            }
            record SegmentingSms(FakeGateway gw) implements Notifier {   // honors the
contract
                public String send(String to, String text) {
                    List<String> p = new ArrayList<>();
                    if (text.length() <= SMS_SINGLE) p.add(text);
                    else for (int i = 0; i < text.length(); i += SMS_SEGMENT)
                        p.add(text.substring(i, Math.min(text.length(), i +
SMS_SEGMENT)));
                    return gw.submit(to, p);
                }
            }

            /** One contract test, reused for every implementation. */
            static String checkContract(Function<FakeGateway, Notifier> factory) {
                FakeGateway gw = new FakeGateway();
                Notifier n = factory.apply(gw);
                for (int len : new int[] {1, 160, 161, 320, MAX_TEXT}) {
```

```
                    String text = "x".repeat(len);
                    String id;
                    try { id = n.send("+15550100", text); }
                    catch (RuntimeException e) { return "FAIL len=" + len + ": threw "
+ e.getMessage(); }
                    if (id == null || id.isEmpty()) return "FAIL len=" + len + ": empty
id";
                    if (!String.join("", gw.parts.get(id)).equals(text)) return "FAIL
len=" + len + ": text altered";
                }
                return "PASS";
            }

            public static void main(String[] args) {
                System.out.println("StrictSms     " + checkContract(StrictSms::new));
// FAIL len=161: threw ...
                System.out.println("TruncatingSms " +
checkContract(TruncatingSms::new));  // FAIL len=161: text altered
                System.out.println("SegmentingSms " +
checkContract(SegmentingSms::new));  // PASS
            }
        }
```

Real-world industry applications

INDUSTRY EXAMPLE

`java.sql.Timestamp` extends `java.util.Date`. `Timestamp` adds nanosecond precision to `Date`. Its own documentation warns that `Timestamp.equals(Object)` is not symmetric with `Date.equals(Object)`, that `hashCode` uses only the underlying `Date` part, and that code should not treat `Timestamp` values generically as `Date` instances, because the inheritance "denotes implementation inheritance, and not type inheritance". A `HashSet<Date>` holding a mix of both can therefore contain values that compare unequal one way and equal the other. This is an LSP violation that the platform documents rather than fixes, for compatibility. *Evidence: Primary* — [Oracle Java SE API: java.sql.Timestamp]

INDUSTRY EXAMPLE

`Stack` extends `Vector`; `Properties` extends `Hashtable`. Bloch cites both as cases where inheritance exposed operations that break the subclass's intended abstraction: a `Stack` lets callers insert into the middle, and a `Properties` object, meant to hold string keys and values, accepts arbitrary objects through inherited `put`, after which some of its own methods no longer work as documented [Bloch 2018]. *Evidence: Primary* — [Bloch 2018], Item 18

Advantages and disadvantages

LSP lets clients be written once against an abstraction, keeps OCP's promise of "add a class, edit nothing", and makes contract tests reusable. Its cost is discipline: base types need written contracts (docstrings, Javadoc, types), and some intuitive "is-a" hierarchies must be abandoned for composition (§35.8). Over-strict contracts can also make legitimate implementations impossible; a contract must describe what clients need, not every detail of the first implementation.

Table 36.5 — LSP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Client crashes with a new subtype	Strengthened precondition or new exception type	Exceptions only for certain implementations	Make the subtype accept the base input, or change the hierarchy	Contract tests at precondition boundaries
Silent data loss (truncation, rounding)	Weakened postcondition	Reconciliation or customer reports; no error logs	Restore the full postcondition	Contract tests that verify outputs, not just "no exception"
`isinstance` / `instanceof` checks spread in clients	Subtypes differ in behavior	Code search for type checks on an abstraction	Split the abstraction or fix the subtype	Treat type checks on an interface as a review flag
Mutable subtype of an immutable type	History constraint violated	Values change under a cache or a map key	Make the subtype immutable or stop subclassing	Do not subclass value types

Common misconceptions

COMMON MISTAKE

"If it type-checks, it is substitutable." Type checkers verify signatures. LSP is about behavior: preconditions, postconditions, invariants and exceptions. `Square` type-checks perfectly.

COMMON MISTAKE

"Throwing `NotImplementedError` or `UnsupportedOperationException` is a fine way to say a subtype cannot do something." It is fine only if the base contract allows it (Java's collections document some operations as optional, §36.6.4). Otherwise it is a strengthened precondition, and usually a sign that the interface is too fat, which is the next principle.

INTERVIEW TIP

LSP in LLD interviews. Expect "is a square a rectangle?" or "should `ElectricCar` extend `Car` if `refuel()` exists?". Answer with contracts: state the base method's pre-condition and postcondition, show the client that breaks, then offer the fix (immutability, a narrower base type, or composition). Mention contract tests to show you know how teams enforce it.

36.6 Interface Segregation Principle

36.6.1 Definition: clients own the shape of their interfaces

DEFINITION

Definition — Interface Segregation Principle (ISP). Clients should not be forced to depend on methods that they do not use [Martin 2002]. A **fat interface** serves many kinds of client; a **role interface** describes what one kind of client needs from its collaborator [Fowler 2006].

First-principles explanation

A restaurant's full menu has 120 dishes; the dessert menu has eight. A guest who only wants dessert can use either, but a dessert menu reprinted every time the kitchen changes a starter would be odd, and a printer who must typeset all 120 dishes to produce eight is wasting work. In code, depending on an interface means depending on *all* of its methods: their signatures, their parameter types, and every change to them. If a client uses one method of eight, seven-eighths of its dependency is pure risk.

Why does this exist?

Martin reports that ISP emerged from consulting work on a printer system at Xerox in which a single large `Job` class served printing, stapling and other tasks; every change to it forced long rebuilds of unrelated code [Martin 2002]. In C++ and Java, a change to an interface's signature recompiles every module that imports it. In dynamic languages the rebuild cost disappears, but two other costs remain. **Implementers** of a fat interface must provide every method, so classes that cannot honor some of them write stubs that throw, which is an LSP violation in waiting. **Readers** cannot tell from a parameter type which of the many methods a function will actually call.

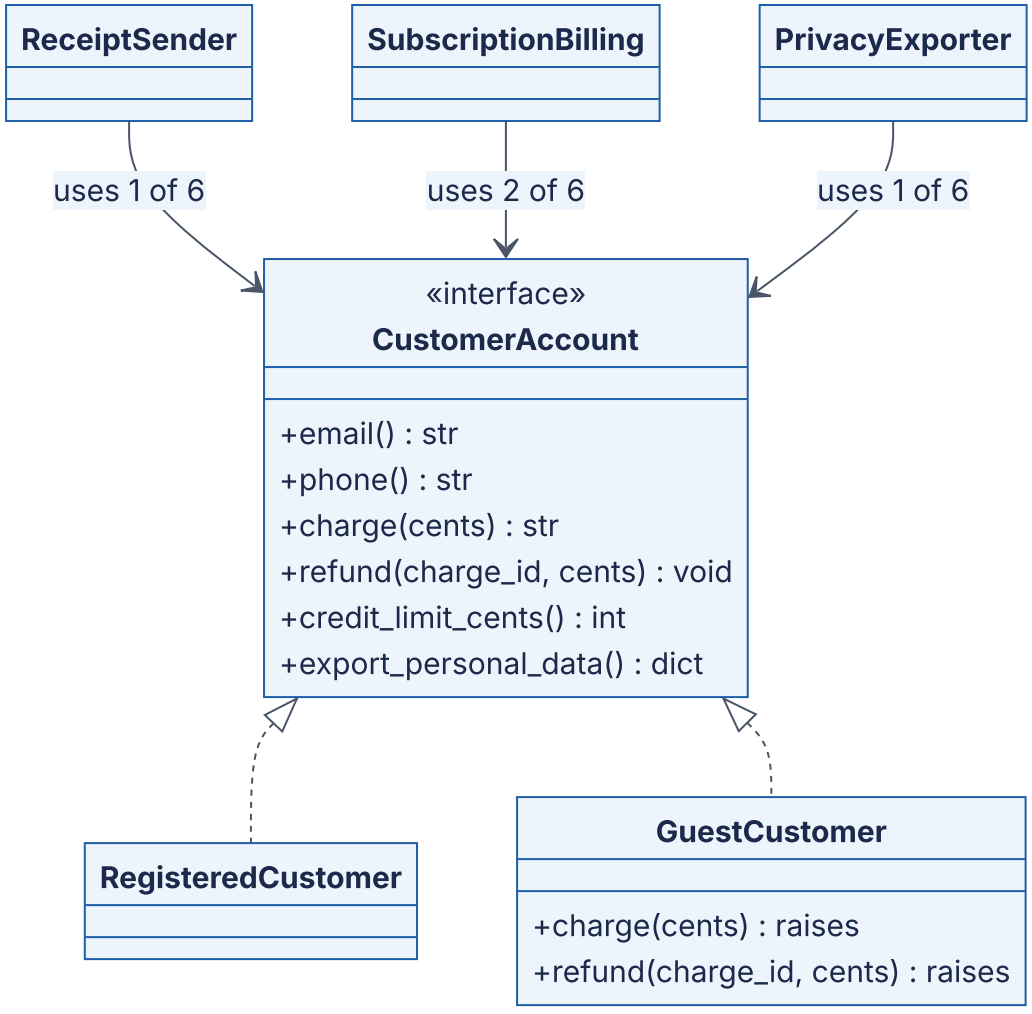
How it works internally

1. For each interface, list its **clients** and the methods each one calls.

2. Group methods by client role (notification needs contact details; billing needs charging).
3. Define one **role interface** per group, named after the role, not the implementer.
4. Let implementers implement several role interfaces; a class can still be “fat” internally.
5. Change each client’s parameter types to the narrowest role it needs.

36.6.2 The violation: a fat CustomerAccount

Figure 36.10 — Before ISP: three clients depend on one fat interface.



Reading the diagram. Three clients hold synchronous references to the same six-method interface, though each uses one or two methods (edge labels). Two classes implement it; `GuestCustomer` cannot charge (guests pay once at checkout and have no stored card), so it implements `charge` and `refund` by raising. That stub is the failure point: `SubscriptionBilling` accepts any `CustomerAccount`, so the type system lets a guest reach the code that charges. A billing signature change also recompiles `ReceiptSender` and `PrivacyExporter`, which never call those methods.

```
        from abc import ABC, abstractmethod

        class CustomerAccount(ABC):
            """Fat interface: every client depends on all six methods."""
            @abstractmethod
            def email(self) -> str: ...
            @abstractmethod
            def phone(self) -> str | None: ...
            @abstractmethod
            def charge(self, cents: int) -> str: ...
            @abstractmethod
            def refund(self, charge_id: str, cents: int) -> None: ...
            @abstractmethod
            def credit_limit_cents(self) -> int: ...
            @abstractmethod
            def export_personal_data(self) -> dict: ...

        class GuestCustomer(CustomerAccount):
            """A guest has no stored card, yet must implement billing methods."""
            def __init__(self, email: str):
                self._email = email
            def email(self): return self._email
            def phone(self): return None
            def charge(self, cents): raise NotImplementedError("guest has no stored
card")
            def refund(self, charge_id, cents): raise NotImplementedError("guest has no
stored card")
            def credit_limit_cents(self): return 0
            def export_personal_data(self): return {"email": self._email}

        def send_receipt(account: CustomerAccount, text: str) -> str:
            return f"to={account.email()} body={text}"     # uses 1 of 6 methods

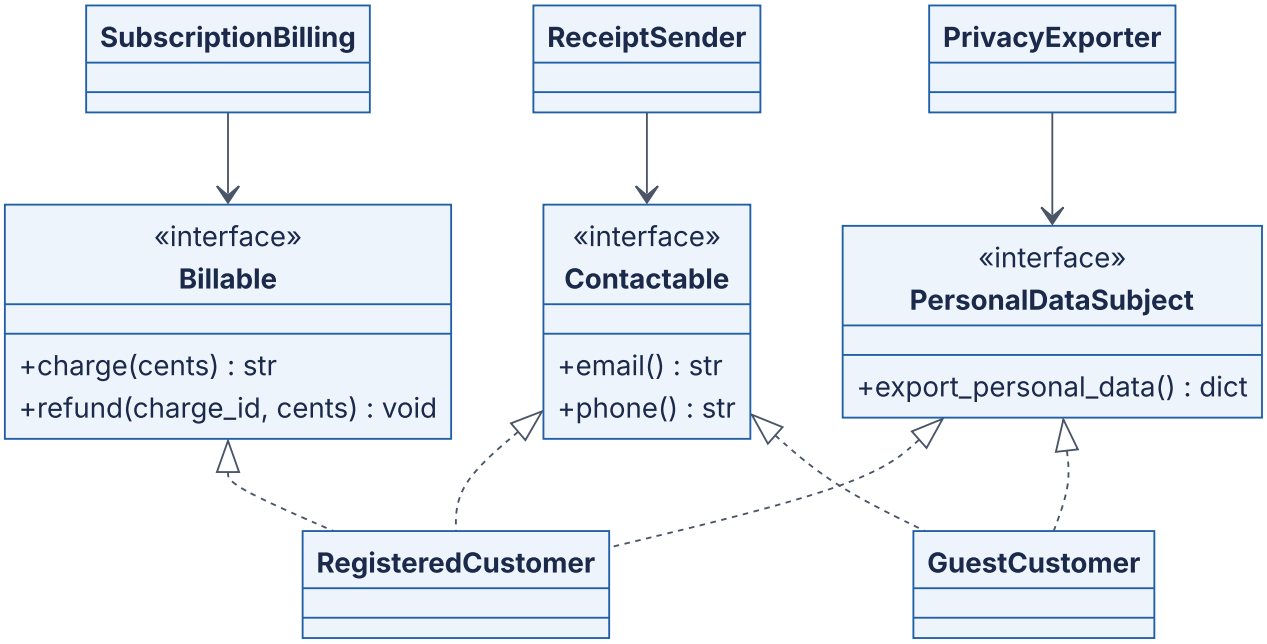
        def bill_monthly_subscriptions(accounts: list[CustomerAccount]) -> None:
            for acct in accounts:
                acct.charge(999)                          # the type checker says this
is fine

        guest = GuestCustomer("guest@example.com")
        print(send_receipt(guest, "Order A-1002 confirmed"))
        try:
            bill_monthly_subscriptions([guest])
        except NotImplementedError as err:
            print("runtime failure:", err)               # runtime failure: guest has no
stored card
```

What to notice: the error that a type checker could have caught is deferred to run time, inside a monthly batch job, because the interface claims every account can be charged.

36.6.3 The refactor: role interfaces

Figure 36.11 — After ISP: each client depends on one role.



Reading the diagram. The fat interface is replaced by three role interfaces, each named for what a client needs. `RegisteredCustomer` realizes all three; `GuestCustomer` realizes only the two it can honor, so it has no stubs. Each client's synchronous dependency now points at one small interface: a change to `Billable` cannot affect `ReceiptSender`. The failure point of Figure 36.10 disappears at compile or type-check time, because a guest is not a `Billable` and cannot be passed to `SubscriptionBilling`.

```
        from typing import Protocol, runtime_checkable

        @runtime_checkable
        class Contactable(Protocol):          # role used by notifications
            def email(self) -> str: ...
            def phone(self) -> str | None: ...

        @runtime_checkable
        class Billable(Protocol):             # role used by billing
            def charge(self, cents: int) -> str: ...
            def refund(self, charge_id: str, cents: int) -> None: ...

        @runtime_checkable
        class PersonalDataSubject(Protocol):  # role used by privacy tooling
            def export_personal_data(self) -> dict: ...

        class RegisteredCustomer:             # plays all three roles
            def __init__(self, email: str, phone: str, card_token: str):
                self._email, self._phone, self._card = email, phone, card_token
                self._charges: dict[str, int] = {}
            def email(self): return self._email
            def phone(self): return self._phone
            def charge(self, cents):
                charge_id = f"ch-{len(self._charges) + 1}"
                self._charges[charge_id] = cents
                return charge_id
            def refund(self, charge_id, cents):
                if cents > self._charges.get(charge_id, 0):
                    raise ValueError("refund exceeds captured amount")
                self._charges[charge_id] -= cents
            def export_personal_data(self):
                return {"email": self._email, "phone": self._phone, "charges":
dict(self._charges)}

        class GuestCustomer:                  # plays only the roles it can honor
            def __init__(self, email: str):
                self._email = email
            def email(self): return self._email
            def phone(self): return None
            def export_personal_data(self): return {"email": self._email}

        def send_receipt(who: Contactable, text: str) -> str:
            return f"to={who.email()} body={text}"

        def bill_monthly_subscriptions(accounts: list[Billable]) -> list[str]:
            return [acct.charge(999) for acct in accounts]

        def export_all(subjects: list[PersonalDataSubject]) -> list[dict]:
            return [s.export_personal_data() for s in subjects]

        ana = RegisteredCustomer("ana@example.com", "+15550100", "tok_visa")
        guest = GuestCustomer("guest@example.com")
        print(send_receipt(guest, "Order A-1002 confirmed"))
        print(bill_monthly_subscriptions([ana]))      # a guest here is a type-checker
error
```

```
        print(export_all([ana, guest]))
        print("guest is Billable?", isinstance(guest, Billable))   # False
```

What to notice:

- Neither customer class names a protocol; conformance is structural. A static checker such as mypy reports `bill_monthly_subscriptions([guest])` as an error.
- `@runtime_checkable` lets `isinstance` test conformance, but it checks only that the methods *exist*, not their signatures or behavior.

```java
        // File: IspAfter.java  (Java 17+)
        import java.util.ArrayList;
        import java.util.List;
        import java.util.Map;
        import java.util.Optional;

        public class IspAfter {
            interface Contactable { String email(); Optional<String> phone(); }
            interface Billable { String charge(long cents); void refund(String
chargeId, long cents); }
            interface PersonalDataSubject { Map<String, String> exportPersonalData(); }

            static final class RegisteredCustomer implements Contactable, Billable,
PersonalDataSubject {
                private final String email, phone;
                private final List<Long> charges = new ArrayList<>();
                RegisteredCustomer(String email, String phone) { this.email = email;
this.phone = phone; }
                public String email() { return email; }
                public Optional<String> phone() { return Optional.of(phone); }
                public String charge(long cents) { charges.add(cents); return "ch-" +
charges.size(); }
                public void refund(String chargeId, long cents) {
                    int idx = Integer.parseInt(chargeId.substring(3)) - 1;
                    if (cents > charges.get(idx)) throw new
IllegalArgumentException("refund exceeds capture");
                    charges.set(idx, charges.get(idx) - cents);
                }
                public Map<String, String> exportPersonalData() {
                    return Map.of("email", email, "phone", phone, "charges",
charges.toString());
                }
            }

            /** Implements only the roles it can honor: no stubs, no
UnsupportedOperationException. */
            static final class GuestCustomer implements Contactable, PersonalDataSubject
{
                private final String email;
                GuestCustomer(String email) { this.email = email; }
                public String email() { return email; }
                public Optional<String> phone() { return Optional.empty(); }
                public Map<String, String> exportPersonalData() { return
Map.of("email", email); }
            }

            // Each client names only the role it uses.
            static String sendReceipt(Contactable who, String text) { return "to=" +
who.email() + " body=" + text; }
            static List<String> billMonthly(List<? extends Billable> accounts) {
                List<String> ids = new ArrayList<>();
                for (Billable b : accounts) ids.add(b.charge(999));
                return ids;
            }

            public static void main(String[] args) {
```

```
                RegisteredCustomer ana = new RegisteredCustomer("ana@example.com",
"+15550100");
                GuestCustomer guest = new GuestCustomer("guest@example.com");
                System.out.println(sendReceipt(guest, "Order A-1002 confirmed"));
                System.out.println(billMonthly(List.of(ana)));                // [ch-1]
                // billMonthly(List.of(guest));   // does not compile: GuestCustomer is
not Billable
                List<PersonalDataSubject> subjects = List.of(ana, guest);
                subjects.forEach(s ->
System.out.println(s.exportPersonalData().get("email")));
            }
        }
```

What to notice: the commented-out line is the payoff. The defect from the “before” version is now a compile error, found in seconds rather than in a monthly batch run.

36.6.4 Industry practice, trade-offs and misconceptions

INDUSTRY EXAMPLE

Python’s `collections.abc` versus Java’s optional operations. Python defines many small abstract base classes (`Sized` , `Iterable` , `Container` , `Collection` , `Sequence` , `MutableSequence` , `Mapping`), and functions such as `len()` need only the one-method `Sized` role. Java’s collections framework went the other way for simplicity: `List` includes mutators such as `add` , and immutable or fixed-size implementations throw `UnsupportedOperationException` , which the Javadoc marks as “optional operations”. Oracle’s design FAQ explains the trade-off: separate interfaces for every combination of modifiable, fixed-size and append-only would have multiplied the number of interfaces. Java accepted a weaker static guarantee in exchange for a small API. *Evidence: Primary* — [Python docs: collections.abc]; [Oracle: Java Collections API Design FAQ]

ISP’s benefits are narrower blast radius for interface changes, no stub methods, clearer function signatures and errors moved from run time to type-check time. Its cost is more interface names, and the Java collections case shows the limit: if every client needs a slightly different subset, segregating perfectly produces a combinatorial explosion. Segregate along *roles that real clients play*, not along every possible subset.

Table 36.6 — ISP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Implementers write throwing stubs	Interface bundles capabilities not all implementers have	Search for `NotImplementedError` / `UnsupportedOperationException` in implementations	Extract role interfaces	Design interfaces from client needs
Unrelated clients rebuild on every change	Fat interface in a compiled language	Build graph shows wide fan-out from one interface	Split by client role	Keep interfaces in the client's package (§36.7)
Dozens of one-method interfaces nobody can navigate	Segregation by every subset	Interfaces with one client and one implementer	Merge interfaces that always travel together	Segregate by real roles

COMMON MISTAKE

"ISP means every interface should have one method." It means each *client* should see only what it uses. A five-method interface used in full by every client is perfectly segregated.

INTERVIEW TIP

ISP in LLD interviews. In a vending machine or parking lot, a single `Machine` or `ParkingLot` interface with admin, payment and display methods is a red flag. Split it into roles such as `PaymentAcceptor`, `InventoryAdmin` and `Display`, and say which client uses which.

36.7 Dependency Inversion Principle

36.7.1 Definition: policy should not depend on detail

> DEFINITION
>
> **Definition — Dependency Inversion Principle (DIP).** (a) High-level modules should not depend on low-level modules; both should depend on abstractions. (b) Abstractions should not depend on details; details should depend on abstractions [Martin 2002]. **High-level** modules hold policy: the business rules that justify the system (checkout, invoicing). **Low-level** modules hold detail: mechanisms that could be swapped without changing the business (a payment vendor's SDK, SMTP, SQL).

First-principles explanation

A company writes a job description ("must hold a forklift license, work night shifts") and then hires someone who fits it. It does not rewrite its operations manual around whichever person it happened to hire. The job description is the abstraction, written in the company's terms and owned by the company; candidates conform to it. If the company instead wrote its procedures around one employee's personal habits, it could never replace that person.

In naive layered code the arrows run the other way: checkout imports the payment vendor's client, so checkout's source code names the vendor, its data shapes and its error codes. Every vendor change ripples upward into the business rules.

Why does this exist?

Source-code dependencies point the same way as control flow by default: if A calls B, A imports B. That makes the most important code (policy) depend on the most volatile code (vendors, frameworks, databases). DIP breaks that coupling by inserting an interface between them and, crucially, **placing the interface on the policy side**. Control still flows from checkout to the vendor at run time, but the source-code dependency now points from the vendor adapter *toward* checkout. That reversal is the "inversion".

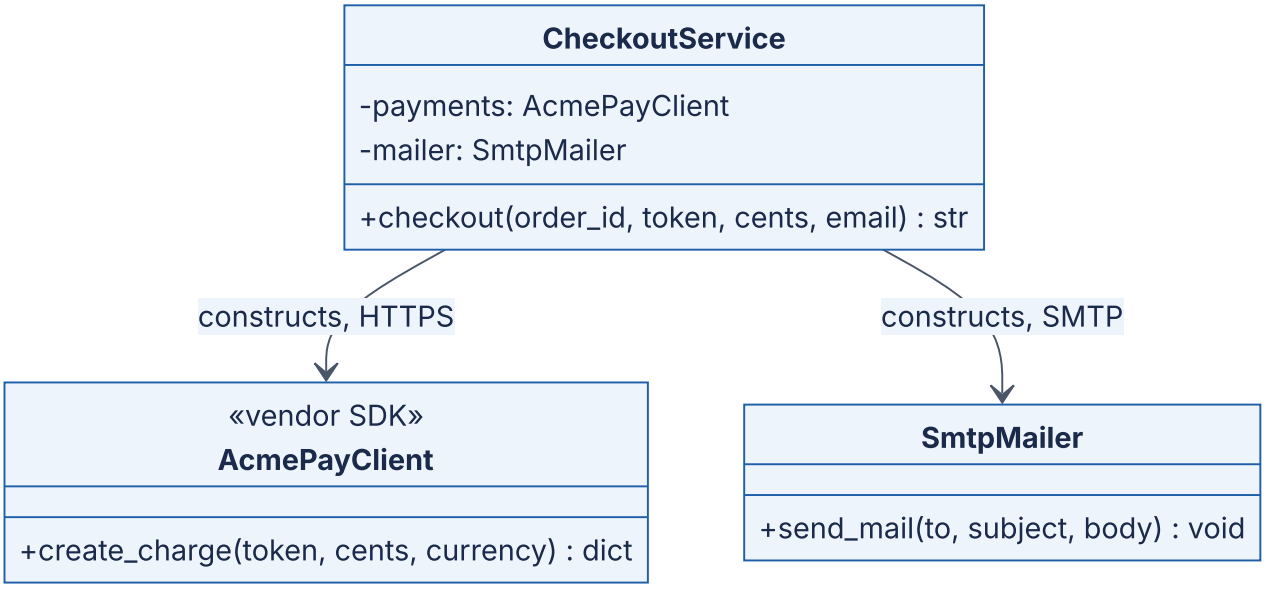
How it works internally

1. Identify policy code and the details it calls.
2. Define, **in the policy module**, an interface expressing what policy needs in its own vocabulary (`PaymentGateway.charge` returns a `ChargeResult`, not the vendor's JSON).
3. Write an **adapter** in a detail module that implements the interface by calling the vendor.

4. Give policy its collaborators from outside (dependency injection, §36.7.4), assembled in one **composition root**.
5. In tests, implement the same interfaces with **fakes**.

36.7.2 The violation: checkout constructs its details

Figure 36.12 — Before DIP: policy depends on concrete details.



Reading the diagram. The high-level `CheckoutService` creates and holds its two low-level collaborators (solid arrows): a vendor SDK that charges cards over HTTPS and an SMTP mailer. Both calls are synchronous. Both collaborators are external failure points, and the service cannot run, even in a unit test, without reaching them. The vendor's response shape leaks into the business rule, so a second provider means editing checkout. Every arrow points from policy to detail.

```
        class AcmePayClient:                        # low-level detail: a vendor SDK
            def create_charge(self, card_token: str, amount_cents: int,
                              currency: str = "usd") -> dict:
                print(f"[HTTPS api.acmepay.example] charge {amount_cents} {currency}")
                return {"id": "ch_1", "status": "succeeded"}

        class SmtpMailer:                           # low-level detail: a mail transport
            def __init__(self, host: str = "smtp.internal", port: int = 587):
                self.host, self.port = host, port
            def send_mail(self, to: str, subject: str, body: str) -> None:
                print(f"[SMTP {self.host}:{self.port}] to={to} subject={subject}")

        class CheckoutService:                      # high-level policy
            def __init__(self):
                self.payments = AcmePayClient()     # policy constructs and names details
                self.mailer = SmtpMailer()

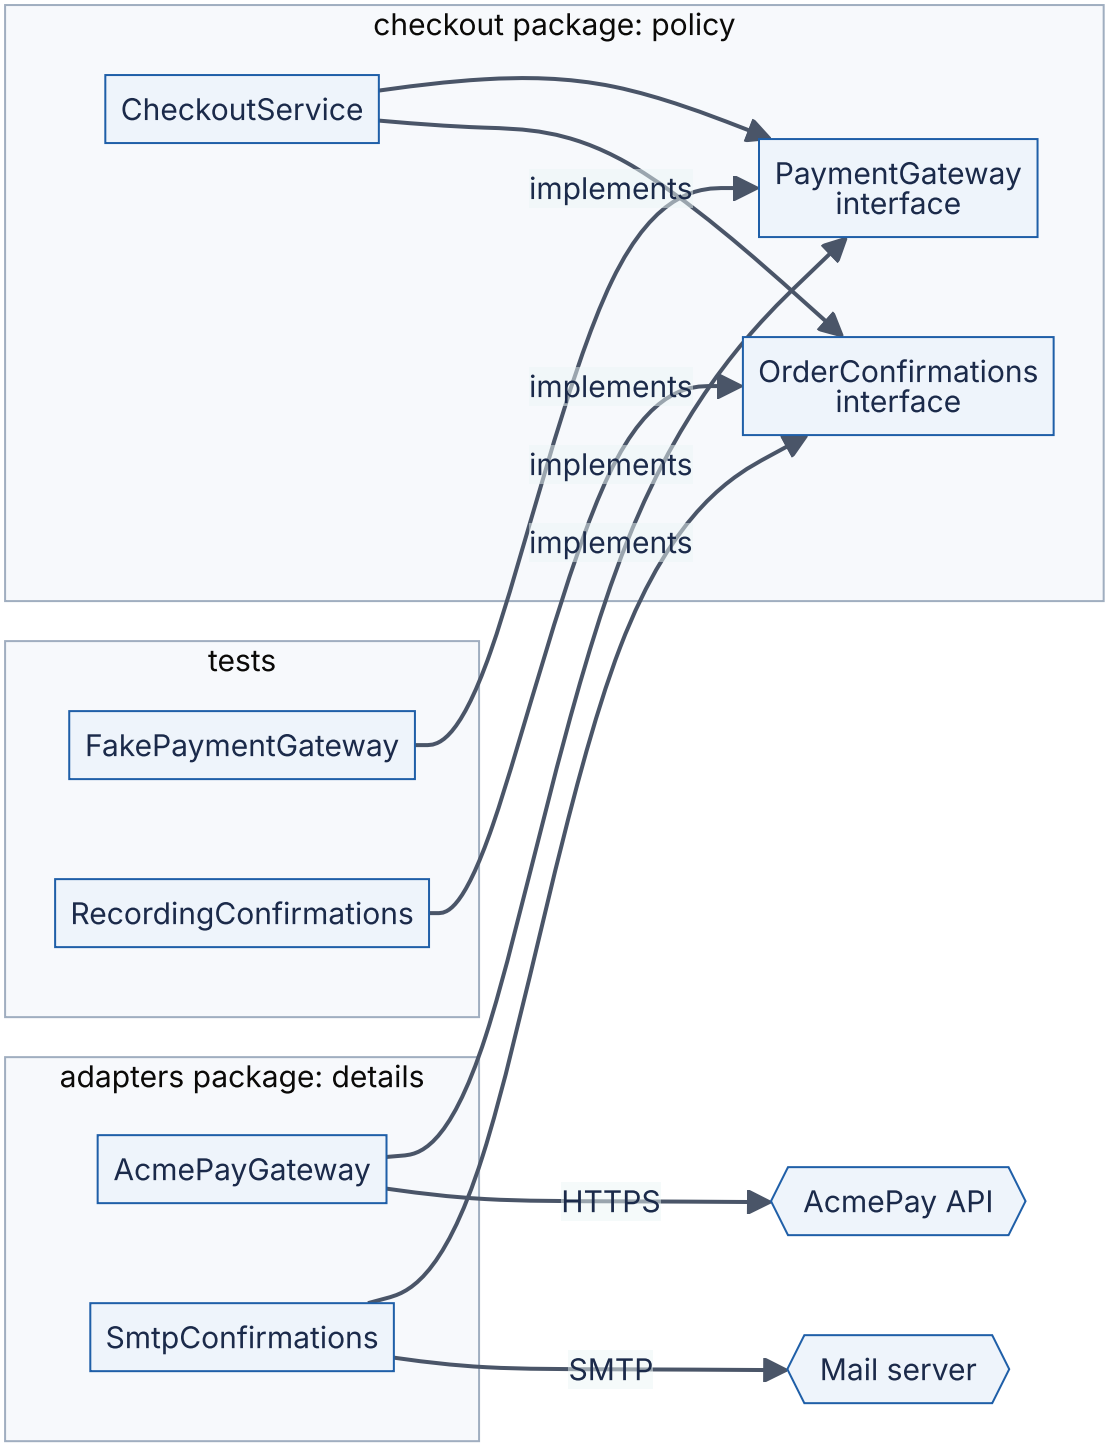
            def checkout(self, order_id: str, card_token: str, amount_cents: int,
                         email: str) -> str:
                result = self.payments.create_charge(card_token, amount_cents)
                if result["status"] != "succeeded":          # vendor vocabulary leaks
in
                    raise RuntimeError("payment declined")
                self.mailer.send_mail(email, "Order confirmed", f"Order {order_id} is
paid")
                return result["id"]

        print(CheckoutService().checkout("A-1001", "tok_visa", 4719, "ana@example.com"))
```

What to notice: to test the decline path you would need a real card that the vendor declines, or a patching library that rewrites `AcmePayClient` at run time. Both are signs that the dependency points the wrong way.

36.7.3 The refactor: ports owned by policy

Figure 36.13 — After DIP: interfaces live with policy; adapters point inward.



Reading the diagram. Arrows are source-code dependencies, which is what DIP is about. Inside the `checkout` package, the service depends only on two interfaces that the package itself defines. Both the production adapters and the test fakes depend *inward* on those interfaces; nothing in `checkout` names an adapter. Only adapters cross the system boundary to the external vendor and mail server (hexagons, the failure points), over HTTPS and SMTP. At run time, calls still flow synchronously from the service through an interface to an adapter; only the compile-time direction is inverted. A second payment

vendor is a new adapter; policy is untouched. Applied to a whole application, this arrangement is hexagonal architecture (ports and adapters, §33.10).

Code example

```
        from dataclasses import dataclass, field
        from typing import Protocol

        # ---------- checkout: high-level policy. It OWNS the ports it needs. ----------
        @dataclass(frozen=True)
        class ChargeResult:
            ok: bool
            charge_id: str = ""
            reason: str = ""

        class PaymentGateway(Protocol):            # port, named in checkout's language
            def charge(self, card_token: str, cents: int) -> ChargeResult: ...

        class OrderConfirmations(Protocol):        # port
            def confirm(self, email: str, order_id: str) -> None: ...

        class PaymentDeclined(Exception):
            pass

        class CheckoutService:
            def __init__(self, payments: PaymentGateway, confirmations:
OrderConfirmations):
                self.payments = payments           # injected through the constructor
                self.confirmations = confirmations

            def checkout(self, order_id: str, card_token: str, cents: int, email: str) -
> str:
                result = self.payments.charge(card_token, cents)
                if not result.ok:
                    raise PaymentDeclined(result.reason)
                self.confirmations.confirm(email, order_id)
                return result.charge_id

        # ---------- adapters: low-level details. They depend on checkout's ports. -----
-----
        class AcmePayClient:                       # vendor SDK (stand-in)
            def create_charge(self, card_token, amount_cents, currency="usd") -> dict:
                return {"id": "ch_1", "status": "succeeded"}

        class AcmePayGateway:                      # implements PaymentGateway
            def __init__(self, client: AcmePayClient):
                self.client = client
            def charge(self, card_token, cents):
                raw = self.client.create_charge(card_token, cents)
                if raw["status"] == "succeeded":
                    return ChargeResult(True, charge_id=raw["id"])
                return ChargeResult(False, reason=raw.get("failure_code", "unknown"))

        class SmtpConfirmations:                   # implements OrderConfirmations
            def __init__(self, host: str):
                self.host = host
            def confirm(self, email, order_id):
                print(f"[SMTP {self.host}] to={email} Order {order_id} is paid")
```

```
        def build_checkout() -> CheckoutService:   # composition root: the only place
            return CheckoutService(AcmePayGateway(AcmePayClient()),   # that names de-
tails
                                   SmtpConfirmations("smtp.internal"))

        # ---------- tests: fakes implement the same ports; no network, no mocks library
----------
        @dataclass
        class FakePaymentGateway:
            declined_tokens: set = field(default_factory=set)
            charges: list = field(default_factory=list)
            def charge(self, card_token, cents):
                if card_token in self.declined_tokens:
                    return ChargeResult(False, reason="card_declined")
                self.charges.append((card_token, cents))
                return ChargeResult(True, charge_id=f"fake-{len(self.charges)}")

        @dataclass
        class RecordingConfirmations:
            sent: list = field(default_factory=list)
            def confirm(self, email, order_id):
                self.sent.append((email, order_id))

        def test_successful_checkout_charges_once_and_confirms():
            pay, mail = FakePaymentGateway(), RecordingConfirmations()
            charge_id = CheckoutService(pay, mail).checkout("A-1", "tok_ok", 4719,
"a@x.com")
            assert charge_id == "fake-1"
            assert pay.charges == [("tok_ok", 4719)]
            assert mail.sent == [("a@x.com", "A-1")]

        def test_declined_card_sends_no_confirmation():
            pay, mail = FakePaymentGateway(declined_tokens={"tok_bad"}),
RecordingConfirmations()
            try:
                CheckoutService(pay, mail).checkout("A-2", "tok_bad", 1000, "b@x.com")
                raise AssertionError("expected PaymentDeclined")
            except PaymentDeclined as err:
                assert str(err) == "card_declined"
            assert mail.sent == []

        test_successful_checkout_charges_once_and_confirms()
        test_declined_card_sends_no_confirmation()
        print("tests passed")
        print("production wiring:", build_checkout().checkout("A-3", "tok_visa", 4719,
"ana@example.com"))
```

What to notice:

- `ChargeResult` and `PaymentDeclined` are checkout's vocabulary. The vendor's `"succeeded"` string appears only in the adapter.
- The decline test, which was hard to write before, is now four lines. A **fake** is a working, simplified implementation (here, an in-memory list); a **mock** is an object preprogrammed with expected calls [Meszaros 2007]. Fakes of owned interfaces tend

to produce tests that survive refactoring, because they check outcomes rather than call sequences.

- `build_checkout` is the only function that knows concrete classes. Everything else receives its collaborators.

                public void confirm(String email, String orderId) { sent.add(email +
":" + orderId); }
            }

            static void check(boolean cond, String msg) { if (!cond) throw new
AssertionError(msg); }

            public static void main(String[] args) {
                // Unit tests with fakes
                FakePaymentGateway pay = new FakePaymentGateway(Set.of("tok_bad"));
                RecordingConfirmations mail = new RecordingConfirmations();
                CheckoutService svc = new CheckoutService(pay, mail);
                check(svc.checkout("A-1", "tok_ok", 4719, "a@x.com").equals("fake-1"),
"charge id");
                check(mail.sent.equals(List.of("a@x.com:A-1")), "confirmation sent");
                try { svc.checkout("A-2", "tok_bad", 1000, "b@x.com"); check(false, "ex-
pected decline"); }
                catch (PaymentDeclined e) {
check(e.getMessage().equals("card_declined"), "reason"); }
                check(mail.sent.size() == 1, "no confirmation after decline");
                System.out.println("tests passed");

                // Composition root: the only place that names concrete classes
                CheckoutService prod = new CheckoutService(new AcmePayGateway(), new
SmtpConfirmations());
                System.out.println(prod.checkout("A-3", "tok_visa", 4719,
"ana@example.com"));
            }
        }
```

What to notice: in a real project the ports and `CheckoutService` sit in one package or module, adapters in another that depends on it, and fakes under `src/test`, with JUnit instead of `main`.

36.7.4 DI, DIP and IoC are three different things

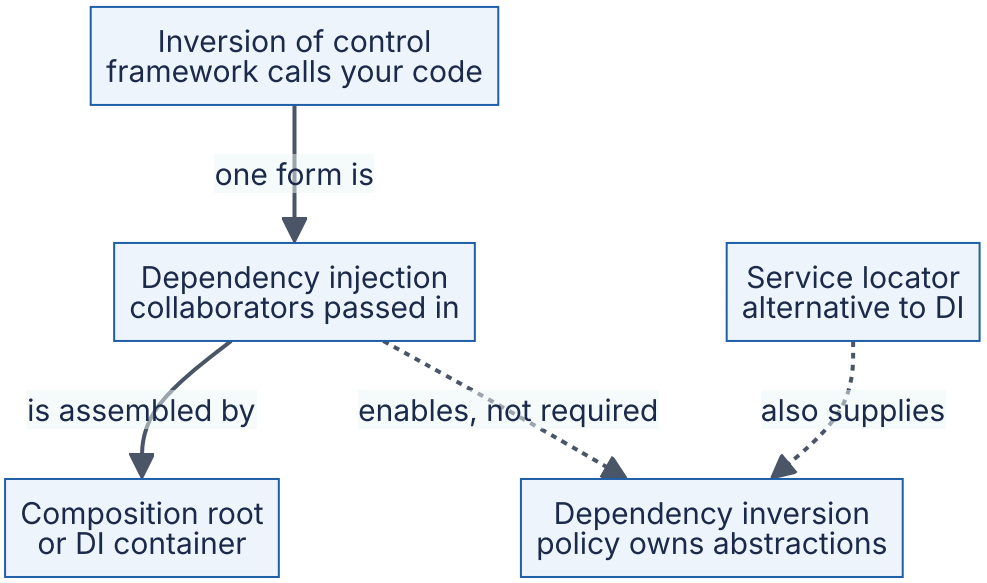
The three terms are often used interchangeably. They are related but distinct.

Table 36.7 — Dependency inversion, dependency injection and inversion of control.

Term	What it is	Question it answers	Example
Dependency Inversion Principle (DIP)	A design principle about the *direction of source-code dependencies*	Which module owns the interface, and which way do imports point?	`checkout` defines `PaymentGateway`; the adapter imports it
Dependency injection (DI)	A *technique*: an object receives its collaborators from outside instead of constructing them	Who creates the collaborators?	`CheckoutService(payments, confirmations)`
Inversion of control (IoC)	A broad *property of frameworks*: the framework calls your code, not the reverse	Who owns the main loop?	A web framework calls your handler; a test runner calls your tests

Fowler's 2004 article explains why he and others coined "dependency injection": "inversion of control" was too generic, since every framework inverts control, and the specific pattern being described was supplying dependencies to an object from outside [Fowler 2004]. He describes constructor injection, setter injection and interface injection, and compares injection with the **service locator** alternative, in which an object asks a registry for its dependencies. A service locator hides dependencies inside method bodies; constructor injection makes them visible in the signature, which is why it is the common default.

Figure 36.14 — How DIP, DI and IoC relate.



Reading the diagram. Read solid arrows as "is a kind of" or "is done by", and dotted arrows as "can support". Inversion of control is the broadest idea; dependency injection is one form of it, in which a composition root (hand-written, as in `build_checkout`, or a container such as Spring or Guice) creates objects and passes them in. DI makes DIP convenient, but you can inject a concrete class (DI without DIP), and you can satisfy DIP with a

service locator (DIP without DI). A common failure is a DI container used without DIP: everything is injected, but the injected types are concrete vendor classes.

Real-world industry applications

INDUSTRY EXAMPLE

JDBC and SLF4J. Java application code programs against `java.sql.Connection` and related interfaces defined by the platform; vendors ship drivers that implement them, and since JDBC 4.0 `DriverManager` discovers drivers through `ServiceLoader`, so the application's source never names the database vendor. SLF4J does the same for logging: libraries depend on the `org.slf4j.Logger` API, and the deployer chooses the logging backend at deployment time. In both cases the abstraction is owned by the client side (the platform or the facade), and the details depend on it. *Evidence: Primary* — [Oracle Java SE API: java.sql.DriverManager, java.util.ServiceLoader]; [SLF4J manual]

Advantages, disadvantages and failure scenarios

DIP makes policy testable in milliseconds, lets you replace vendors and databases by writing adapters, and keeps business rules readable in business terms. It costs an interface and an adapter per external dependency, plus a composition root to maintain. Interfaces that merely mirror one vendor's SDK method for method give the cost without the benefit, because a second vendor will not fit them.

Table 36.8 — DIP failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Swapping vendors requires editing business rules	Policy imports the SDK or its data types	Import graph: core package imports vendor package	Introduce a port in the core; move vendor code to an adapter	Architecture tests that forbid core-to-adapter imports
Interface changes whenever the vendor changes	Interface owned by, or copied from, the detail	Port signatures use vendor types or names	Rewrite the port in domain vocabulary	Define ports from the policy's needs
Tests pass but production fails	Fake diverges from the real adapter's behavior	Bugs found only in integration	Run the same contract tests (§36.5.3) on fake and real adapter	Contract-test every fake

COMMON MISTAKE

"Using a DI container means the code follows DIP." A container only wires objects. If `CheckoutService` is injected with an `AcmePayClient`, the dependency still points from policy to detail. DIP is about *which module owns the abstraction*.

INTERVIEW TIP

DIP in LLD interviews. When you introduce a repository or gateway interface, say who owns it ("the domain layer defines `OrderRepository`; the Postgres adapter implements it") and how you would test the domain with an in-memory fake. Distinguishing DI from DIP in one sentence is a common senior-level signal.

36.8 SOLID at the architecture level

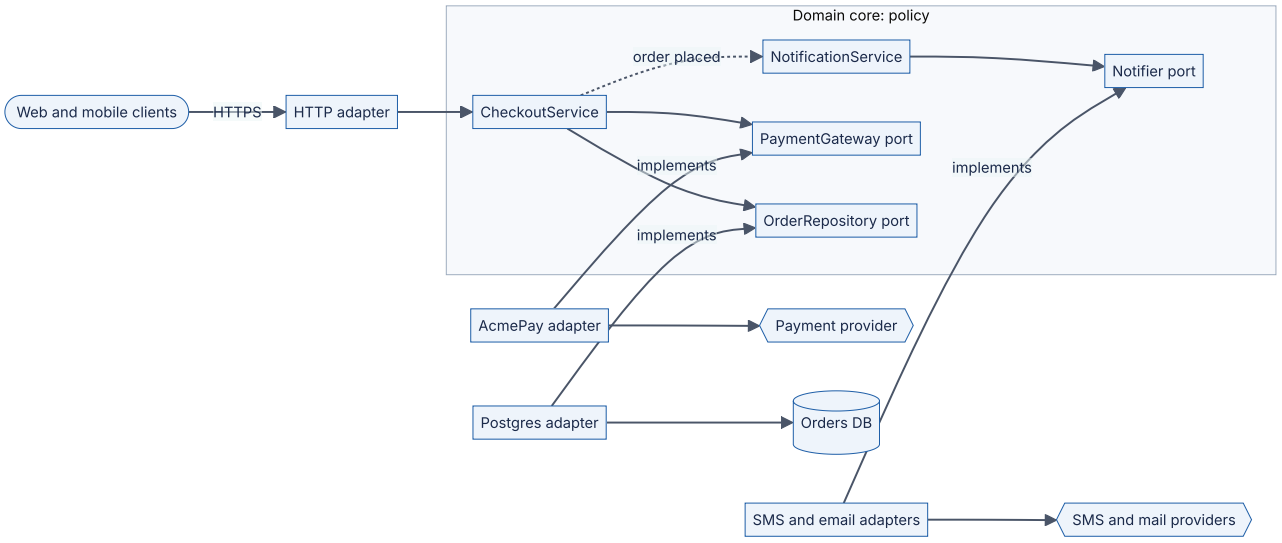
36.8.1 From classes to components and services

The same forces that act on classes act on packages, deployable components and services, only with higher costs: a change that crosses a service boundary needs coordinated releases, API versioning and sometimes a data migration. Martin restated the principles for components in his component cohesion and coupling principles [Martin 2002; Martin 2017].

Table 36.9 — Each SOLID principle at the component and service level.

Principle	Class level	Component and service level
SRP	One actor per class	**Common Closure Principle**: group into one component the classes that change for the same reasons; split services along business capabilities and teams (§34.3)
OCP	New variant = new class	**Plugin architecture**: the core exposes extension points; features ship as plugins or new services consuming events
LSP	Subtypes honor contracts	Every implementation of an API, and every new version of a service, honors the published contract; breaking changes need a new version
ISP	Role interfaces	**Common Reuse Principle**: do not force users of a component to depend on classes they do not use; per-client APIs such as the back-end-for-frontend (§34.6)
DIP	Policy owns interfaces	Hexagonal **ports and adapters** (§33.10) and the clean-architecture dependency rule (§33.11): source dependencies point toward the domain

Figure 36.15 — The order module as ports and adapters.



Reading the diagram. The domain core contains the policy classes and the ports they own; it imports nothing outside itself. Driving adapters (the HTTP adapter receiving HTTPS requests from clients) call into the core; driven adapters (payment, persistence, messaging) implement the core's ports and are the only components that talk to external systems (hexagons) and the database (cylinder, the storage boundary). Solid arrows are synchronous calls or source dependencies; the dotted arrow is the asynchronous order-placed event that triggers notification. Failure points are concentrated in adapters, where timeouts, retries and circuit breakers belong (§22.11–§22.13). Adapters scale and deploy independently.

36.8.2 Measuring dependency direction: stability and abstractness

DIP at the component level says that dependencies should point toward stable, abstract components. Martin made this measurable with three metrics [Martin 2002; Martin 2017].

FORMULA

Instability, abstractness and distance from the main sequence

$$I = \frac{C_e}{C_a + C_e} \qquad A = \frac{N_a}{N_c} \qquad D = |A + I - 1|$$

Symbol	Meaning	Units
C_a	Afferent couplings: number of other components that depend on this one (fan-in)	components
C_e	Efferent couplings: number of other components this one depends on (fan-out)	components
I	Instability: 0 = maximally stable (many dependents, no dependencies), 1 = maximally unstable	dimensionless, 0–1
N_a	Number of abstract classes and interfaces in the component	types
N_c	Total number of classes and interfaces in the component	types
A	Abstractness	dimensionless, 0–1
D	Distance from the "main sequence" line $A + I = 1$; 0 is ideal	dimensionless, 0–1

The **Stable Dependencies Principle** says to depend in the direction of stability (decreasing I). The **Stable Abstractions Principle** says a component should be as abstract as it is stable: stable components ($I \approx 0$) should be abstract ($A \approx 1$) so that they can be extended without modification, while unstable ones ($I \approx 1$) can be concrete. A component that is stable and concrete (D near 1 with low I, low A) sits in the **zone of pain**: many things depend on it, so it is hard to change, yet it is full of details that want to change.

WORKED EXAMPLE

Worked example — Metrics for the order module. The components of Figure 36.15 have these dependencies: `web-api` depends on `checkout-core` and `notification-core`; the payment and Postgres adapters depend on `checkout-core`; the SMS and SMTP adapters depend on `notification-core`; `checkout-core` depends on `notification-core`. `checkout-core` has 8 types, 3 of them interfaces; `notification-core` has 4 types, 2 of them interfaces.

1. `checkout-core`: $C_a = 3$ (web-api, payment adapter, Postgres adapter); $C_e = 1$ (notification-core). $I = 1/(3 + 1) = 0.25$. $A = 3/8 = 0.375$. $D = |0.375 + 0.25 - 1| = 0.375$.
2. `notification-core`: $C_a = 4$ (web-api, two adapters, checkout-core); $C_e = 0$. $I = 0/4 = 0$. $A = 2/4 = 0.5$. $D = |0.5 + 0 - 1| = 0.5$.
3. Each adapter: $C_a = 0$, $C_e = 1$, so $I = 1$; with no interfaces, $A = 0$ and $D = |0 + 1 - 1| = 0$.

Interpretation. All dependencies point from $I = 1$ (adapters, web-api) toward $I = 0.25$ and $I = 0$: the Stable Dependencies Principle holds. The adapters sit exactly on the main sequence. The two cores are more concrete than their stability suggests ($D =$ 0.375 and 0.5). **Engineering implication.** That is acceptable for concrete classes that rarely change, such as the `Invoice` value object; it becomes a problem if volatile logic lives in `notification-core`, because four components must be retested whenever it changes. Watch D over time rather than chasing 0.

The arithmetic is easy to automate from an import graph:

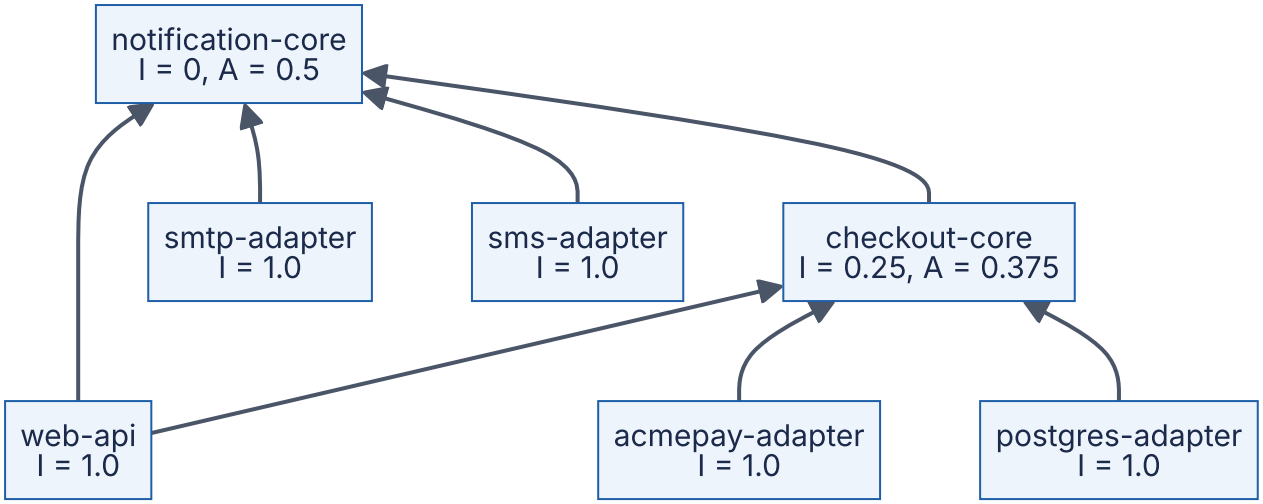
```
        # Martin's component metrics: instability I, abstractness A, distance D.
        DEPENDS_ON = {                      # component -> components it imports
            "web-api":           ["checkout-core", "notification-core"],
            "acmepay-adapter":   ["checkout-core"],
            "postgres-adapter":  ["checkout-core"],
            "smtp-adapter":      ["notification-core"],
            "sms-adapter":       ["notification-core"],
            "checkout-core":     ["notification-core"],
            "notification-core": [],
        }
        CLASSES = {                         # component -> (abstract types, all types)
            "web-api": (0, 6), "acmepay-adapter": (0, 2), "postgres-adapter": (0, 3),
            "smtp-adapter": (0, 1), "sms-adapter": (0, 2),
            "checkout-core": (3, 8), "notification-core": (2, 4),
        }

        def metrics(deps: dict, classes: dict) -> dict:
            fan_in = {c: 0 for c in deps}
            for targets in deps.values():
                for t in targets:
                    fan_in[t] += 1
            out = {}
            for c, targets in deps.items():
                ca, ce = fan_in[c], len(targets)
                i = ce / (ca + ce) if ca + ce else 0.0
                n_abstract, n_total = classes[c]
                a = n_abstract / n_total
                out[c] = (ca, ce, round(i, 3), round(a, 3), round(abs(a + i - 1), 3))
            return out

        print(f"{'component':<18} Ca Ce     I     A     D")
        for name, (ca, ce, i, a, d) in sorted(metrics(DEPENDS_ON, CLASSES).items(),
                                              key=lambda kv: kv[1][2]):
            print(f"{name:<18} {ca:>2} {ce:>2} {i:>5} {a:>5} {d:>5}")
        # notification-core   4  0   0.0   0.5   0.5
        # checkout-core       3  1  0.25 0.375 0.375
        # web-api             0  2   1.0   0.0   0.0   (adapters likewise: I=1, A=0,
D=0)
```

What to notice: an isolated component ($C_a = C_e = 0$) gets $I = 0$ here to avoid division by zero; real dependency maps come from import analysis.

Figure 36.16 — Component dependencies point toward stability.



Reading the diagram. Each node is a component (a package or deployable module) labeled with its computed metrics; arrows are compile-time dependencies, drawn upward toward stability. Every arrow goes from a higher *I* to a lower *I*, which is the Stable Dependencies Principle in picture form. A dependency arrow pointing downward, for example `notification-core` importing `sms-adapter`, would be a DIP violation and would raise the core's instability.

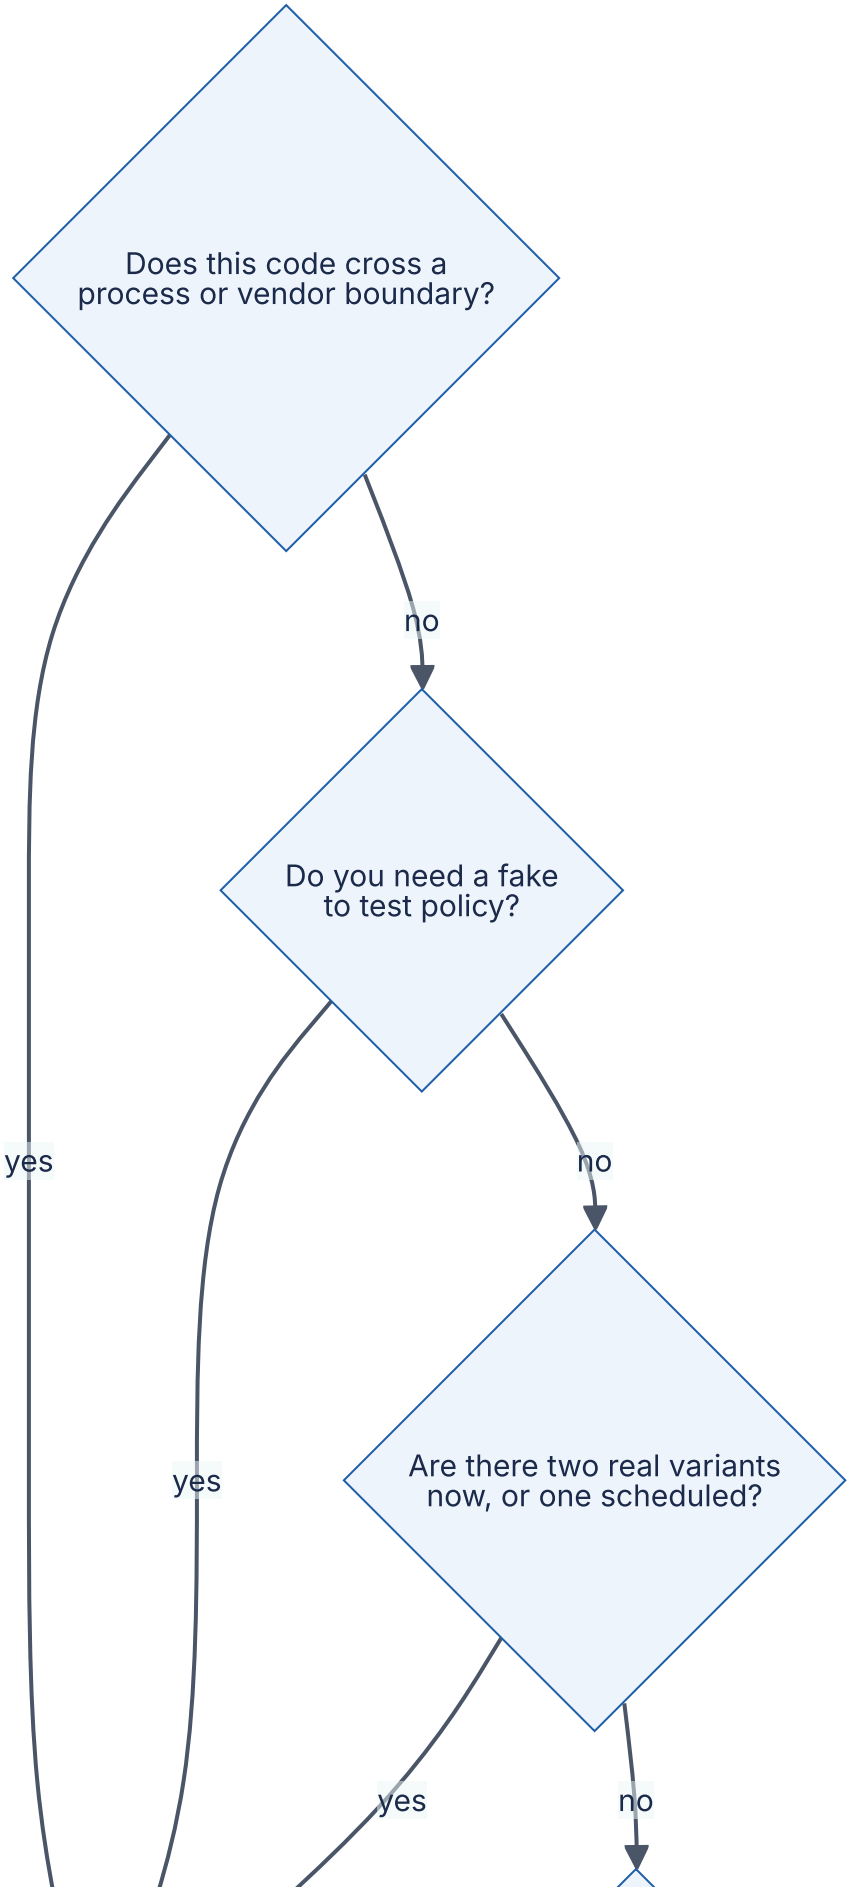
36.8.3 When SOLID is over-applied

Every principle in this chapter adds structure: more classes, more interfaces, more indirection. Structure pays for itself only when the change it anticipates actually happens. Martin himself lists **needless complexity** among the symptoms of poor design, alongside rigidity and fragility [Martin 2002]. Extreme Programming's **YAGNI** ("you aren't gonna need it") rule says not to build capability for features you only presume you will need, because the presumed need often never arrives and the unused structure still costs effort to carry [Fowler 2015]. Fowler's catalog of code smells calls the result **speculative generality** [Fowler 2018].

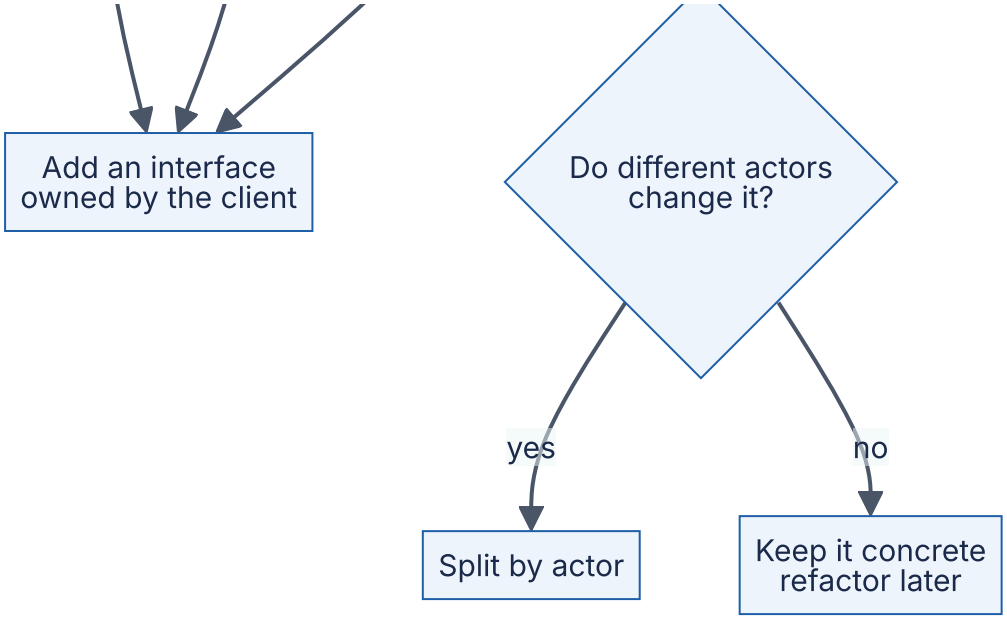
Table 36.10 — Signs that SOLID has been over-applied.

Symptom	Example	Better default
Interface with exactly one implementation and no test fake	`IInvoiceCalculator` with `InvoiceCalculatorImpl`	Use the concrete class; extract an interface when a second implementation or a fake is needed
Abstraction for a variation that never came	`TaxStrategyFactoryProvider` for one country	Wait for the second real variant (“rule of three”)
Classes split by technical step, not by actor	`OrderValidator`, `OrderMapper`, `OrderHelper` all edited together	Merge classes that always change together
Every call goes through a DI container	Business logic unreadable without the container configuration	Hand-written composition root for small systems
Ports that mirror one vendor’s SDK	`PaymentGateway.createStripeCharge(...)`	Write ports in domain vocabulary, or skip the port

Figure 36.17 — Should you add an abstraction here?



Does this code cross a process or vendor boundary?
yes
no
Do you need a fake to test policy?
yes
no
Are there two real variants now, or one scheduled?
yes
no



Reading the diagram. Diamonds are decisions, evaluated top to bottom; rectangles are outcomes. The first two questions capture the cheap, almost always justified uses of DIP: external boundaries (databases, vendors, networks, clocks), which are failure points and slow in tests, and policy that needs a fake. The third applies OCP only when variation is real. The fourth applies SRP when more than one actor edits the code. The default is concrete code: extracting an interface later is a mechanical refactor, while removing a wrong abstraction is manual work.

RECOMMENDATION

A practical rule. Apply DIP at every boundary to I/O and to other teams' systems from day one; apply SRP when you can name two actors; apply OCP and ISP when you see the second variant or the second kind of client. Revisit when change history (which files change together, which teams edit them) tells you where the real axes are.

INTERVIEW TIP

SOLID in LLD interviews, overall. Interviewers rarely ask "recite SOLID". They give a design (parking lot, notification service, rate limiter) and ask for an extension. Show a small, concrete design first, name the axis of change you are protecting, and justify each interface by a client, a test fake or a real variant. Saying "I would not add an interface here yet, because…" is a strong signal, not a weak one.

36.9 Summary and revision notes

SUMMARY

- SOLID limits how far a change spreads. Each principle blocks one path along which changes ripple.
- **SRP**: a module answers to one actor. Shared helpers between actors are accidental coupling; split by actor behind a facade.
- **OCP**: add expected variants as new classes behind a stable abstraction. Meyer used implementation inheritance; Martin uses interfaces and polymorphism. Closure is strategic: choose the axis.
- **LSP**: subtypes may weaken preconditions and strengthen postconditions, never the reverse; they keep invariants and history. Enforce with contract tests at the boundaries.
- **ISP**: clients see role interfaces sized to their needs. Throwing stubs signal a fat interface.
- **DIP**: policy owns the interfaces; details implement them. DI is a technique, IoC a framework property, DIP a rule about dependency direction. Fakes of owned ports make policy testable without I/O.
- At architecture level: Common Closure (SRP), plugins (OCP), versioned contracts (LSP), Common Reuse and BFFs (ISP), ports and adapters (DIP). Instability $I = C_e/(C_a + C_e)$ should decrease along dependencies.
- Over-application costs real money: add abstractions for boundaries, fakes, real variants and real actors, not for imagined ones.

36.10 Knowledge checkpoint

1. Restate SRP using the word “actor”, and explain why “a class should do one thing” is a different rule.
2. In the worked example of §36.3.2, what was the receipt’s unexplained difference after finance’s change, and why?
3. How does Meyer’s mechanism for the open–closed principle differ from Martin’s?
4. What is “strategic closure”?
5. Write the Liskov–Wing precondition and postcondition rules as implications.
6. Why does a mutable `Square` subclass of a mutable `Rectangle` violate LSP, while an immutable one need not?
7. How many SMS parts does a 500-character message need under GSM-7 concatenation?
8. Which is worse, a subtype that strengthens a precondition or one that weakens a postcondition, and why?
9. Give two symptoms of a fat interface.

10. In DIP, which module should own the `PaymentGateway` interface, and why?
11. Distinguish DIP, DI and IoC in one sentence each.
12. Compute *I* for a component with 6 dependents and 2 dependencies.
13. Name two signs that SOLID has been over-applied.

Answers

1. A module should be responsible to one, and only one, actor: one group of people who request its changes for the same reasons. “Do one thing” is about function size; a class can do many things that all change for one actor’s reasons.
2. $6.90 between “items 40.00” and “total due 46.90”: the $4.00 wrap fee disappeared from the items line because the shared `_subtotal` changed for finance’s reasons.
3. Meyer closes a module by freezing it and extends it through implementation inheritance; Martin closes clients by having them depend on an abstraction, with new behavior added as new implementations.
4. Choosing which kinds of change a design is closed against, since no design is closed against all changes.
5. $\text{Pre}_T \Rightarrow \text{Pre}_S$ and $\text{Post}_S \Rightarrow \text{Post}_T$.
6. The mutable rectangle promises that setting the width leaves the height unchanged; a square cannot keep that promise. With no mutators there is no such promise to break, and a rectangle’s history cannot reach a non-square state through a square.
7. $\lceil 500 / 153 \rceil = \lceil 3.27 \rceil = 4$ parts.
8. Usually the weakened postcondition, because it fails silently (truncated text, lost data), while a strengthened precondition fails loudly.
9. Implementers write throwing stubs; unrelated clients rebuild or retest when methods they do not call change; signatures do not reveal what a function uses.
10. The high-level checkout module, so that the interface is written in policy terms and source dependencies point from the adapter toward policy.
11. DIP: policy and detail both depend on abstractions owned by policy. DI: collaborators are passed in rather than constructed. IoC: the framework calls your code.
12. $I = 2/(6 + 2) = 0.25$.
13. Interfaces with one implementation and no fake; abstractions for variants that never arrived; classes that always change together; ports that mirror one vendor’s SDK.

36.11 Interview questions

Basic

Q1. What is the Single Responsibility Principle? Give an example. Answer. A module should answer to one actor. An `Employee` or `Order` class that computes pay or tax (finance), formats reports (operations or communications) and saves itself (DBA) answers to

three actors; a change for one can break another through shared code. Split it into a calculator, a formatter and a repository, with a facade if callers want one entry point.

Q2. How would you add a new payment method to an existing checkout without modifying it? Answer. Checkout depends on a `PaymentMethod` (or `PaymentGateway`) interface; each method is a class implementing it, selected by a registry or configuration. The new method is a new class plus one registration line. That is OCP, and it holds only if the new class honors the interface's contract (LSP).

Intermediate

Q3. Is a square a rectangle? Answer as a software designer. Answer. It depends on the contract. If `Rectangle` has independent setters whose postconditions leave the other side unchanged, a mutable `Square` cannot honor them, and code like "set width 5, set height 4, expect area 20" breaks. If rectangles are immutable values, a square can be a rectangle, because no operation promises independent mutation.

Q4. What is the difference between dependency injection and dependency inversion? Answer. DI is a technique: pass collaborators in. DIP is a structural rule: high-level policy defines the interfaces it needs, and low-level details implement them, so source dependencies point toward policy. You can inject a concrete vendor class (DI without DIP) or follow DIP with a service locator.

Advanced

Q5. A team's codebase has an interface for every class, a DI container and 40% of its classes named `*Impl`. Changes are still slow. What is going on? Answer. Likely speculative generality: interfaces mirror classes one to one, so they add indirection without changing dependency direction or isolating actors. Check whether core packages still import infrastructure, whether interfaces have a second implementation or a fake, and which files change together. Remove single-implementation interfaces not at I/O boundaries, split by actor where change history shows conflicts, and move ports into the policy packages.

Q6. How do SOLID principles map to a microservice architecture, and where does the analogy break? Answer. SRP becomes services aligned to business capabilities and teams; OCP becomes event-driven extension (new consumers without changing producers); LSP becomes backward-compatible API versions; ISP becomes client-specific APIs (BFFs); DIP becomes ports and adapters inside each service. The analogy breaks on cost: crossing a service boundary adds network latency, partial failure and data consistency problems that do not exist between classes, so service boundaries should be fewer and coarser than class boundaries.

36.12 Practical exercises

1. **Actor audit.** Take a 300+ line class from a codebase you know. List each public method's actor, draw a Figure 36.3-style diagram, and propose a split.
2. **Contract test.** Write a pytest or JUnit contract test for a `Repository` interface (save, find by id, delete) and run it against an in-memory fake and a SQLite implementation.
3. **Remove a switch.** Find an `if/elif` or `switch` on a type code repeated in more than one place and replace it with polymorphism. Count files touched before and after when adding a new type.
4. **Metrics.** Run the §36.8.2 script on a real project's import graph (generate it with a tool such as `pydeps` or `jdeps`) and identify components in the zone of pain.

36.13 Design challenges

1. **Notification platform.** Extend the running example to support quiet hours, per-customer channel preferences and per-channel rate limits. Show which classes change, which are added, and which principle protects each existing class.
2. **Multi-provider payments.** Design ports and adapters for two payment providers with different refund semantics (one allows partial refunds, one does not). Make the base contract honest so that both adapters satisfy LSP.
3. **Plugin pricing engine.** Design a pricing core that lets regional teams add discount rules without redeploying the core. Decide what is closed, what is open, and how a faulty plugin is contained.

36.15 Open verification items

- The Xerox `Job`-class origin story of ISP: confirm it appears in Martin 2002 (it may come from Martin’s 1996 C++ Report column or a later talk).
- Exact URL of Martin’s 2014 SRP blog post (the path is spelled “SingleReponsibilityPrinciple” as recalled).
- Wording of Liskov’s 1987 substitution property quoted from the SIGPLAN Notices reprint; page numbers not checked.
- Attribution of the “SOLID” acronym (commonly credited to Michael Feathers, c. 2004) was not verified and is not asserted in the text.

Chapter 37 — Design Patterns

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3.5 h

A carpenter who has built a hundred staircases does not reinvent the stringer, the tread and the riser each time. They recognize the problem ("connect two floors safely in this much space"), recall a solution shape that has worked before, and adapt it to the room. Software has the same kind of recurring problems: "create the right object without hard-coding its class", "add retries to a client without editing it", "let five subsystems react when an order is placed". A **design pattern** is a named, reusable solution shape for one of these problems. This chapter catalogs the patterns that keep appearing in the code behind large systems, shows each one in runnable Python, and connects each to the system-level idea it foreshadows: Observer to publish/subscribe, Proxy to API gateways and sidecars, Chain of Responsibility to middleware, producer–consumer to message queues.

DEFINITION

Definition — Design pattern. A named description of a recurring design problem, the core of a solution (a set of collaborating classes or functions and their responsibilities), and the trade-offs of applying it. A pattern is a template you adapt, not a library you import [Gamma et al. 1994].

The canonical catalog is the "Gang of Four" (GoF) book, which grouped 23 patterns into three families [Gamma et al. 1994]: **creational** patterns (how objects are made: Factory Method, Abstract Factory, Builder, Singleton, Prototype), **structural** patterns (how objects are composed: Adapter, Decorator, Proxy, Facade, Composite, Bridge, Flyweight) and **behavioral** patterns (how objects divide work and communicate: Strategy, Observer, Command, State, Template Method, Chain of Responsibility and others). Two further families matter for system design: **enterprise** patterns such as Repository [Fowler 2002] and Dependency Injection [Fowler 2004], and **concurrency** patterns such as producer–consumer and thread pools [Schmidt et al. 2000; Goetz et al. 2006].

KEY CONCEPT

Patterns depend on the language. The GoF book was written for C++ and Smalltalk. In a language with first-class functions, modules and duck typing, several patterns shrink: a Strategy becomes a function argument, a Singleton becomes a module, a Command becomes a closure. Norvig observed in 1996 that most GoF patterns are simpler or invisible in dynamic languages [Norvig 1996]. This chapter shows the classic structure first, because interviewers and Java codebases use it, and then the idiomatic Python form.

Every pattern below uses the same compact structure: intent, the problem it solves in a real system, the structure as a Mermaid class diagram, a Python implementation (all run under Python 3.13), a short Java sketch only where Java adds something language-specific, when to use and when not, related patterns, and one interview question. Most examples share one running system: the order service of an online store, which takes orders, charges payments, sends notifications and talks to cloud storage.

37.1 Learning objectives

After this chapter you should be able to:

- State the intent, structure and trade-offs of the Factory, Abstract Factory, Builder, Singleton, Strategy, Observer, Adapter, Decorator, Proxy, Command, Repository, State, Template Method and Chain of Responsibility patterns, and draw each as a class diagram.
- Implement each pattern in idiomatic Python and recognize where a function, module or closure replaces a class hierarchy.
- Explain why Singleton is often an anti-pattern, write a thread-safe variant, and explain why a “singleton” in a 50-pod deployment is really 50 objects.
- Distinguish the GoF Decorator from the Python `@decorator` syntax, and Adapter from Decorator from Proxy.
- Apply constructor injection and a composition root, and relate them to the Dependency Inversion Principle (§36.7).
- Build producer–consumer pipelines, thread pools and futures, size a thread pool with the utilization formula, and explain why double-checked locking is broken without a memory-model guarantee.
- Choose a pattern for a stated problem and name the trade-off you accept.

37.2 Prerequisites

- Classes, interfaces, polymorphism and composition over inheritance — §35.3–§35.9 (every pattern here is built from them).
- Cohesion and coupling — §35.10 (most patterns trade a little indirection for lower coupling).
- SOLID principles, especially Open/Closed (§36.4) and Dependency Inversion (§36.7) — patterns are the concrete mechanisms that realize them.
- Threads, locks, condition variables and read-write locks — §6.3, §6.9–§6.10 (needed for Singleton thread safety and §37.16).
- Little's Law — §4.11 (used to size thread pools).

37.3 Factory

Creating an object with `EmailNotifier()` is the simplest thing in programming, and it is also a hidden decision: the calling code now knows, and depends on, one concrete class. When the choice of class depends on configuration, input or environment, that decision should live in exactly one place. Factories put it there.

37.3.1 Simple factory

Intent

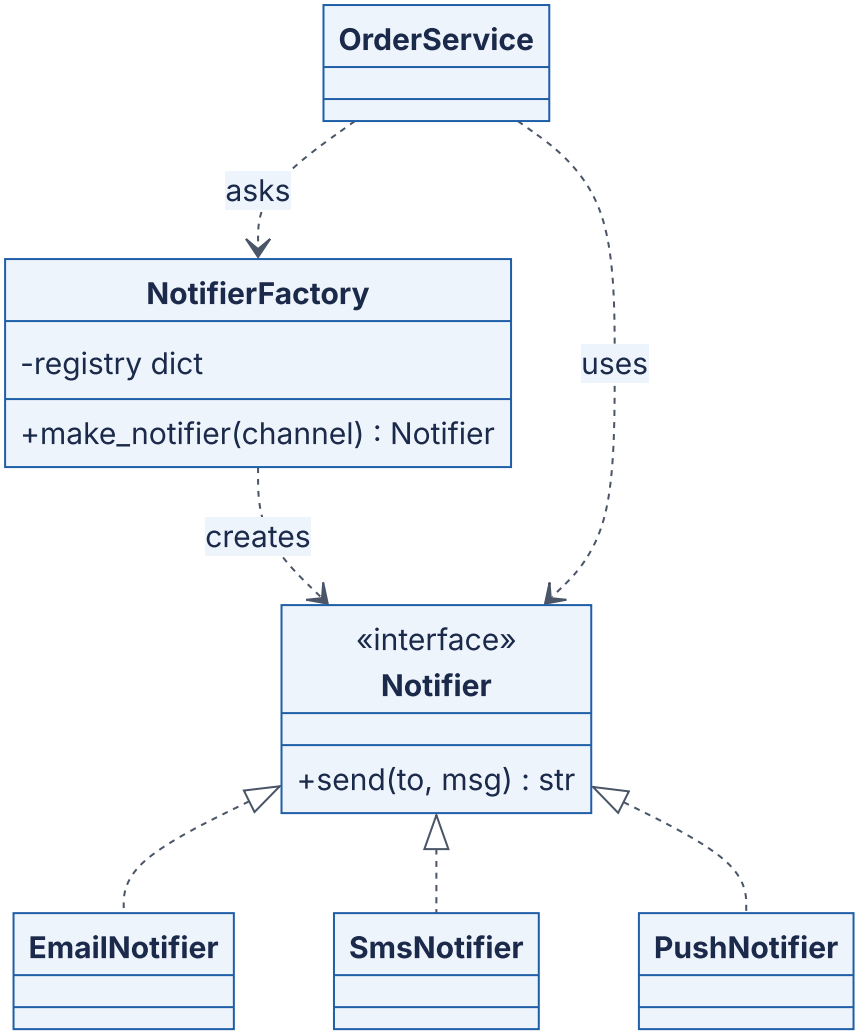
> DEFINITION
>
> **Definition — Simple factory.** A function or static method that takes a description of what is wanted (a string, an enum, a config value) and returns an instance of the matching concrete class, behind a common interface. It is an idiom rather than a GoF pattern, but it is the most common factory in practice.

Problem it solves

The order service sends notifications by email, SMS or push, and the channel comes from each user's preferences. Without a factory, every call site contains the same `if channel == "email": ... elif ...` chain, and adding WhatsApp means editing all of them. With a factory, call sites ask for "a notifier for this channel" and only the factory knows the mapping.

Structure

Figure 37.1 — Simple factory for notifiers.



Reading the diagram. `Notifier` is the interface every channel implements; the three concrete classes realize it (dotted arrows with hollow heads). `NotifierFactory` owns a registry from channel name to class and is the only component that names concrete classes. `OrderService` depends on the factory and on the interface, never on a concrete notifier. All calls are synchronous, in-process method calls. The registry is the only state, held in memory. The failure point is an unknown channel name, which the factory should reject loudly rather than return `None`. Adding a channel extends the registry without touching callers, which is the Open/Closed Principle (§36.4) in action.

37.3.2 Factory method

Intent

DEFINITION

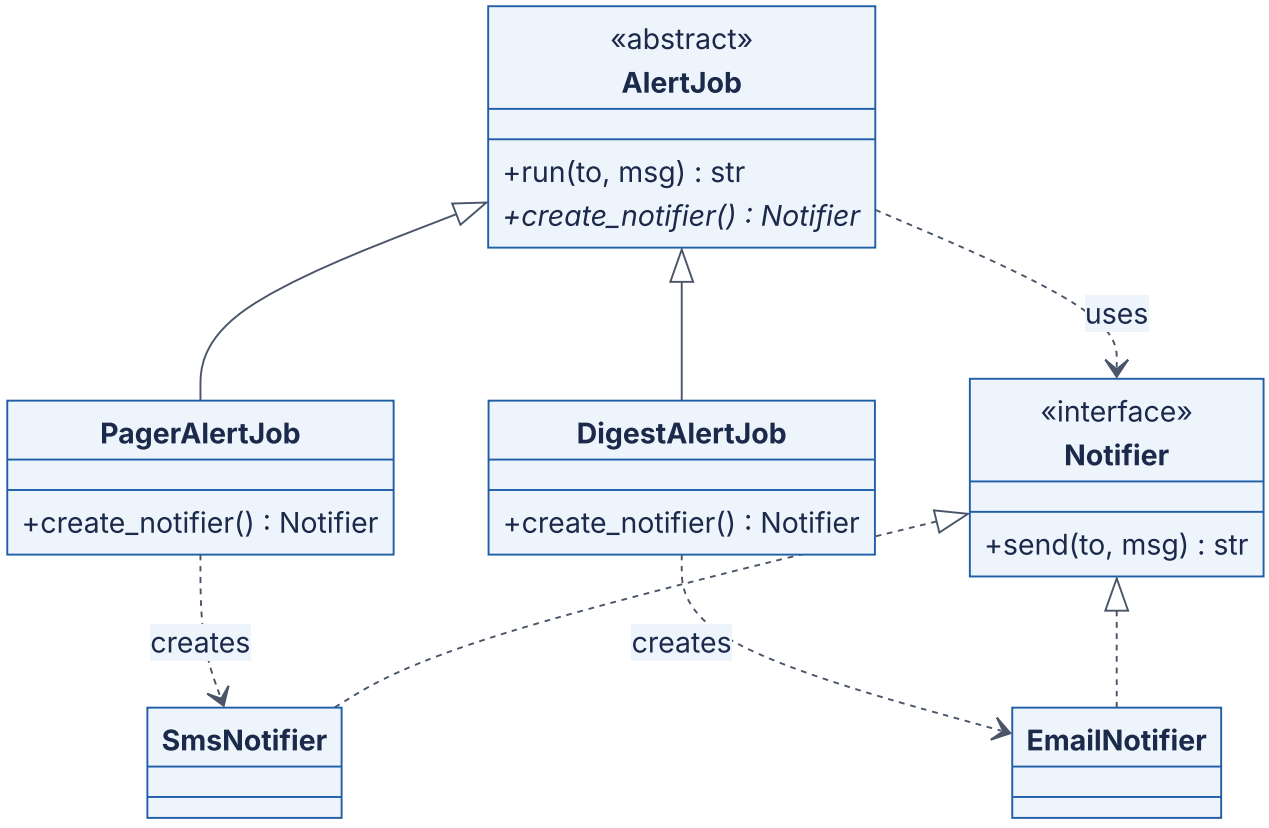
Definition — Factory method. A method declared in a base class that returns a product through an interface, which subclasses override to decide which concrete product to create. The base class's other methods use the product without knowing its class [Gamma et al. 1994].

Problem it solves

A framework defines the workflow and lets applications supply the parts. An alerting framework's `AlertJob.run()` always formats a message and sends it, but a paging job must use SMS and a daily digest job must use email. The base class cannot know which; the subclass can. Real frameworks are full of factory methods: Python's `socketserver` and `unittest` let subclasses decide the handler or test objects the framework creates, and Java's `Collection.iterator()` lets each collection return its own iterator class.

Structure

Figure 37.2 — Factory method.



Reading the diagram. The abstract creator `AlertJob` defines `run()`, which calls the abstract `create_notifier()` (the asterisk marks it abstract). Each concrete creator overrides that one method and names one concrete product. Control flows downward through inheritance (solid arrows with hollow heads) and the creation dependency points from each subclass to its product. Everything is synchronous and in-process; no state is stored beyond the objects themselves. The design scales by adding a creator subclass per product variant, which is also its weakness: two independent variation axes (channel and urgency, say) multiply subclasses, and composition (Strategy, §37.7, or injection, §37.14) is then the better tool.

Python implementation

```
from abc import ABC, abstractmethod

class Notifier(ABC):
    @abstractmethod
    def send(self, to: str, msg: str) -> str: ...

class EmailNotifier(Notifier):
    def send(self, to, msg):
        return f"email to {to}: {msg}"

class SmsNotifier(Notifier):
    def send(self, to, msg):
        return f"sms to {to}: {msg[:160]}"          # SMS segments are 160 chars

class PushNotifier(Notifier):
    def send(self, to, msg):
        return f"push to {to}: {msg}"

# --- Simple factory: one place owns the "which class?" decision ---
_REGISTRY: dict[str, type[Notifier]] = {
    "email": EmailNotifier, "sms": SmsNotifier, "push": PushNotifier,
}

def make_notifier(channel: str) -> Notifier:
    try:
        return _REGISTRY[channel]()
    except KeyError:
        raise ValueError(f"unknown channel {channel!r}") from None

# --- Factory method: subclasses decide what the base class creates ---
class AlertJob(ABC):
    @abstractmethod
    def create_notifier(self) -> Notifier: ...      # the factory method

    def run(self, to: str, msg: str) -> str:        # fixed workflow uses it
        return self.create_notifier().send(to, f"[ALERT] {msg}")

class PagerAlertJob(AlertJob):
    def create_notifier(self):
        return SmsNotifier()

class DigestAlertJob(AlertJob):
    def create_notifier(self):
        return EmailNotifier()
```

```
        if __name__ == "__main__":
            print(make_notifier("push").send("user-42", "Order shipped"))
            for job in (PagerAlertJob(), DigestAlertJob()):
                print(job.run("oncall", "p99 latency above SLO"))
            try:
                make_notifier("fax")
            except ValueError as e:
                print("rejected:", e)
```

Output:

```
push to user-42: Order shipped
sms to oncall: [ALERT] p99 latency above SLO
email to oncall: [ALERT] p99 latency above SLO
rejected: unknown channel 'fax'
```

What to notice:

- The registry is a dictionary of classes. In Python, classes are objects, so a simple factory needs no `if` chain and plugins can register themselves at import time.
- The factory fails loudly on unknown input. A factory that returns `None` moves the crash to a distant call site.
- `AlertJob.run()` never names a concrete class; only the one-line overrides do.

When to use and when not

Use a simple factory when the concrete class is chosen at run time from data (config, a request field, a feature flag). Use a factory method when a base class or framework owns a workflow and subclasses supply a part. Do not add a factory when there is only one implementation and no realistic second one: `Thing()` is clearer than `ThingFactory.create()`. In Python, passing a class or a callable (`notifier_cls=SmsNotifier`) often replaces a factory-method hierarchy.

Related patterns

Abstract Factory (§37.4) is a set of factory methods for a family of products. Template Method (§37.15.2) is the general form of “base class owns the workflow”. Dependency injection (§37.14) usually decides which factory is used.

Interview question

INTERVIEW TIP

Q. What is the difference between a simple factory and the factory method pattern?
A. A simple factory is one function that maps a parameter to a concrete class; callers pass data in. A factory method is an overridable method in a class hierarchy; the subclass, not a parameter, decides the product, and the base class's own logic uses it. The first centralizes a run-time choice; the second lets a framework defer a decision to its extensions.

37.4 Abstract factory

Intent

DEFINITION

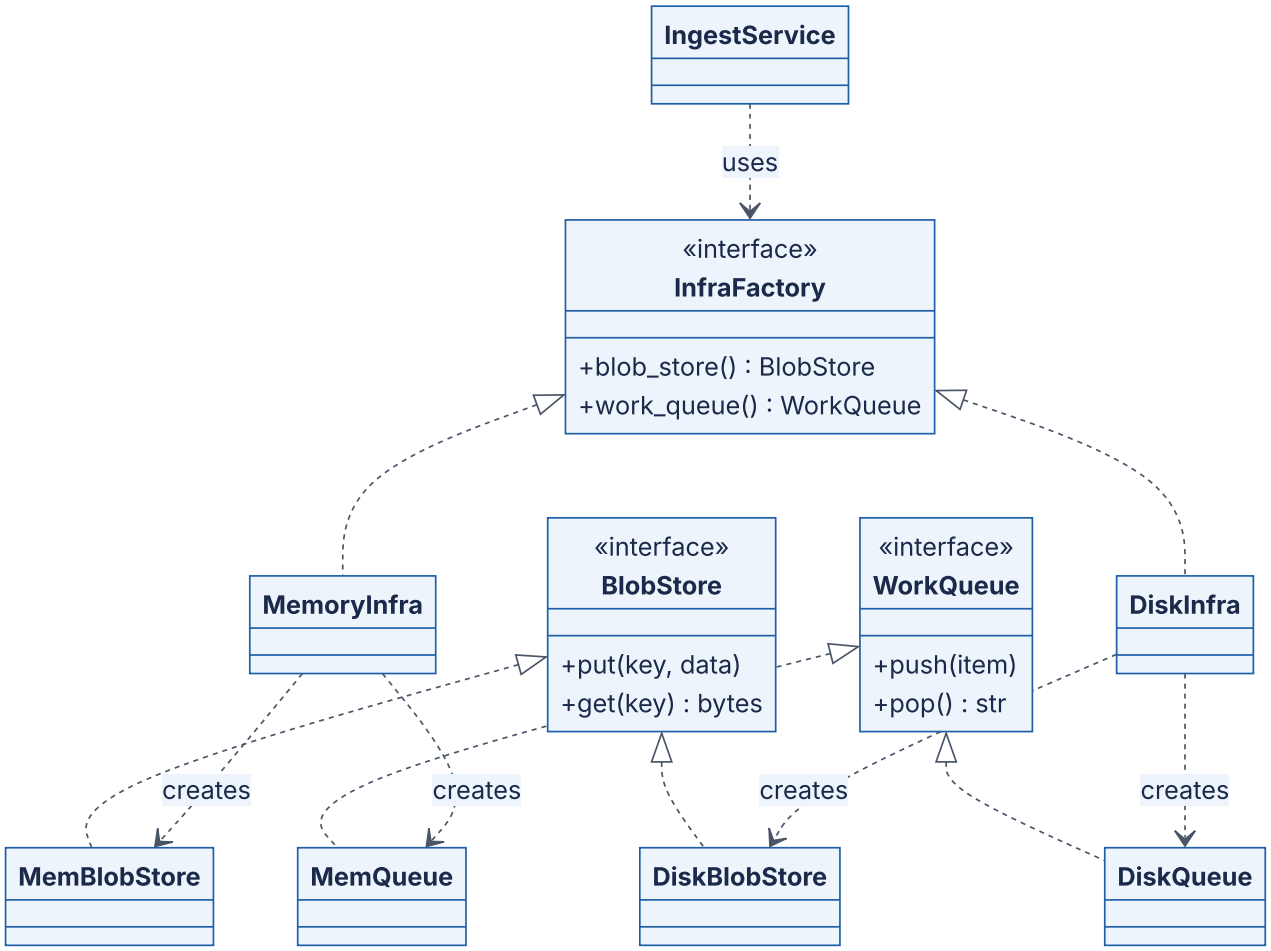
Definition — Abstract factory. An interface for creating a *family* of related objects (for example a blob store and a work queue) without naming their concrete classes, so that a client receives products that are guaranteed to belong together [Gamma et al. 1994].

Problem it solves

The order service stores invoices as blobs and enqueues work for a background worker. In production it uses a cloud object store and a cloud queue; in unit tests it uses in-memory fakes; on a laptop it uses the local disk. Mixing families (a disk blob store with a cloud queue whose workers cannot read the disk) is a bug that type checks cannot catch unless the families are created together. An abstract factory makes "which environment am I in?" one decision, made once, at startup. Portable libraries use the same idea: Java's `javax.xml.parsers.DocumentBuilderFactory` hides which XML parser implementation is installed.

Structure

Figure 37.3 — Abstract factory for infrastructure families.



Reading the diagram. There are two product interfaces (`BlobStore`, `WorkQueue`) and one factory interface with one creation method per product. Each concrete factory creates one consistent family: `MemoryInfra` creates the in-memory store and queue, `DiskInfra` the file-based ones. `IngestService` depends only on the three interfaces. Calls are synchronous and in-process here; in production the products would wrap network clients, and the storage boundary would sit behind `BlobStore.put` and `WorkQueue.push`, which are the failure points (timeouts, throttling). Adding a family (a cloud one) is easy; adding a product type (a cache) is hard, because every factory must change.

Python implementation

```
import os
import tempfile
from abc import ABC, abstractmethod
from collections import deque

class BlobStore(ABC):
    @abstractmethod
    def put(self, key: str, data: bytes) -> None: ...
    @abstractmethod
    def get(self, key: str) -> bytes: ...

class WorkQueue(ABC):
    @abstractmethod
    def push(self, item: str) -> None: ...
    @abstractmethod
    def pop(self) -> str | None: ...

            def work_queue(self): return DiskQueue(self.root)

        def ingest(infra: InfraFactory, name: str, payload: bytes) -> str:
            store, queue = infra.blob_store(), infra.work_queue()   # one consistent
family
            store.put(name, payload)
            queue.push(name)
            key = queue.pop()
            return f"{type(infra).__name__}: {key} -> {store.get(key)!r}"

        if __name__ == "__main__":
            factories = {"test": MemoryInfra, "dev": DiskInfra}
            for env in ("test", "dev"):
                print(ingest(factories[env](), "invoice-17.txt", b"total=4999"))
```

Output:

```
MemoryInfra: invoice-17.txt -> b'total=4999'
DiskInfra: invoice-17.txt -> b'total=4999'
```

What to notice:

- `ingest` is written once and runs unchanged against both families; the environment is chosen in one dictionary lookup at the top.
- The factory guarantees compatibility: `DiskQueue` items name files that `DiskBlobStore` can read.
- The cost is many small classes. In Python you can often replace the factory class with a small dataclass of two callables, or a module per environment.

When to use and when not

Use an abstract factory when you have several product types that must vary together (per cloud, per database vendor, per UI theme, per test versus production). Do not use it when products vary independently, when there is only one family, or when you expect to add product types frequently, since each new product forces a change to every factory.

Related patterns

Each creation method is a factory method (§37.3.2). Concrete factories are often configured by dependency injection (§37.14) and are sometimes, unwisely, made singletons (§37.6). Hexagonal architecture (§33.10) generalizes the idea: ports are the product interfaces and each environment supplies adapters.

Interview question

> INTERVIEW TIP
>
> **Q.** Your service must run on two cloud providers. How would you keep provider-specific code out of business logic? **A.** Define ports for each capability (blob storage, queue, secrets) and one abstract factory per provider that builds a consistent set of adapters. Business logic receives the factory or the built adapters via constructor injection; provider choice is made once in the composition root from configuration. Contract tests run against every family. Accept that new capabilities require changes to every provider’s factory.

37.5 Builder

Intent

> DEFINITION
>
> **Definition — Builder.** A separate object that assembles a complex product step by step, validates the combination of choices, and returns a finished (ideally immutable) product from a final `build()` call [Gamma et al. 1994; Bloch 2018].

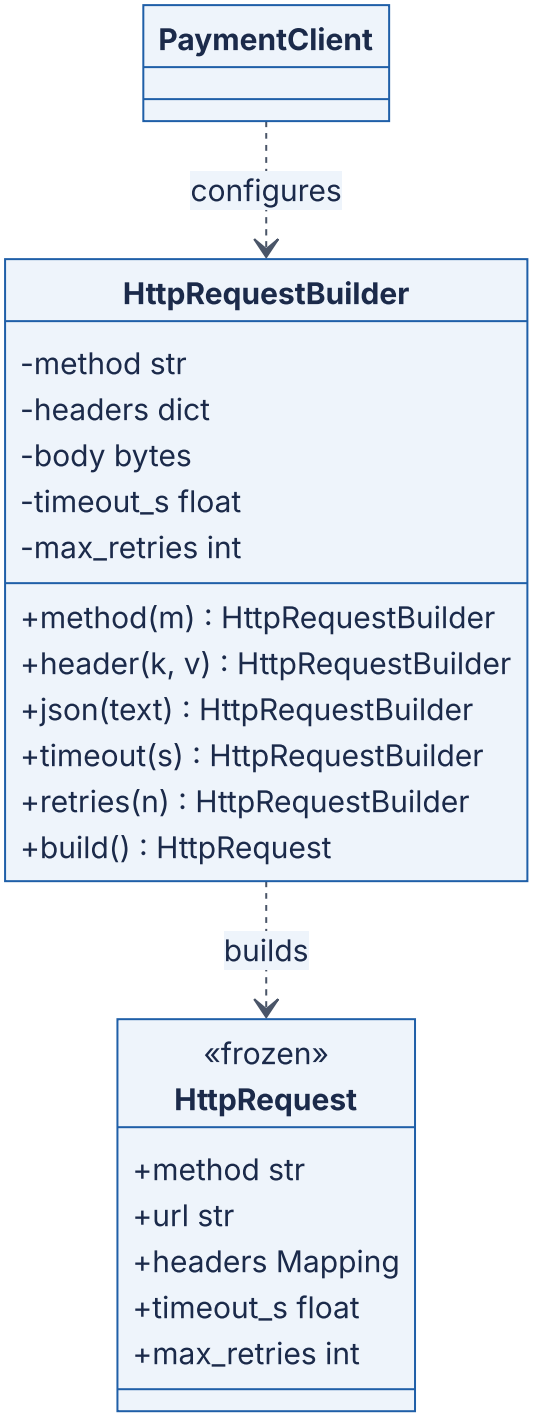
Problem it solves

An outbound HTTP request in the order service has a method, URL, headers, an optional body, a timeout and a retry count, and some combinations are invalid: a `GET` with a body, a timeout of 0, or a retried `POST` without an idempotency key (which risks charging a customer twice, §22.15). A constructor with eight positional arguments is unreadable, and

setters on a mutable object allow half-built requests to escape. A builder collects choices fluently, checks cross-field rules once, and emits a frozen object. Real APIs use exactly this shape: Java 11's `HttpRequest.newBuilder()`, and the `newBuilder()` methods that Protocol Buffers generates for every Java message class.

Structure

Figure 37.4 — Builder producing an immutable request.



Reading the diagram. The client (`PaymentClient`) talks only to the mutable builder, whose setters each return the builder so calls chain. `build()` is the single validation point and the only path to the immutable `HttpRequest`. Everything is synchronous and in memory; no I/O happens until a transport later sends the product. The failure point is `build()`, which raises on an invalid combination, so an invalid request can never exist. Immutable products are safe to share across threads and to cache.

Python implementation

```
        from dataclasses import dataclass
        from types import MappingProxyType

        @dataclass(frozen=True)
        class HttpRequest:
            method: str
            url: str
            headers: MappingProxyType
            body: bytes | None
            timeout_s: float
            max_retries: int

        class HttpRequestBuilder:
            def __init__(self, url: str):
                self._url, self._method = url, "GET"
                self._headers: dict[str, str] = {}
                self._body: bytes | None = None
                self._timeout_s, self._max_retries = 2.0, 0

            def method(self, m):   self._method = m.upper(); return self
            def header(self, k, v): self._headers[k.lower()] = v; return self
            def timeout(self, s):  self._timeout_s = s; return self
            def retries(self, n):  self._max_retries = n; return self

            def json(self, text: str):
                self._body = text.encode()
                return self.header("Content-Type", "application/json")

            def build(self) -> HttpRequest:
                if self._body is not None and self._method in ("GET", "HEAD"):
                    raise ValueError(f"{self._method} must not carry a body")
                if self._max_retries and self._method == "POST" \
                        and "idempotency-key" not in self._headers:
                    raise ValueError("retried POST needs an Idempotency-Key header")
                if not 0 < self._timeout_s <= 30:
                    raise ValueError("timeout must be in (0, 30] seconds")
                return HttpRequest(self._method, self._url,
                                   MappingProxyType(dict(self._headers)),  # read-only
copy
                                   self._body, self._timeout_s, self._max_retries)

        if __name__ == "__main__":
            req = (HttpRequestBuilder("https://payments.internal/charges")
                   .method("post").json('{"amount": 4999}')
                   .header("Idempotency-Key", "order-17-charge").timeout(0.5).retries(3)
                   .build())
            print(req.method, req.timeout_s, req.max_retries, dict(req.headers))
            try:

HttpRequestBuilder("https://payments.internal/charges").method("POST").retries(3).build(
)
```

```
        except ValueError as e:
            print("rejected:", e)
```

Output:

```
POST 0.5 3 {'content-type': 'application/json', 'idempotency-key': 'order-17-charge'}
rejected: retried POST needs an Idempotency-Key header
```

What to notice:

- Cross-field rules (retries require an idempotency key) live in `build()`, the one place that sees all fields together.
- The product is frozen and its headers are a read-only `MappingProxyType` copy, so later builder calls cannot mutate a request already in flight.

Java sketch

Python has keyword arguments with defaults, so `HttpRequest(url=..., timeout_s=0.5)` already reads well; a builder earns its keep mainly for cross-field validation. Java has no named or default parameters, so constructors with many parameters (“telescoping constructors”) are common, and the static nested Builder is the standard cure [Bloch 2018]:

```
        public final class RequestSpec {
            private final String url, method;
            private final int timeoutMs, maxRetries;

            private RequestSpec(Builder b) {                        // only the builder
can construct
                url = b.url; method = b.method; timeoutMs = b.timeoutMs; maxRetries =
b.maxRetries;
            }
            public static Builder newBuilder(String url) { return new Builder(url); }

            public static final class Builder {
                private final String url;
                private String method = "GET";
                private int timeoutMs = 2000, maxRetries = 0;
                private Builder(String url) { this.url = url; }
                public Builder method(String m)     { method = m; return this; }
                public Builder timeoutMs(int t)     { timeoutMs = t; return this; }
                public Builder maxRetries(int n)    { maxRetries = n; return this; }
                public RequestSpec build() {
                    if (timeoutMs <= 0) throw new IllegalStateException("timeout must be
positive");
                    return new RequestSpec(this);
                }
            }
        }
        // RequestSpec r = RequestSpec.newBuilder("https://api.example.com/orders")
        //
.method("POST").timeoutMs(500).maxRetries(3).build();
```

When to use and when not

Use a builder for objects with many optional parts, cross-field invariants, or a need for immutability after construction (requests, queries, configuration, test fixtures). Do not use one for objects with two or three fields; in Python, a frozen dataclass with keyword arguments and a `__post_init__` check is usually enough.

Related patterns

Abstract Factory (§37.4) returns a product in one call; Builder assembles one in steps. A builder is often created by a factory method (`newBuilder()`). Test-data builders are a common use in tests of Repository-based code (§37.13).

Interview question

INTERVIEW TIP

Q. Why make the built object immutable? **A.** Immutability means validation in `build()` holds forever: no later setter can break an invariant. Immutable objects can be shared between threads without locks, used as cache keys and dictionary keys, and retried safely because the request that is retried is exactly the one that was validated.

37.6 Singleton

Intent

DEFINITION

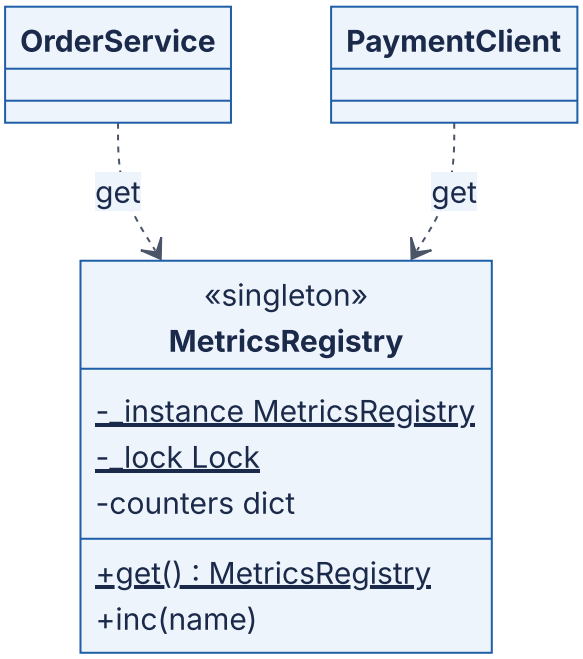
Definition — Singleton. A class that guarantees it has exactly one instance within a scope and provides a global access point to it [Gamma et al. 1994]. The scope is almost always one process, a fact that matters greatly in distributed systems.

Problem it solves

Some resources should exist once per process: a metrics registry that aggregates counters before export, a connection pool, a configuration object loaded at startup, the logging hierarchy. Creating a second connection pool by accident doubles database connections; two metrics registries split counters so dashboards undercount. Python's `logging.getLogger(name)` returns the same logger object for the same name every time, which is a registry of singletons keyed by name.

Structure

Figure 37.5 — Singleton with lazy, thread-safe creation.



Reading the diagram. `MetricsRegistry` holds a class-level (static, underlined `$`) reference to its only instance and a lock that guards first creation. Any component calls the static `get()` and receives the same object, synchronously and in-process. The state (counters) lives in that process's memory only. The failure points are a race during first creation (two threads both see "no instance"), hidden coupling (callers do not declare the dependency, so tests cannot substitute it), and shared mutable state that every caller can corrupt. It does not scale across processes: each process has its own.

Python implementation

```
        import json
        import sys
        import threading
        import time

        class NaiveRegistry:
            _instance, created = None, 0

            @classmethod
            def get(cls):
                if cls._instance is None:           # check ...
                    time.sleep(0.05)                # slow initialization widens the
window
                    cls.created += 1
                    cls._instance = cls()           # ... then act: not atomic
                return cls._instance

        class SafeRegistry:
            _instance, created = None, 0
            _lock = threading.Lock()

            @classmethod
            def get(cls):
                if cls._instance is None:           # fast path: no lock after creation
                    with cls._lock:
                        if cls._instance is None:   # re-check while holding the lock
                            time.sleep(0.05)
                            cls.created += 1
                            cls._instance = cls()
                return cls._instance

        def hammer(getter, n_threads=8):
            barrier = threading.Barrier(n_threads)   # release all threads at once
            def worker():
                barrier.wait()
                getter()
            threads = [threading.Thread(target=worker) for _ in range(n_threads)]
            for t in threads: t.start()
            for t in threads: t.join()

        if __name__ == "__main__":
            hammer(NaiveRegistry.get)
            hammer(SafeRegistry.get)
            print("naive instances created:", NaiveRegistry.created)
            print("safe instances created: ", SafeRegistry.created)
            # The idiomatic Python singleton is a module: imports are cached.
            import json as again
            print("module is cached:", again is json is sys.modules["json"])
```

Output (the naive count can vary between runs; it was 8 in every run we tried):

```
naive instances created: 8
safe instances created:  1
module is cached: True
```

What to notice:

- Check-then-act without a lock is a race condition (§6.9): all eight threads saw `None` before any assigned.
- The safe version re-checks under the lock. In CPython this double-check is correct because an object is fully built before the assignment publishes it; the same code in Java needs `volatile` (§37.16.5).
- A **module-level singleton** is the Python idiom: put `registry = MetricsRegistry()` in `metrics.py`, and every `import metrics` returns the module object cached in `sys.modules`. Import itself is protected by the interpreter's import lock.

Java sketch

Java offers two idioms that use language guarantees instead of hand-written locking. An `enum` with one constant is serialization-safe and reflection-safe [Bloch 2018]; the **initialization-on-demand holder** relies on the JVM's guarantee that class initialization is lazy and thread-safe:

```
        public enum MetricsRegistry {
            INSTANCE;
            private final java.util.concurrent.ConcurrentHashMap<String, Long> counters
=
                new java.util.concurrent.ConcurrentHashMap<>();
            public void inc(String name) { counters.merge(name, 1L, Long::sum); }
        }

        final class AppConfig {
            private AppConfig() { /* read files, environment */ }
            private static final class Holder { static final AppConfig INSTANCE = new
AppConfig(); }
            static AppConfig get() { return Holder.INSTANCE; }   // Holder initialized
on first call
        }
```

When to use and when not

Singleton is often an **anti-pattern** because it is a global variable with a class around it. It hides dependencies (a function's signature does not reveal that it writes metrics), makes tests order-dependent (state leaks from one test to the next), prevents running two configurations side by side, and invites lock contention on a hot shared object. Prefer creat-

ing one instance in the composition root and passing it in (§37.14); you keep "exactly one" by construction and gain testability. Reserve true singletons for stateless or effectively immutable process-wide facilities (logging, a metrics registry), and give them a reset hook for tests.

COMMON MISTAKE

Mistake — "A singleton guarantees one instance in the system." It guarantees one per process (per class loader in Java). An order service running 50 pods with 4 worker processes each has 200 "singleton" connection pools; at 10 connections each, that is 2,000 database connections, which can exhaust a PostgreSQL server configured for a few hundred. A system-wide single instance (one scheduler, one leader) needs leader election and leases (§26.5, §26.11), not a class pattern.

Related patterns

Dependency injection (§37.14) is the usual replacement. Abstract factories and registries are sometimes singletons. Double-checked locking (§37.16.5) is the classic lazy-initialization idiom and its classic bug.

Interview question

INTERVIEW TIP

Q. How would you make a singleton testable? **A.** Stop calling `get()` from business code. Create the instance once at startup and inject it through constructors; tests then pass a fake. If legacy code must call a global accessor, provide a test-only `reset()` or an override hook, and keep the singleton's state immutable or behind a narrow interface.

37.7 Strategy

Intent

DEFINITION

Definition — Strategy. A family of interchangeable algorithms, each behind a common interface, so that a client can be configured with one at run time without changing its code [Gamma et al. 1994].

Problem it solves
