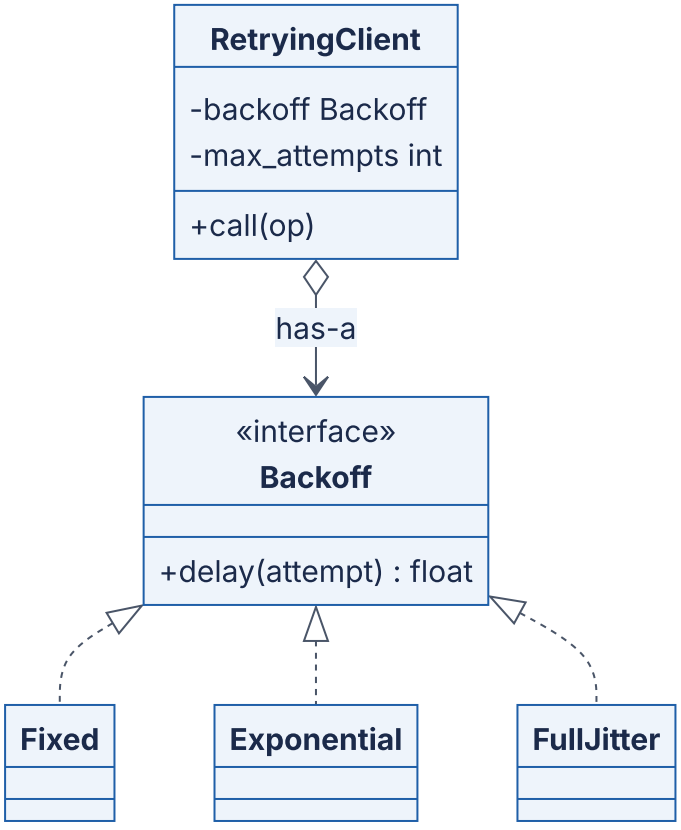
The order service retries calls to the payment provider. Which backoff policy is right depends on the dependency: a fixed delay for an internal cache, exponential backoff with **full jitter** for a shared external API, where synchronized retries from thousands of clients would otherwise arrive in waves (§22.12) [Brooker 2015]. Hard-coding the policy in the retry loop means editing and retesting the loop for every new policy. Strategy separates "when to retry" (the client's job) from "how long to wait" (the policy). The standard library is full of strategies: the `key=` argument of Python's `sorted`, Java's `Comparator`, and pluggable load-balancing policies (Chapter 19).

Structure

Figure 37.6 — Strategy for retry backoff.



Reading the diagram. `RetryingClient` (the context) holds a reference to one `Backoff` (aggregation, hollow diamond) and asks it for a delay after each failure. Three concrete strategies implement the same one-method interface. The call to the strategy is synchronous and in-process; the expensive, failure-prone call is the remote operation the client wraps. Strategies here are stateless except for the random generator, so one instance can be shared by many clients. Adding a policy adds a class (or function) and touches nothing else.

Python implementation

In Python a one-method interface is just a callable, so strategies are functions.

```
        import random
        from typing import Callable

        Backoff = Callable[[int], float]      # attempt number (0-based) -> seconds to
wait

        def fixed(delay: float) -> Backoff:
            return lambda attempt: delay

        def exponential(base: float, cap: float) -> Backoff:
            return lambda attempt: min(cap, base * 2 ** attempt)

        def full_jitter(base: float, cap: float, rng: random.Random) -> Backoff:
            return lambda attempt: rng.uniform(0, min(cap, base * 2 ** attempt))

        class RetryingClient:
            def __init__(self, backoff: Backoff, max_attempts: int = 5):
                self.backoff, self.max_attempts = backoff, max_attempts

            def call(self, op, sleep=lambda s: None):
                waits = []
                for attempt in range(self.max_attempts):
                    try:
                        return op(), waits
                    except ConnectionError:
                        wait = self.backoff(attempt)
                        waits.append(round(wait, 3))
                        sleep(wait)                    # injected so the demo runs in-
stantly
                raise TimeoutError(f"gave up after {self.max_attempts} attempts; waits=
{waits}")

        def flaky(fail_times: int):
            state = {"n": 0}
            def op():
                state["n"] += 1
                if state["n"] <= fail_times:
                    raise ConnectionError("503")
                return "charged"
            return op

        if __name__ == "__main__":
            rng = random.Random(7)
            for name, policy in [("fixed", fixed(0.2)),
                                 ("exponential", exponential(0.1, 2.0)),
                                 ("full jitter", full_jitter(0.1, 2.0, rng))]:
                result, waits = RetryingClient(policy).call(flaky(fail_times=4))
                print(f"{name:12} {result} after waits {waits}")
```

Output:

```
fixed        charged after waits [0.2, 0.2, 0.2, 0.2]
exponential  charged after waits [0.1, 0.2, 0.4, 0.8]
full jitter  charged after waits [0.032, 0.03, 0.26, 0.058]
```

What to notice:

- The retry loop never changes; swapping a closure changes the policy.
- Closures capture configuration (`base`, `cap`, `rng`), which is all a strategy object's fields would do.
- Injecting `sleep` and a seeded `rng` makes time-dependent code deterministic in tests, a small taste of §37.14.

When to use and when not

Use Strategy when several algorithms solve the same problem and the choice depends on configuration, data or tenant (pricing rules, compression codecs, eviction policies, load-balancing algorithms). Do not use it for a choice that never varies, and do not build a class hierarchy in Python when a function argument suffices.

Related patterns

State (§37.15.1) has the same structure, but the state object changes itself; a strategy is chosen from outside. Template Method (§37.15.2) varies steps by inheritance; Strategy varies them by composition. Decorator (§37.10) adds behavior around a call; Strategy replaces the algorithm inside.

Interview question

> INTERVIEW TIP
>
> **Q.** How does Strategy relate to the Open/Closed Principle? **A.** The context is closed for modification and open for extension: new behavior arrives as a new strategy, not as another `elif` in the context. The choice of strategy moves to configuration or the composition root, and each strategy can be unit-tested in isolation.

37.8 Observer

Intent

DEFINITION

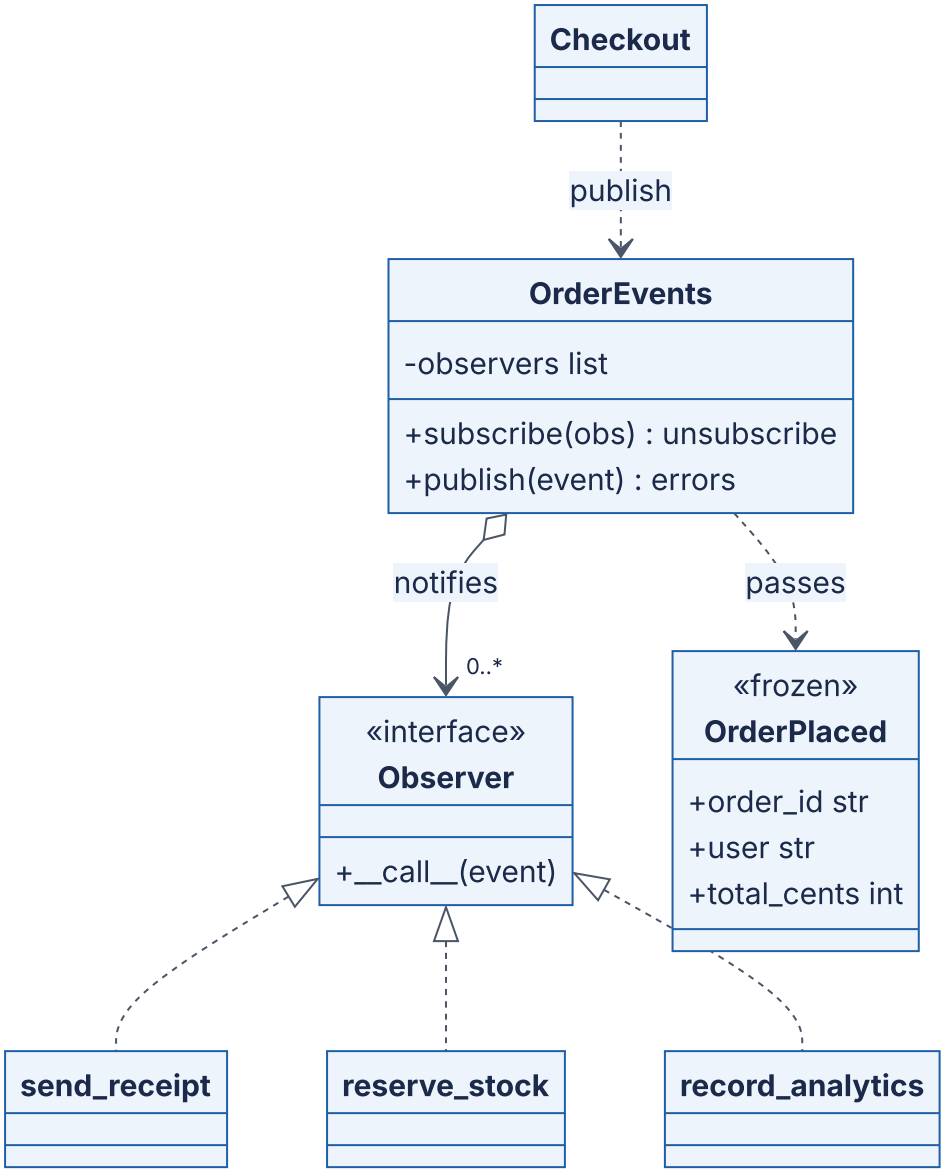
Definition — Observer. A one-to-many dependency in which a **subject** keeps a list of **observers** and notifies each of them when its state changes, so that the subject does not depend on what the observers do [Gamma et al. 1994].

Problem it solves

When an order is placed, the store must send a receipt, reserve stock and record analytics, and next quarter it will also award loyalty points. If `place_order()` calls each of these directly, the order module imports every other module, and adding loyalty means editing checkout. With Observer, checkout announces "an order was placed" and each interested module subscribes. GUI toolkits (button click listeners), Java's `PropertyChangeListener`, and Kubernetes client informers with registered event handlers all follow this shape.

Structure

Figure 37.7 — Observer for order events.



Reading the diagram. `Checkout` publishes an immutable `OrderPlaced` event to the subject, `OrderEvents`, which holds zero or more observers and calls each in turn. In the classic pattern every call is synchronous and in-process, so checkout's latency includes every observer's latency and an observer that blocks blocks checkout. The subscriber list is in-memory state; it is lost on restart, and so is any event being delivered when the process crashes. Failure points are a throwing observer (must be isolated) and a slow one (must be moved off the request path). Scaling beyond one process is where the pattern becomes publish/subscribe through a broker.

Python implementation

```
        from dataclasses import dataclass
        from typing import Callable

        @dataclass(frozen=True)
        class OrderPlaced:
            order_id: str
            user: str
            total_cents: int

        Observer = Callable[[OrderPlaced], None]

        class OrderEvents:                                  # the subject
            def __init__(self):
                self._observers: list[Observer] = []

            def subscribe(self, obs: Observer) -> Callable[[], None]:
                self._observers.append(obs)
                return lambda: self._observers.remove(obs)   # caller keeps the unsub-
scribe handle

            def publish(self, event: OrderPlaced) -> list[str]:
                errors = []
                for obs in list(self._observers):            # copy: observers may un-
subscribe
                    try:
                        obs(event)
                    except Exception as e:                   # isolate a failing ob-
server
                        errors.append(f"{obs.__name__}: {e}")
                return errors

        log = []
        def send_receipt(e):     log.append(f"receipt to {e.user}")
        def record_analytics(e): log.append(f"analytics +{e.total_cents}")
        def reserve_stock(e):
            if e.order_id == "o-2":
                raise RuntimeError("warehouse timeout")
            log.append(f"stock reserved for {e.order_id}")

        if __name__ == "__main__":
            events = OrderEvents()
            events.subscribe(send_receipt)
            events.subscribe(reserve_stock)
            stop_analytics = events.subscribe(record_analytics)
            print(events.publish(OrderPlaced("o-1", "ana", 4999)), log)
            log.clear(); stop_analytics()
            print(events.publish(OrderPlaced("o-2", "ben", 1999)), log)
```

Output:

```
[] ['receipt to ana', 'stock reserved for o-1', 'analytics +4999']
['reserve_stock: warehouse timeout'] ['receipt to ben']
```

What to notice:

- A failing observer is reported but does not stop the receipt from being sent; without the `try`, one bug in analytics would break checkout.
- `subscribe` returns an unsubscribe handle. Forgotten subscriptions are a classic memory leak (the "lapsed listener" problem): the subject keeps dead observers alive. `weakref.WeakMethod` is the Python remedy for bound methods.
- Observers run in subscription order and synchronously. Code must not depend on that order.

Observer and publish/subscribe

Observer is publish/subscribe inside one process. Chapter 30 (§30.5) takes the idea across the network.

Table 37.1 — Observer versus broker-based publish/subscribe.

Aspect	Observer (in-process)	Publish/subscribe (§30.5)
Coupling	Subject holds observer references	Publisher knows only a topic
Timing	Synchronous, same call stack	Asynchronous; subscribers may be offline
Durability	None; lost on crash	Broker persists messages
Failure isolation	Manual (`try` per observer)	Process boundary; retries, dead-letter queues (§30.11)
Latency	Microseconds	Milliseconds
Choose when	Same deployable, same transaction	Different services, independent scaling

A common production arrangement uses both: an in-process observer writes the event to an outbox table in the same database transaction, and a relay publishes it to the broker (the transactional outbox, §32.5).

When to use and when not

Use Observer when one change must trigger an open-ended set of reactions inside a process (UI updates, cache invalidation, domain events). Do not use it when the reactions must be atomic with the change and failure must roll it back (call them directly in the transaction), or when observers live in other services (use a broker).

Related patterns

Mediator centralizes many-to-many communication; Observer distributes one-to-many. Command (§37.12) objects are often what gets queued when observers become asynchronous. Publish/subscribe (§30.5) and event-driven architecture (§30.6) are the distributed forms.

Interview question

INTERVIEW TIP

Q. A slow analytics observer is adding 300 ms to checkout. What do you do? **A.** Take it off the request path: have the observer enqueue the event (an in-process queue drained by a worker, or a broker topic) and return immediately. If the event must not be lost, write it to an outbox in the order's transaction. Then decide the delivery guarantee (at-least-once plus an idempotent consumer is typical, §30.8).

37.9 Adapter

Intent

DEFINITION

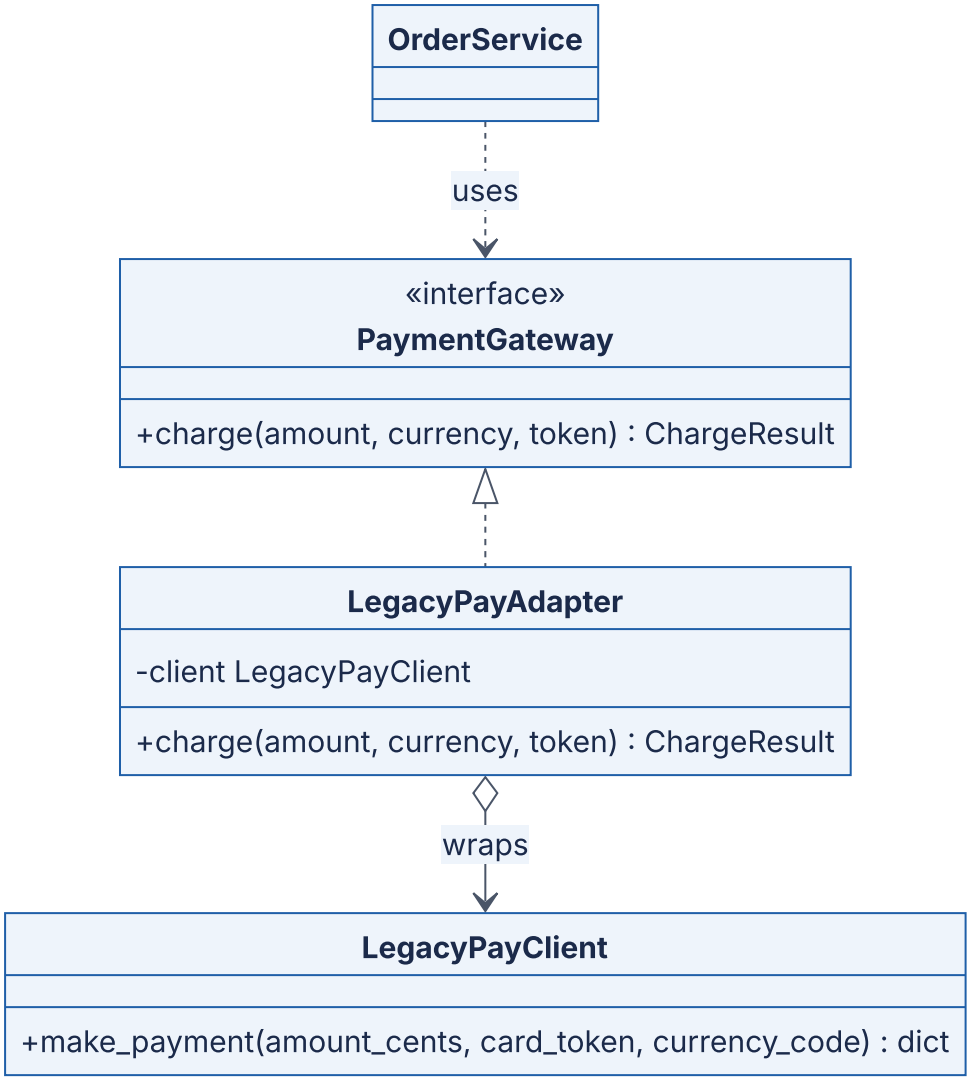
Definition — Adapter. A wrapper that converts the interface of an existing class into the interface its clients expect, so that classes with incompatible interfaces can work together [Gamma et al. 1994].

Problem it solves

The order service defines its own `PaymentGateway.charge(amount, currency, token)` port, returning a `ChargeResult`. The acquiring bank's SDK, which you cannot modify, exposes `make_payment(amount_cents, card_token, currency_code)` and returns a dictionary of status codes. An adapter translates units (decimal to integer cents), argument order and error conventions in one class, so neither side changes. SLF4J's bindings, which route one logging API to Logback, Log4j or `java.util.logging`, are adapters, as are JDBC drivers that present each database's wire protocol through one Java interface.

Structure

Figure 37.8 — Object adapter for a legacy payment SDK.



Reading the diagram. `OrderService` depends on its own interface (the **target**). `LegacyPayAdapter` implements the target and holds the third-party **adaptee**, translating every call. Calls are synchronous; the adaptee call crosses the network to the payment processor, so it is the failure point (timeouts, declines, malformed responses), and the adapter is where vendor error codes become your domain's results. The adapter holds no state of its own. Swapping vendors means writing a new adapter, not editing the service.

Python implementation

```
        from abc import ABC, abstractmethod
        from dataclasses import dataclass
        from decimal import Decimal

        class LegacyPayClient:                          # third-party SDK: cannot be
changed
            def make_payment(self, amount_cents, card_token, currency_code):
                if card_token.startswith("tok_bad"):
                    return {"status_code": 402, "err": "card_declined"}
                return {"status_code": 200, "txn": f"T-{amount_cents}-{currency_code}"}

        @dataclass(frozen=True)
        class ChargeResult:
            ok: bool
            reference: str

        class PaymentGateway(ABC):                      # our port (the target interface)
            @abstractmethod
            def charge(self, amount: Decimal, currency: str, token: str) ->
ChargeResult: ...

        class LegacyPayAdapter(PaymentGateway):
            def __init__(self, client: LegacyPayClient):
                self._client = client

            def charge(self, amount, currency, token):
                cents = int((amount * 100).to_integral_value())     # Decimal -> integer
cents
                resp = self._client.make_payment(cents, token, currency.upper())
                if resp["status_code"] == 200:
                    return ChargeResult(True, resp["txn"])
                return ChargeResult(False, resp.get("err", f"http
{resp['status_code']}"))

        if __name__ == "__main__":
            gateway: PaymentGateway = LegacyPayAdapter(LegacyPayClient())
            print(gateway.charge(Decimal("49.99"), "usd", "tok_visa"))
            print(gateway.charge(Decimal("19.99"), "eur", "tok_bad_cvc"))
```

Output:

```
ChargeResult(ok=True, reference='T-4999-USD')
ChargeResult(ok=False, reference='card_declined')
```

What to notice:

- All translation lives in one place: unit conversion, argument order, casing, and error codes become domain values.
- Money uses `Decimal`; converting a binary float like `49.99` to cents can be off by one.
- Tests of `OrderService` use a fake `PaymentGateway`; only the adapter's own tests touch the SDK.

When to use and when not

Use an adapter at every boundary with code you do not own (vendor SDKs, legacy modules, another team's API) and when migrating between implementations. Do not use one to paper over your own inconsistent interfaces; fix those instead. An adapter that grows business logic has become a service and should be named and tested as one.

Related patterns

Decorator (§37.10) keeps the interface and adds behavior; Adapter changes the interface. Facade simplifies a whole subsystem behind a new, smaller interface. Hexagonal architecture (§33.10) is named "ports and adapters" after this pattern, and the anti-corruption layer of domain-driven design (§34.5) is an adapter at a bounded-context boundary.

Interview question

INTERVIEW TIP

Q. What is the difference between an object adapter and a class adapter? **A.** An object adapter holds an instance of the adaptee and delegates (composition); it works with any subclass of the adaptee and is the norm in Python and Java. A class adapter inherits from both the target and the adaptee (multiple inheritance in C++, or extending the adaptee class while implementing the target interface in Java); it can override adaptee behavior but couples you to one concrete class.

37.10 Decorator

Intent

DEFINITION

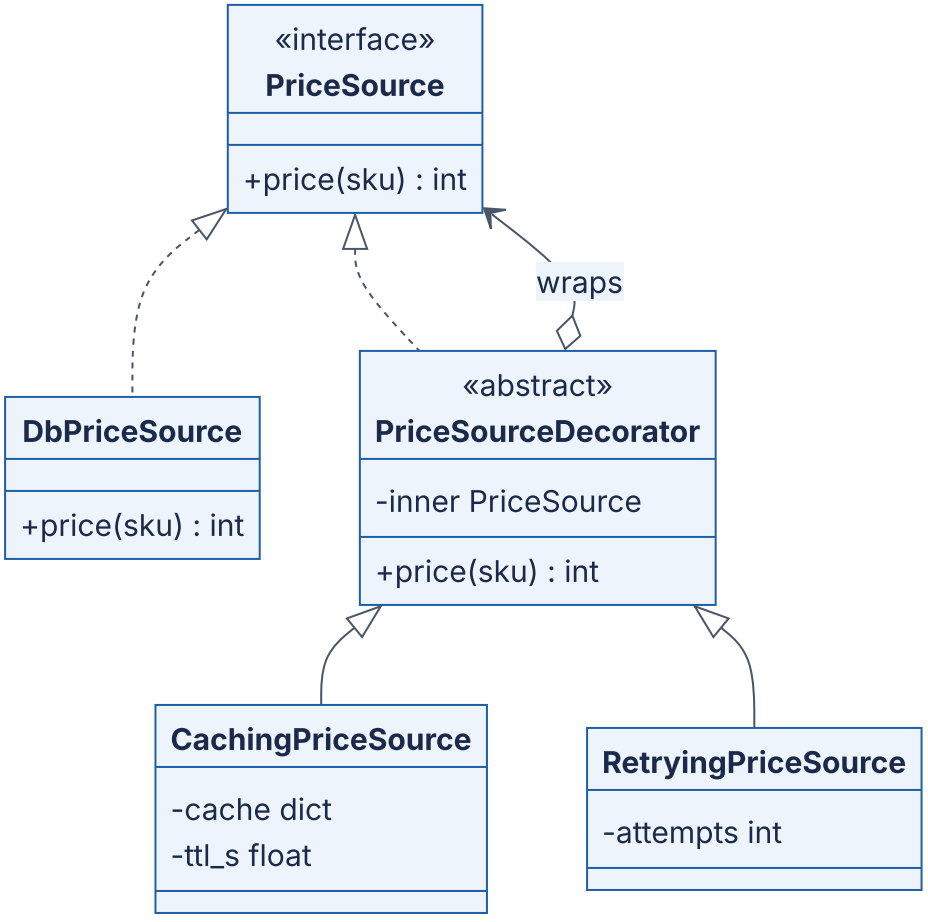
Definition — Decorator (GoF). An object that implements the same interface as the object it wraps, forwards calls to it, and adds behavior before or after them, so responsibilities can be added at run time and stacked in any order without subclassing [Gamma et al. 1994].

Problem it solves

The order service reads prices from a database-backed `PriceSource`. Some deployments need a cache, all need retries on transient errors, and some need metrics. Subclassing gives a class per combination (`CachingRetryingMetricsDbPriceSource`): with three optional behaviors that is $2^3 = 8$ classes. Decorators give three small wrappers that compose. Java's I/O library is the textbook case: `new BufferedInputStream(new GZIPInputStream(new FileInputStream(f)))` stacks buffering and decompression on a file stream, and Python's `io` module layers a `TextIOWrapper` over a `BufferedReader` over a raw `FileIO` in the same way.

Structure

Figure 37.9 — Decorators stacked around a price source.



Reading the diagram. Every decorator *is a* `PriceSource` and *has a* `PriceSource`; that double relationship is what lets wrappers nest to any depth. A call enters the outermost decorator and flows inward to `DbPriceSource`, the only component that crosses the storage boundary; results flow back out. Everything is synchronous. The cache holds in-process state with a TTL (stale reads are the trade-off, §20.8). Failure points: the database call, which the retry wrapper absorbs for transient errors, and the stacking order,

which changes behavior (a cache outside the retry hides retries on hits; inside, it does not).

Python implementation

```
        import functools
        import time
        from abc import ABC, abstractmethod

        class PriceSource(ABC):
            @abstractmethod
            def price(self, sku: str) -> int: ...

        class DbPriceSource(PriceSource):
            def __init__(self, failures_before_success=1):
                self.calls, self._fail = 0, failures_before_success
            def price(self, sku):
                self.calls += 1
                if self._fail:
                    self._fail -= 1
                    raise ConnectionError("db connection reset")
                return {"A1": 1999, "B2": 4999}[sku]

        class CachingPriceSource(PriceSource):            # GoF decorator 1
            def __init__(self, inner, ttl_s=60.0, clock=time.monotonic):
                self._inner, self._ttl, self._clock, self._cache = inner, ttl_s, clock,
{}
            def price(self, sku):
                hit = self._cache.get(sku)
                if hit and self._clock() - hit[1] < self._ttl:
                    return hit[0]
                value = self._inner.price(sku)
                self._cache[sku] = (value, self._clock())
                return value

        class RetryingPriceSource(PriceSource):           # GoF decorator 2
            def __init__(self, inner, attempts=3):
                self._inner, self._attempts = inner, attempts
            def price(self, sku):
                for i in range(self._attempts):
                    try:
                        return self._inner.price(sku)
                    except ConnectionError:
                        if i == self._attempts - 1:
                            raise

        # Python's @decorator syntax: wraps a *function* at definition time.
        def timed(fn):
            @functools.wraps(fn)                          # keep name, docstring
            def wrapper(*args, **kwargs):
                start = time.perf_counter()
                try:
                    return fn(*args, **kwargs)
                finally:
```

```
                    wrapper.last_ms = (time.perf_counter() - start) * 1000
            return wrapper

        @timed
        def quote(source: PriceSource, sku: str, qty: int) -> int:
            return source.price(sku) * qty

        if __name__ == "__main__":
            db = DbPriceSource()
            source = CachingPriceSource(RetryingPriceSource(db))     # stack at run time
            print(quote(source, "B2", 2), quote(source, "B2", 1), "db calls:", db.calls)
            print(quote.__name__, f"{quote.last_ms:.3f} ms" if quote.last_ms < 5 else
"slow")
```

Output (the time varies by machine):

```
9998 4999 db calls: 2
quote 0.002 ms
```

What to notice:

- Two database calls: the first failed and was retried; the second quote was a cache hit.
- The stack is built at run time from configuration; no class names the combination.
- `@timed` is Python syntax for `quote = timed(quote)`. `functools.wraps` copies `__name__` and `__doc__`, without which logs and tracebacks name every function `wrapper`.

> WARNING / TRADE-OFF
>
> **Python decorators are not the GoF Decorator.** The GoF pattern wraps an *object* at run time behind the *same interface*. Python's `@decorator` (PEP 318) is syntax that passes a function or class to another callable at *definition time* and rebinds the name to whatever it returns [PEP 318]. It can implement a GoF-style wrapper for a function (`@functools.lru_cache`, a retry decorator), but it is equally used for registration (`@app.route("/orders")` adds a URL mapping and returns the function unchanged), for `@property`, and for class transformations (`@dataclass`), none of which is the GoF pattern. Ask "does this wrap an object and keep its interface?"

When to use and when not

Use decorators for cross-cutting concerns that you want to combine freely: caching, retries, metrics, logging, authorization, compression, rate limiting. Do not use them when the wrapped interface is wide (every method must be forwarded; Python's `__getattr__`

helps but hides the contract), when order-dependent stacks become hard to reason about, or when identity matters (`wrapped is not inner`).

Related patterns

Proxy (§37.11) has the same structure but controls access rather than adding features. Adapter (§37.9) changes the interface. Chain of Responsibility (§37.15.3) is a decorator stack expressed as a pipeline; HTTP middleware is both.

Interview question

> INTERVIEW TIP
>
> **Q.** Design a client library that supports optional caching, retries and circuit breaking. **A.** Define one client interface; implement the network client; implement each concern as a decorator of that interface; build the stack in a factory from configuration. Document the order: retry inside the circuit breaker so an open circuit stops retries (§22.13), cache outermost so hits avoid both.

37.11 Proxy

Intent

> DEFINITION
>
> **Definition — Proxy.** A surrogate that implements the same interface as a real subject and controls access to it [Gamma et al. 1994]. A **virtual proxy** delays creating an expensive object until first use; a **protection proxy** checks permissions before forwarding; a **remote proxy** (a stub) makes an object in another address space look local.

Problem it solves

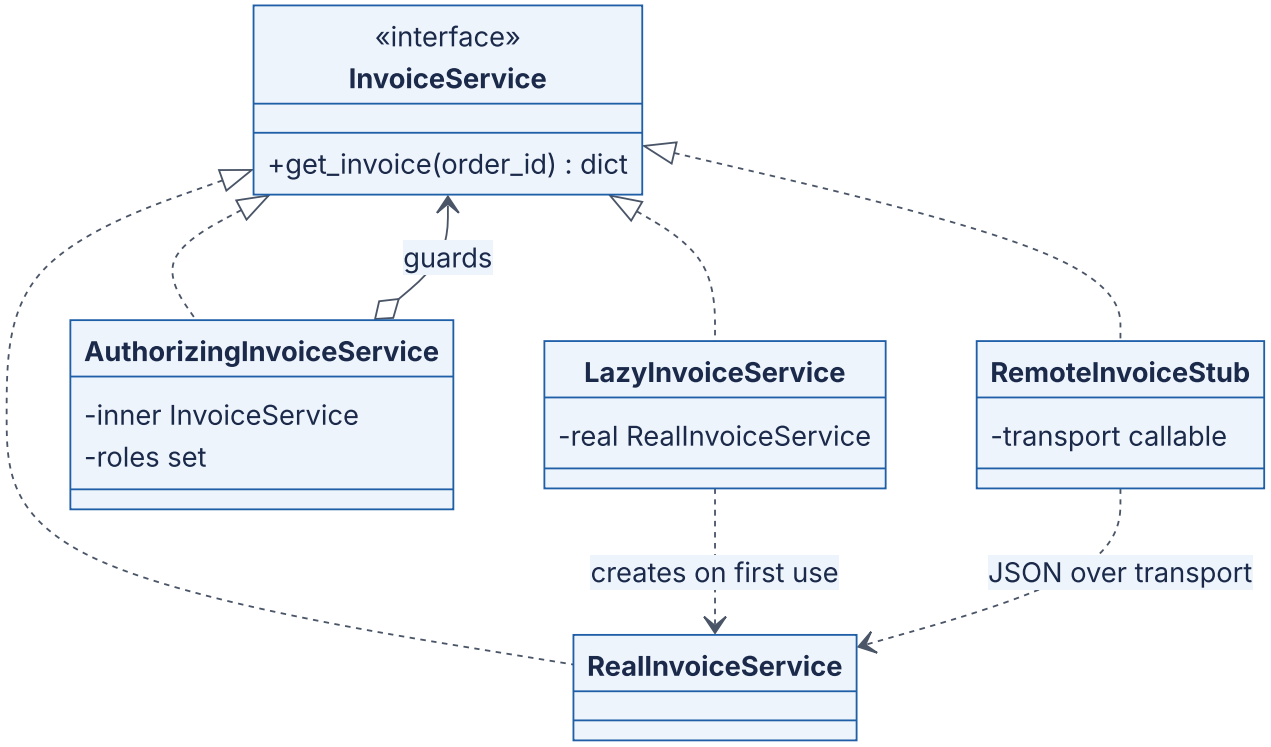
The invoice service is expensive to start (it loads templates and opens a connection pool) but most requests never need it; a virtual proxy defers that cost. Only users with the billing role may read invoices; a protection proxy enforces that at one choke point. In a microservice deployment the invoice service runs elsewhere; a remote proxy (a gRPC or REST client stub) lets callers write `invoices.get_invoice("o-17")`.

INDUSTRY EXAMPLE

Spring Framework transactions. Spring applies `@Transactional` and other aspects by wrapping a bean in a proxy, a JDK dynamic proxy when the bean implements an interface and a generated subclass otherwise. The proxy begins the transaction, calls the real method and commits or rolls back. The documented trade-off: a call from one method of the bean to another on `this` bypasses the proxy, so the annotation on the inner method has no effect. *Evidence: Primary* — [Spring Docs]

Structure

Figure 37.10 — Virtual, protection and remote proxies.



Reading the diagram. All four classes share one interface, so a client cannot tell which it holds. The virtual proxy creates the real subject on first call and caches it. The protection proxy wraps any `InvoiceService` and refuses calls that fail its check. The remote stub serializes the call, sends it over a transport (HTTP or gRPC in production; a function here), and deserializes the reply; that edge crosses a process and network boundary, so it adds latency (~0.5 ms in a datacenter at best) and new failure modes (timeouts, partial failure, retries). Scaling the remote side happens behind the stub (load balancing, §19).

Python implementation

```
        import json
        from abc import ABC, abstractmethod

        class InvoiceService(ABC):
            @abstractmethod
            def get_invoice(self, order_id: str) -> dict: ...

        class RealInvoiceService(InvoiceService):
            def __init__(self):
                print("  (expensive init: templates loaded, DB pool opened)")
                self._db = {"o-17": {"order_id": "o-17", "total_cents": 4999}}
            def get_invoice(self, order_id):
                return self._db[order_id]

        class LazyInvoiceService(InvoiceService):           # virtual proxy
            def __init__(self):
                self._real = None
            def get_invoice(self, order_id):
                if self._real is None:
                    self._real = RealInvoiceService()
                return self._real.get_invoice(order_id)

        class AuthorizingInvoiceService(InvoiceService):    # protection proxy
            def __init__(self, inner: InvoiceService, roles: set[str]):
                self._inner, self._roles = inner, roles
            def get_invoice(self, order_id):
                if "billing" not in self._roles:
                    raise PermissionError("billing role required")
                return self._inner.get_invoice(order_id)

        class RemoteInvoiceStub(InvoiceService):            # remote proxy (client
stub)
            def __init__(self, transport):
                self._send = transport
            def get_invoice(self, order_id):
                reply = json.loads(self._send(json.dumps(
                    {"method": "get_invoice", "args": [order_id]})))
                if "error" in reply:
                    raise RuntimeError(reply["error"])
                return reply["result"]

        def make_server(impl: InvoiceService):              # server skeleton
            allowed = {"get_invoice"}                       # never dispatch arbitrary
names
            def handle(wire: str) -> str:
                req = json.loads(wire)
                try:
                    if req["method"] not in allowed:
```

```
                        raise ValueError("no such method")
                    return json.dumps({"result": getattr(impl, req["method"])
(*req["args"])})
                except Exception as e:
                    return json.dumps({"error": repr(e)})
            return handle

        if __name__ == "__main__":
            lazy = LazyInvoiceService()
            print("proxy created; nothing loaded yet")
            print(lazy.get_invoice("o-17"))
            try:
                AuthorizingInvoiceService(lazy, {"support"}).get_invoice("o-17")
            except PermissionError as e:
                print("denied:", e)
            stub = RemoteInvoiceStub(make_server(lazy))
            print(stub.get_invoice("o-17"))
            try:
                stub.get_invoice("o-99")
            except RuntimeError as e:
                print("remote error:", e)
```

Output:

```
proxy created; nothing loaded yet
  (expensive init: templates loaded, DB pool opened)
{'order_id': 'o-17', 'total_cents': 4999}
denied: billing role required
{'order_id': 'o-17', 'total_cents': 4999}
remote error: KeyError('o-99')
```

What to notice:

- The expensive initialization ran once, on first use, not at construction.
- The remote stub changes failure semantics: a `KeyError` on the server becomes a `RuntimeError` carrying a string. Remote proxies cannot fully hide the network, which is the first fallacy of distributed computing (§24.5).
- The skeleton dispatches only allowed method names. Dispatching any name from the wire is a remote-code-execution hole.

Java sketch

Java can generate proxies at run time for any interface with `java.lang.reflect.Proxy`, which is how frameworks add transactions, security checks and tracing without hand-written wrapper classes:

```
        import java.lang.reflect.Proxy;

        interface Invoices { String get(String orderId); }

        class Proxies {
            @SuppressWarnings("unchecked")
            static <T> T timed(T target, Class<T> iface) {
                return (T) Proxy.newProxyInstance(iface.getClassLoader(), new Class<?>[]
{iface},
                    (proxy, method, args) -> {
                        long t0 = System.nanoTime();
                        try { return method.invoke(target, args); }
                        finally { System.out.printf("%s took %d us%n", method.getName(),
                                                    (System.nanoTime() - t0) / 1000); }
                    });
            }
        }
        // Invoices inv = Proxies.timed(orderId -> "invoice " + orderId,
Invoices.class);
```

Proxies at the system level

The same three roles reappear as infrastructure. A reverse proxy (§7.12) and an API gateway (§34.6) are protection proxies for whole services: they authenticate, authorize and rate-limit before forwarding. A service-mesh sidecar such as Envoy (§34.10) is a remote proxy deployed next to each service: the application talks to `localhost`, and the sidecar handles discovery, TLS, retries and telemetry. Content delivery networks (Chapter 21) act as caching proxies.

Table 37.2 — Four wrappers that look alike.

Pattern	Interface seen by client	Purpose	Typical example
Adapter	Different from the wrapped object	Make incompatible interfaces fit	Vendor SDK behind your port
Decorator	Same	Add behavior, stackable	Caching, retries, buffering
Proxy	Same	Control access: lazy, permission, remote	Lazy entity, auth check, RPC stub
Facade	New, simpler	Hide a subsystem	One `checkout()` over five services

When to use and when not

Use a proxy when access needs control: deferred creation of something expensive, a permission check at one point, a remote object, or a smart reference that counts or logs. Avoid remote proxies that make chatty remote calls look like cheap local ones; design coarse-grained remote interfaces instead.

Related patterns

Decorator (§37.10) is structurally identical; the difference is intent. Adapter changes the interface. API gateways and sidecars are proxies at deployment scale.

Interview question

> INTERVIEW TIP
>
> **Q.** Why are lazy-loading ORM proxies a common source of performance bugs? **A.** Each proxy triggers a query on first access, so iterating 100 orders and touching each order's lazily loaded customer issues 1 + 100 queries (the N+1 problem). The proxy hides the I/O. Fix it with eager fetching or a join for that query, and detect it by counting queries per request in tests.

37.12 Command

Intent

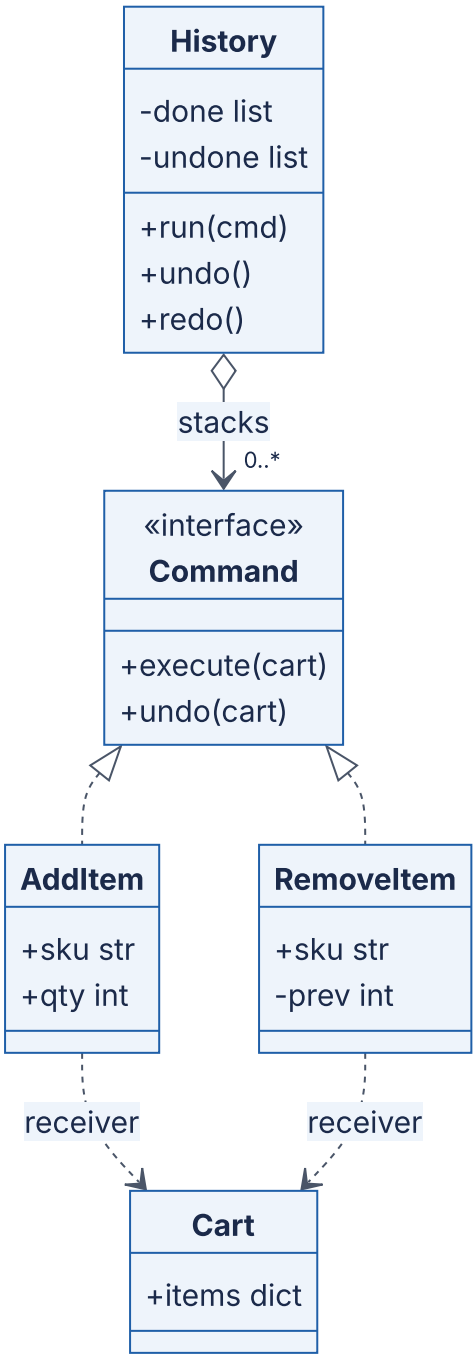
> DEFINITION
>
> **Definition — Command.** An object that encapsulates a request (the operation and its arguments) so that it can be stored, passed around, queued, logged, replayed and undone [Gamma et al. 1994]. In this book's terminology a command is a request to do something, as opposed to an event, a fact that has happened.

Problem it solves

A shopping cart editor needs undo and redo. A background job system needs to put "send receipt for order 17" on a queue and run it later on another machine. An audit log needs a durable record of every requested change. All three need the request itself to be a value, not just a method call that vanishes once made. Java's `Runnable` and `Callable` passed to an executor, Celery tasks, and the operations in a write-ahead log are commands.

Structure

Figure 37.11 — Command with undo/redo history.



Reading the diagram. The **invoker** (`History`) runs commands and keeps two stacks. Each concrete command knows its **receiver** (`Cart`) and how to reverse itself; `RemoveItem` stores the quantity it removed so that undo can restore it. Calls are synchronous here, but because a command is a value it can cross an asynchronous boundary: serialize it, put it on a queue, execute it on a worker. State lives in the receiver and, for undo, in the history stacks; those stacks are in memory unless you persist them. Failure points: a command whose undo is not the exact inverse, and a queued command executed twice (make handlers idempotent, §32.10).

Python implementation

```
        import json
        from abc import ABC, abstractmethod
        from dataclasses import asdict, dataclass, field

        class Cart:
            def __init__(self):
                self.items: dict[str, int] = {}

        class Command(ABC):
            @abstractmethod
            def execute(self, cart: Cart) -> None: ...
            @abstractmethod
            def undo(self, cart: Cart) -> None: ...

        @dataclass
        class AddItem(Command):
            sku: str
            qty: int
            def execute(self, cart):
                cart.items[self.sku] = cart.items.get(self.sku, 0) + self.qty
            def undo(self, cart):
                left = cart.items[self.sku] - self.qty
                if left:
                    cart.items[self.sku] = left
                else:
                    del cart.items[self.sku]

        @dataclass
        class RemoveItem(Command):
            sku: str
            _prev: int = field(default=0, repr=False)   # captured for undo
            def execute(self, cart):
                self._prev = cart.items.pop(self.sku, 0)
            def undo(self, cart):
                if self._prev:
                    cart.items[self.sku] = self._prev

        class History:                                  # the invoker
            def __init__(self, cart):
                self.cart, self._done, self._undone = cart, [], []
            def run(self, cmd):
                cmd.execute(self.cart); self._done.append(cmd); self._undone.clear()
            def undo(self):
                if self._done:
                    cmd = self._done.pop(); cmd.undo(self.cart);
self._undone.append(cmd)
            def redo(self):
                if self._undone:
                    cmd = self._undone.pop(); cmd.execute(self.cart);
```

```
self._done.append(cmd)

        TYPES = {"AddItem": AddItem, "RemoveItem": RemoveItem}

        def to_message(cmd: Command) -> str:            # commands are values: serial-
ize them
            data = {k: v for k, v in asdict(cmd).items() if not k.startswith("_")}
            return json.dumps({"type": type(cmd).__name__, **data})

        def from_message(text: str) -> Command:
            data = json.loads(text)
            return TYPES[data.pop("type")](**data)

        if __name__ == "__main__":
            h = History(Cart())
            for cmd in (AddItem("A1", 2), AddItem("B2", 1), RemoveItem("A1")):
                h.run(cmd)
            print("after 3 commands:", h.cart.items)
            h.undo(); h.undo()
            print("after 2 undos:   ", h.cart.items)
            h.redo()
            print("after redo:      ", h.cart.items)

            queue = [to_message(c) for c in (AddItem("A1", 2), RemoveItem("A1"),
AddItem("C3", 5))]
            print("queued:", queue[0])
            replica = Cart()
            for msg in queue:                           # a worker replays the queue
                from_message(msg).execute(replica)
            print("replayed cart:   ", replica.items)
```

Output:

```
after 3 commands: {'B2': 1}
after 2 undos:    {'A1': 2}
after redo:       {'A1': 2, 'B2': 1}
queued: {"type": "AddItem", "sku": "A1", "qty": 2}
replayed cart:    {'C3': 5}
```

What to notice:

- Running a new command clears the redo stack; otherwise redo would reapply a change on top of a different history.
- `RemoveItem` captures the state it destroys (a small memento) so undo is exact.
- Serialized commands are messages: a queue of them is a job queue, and a durable, ordered log of them is a replay log, the core idea behind write-ahead logs and, with events instead of commands, event sourcing (§32.3).

When to use and when not

Use Command for undo/redo, job queues, scheduled or retried work, macro recording, transactional scripts that must be logged before execution, and any API where the caller and executor are separated in time or space. In Python, a closure or `functools.partial` is enough when you only need deferred execution; reach for command classes when you need undo, serialization or introspection.

Related patterns

Memento stores the state that undo restores. Strategy (§37.7) varies *how* something is done; Command captures *what* to do. Producer–consumer (§37.16.1) and message queues (§30.4) transport commands. CQRS (§32.4) separates command handling from queries.

Interview question

> INTERVIEW TIP
>
> **Q.** How would you implement undo for operations that call external systems, such as "send email"? **A.** You cannot unsend an email, so undo must be a compensating action (send a correction) or the operation must be delayed until undo is no longer possible (an "undo send" window that queues the command and executes it after 10 s). The same reasoning drives compensating transactions in sagas (§32.7).

37.13 Repository

Intent

> DEFINITION
>
> **Definition — Repository.** An object that mediates between the domain model and data storage, presenting stored aggregates as an in-memory collection with methods such as `add`, `get` and domain-specific finders, so that domain code never sees SQL, ORM sessions or storage APIs [Fowler 2002; Evans 2003].

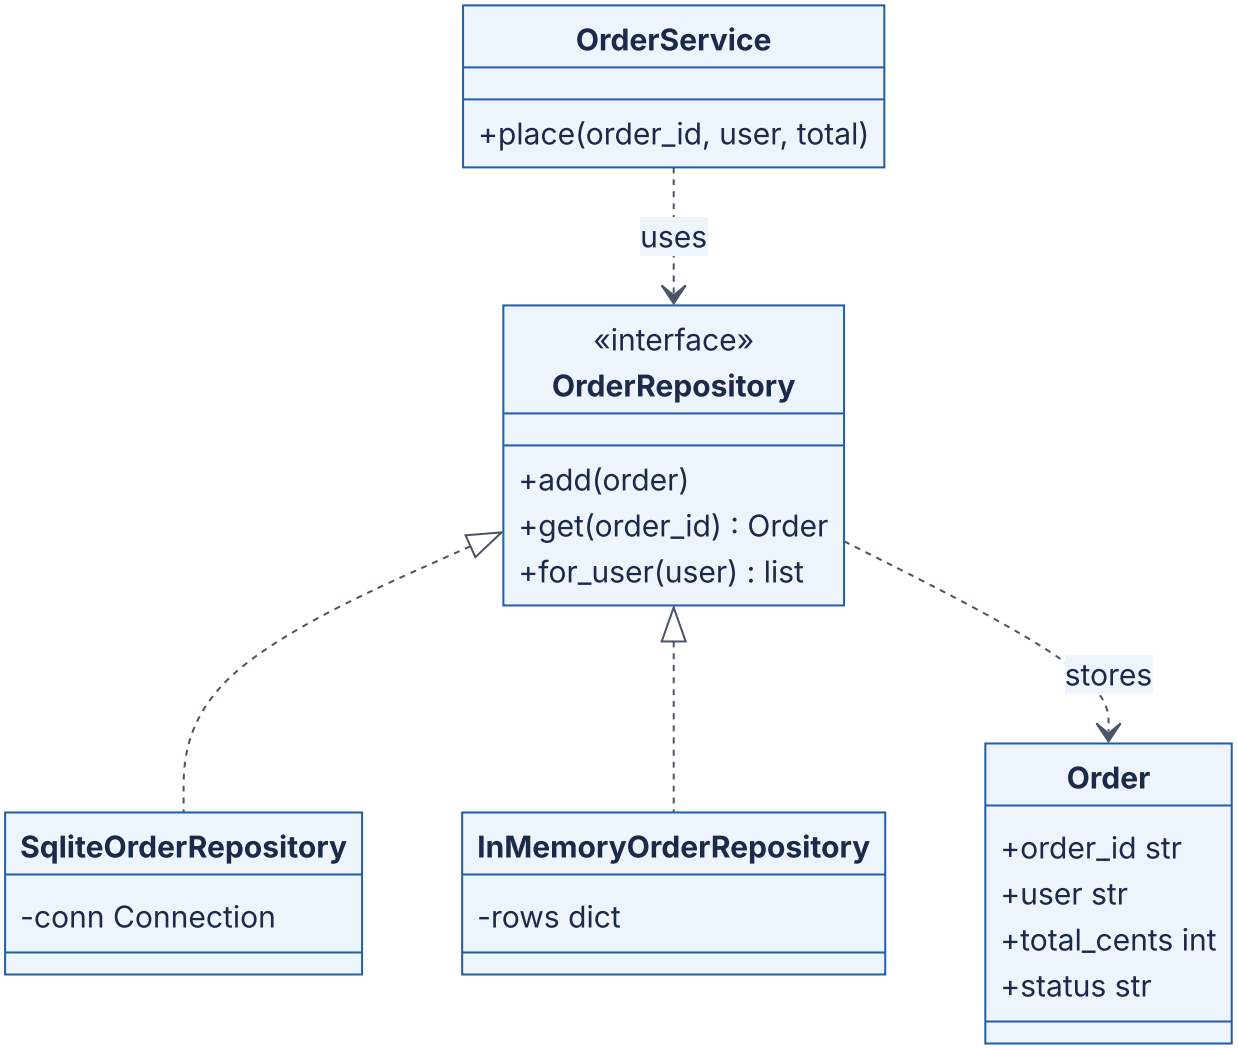
Problem it solves

If `OrderService.place()` builds SQL strings, then every business rule test needs a database, the service cannot move from PostgreSQL to DynamoDB without rewriting business logic, and query code is scattered. A repository gives the domain one interface (`OrderRepository`) expressed in domain terms ("orders for this user"), with a database implementation for production and an in-memory one for fast tests. Spring Data generates

repository implementations from interfaces such as `interface OrderRepository extends CrudRepository<Order, Long>` [Spring Data Docs].

Structure

Figure 37.12 — Repository with interchangeable storage.



Reading the diagram. `OrderService` depends on the `OrderRepository` interface and on the domain object `Order`, nothing else. Two implementations sit behind the interface: the SQLite one crosses the storage boundary (SQL over a database connection; in production a network hop to a database server, where timeouts and constraint violations occur) and the in-memory one keeps rows in a dictionary for tests. Calls are synchronous. Scaling concerns such as read replicas, partitioning (Chapter 14) and caching can be hidden inside an implementation without changing the service.

Python implementation

```
        import sqlite3
        from abc import ABC, abstractmethod
        from dataclasses import dataclass

        @dataclass(frozen=True)
        class Order:
            order_id: str
            user: str
            total_cents: int
            status: str = "PENDING"

        class OrderRepository(ABC):
            @abstractmethod
            def add(self, order: Order) -> None: ...
            @abstractmethod
            def get(self, order_id: str) -> Order | None: ...
            @abstractmethod
            def for_user(self, user: str) -> list[Order]: ...

        class InMemoryOrderRepository(OrderRepository):
            def __init__(self): self._rows: dict[str, Order] = {}
            def add(self, order): self._rows[order.order_id] = order
            def get(self, order_id): return self._rows.get(order_id)
            def for_user(self, user):
                return sorted((o for o in self._rows.values() if o.user == user),
                              key=lambda o: o.order_id)

        class SqliteOrderRepository(OrderRepository):
            def __init__(self, conn: sqlite3.Connection):
                self._conn = conn
                conn.execute("CREATE TABLE IF NOT EXISTS orders (order_id TEXT PRIMARY
KEY, "
                             "user TEXT NOT NULL, total_cents INTEGER NOT NULL, status
TEXT NOT NULL)")
                conn.execute("CREATE INDEX IF NOT EXISTS orders_user ON orders(user)")
            def add(self, order):
                with self._conn:                                    # one transaction
                    self._conn.execute("INSERT OR REPLACE INTO orders VALUES (?, ?, ?,
?)",
                                       (order.order_id, order.user, order.total_cents,
order.status))
            def get(self, order_id):
                row = self._conn.execute("SELECT * FROM orders WHERE order_id = ?",
                                         (order_id,)).fetchone()
                return Order(*row) if row else None
            def for_user(self, user):
                rows = self._conn.execute("SELECT * FROM orders WHERE user = ? ORDER BY
order_id",
                                          (user,)).fetchall()
                return [Order(*r) for r in rows]
```

```
        class OrderService:
            def __init__(self, repo: OrderRepository):
                self._repo = repo
            def place(self, order_id, user, total_cents):
                if total_cents <= 0:
                    raise ValueError("total must be positive")
                if self._repo.get(order_id):
                    return "duplicate"                                  # idempotent retry
                self._repo.add(Order(order_id, user, total_cents))
                return "placed"

        def contract_test(repo: OrderRepository) -> str:                # same test, every
implementation
            svc = OrderService(repo)
            assert svc.place("o-1", "ana", 4999) == "placed"
            assert svc.place("o-1", "ana", 4999) == "duplicate"
            svc.place("o-2", "ana", 1999); svc.place("o-3", "ben", 500)
            assert [o.order_id for o in repo.for_user("ana")] == ["o-1", "o-2"]
            assert repo.get("o-9") is None
            return f"{type(repo).__name__}: contract passed"

        if __name__ == "__main__":
            print(contract_test(InMemoryOrderRepository()))
            print(contract_test(SqliteOrderRepository(sqlite3.connect(":memory:"))))
```

Output:

```
InMemoryOrderRepository: contract passed
SqliteOrderRepository: contract passed
```

What to notice:

- `OrderService` contains the business rules and no SQL; it runs against either implementation.
- One **contract test** runs against every implementation. This is what keeps the in-memory fake honest; a fake that drifts from the real repository makes tests pass while production fails.
- Queries use placeholders (`?`), never string formatting, which prevents SQL injection (Chapter 10).

When to use and when not

Use a repository per **aggregate** (a cluster of objects changed together, such as an order and its lines, §34.4) when domain logic is rich enough to be worth testing without a database. Avoid a generic `Repository<T>` with `find_by_anything(**filters)`: it leaks query concerns back into the domain and becomes a weak ORM. For reporting and read-heavy

screens, query the database directly or use a separate read model (CQRS, §32.4); forcing analytics through aggregate repositories causes N+1 queries.

Related patterns

Unit of Work tracks changes across repositories and commits them in one transaction [Fowler 2002]. Data Mapper and Active Record are the alternatives Fowler catalogs for mapping objects to tables. Adapter (§37.9): a repository implementation is an adapter from a domain port to a storage technology. Dependency injection (§37.14) supplies the right implementation.

Interview question

INTERVIEW TIP

Q. Is a repository just a DAO? **A.** A data access object is organized around tables and storage operations; a repository is organized around domain aggregates and speaks the domain's language (`orders.for_user(ana)` rather than `select(table="orders", where=...)`). In small systems they converge. The distinction matters when one aggregate spans several tables or stores: the repository hides that, a DAO usually does not.

37.14 Dependency injection

Intent

DEFINITION

Definition — Dependency injection (DI). A technique in which an object receives the objects it depends on (its dependencies) from outside, typically through its constructor, instead of creating or looking them up itself. The code that creates and connects all objects is the **composition root** [Fowler 2004].

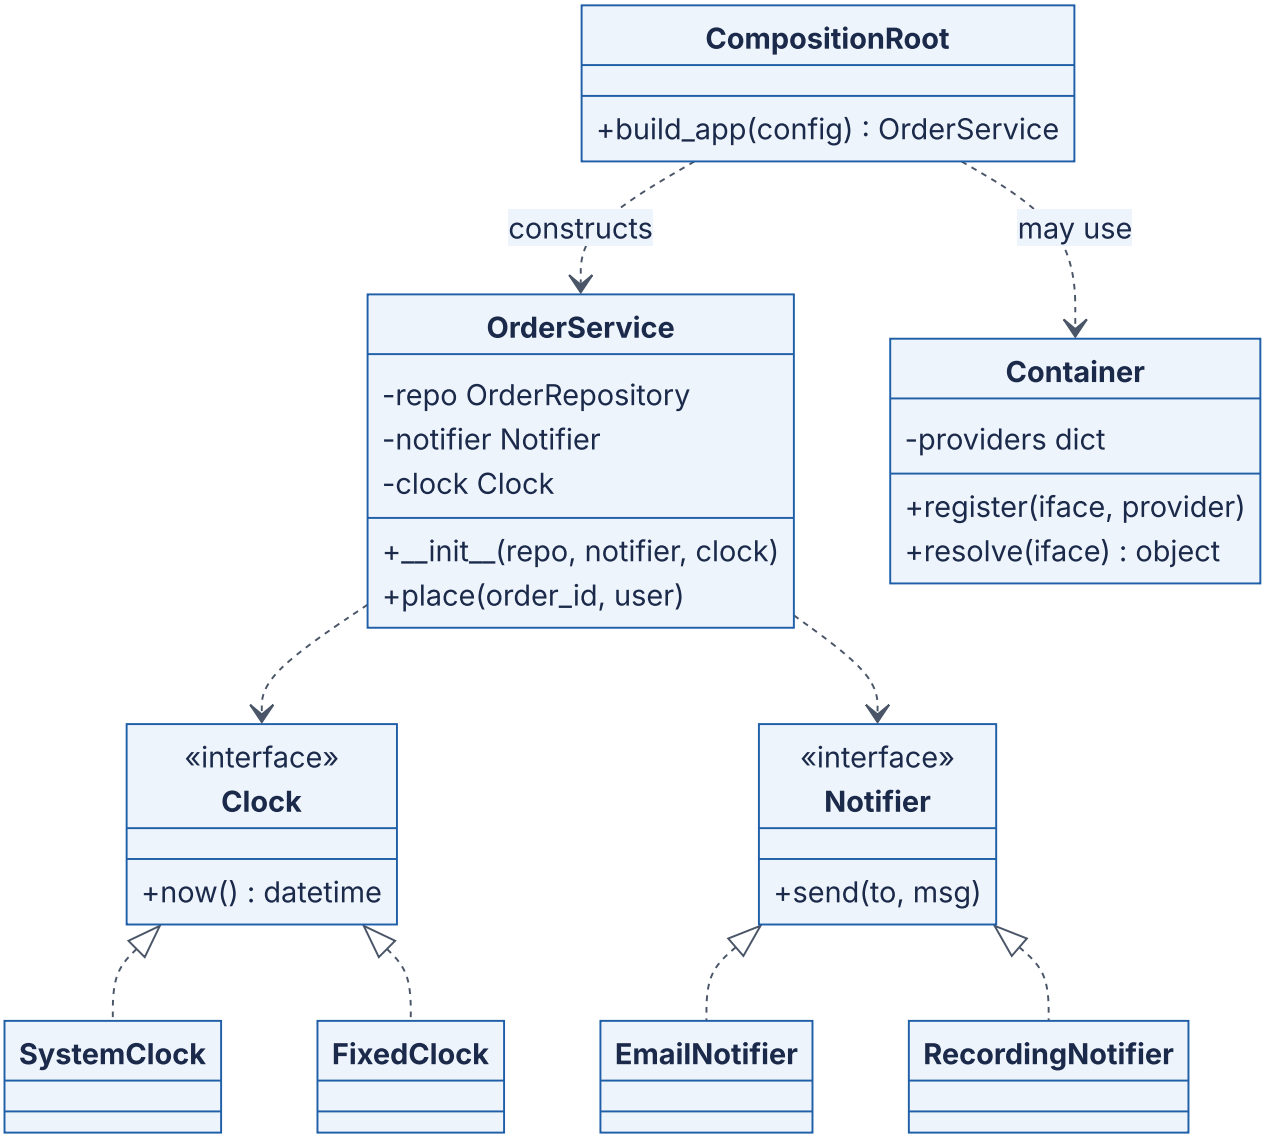
Problem it solves

An `OrderService` that calls `PostgresOrderRepository()`, `VendorPayClient()` and `datetime.now()` inside its methods cannot be tested without a database, a payment sandbox and a frozen clock, and it cannot be reconfigured without editing it. The Dependency Inversion Principle (§36.7) says high-level policy should depend on abstractions; DI is the mechanism that hands the concrete implementations of those abstractions in. Fowler named the pattern in 2004 to distinguish it from the broader term "inversion of control",

and contrasted it with the **Service Locator**, in which objects ask a global registry for dependencies [Fowler 2004]. Section 36.7.4 separates DI, dependency inversion and inversion of control in detail.

Structure

Figure 37.13 — Constructor injection with a composition root.



Reading the diagram. `OrderService` declares its dependencies as constructor parameters typed by interfaces and never constructs them. The composition root, at the program's entry point (`main`, the web app factory, the test fixture), chooses implementations: `SystemClock` and `EmailNotifier` in production, `FixedClock` and `RecordingNotifier` in tests. A container is optional automation of that wiring. Wiring happens once at startup, synchronously; the failure point moves there too, which is good: a missing dependency fails at boot rather than on the first request at 3 a.m.

Python implementation

```
        from abc import ABC, abstractmethod
        from datetime import datetime, timezone
        from typing import get_type_hints
        import inspect

        class Clock(ABC):
            @abstractmethod
            def now(self) -> datetime: ...

        class Notifier(ABC):
            @abstractmethod
            def send(self, to: str, msg: str) -> None: ...

        class SystemClock(Clock):
            def now(self): return datetime.now(timezone.utc)

        class FixedClock(Clock):
            def __init__(self): self._t = datetime(2026, 1, 1, 9, 0,
tzinfo=timezone.utc)
            def now(self): return self._t

        class RecordingNotifier(Notifier):
            def __init__(self): self.sent = []
            def send(self, to, msg): self.sent.append((to, msg))

        class OrderService:
            def __init__(self, notifier: Notifier, clock: Clock):    # constructor in-
jection
                self._notifier, self._clock = notifier, clock
            def place(self, order_id: str, user: str) -> str:
                stamp = self._clock.now().isoformat()
                self._notifier.send(user, f"order {order_id} placed at {stamp}")
                return stamp

        class Container:                                    # a minimal auto-wiring con-
tainer
            def __init__(self):
                self._providers, self._instances = {}, {}
            def register(self, iface, impl):
                self._providers[iface] = impl
            def resolve(self, iface):
                if iface not in self._instances:           # one instance per container
                    impl = self._providers.get(iface, iface)
                    hints = get_type_hints(impl.__init__) if inspect.isclass(impl) else
{}
                    deps = {n: self.resolve(t) for n, t in hints.items() if n != "re-
turn"}
                    self._instances[iface] = impl(**deps)
                return self._instances[iface]
```

```
        if __name__ == "__main__":
            # 1. Test: wire by hand with fakes -- no framework needed.
            notifier = RecordingNotifier()
            OrderService(notifier, FixedClock()).place("o-17", "ana")
            print(notifier.sent)
            # 2. Container: same graph, wired from registrations.
            c = Container()
            c.register(Notifier, RecordingNotifier)
            c.register(Clock, FixedClock)
            svc = c.resolve(OrderService)
            svc.place("o-18", "ben")
            print(c.resolve(Notifier).sent, c.resolve(Notifier) is c.resolve(Notifier))
```

Output:

```
[('ana', 'order o-17 placed at 2026-01-01T09:00:00+00:00')]
[('ben', 'order o-18 placed at 2026-01-01T09:00:00+00:00')] True
```

What to notice:

- The test needs no mocking library: fakes are ordinary classes passed to the constructor.
- The container reads constructor type hints, resolves each recursively, and caches instances; that cache gives you “one per application” without a Singleton class (§37.6).
- The container is the only code that knows concrete classes. Business code never calls `resolve`; if it did, the container would degrade into a service locator with hidden dependencies.

Java and frameworks

In Java, DI containers are the norm: Spring and Guice build the object graph from annotations or configuration, and Spring recommends constructor injection for required dependencies, which keeps fields `final` and objects complete after construction [Spring Docs]. Python services more often wire by hand in the composition root or use framework hooks such as FastAPI’s `Depends`. Either way the principle is the same; a container is a convenience, not the pattern.

When to use and when not

Use constructor injection by default for anything with I/O, time, randomness or configuration, which is what tests need to control. Prefer constructor injection over setter injection (objects are never half-built) and over field injection (dependencies stay visible in the signature). A constructor with eight parameters is a design smell revealing a class with too many responsibilities (§36.3), not a reason to switch to a locator. Do not inject value objects or pure utilities.

Related patterns

Factory (§37.3) and Abstract Factory (§37.4) are often what you inject when an object must create things later. Service Locator is the alternative Fowler contrasts it with. Strategy (§37.7) and Repository (§37.13) are the most commonly injected roles.

Interview question

> INTERVIEW TIP
>
> **Q.** What is the difference between dependency injection and the Dependency Inversion Principle? **A.** Dependency inversion is a design principle: high-level modules and low-level modules should both depend on abstractions, and the abstraction is owned by the high-level side (§36.7). Dependency injection is a technique for supplying concrete implementations from outside. You can inject concrete classes (DI without inversion) or depend on abstractions but look them up from a global (inversion without injection); good designs do both.

37.15 State, Template Method and Chain of Responsibility

These three behavioral patterns each organize *control flow*: State by the object's current mode, Template Method by a fixed skeleton with variable steps, Chain of Responsibility by a sequence of handlers.

37.15.1 State

Intent

> DEFINITION
>
> **Definition — State.** An object delegates its behavior to a separate state object and changes behavior by swapping that state object, so it appears to change its class; each state class handles the transitions that are legal from it [Gamma et al. 1994].

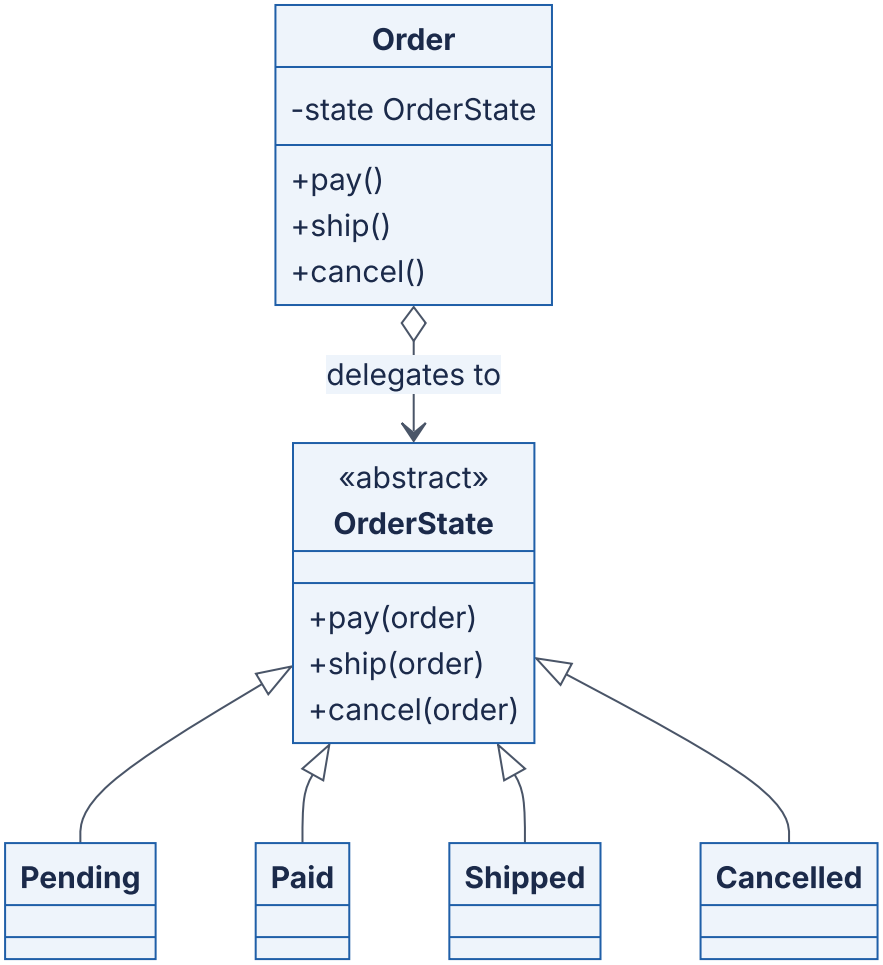
Problem it solves

An order moves from `PENDING` to `PAID` to `SHIPPED`, and can be canceled while pending or paid (with a refund if paid) but not after shipping. Implemented with `if self.status == ...` inside every method, the rules for one state are spread across all methods, and an illegal transition (shipping an unpaid order) slips through whichever method forgot a check. The GoF book's own motivating example was a `TCPConnection` whose `open()`,

`close()` and `acknowledge()` behave differently in the Established, Listen and Closed states.

Structure

Figure 37.14 — State pattern for the order lifecycle.



Reading the diagram. `Order` (the context) forwards every action to its current `OrderState`. The abstract state rejects every action by default; each concrete state overrides only the actions legal from it and performs the transition by replacing the context's state object. Calls are synchronous. The current state is the only data that must be persisted (a status column); the state objects are stateless and can be shared. The failure point is concurrent transitions on the same order from two requests; protect them with optimistic concurrency (a version column) in the repository.

Python implementation

```
        class IllegalTransition(Exception):
            pass

        class OrderState:
            name = "?"
            def _reject(self, action):
                raise IllegalTransition(f"cannot {action} an order that is {self.name}")
            def pay(self, order):    self._reject("pay")
            def ship(self, order):   self._reject("ship")
            def cancel(self, order): self._reject("cancel")

        class Pending(OrderState):
            name = "PENDING"
            def pay(self, order):    order.state = PAID
            def cancel(self, order): order.state = CANCELLED

        class Paid(OrderState):
            name = "PAID"
            def ship(self, order):   order.state = SHIPPED
            def cancel(self, order):
                order.refund_due = True
                order.state = CANCELLED

        class Shipped(OrderState):   name = "SHIPPED"
        class Cancelled(OrderState): name = "CANCELLED"

        PENDING, PAID, SHIPPED, CANCELLED = Pending(), Paid(), Shipped(), Cancelled()  # shared

        class Order:
            def __init__(self):
                self.state, self.refund_due = PENDING, False
            def pay(self):    self.state.pay(self)
            def ship(self):   self.state.ship(self)
            def cancel(self): self.state.cancel(self)

        if __name__ == "__main__":
            for actions in (["pay", "ship"], ["pay", "cancel"], ["ship"], ["pay", "ship", "cancel"]):
                o = Order()
                try:
                    for a in actions:
                        getattr(o, a)()
                    print(f"{'+'.join(actions):16} -> {o.state.name}, refund_due={o.refund_due}")
                except IllegalTransition as e:
                    print(f"{'+'.join(actions):16} -> rejected: {e}")
```

Output:

```
pay+ship         -> SHIPPED, refund_due=False
pay+cancel       -> CANCELLED, refund_due=True
ship             -> rejected: cannot ship an order that is PENDING
pay+ship+cancel  -> rejected: cannot cancel an order that is SHIPPED
```

What to notice: every rule about the `PAID` state is in one class; illegal transitions are rejected by default rather than by remembered checks; and the state objects hold no per-order data, so four shared instances serve every order. For small machines, a transition table (`{(PENDING, "pay"): PAID, ...}`) is a lighter alternative; Chapter 38 draws such machines as state diagrams.

When to use and when not

Use State when behavior differs substantially per mode and transitions have rules (orders, payments, connections, workflow steps, circuit breakers with closed, open and half-open states, §22.13). Use a table or an enum with a transition map when states differ only in which transitions are allowed. Related: Strategy (§37.7) has the same shape but is chosen externally. **Interview question:** *Where does the state live when the service has 20 replicas?* In the database row, not in memory; each request loads the order, applies the transition through the state object, and writes back with a version check so two replicas cannot both ship and cancel the same order.

37.15.2 Template Method

Intent

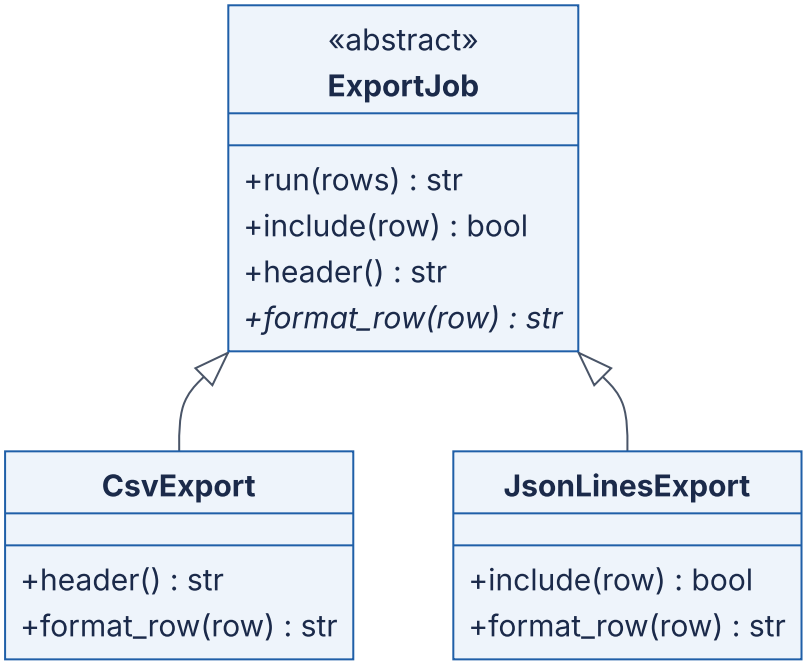
> DEFINITION
>
> **Definition — Template Method.** A method in a base class that defines the skeleton of an algorithm as a fixed sequence of steps, some of which are abstract **primitive operations** or overridable **hooks** that subclasses supply, so subclasses vary steps without changing the sequence [Gamma et al. 1994].

Problem it solves

The store exports orders nightly in CSV for finance and JSON Lines for the data lake. Both exports filter, format each row, add an optional header and write output, in that order; only the filter and formatting differ. Duplicating the loop means a fix to one (say, skipping test orders) is forgotten in the other. Frameworks use template methods everywhere: `unittest.TestCase.run()` calls your `setUp`, test method and `tearDown`; `threading.Thread.start()` arranges for your `run()` to execute; Java's `AbstractList` implements iteration on top of your `get()` and `size()`.

Structure

Figure 37.15 — Template Method for export jobs.



Reading the diagram. `run()` in the base class is the template method; it is not overridden. `format_row()` is abstract (a primitive operation every subclass must supply), while `include()` and `header()` are hooks with defaults that subclasses may override. Control flows from the base class down into subclass code, the “Hollywood principle” (“don’t call us, we’ll call you”). Everything is synchronous; output would cross a storage boundary when written to object storage. The fragility point is the inheritance coupling: a change to the skeleton affects every subclass.

Python implementation

```
        import json
        from abc import ABC, abstractmethod

        class ExportJob(ABC):
            def run(self, rows: list[dict]) -> str:          # the template method
                kept = [r for r in rows if self.include(r)]
                lines = [self.format_row(r) for r in kept]
                header = self.header()
                return "\n".join(([header] if header else []) + lines)

            def include(self, row) -> bool: return not row.get("test", False)   # hook
            def header(self) -> str | None: return None                         # hook
            @abstractmethod
            def format_row(self, row) -> str: ...                               # primi-
tive op

        class CsvExport(ExportJob):
            def header(self): return "order_id,total_cents"
            def format_row(self, r): return f"{r['order_id']},{r['total_cents']}"

        class JsonLinesExport(ExportJob):
            def include(self, r): return super().include(r) and r["status"] == "PAID"
            def format_row(self, r): return json.dumps(r, sort_keys=True)

        if __name__ == "__main__":
            rows = [{"order_id": "o-1", "total_cents": 4999, "status": "PAID"},
                    {"order_id": "o-2", "total_cents": 1999, "status": "PENDING"},
                    {"order_id": "o-3", "total_cents": 100, "status": "PAID", "test":
True}]
            print(CsvExport().run(rows))
            print(JsonLinesExport().run(rows))
```

Output:

```
order_id,total_cents
o-1,4999
o-2,1999
{"order_id": "o-1", "status": "PAID", "total_cents": 4999}
```

What to notice: the test-order filter lives once, in the base hook, and `JsonLinesExport` extends it with `super()`; neither subclass can reorder the steps.

When to use and when not

Use Template Method in frameworks and base classes where the sequence is invariant and must be enforced (test lifecycles, request handling, ETL jobs). Prefer Strategy (§37.7)

or passing functions when steps vary independently or must be combined at run time, since inheritance fixes the combination at class-definition time (composition over inheritance, §35.8). **Interview question:** *Template Method or Strategy for a pluggable ETL pipeline?* Template Method if the pipeline shape is fixed and you own the base class; Strategy (inject `extract`, `transform` and `load` objects) if teams must mix and match steps, which is the usual case at scale.

37.15.3 Chain of Responsibility

Intent

DEFINITION

Definition — Chain of Responsibility. A request is passed along a chain of handler objects; each handler either handles it, or does some work and passes it to the next, so the sender does not know which handler will act [Gamma et al. 1994].

Problem it solves

Every HTTP request to the order API must be logged, authenticated and rate-limited before reaching the application, and some requests must be stopped early (401, 429). Putting all of that at the top of every endpoint duplicates code and mixes concerns. A chain of middleware applies the concerns in a configured order, and any link can short-circuit. Java servlet filters, Express and ASGI middleware, gRPC interceptors and Envoy's HTTP filter chain all work this way.

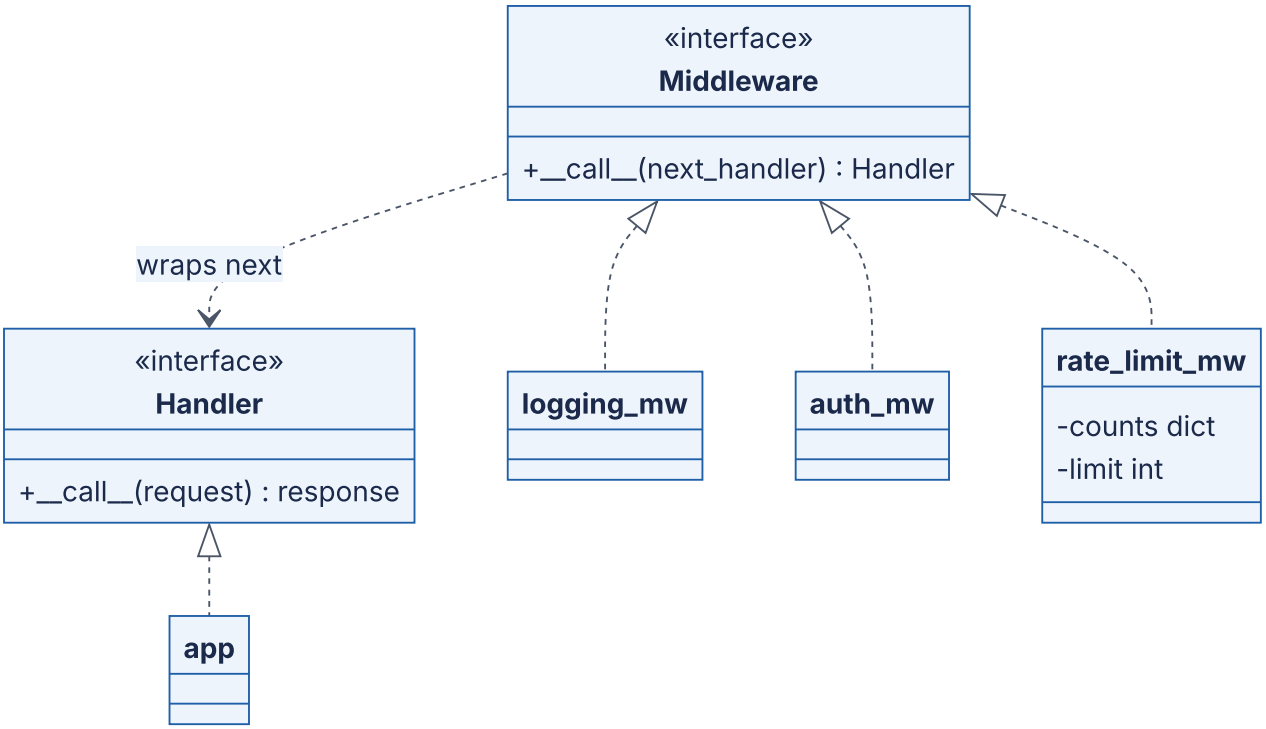
INDUSTRY EXAMPLE

Django middleware. Django builds its request pipeline from the `MIDDLEWARE` setting: each middleware is a factory that receives `get_response` (the next handler) and returns a callable. Requests pass through the list top to bottom and responses bottom to top, and a middleware can return a response without calling `get_response`, short-circuiting the chain. The documentation stresses that order matters, for example placing session middleware before authentication middleware, which reads the session. *Evidence: Primary* — [Django Docs]

The classic GoF form, in which exactly one handler takes the request (a support ticket escalating from bot to agent to engineer, or nested exception handlers), is the same structure with a different stopping rule.

Structure

Figure 37.16 — Middleware pipeline as a chain of responsibility.



Reading the diagram. A `Handler` turns a request into a response. A `Middleware` takes the next handler and returns a new handler that wraps it, so building the chain is function composition: `logging(auth(rate_limit(app)))`. A request flows inward through each link and the response flows back out, so the first middleware sees both the raw request and the final response (ideal for logging and timing). Links run synchronously in one request's call stack. `rate_limit_mw` holds in-memory per-client counters; across replicas this state must move to a shared store (§22.8). Any link can short-circuit, which is also the main failure mode: a misordered chain (rate limiting before authentication, so attackers exhaust real users' quotas).

Python implementation

```
        from typing import Callable

        Request = dict
        Response = tuple[int, str]
        Handler = Callable[[Request], Response]
        LOG: list[str] = []

        def logging_mw(next_h: Handler) -> Handler:
            def handle(req):
                status, body = next_h(req)
                LOG.append(f"{req['client']} {req['path']} -> {status}")
                return status, body
            return handle

        def auth_mw(next_h: Handler) -> Handler:
            def handle(req):
                if req.get("token") != "valid":
                    return 401, "unauthorized"                # short-circuit the chain
                return next_h(req)
            return handle

        def rate_limit_mw(limit: int):
            counts: dict[str, int] = {}
            def middleware(next_h: Handler) -> Handler:
                def handle(req):
                    counts[req["client"]] = counts.get(req["client"], 0) + 1
                    if counts[req["client"]] > limit:
                        return 429, "too many requests"
                    return next_h(req)
                return handle
            return middleware

        def app(req: Request) -> Response:
            return 200, f"orders for {req['client']}"

        def build(handler: Handler, middlewares) -> Handler:   # first listed = outer-
most
            for mw in reversed(middlewares):
                handler = mw(handler)
            return handler

        if __name__ == "__main__":
            pipeline = build(app, [logging_mw, auth_mw, rate_limit_mw(limit=2)])
            for client, token in [("ana", "valid")] * 3 + [("eve", "forged")]:
                pipeline({"client": client, "token": token, "path": "/orders"})
            print("\n".join(LOG))
```

Output:

```
ana /orders -> 200
ana /orders -> 200
ana /orders -> 429
eve /orders -> 401
```

What to notice: because authentication runs before rate limiting, the forged request never consumes a rate-limit slot; and because logging is outermost, it records short-circuited responses too. Reordering the list changes behavior without changing any handler.

When to use and when not

Use a chain when several independent handlers must process or filter a request in a configurable order: middleware, validation pipelines, approval workflows, event filters. Avoid long chains with no clear ordering contract; debugging "which link swallowed my request?" requires per-link logging or tracing. **Interview question:** *In what order would you put authentication, rate limiting, request logging, compression and caching middleware, and why?* Logging and tracing outermost to see everything; then a coarse per-IP rate limit to shed floods cheaply; then authentication; then per-user rate limiting; then the cache (keyed by user if responses are personalized); compression closest to the network on the way out.

37.16 Concurrency patterns

The patterns so far organize code within one thread of control. Concurrency patterns organize work across threads: who produces work, who executes it, how results come back, and how shared data is protected. They are cataloged in *Pattern-Oriented Software Architecture, Volume 2* [Schmidt et al. 2000], which also covers Reactor and Proactor (the event-loop designs of §6.13), Active Object, Monitor Object and Leader/Followers, and they are treated for the JVM in *Java Concurrency in Practice* [Goetz et al. 2006]. The primitives underneath (mutexes, condition variables, atomics) are in §6.10.

> NOTE
>
> **Python and the GIL.** In standard CPython builds the global interpreter lock lets only one thread execute Python bytecode at a time, so threads speed up I/O-bound work (the lock is released while waiting on sockets and disks) but not CPU-bound Python code; use processes (`ProcessPoolExecutor`) for that. Python 3.13 added an experimental free-threaded build without the GIL [PEP 703]. Correct code must not rely on the GIL for thread safety in either case.

37.16.1 Producer–consumer

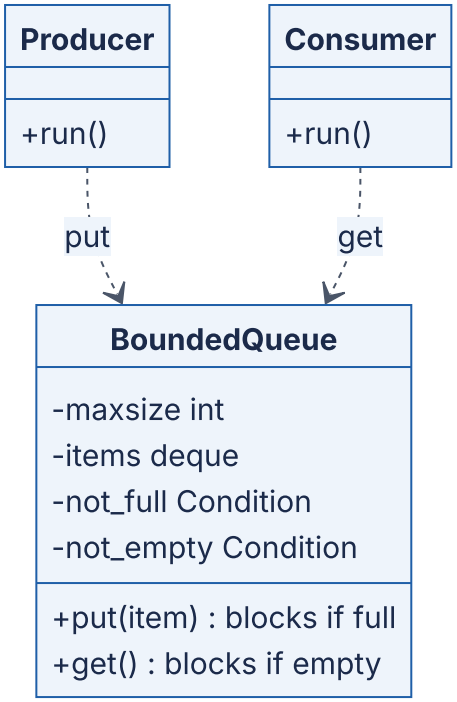
Intent and problem

DEFINITION

Definition — Producer-consumer. Producers put work items into a shared **bounded** buffer and consumers take them out, decoupling the rate at which work is created from the rate at which it is processed; when the buffer is full, producers block or are rejected, which is **backpressure** (§22.10).

The order service's request threads produce "send receipt" jobs faster at peak than the email provider accepts them. Calling the provider inline couples checkout latency to the provider; an unbounded in-memory list grows until the process runs out of memory. A bounded queue between request threads and a fixed set of sender threads absorbs bursts and pushes back when sustained load exceeds capacity. Message brokers (Chapter 30) are this pattern across machines.

Figure 37.17 — Producer-consumer with a bounded queue.



Reading the diagram. Producers and consumers never reference each other; both depend only on the queue. Inside the queue a lock and two condition variables (§6.10.3) implement blocking: `put` waits on "not full", `get` waits on "not empty". The hand-off is asynchronous from the producer's point of view. Items in the queue live only in process memory and are lost if the process crashes, which is the reason to use a durable broker when jobs must survive restarts. Failure points: a consumer that dies silently (work piles up), a

poison item that crashes every consumer, and shutdown (consumers must be told to stop). Scale by adding consumers until the downstream resource saturates.

```
        import queue
        import threading
        import time

        def producer(q: queue.Queue, pid: int, n: int, stats: dict):
            for i in range(n):
                t0 = time.perf_counter()
                q.put(f"receipt-{pid}-{i}")                    # blocks while the queue
is full
                stats["blocked_s"] += time.perf_counter() - t0

        def consumer(q: queue.Queue, done: list, lock: threading.Lock):
            while True:
                item = q.get()
                if item is None:                               # sentinel: shut down
                    break
                time.sleep(0.002)                              # simulated call to email
provider
                with lock:
                    done.append(item)

        if __name__ == "__main__":
            q: queue.Queue = queue.Queue(maxsize=10)           # bounded: backpressure
            done, lock, stats = [], threading.Lock(), {"blocked_s": 0.0}
            consumers = [threading.Thread(target=consumer, args=(q, done, lock)) for _
in range(4)]
            producers = [threading.Thread(target=producer, args=(q, p, 100, stats)) for
p in range(2)]
            for t in consumers + producers:
                t.start()
            for t in producers:
                t.join()
            for _ in consumers:
                q.put(None)                                    # one sentinel per con-
sumer
            for t in consumers:
                t.join()
            print(f"processed {len(done)} jobs; queue never exceeded {q.maxsize}; "
                  f"producers spent time blocked: {stats['blocked_s'] > 0.01}")
```

Output:

```
processed 200 jobs; queue never exceeded 10; producers spent time blocked: True
```

What to notice: producers generate 200 jobs instantly but consumers handle about 4 / 0.002 s = 2,000 jobs/s, so producers spend time blocked in `put`; that waiting is backpres-

sure doing its job. One sentinel per consumer gives a clean shutdown. In a web request path, prefer `put(timeout=...)` or `put_nowait` and return 503 rather than blocking a request thread indefinitely (load shedding, §22.9).

37.16.2 Thread pool

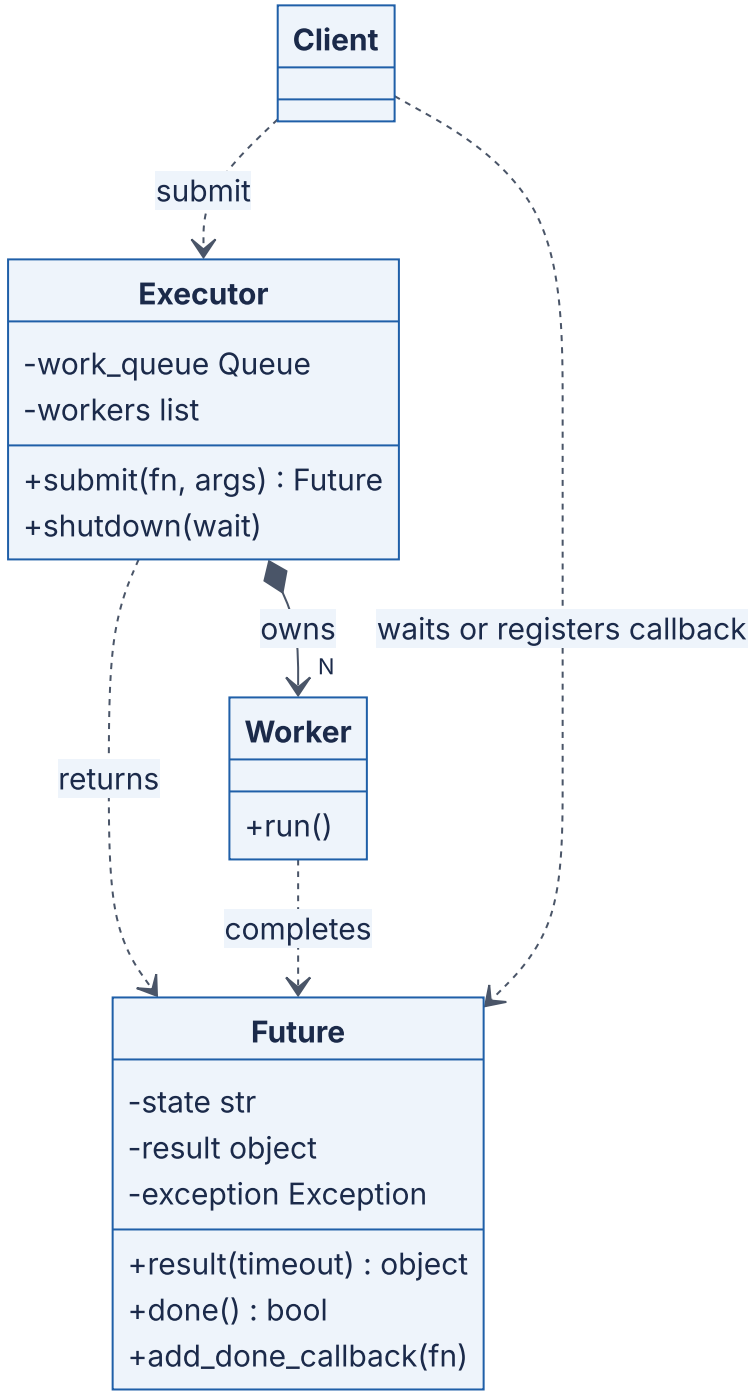
Intent and problem

DEFINITION

Definition — Thread pool. A fixed or bounded set of worker threads that take tasks from a queue and execute them, so the cost of creating threads is paid once and the number of concurrent tasks is capped [Goetz et al. 2006].

Creating a thread per request costs memory (often 1 MiB or more of reserved stack per thread, §6.3.5) and scheduling overhead, and under a spike it creates thousands of threads that thrash. A pool is producer–consumer with tasks as the items: callers submit tasks (Commands, §37.12) and receive futures. Java's `ThreadPoolExecutor` and Python's `concurrent.futures.ThreadPoolExecutor` are standard implementations. The key design decision is the pool size.

Figure 37.18 — Thread pool returning futures.



Reading the diagram. The client submits a callable and immediately receives a `Future`; submission is asynchronous. The executor owns N workers (composition, filled diamond), which pull tasks from the internal queue, run them, and complete the matching future with a result or an exception. The client later blocks on `result(timeout)` or registers a callback. State lives in memory: the task queue (which should be bounded) and the futures. Failure points: an unbounded queue that hides overload until memory runs out, tasks that block forever and starve the pool, and exceptions that vanish if no one calls `result()`. Scale by sizing N (below) and by separate pools per dependency (bulkheads, §22.14).

Mathematical foundations

FORMULA

Thread-pool sizing for mixed CPU and I/O work [Goetz et al. 2006]

$$N_{threads} = N_{cpu} \times U_{cpu} \times (1 + \frac{W}{C})$$

Symbol	Meaning	Units
$N_{threads}$	Number of worker threads that keeps the CPU at the target utilization	threads
N_{cpu}	Number of CPU cores available to the process	cores
U_{cpu}	Target CPU utilization, between 0 and 1	dimensionless
W	Time a task spends waiting (I/O, locks) per task	ms
C	CPU time a task spends computing per task	ms

WORKED EXAMPLE

Worked example — Sizing the receipt-rendering pool. Each task spends $C = 5$ ms of CPU rendering a receipt and $W = 95$ ms waiting on the template store and the email provider. The service has $N_{cpu} = 8$ cores and you target $U_{cpu} = 0.75$ to leave headroom.

1. Wait-to-compute ratio: $W/C = 95/5 = 19$.
2. Threads: $N_{threads} = 8 \times 0.75 \times (1 + 19) = 8 \times 0.75 \times 20 = 120$.
3. Throughput ceiling, by Little's Law (§4.11) with each task holding a thread for $W + C = 100$ ms: $\lambda_{max} = 120/0.1\ \text{s} = 1,200$ tasks/s.
4. CPU check: $1,200 \times 5$ ms $= 6$ core-seconds per second, which is $6/8 = 75\%$ of the cores, matching the target.

Interpretation. A pool of 8 (one per core) would cap throughput at $8/0.1 = 80$ tasks/s with the CPU 95% idle; a pool of 1,000 would not raise throughput above what the CPU and the downstream provider allow, and would add memory and contention.
Engineering implication. Measure W and C under realistic load, size the pool from the formula, and check the downstream limit separately: if the email provider allows only 500 requests/s, the provider, not the pool, is the bottleneck, and the pool should be sized for 500 tasks/s ($500 \times 0.1 = 50$ threads).

```
        import time
        from concurrent.futures import ThreadPoolExecutor, as_completed

        def fetch_rate(currency: str) -> tuple[str, float]:
            time.sleep(0.05)                                    # simulated 50 ms I/O
call
            if currency == "XXX":
                raise ValueError("unknown currency")
            return currency, {"USD": 1.0, "EUR": 1.08}.get(currency, 0.5)

        if __name__ == "__main__":
            currencies = ["USD", "EUR"] * 31 + ["GBP", "XXX"]  # 64 tasks
            t0 = time.perf_counter()
            ok, failed = 0, []
            with ThreadPoolExecutor(max_workers=16) as pool:
                futures = {pool.submit(fetch_rate, c): c for c in currencies}
                for fut in as_completed(futures):               # in completion order
                    try:
                        fut.result(timeout=1.0)
                        ok += 1
                    except ValueError as e:
                        failed.append(f"{futures[fut]}: {e}")
            elapsed = time.perf_counter() - t0
            print(f"{ok} ok, failed={failed}")
            print(f"sequential would take {len(currencies) * 0.05:.1f} s; pool took
{elapsed:.1f} s")
```

Output:

```
63 ok, failed=['XXX: unknown currency']
sequential would take 3.2 s; pool took 0.2 s
```

What to notice: 64 tasks of 50 ms on 16 workers take $\lceil 64/16 \rceil \times 0.05 = 0.2$ s. The exception raised inside a worker is re-raised by `result()` in the caller; if nobody calls `result()`, it is silently lost. The `with` block shuts the pool down and waits for running tasks.

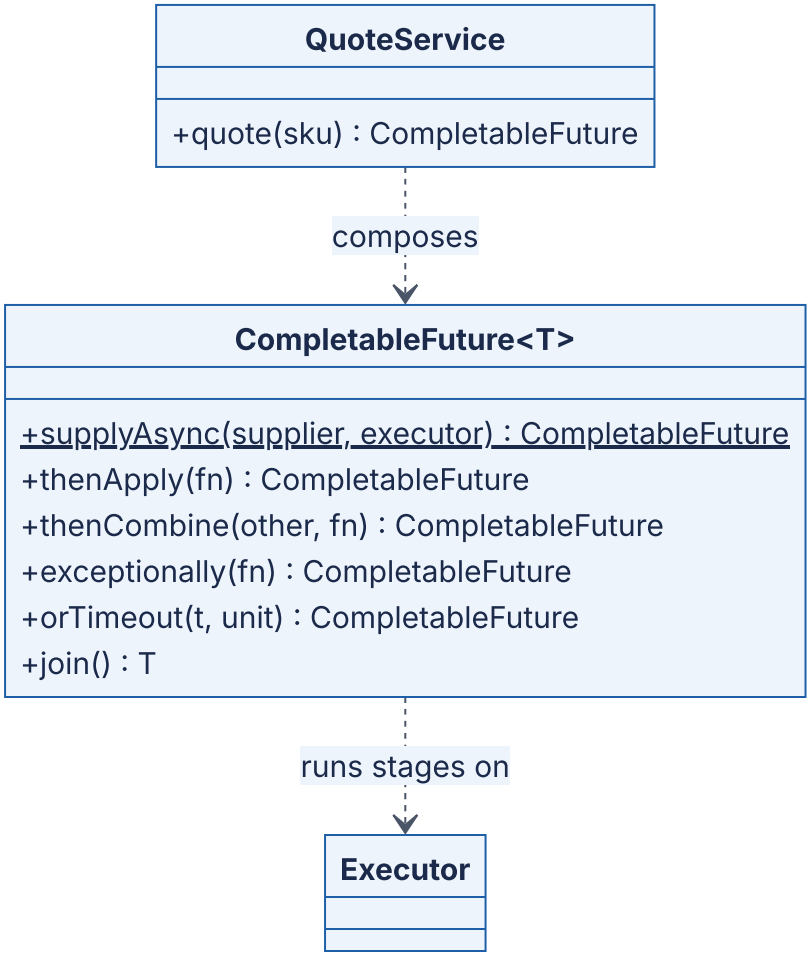
37.16.3 Future and promise

DEFINITION

Definition — Future and promise. A **future** is a read-only placeholder for a result that will be available later; a **promise** (Java's `CompletableFuture`, Python's `asyncio.Future`) is the writable side that the producer completes with a value or an error. Together they let a caller start work, continue, and later wait for or chain on the result.

Futures turn “call and wait” into “call, do other work, join”. Their real power is composition: start the price lookup and the stock check in parallel and combine them when both finish, so latency is the maximum of the two rather than the sum. Composition is where Java adds something language-specific: `CompletableFuture` chains asynchronous stages without blocking a thread.

Figure 37.19 — Composing futures.



Reading the diagram. `QuoteService` starts two asynchronous stages on an executor and combines their futures with `thenCombine`; each stage runs on a pool thread and completes its future, which triggers dependent stages. No thread blocks until the final `join()` (or never, if the result is returned as a future to an asynchronous web framework). Results live in memory. Failure points are a stage that never completes (add `orTimeout`) and errors, which propagate along the chain until handled by `exceptionally`. Scaling depends on the executor; using the default common pool for blocking I/O is a classic mistake.

```
        import java.util.concurrent.*;

        public class Quote {
            public static void main(String[] args) {
                ExecutorService io = Executors.newFixedThreadPool(8);   // dedicated
pool for I/O
                CompletableFuture<Integer> price = CompletableFuture.supplyAsync(() ->
sleepThen(80, 4999), io);
                CompletableFuture<Integer> stock = CompletableFuture.supplyAsync(() ->
sleepThen(60, 3), io);
                long t0 = System.nanoTime();
                String quote = price.thenCombine(stock, (p, s) -> s > 0 ? "price " + p
: "out of stock")
                                    .orTimeout(500, TimeUnit.MILLISECONDS)
                                    .exceptionally(e -> "fallback: cached price")
                                    .join();
                System.out.printf("%s in ~%d ms%n", quote, (System.nanoTime() - t0) /
1_000_000);
                io.shutdown();
            }
            static int sleepThen(int ms, int v) {
                try { Thread.sleep(ms); } catch (InterruptedException e) { throw new
RuntimeException(e); }
                return v;
            }
        }
```

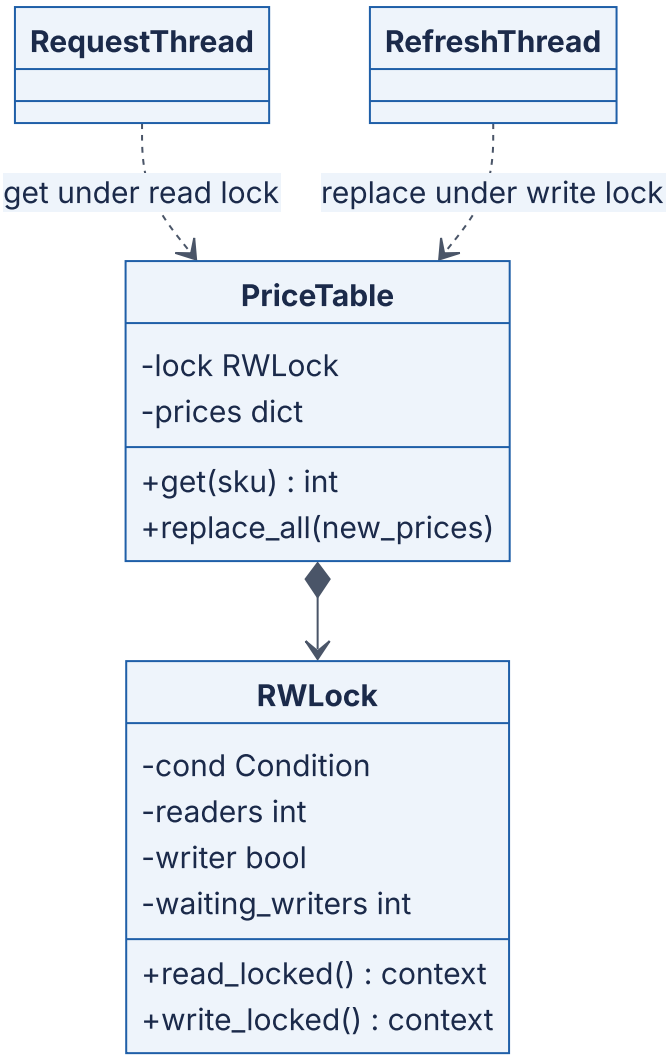
The program prints `price 4999 in ~80 ms` (the time varies slightly): the two calls overlap, so latency is the longer one, not 140 ms. In Python the same composition is `asyncio.gather(price(), stock())` inside an event loop, or two `executor.submit` calls followed by two `result()` calls.

37.16.4 Read-write lock

> DEFINITION
>
> **Definition — Read-write lock.** A lock that allows any number of concurrent readers or exactly one writer, never both; it improves throughput when reads greatly outnumber writes and each read holds the lock long enough for contention to matter (§6.10.5).

A routing table or price list in memory is read by every request and replaced a few times per minute. A plain mutex serializes all readers; a read-write lock lets them proceed together. The design question is fairness: a reader-preferring lock can starve writers forever under constant reads, so most implementations prefer waiting writers. Python's standard library has no read-write lock; Java provides `ReentrantReadWriteLock` and `StampedLock` (which adds optimistic reads).

Figure 37.20 — A writer-preferring read-write lock.



Reading the diagram. `PriceTable` owns a `RWLock` built from one condition variable and three counters. Many request threads read at once; the refresh thread takes the write lock, which waits for active readers to drain and blocks new readers while it waits (writer preference). All access is synchronous and in-process; the protected data is in memory. Failure points: writer starvation (prevented here), upgrading a read lock to a write lock (deadlocks if two readers try), and long work done while holding the lock. An alternative that often scales better is copy-on-write: build a new immutable table and swap one reference, so readers take no lock at all.

```
        import threading
        import time
        from contextlib import contextmanager

        class RWLock:
            def __init__(self):
                self._cond = threading.Condition()
                self._readers, self._writer, self._waiting_writers = 0, False, 0

            @contextmanager
            def read_locked(self):
                with self._cond:
                    while self._writer or self._waiting_writers:   # writer preference
                        self._cond.wait()
                    self._readers += 1
                try:
                    yield
                finally:
                    with self._cond:
                        self._readers -= 1
                        if self._readers == 0:
                            self._cond.notify_all()

            @contextmanager
            def write_locked(self):
                with self._cond:
                    self._waiting_writers += 1
                    while self._writer or self._readers:
                        self._cond.wait()
                    self._waiting_writers -= 1
                    self._writer = True
                try:
                    yield
                finally:
                    with self._cond:
                        self._writer = False
                        self._cond.notify_all()

        if __name__ == "__main__":
            lock, accounts = RWLock(), {"a": 500, "b": 500}     # invariant: a + b ==
1000
            stats = {"violations": 0, "active": 0, "peak": 0}
            stats_lock = threading.Lock()

            def reader():
                for _ in range(300):
                    with lock.read_locked():
                        with stats_lock:
                            stats["active"] += 1
                            stats["peak"] = max(stats["peak"], stats["active"])
                        time.sleep(0.0002)                      # simulated work: read-
ers overlap
                        if accounts["a"] + accounts["b"] != 1000:
                            stats["violations"] += 1
```

```
                        with stats_lock:
                            stats["active"] -= 1

            def writer():
                for i in range(200):
                    with lock.write_locked():
                        accounts["a"] -= 1                     # invariant broken ...
                        time.sleep(0)                          # yield mid-update
                        accounts["b"] += 1                     # ... and restored
            threads = [threading.Thread(target=reader) for _ in range(6)] +
[threading.Thread(target=writer)]
            for t in threads: t.start()
            for t in threads: t.join()
            print(f"violations seen by readers: {stats['violations']}; "
                  f"readers overlapped: {stats['peak'] > 1}; final {accounts}")
```

Output:

```
violations seen by readers: 0; readers overlapped: True; final {'a': 300, 'b': 700}
```

What to notice: readers never observe the moment between the writer's two updates, yet several readers hold the lock simultaneously. Releasing in `finally` ensures an exception inside the critical section cannot leave the lock held forever.

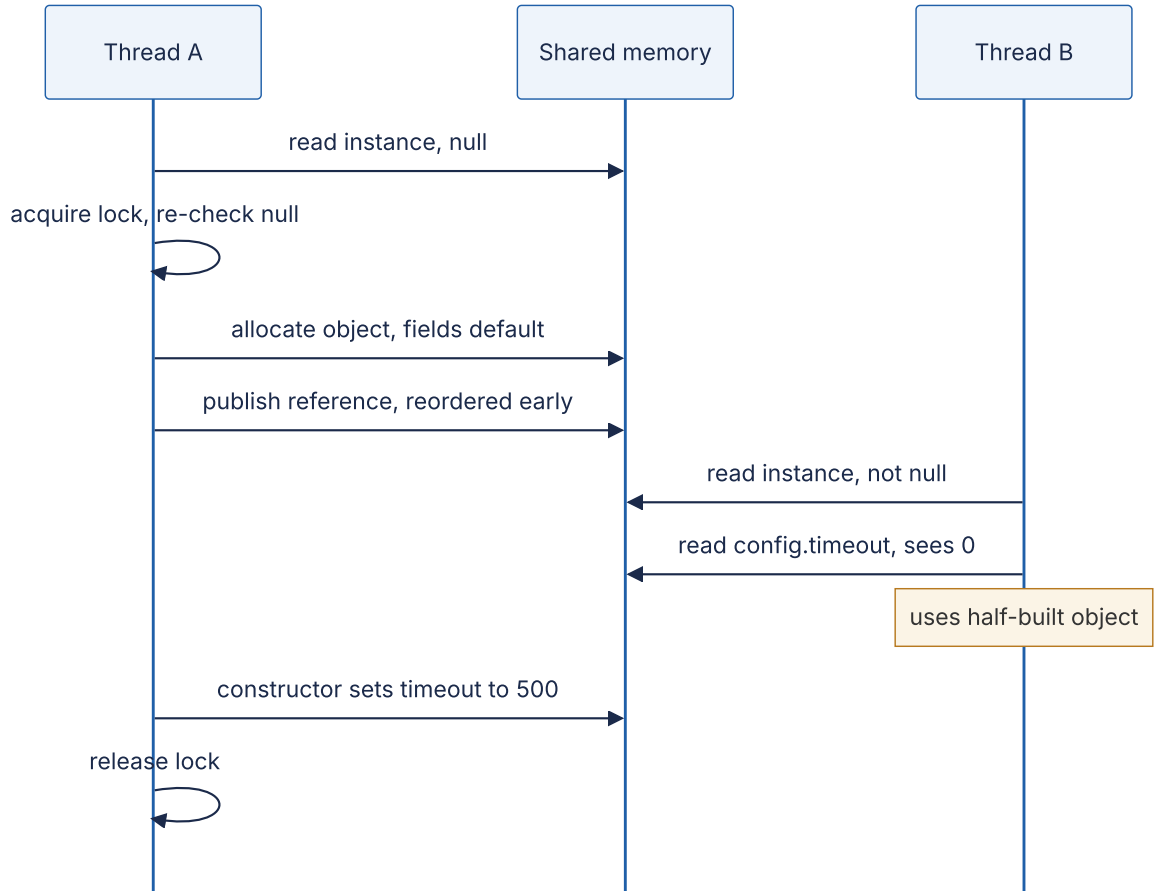
37.16.5 Double-checked locking and its pitfalls

DEFINITION

Definition — Double-checked locking. A lazy-initialization idiom that checks whether an object exists without a lock (fast path), and only if it does not, takes a lock, checks again, and creates it. It avoids locking on every access but is only correct if the language's memory model guarantees that a thread seeing the reference also sees the fully constructed object.

The Singleton in §37.6 used this idiom safely in Python. In Java before the Java 5 memory model (JSR-133, 2004), and in Java today without `volatile`, it is broken [Bacon et al.; Manson et al. 2005]. The compiler and CPU may reorder the steps of `instance = new Config()` (allocate memory, run the constructor, publish the reference) so that the reference is published *before* the constructor finishes. A second thread on the fast path sees a non-null reference, skips the lock, and reads fields that still hold default values.

Figure 37.21 — How double-checked locking fails without volatile.



Reading the diagram. Thread A takes the slow path and Thread B the fast path; both read and write shared memory. Without a happens-before edge, A's write of the reference may become visible to B before A's writes of the fields: B never takes the lock, so nothing orders its reads after A's constructor. The failure is silent and rare, appearing under load on weakly ordered hardware or after a JIT optimization. The fixes below create the missing ordering; none adds a lock to the fast path.

```
        public final class ConfigHolder {
            private static volatile Config instance;      // volatile: safe publication

            static Config get() {
                Config local = instance;                   // one volatile read on the
fast path
                if (local == null) {
                    synchronized (ConfigHolder.class) {
                        local = instance;
                        if (local == null) {
                            instance = local = new Config(500);   // fully built before
publication
                        }
                    }
                }
                return local;
            }

            static final class Config {
                final int timeoutMs;                       // final fields add a further
guarantee
                Config(int timeoutMs) { this.timeoutMs = timeoutMs; }
            }
        }
```

What to notice: `volatile` makes the write of `instance` a release and the read an acquire, so a thread that sees the reference also sees the constructor's writes. Simpler fixes usually win: the holder idiom or an enum (§37.6), eager initialization, or a plain `synchronized` method if the access is not hot. In Python, the risk is not reordering but the unlocked check-then-act race shown in §37.6.

Table 37.3 — Concurrency failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Unbounded queue exhausts memory	Producers faster than consumers, no backpressure	Queue depth and memory climb steadily	Shed load, restart	Bounded queues, reject or block when full
Pool starvation	Tasks block waiting on tasks in the same pool	All workers busy, throughput zero, no CPU	Restart, raise timeouts	Separate pools per dependency; no nested waits
Lost exceptions	Future never inspected	Missing results, no error logs	Re-run failed tasks	Always call `result()` or attach a callback that logs
Writer starvation	Reader-preferring lock under constant reads	Config refresh latency grows without bound	Pause readers	Writer-preferring lock or copy-on-write swap
Half-built object visible	Unsafe publication in double-checked locking	Rare `NullPointerException` or default values under load	Restart	`volatile`, holder idiom, immutable objects

37.17 Choosing a pattern

Patterns are answers; start from the question. Name the force that hurts (a growing `if` chain, an untestable class, a slow dependency on the request path), find the pattern that addresses that force, and state the trade-off you accept. If you cannot name the force, you do not need the pattern.

Table 37.4 — Pattern selection: problem → pattern → trade-off.

Problem you have	Pattern	Trade-off you accept
Concrete class chosen at run time from data	Simple factory (§37.3.1)	One more indirection; registry must be kept complete
Framework workflow needs a part supplied by extensions	Factory method (§37.3.2)	A subclass per variant
Several products must vary together per environment	Abstract factory (§37.4)	Adding a product type changes every factory
Object with many optional parts and cross-field rules	Builder (§37.5)	Extra class; mostly unnecessary with keyword arguments
Exactly one instance per process	Module or composition-root instance; Singleton (§37.6)	Global state, hidden dependencies, test leakage
Interchangeable algorithms chosen by config	Strategy (§37.7)	Clients must know which strategy to pick
Open-ended reactions to a change in one process	Observer (§37.8)	Synchronous fan-out latency; lapsed listeners
Third-party interface does not match yours	Adapter (§37.9)	Translation layer to maintain
Optional cross-cutting behavior to combine freely	Decorator (§37.10)	Many small objects; order-dependent stacks
Lazy creation, access control or remote object	Proxy (§37.11)	Hidden cost (N+1 queries, network calls)
Undo, queueing, logging or replaying requests	Command (§37.12)	A class per operation; undo must be exact
Domain logic tangled with storage code	Repository (§37.13)	Fake drifts unless contract-tested; poor for reporting
Classes create their own dependencies; hard to test	Dependency injection (§37.14)	Wiring code or a container to understand
Behavior and legal actions depend on mode	State (§37.15.1)	A class per state; transition logic spread across classes
Fixed algorithm skeleton with variable steps	Template Method (§37.15.2)	Inheritance coupling
Ordered, short-circuiting request processing	Chain of Responsibility (§37.15.3)	Order bugs; harder debugging
Bursty work must not overwhelm a slow consumer	Producer–consumer (§37.16.1)	Queueing delay; in-memory work lost on crash
Many short tasks, bounded concurrency	Thread pool + futures (§37.16.2–3)	Sizing, starvation and lost exceptions to manage
Read-mostly shared data	Read-write lock or copy-on-write (§37.16.4)	Writer starvation or copy cost
Hot lazy initialization	Holder idiom, `volatile` DCL (§37.16.5)	Subtle memory-model reasoning

RECOMMENDATION

Recommendation — Earn each pattern. Write the straightforward version first. Introduce a pattern when the second variant arrives (a second notifier, a second storage backend) or when a test cannot be written. In Python, try the lightest form first: a function argument before a Strategy hierarchy, a module before a Singleton, a closure before a Command class. Patterns applied speculatively add indirection that every future reader pays for.

37.18 Summary and revision notes

SUMMARY

- A **design pattern** is a named solution shape with known trade-offs. GoF groups patterns as creational, structural and behavioral; Repository and DI are enterprise patterns; producer–consumer, thread pools and futures are concurrency patterns.
- **Creational:** a simple factory centralizes a run-time class choice; a factory method lets subclasses choose the product; an abstract factory creates consistent families; a builder validates cross-field rules and emits an immutable product.
- **Singleton** means one instance *per process*; prefer one instance created in the composition root and injected. In Python, a module is the idiomatic singleton; in Java, the enum or holder idiom.
- **Strategy** swaps algorithms by composition; in Python a strategy is often a function. **State** swaps behavior as the object changes mode. **Template Method** fixes a skeleton and varies steps through inheritance.
- **Observer** is in-process, synchronous publish/subscribe; isolate failing observers and move slow ones behind a queue or broker (§30.5).
- **Adapter** changes an interface, **Decorator** keeps it and adds behavior, **Proxy** keeps it and controls access, **Facade** simplifies a subsystem. Python's `@decorator` syntax is a language feature, not the GoF pattern.
- **Command** turns requests into values for undo, queueing and replay. **Chain of Responsibility** underlies middleware; order matters.
- **Repository** hides storage behind a domain collection interface; contract-test every implementation. **Dependency injection** supplies dependencies from a composition root and realizes dependency inversion (§36.7).
- **Concurrency:** bound every queue; size pools with $N_{cpu}U_{cpu}(1+W/C)$ and check downstream limits; always inspect futures; prefer writer-preferring read-write locks or copy-on-write for read-mostly data; double-checked locking in Java requires `volatile`.

37.19 Knowledge checkpoint

1. What problem does a simple factory solve that a constructor call does not?
2. When does an abstract factory become painful to extend?
3. Name two reasons to make a builder's product immutable.
4. A service with a "singleton" cache runs 30 pods with 2 processes each. How many caches exist?
5. Why does the naive singleton in §37.6 create several instances under concurrency?

6. How do Strategy and State differ, given that their class diagrams are almost identical?
7. List two differences between Observer and broker-based publish/subscribe.
8. Classify each as Adapter, Decorator or Proxy: a retry wrapper; a gRPC client stub; a wrapper converting a vendor SDK's dictionaries into domain objects.
9. Name two uses of Python's `@` decorator syntax that are not the GoF Decorator.
10. Why does running a new command clear the redo stack?
11. What keeps an in-memory fake repository honest?
12. What is the difference between dependency injection and a service locator?
13. Using the sizing formula, how many threads for 16 cores, 50% target utilization, $W = 40$ ms and $C = 10$ ms?
14. Why should authentication run before per-user rate limiting in a middleware chain?
15. What exactly goes wrong in Java double-checked locking without `volatile`?

Answers

1. It moves the "which concrete class?" decision, driven by run-time data, into one place, so callers depend only on the interface and new variants do not touch call sites.
2. When you add a new product type: every concrete factory must implement a new creation method.
3. Invariants checked in `build()` cannot later be broken; immutable objects are thread-safe to share and safe to use as cache keys or to retry.
4. $30 \times 2 = 60$ independent caches, each with its own contents.
5. Check-then-act is not atomic: all threads read `None` before any assigns, and each constructs an instance.
6. A strategy is chosen by the client from outside and usually stays fixed; a state object changes the context's state itself as transitions occur.
7. Observer is synchronous and in-process with no durability; pub/sub through a broker is asynchronous, durable, and decouples publisher and subscribers in time and deployment.
8. Retry wrapper: Decorator. gRPC stub: Proxy (remote). SDK translator: Adapter.
9. Registration (`@app.route`), `@property`, `@dataclass` and `@staticmethod` transform or register rather than wrap an object behind the same interface.
10. Redo replays undone commands on the state they were undone from; after a new command, that state no longer exists, so replaying them would corrupt the history.
11. A shared contract test suite run against both the fake and the real implementation.
12. With DI, dependencies are passed in and visible in the constructor; with a service locator, the object fetches them from a registry, hiding them and coupling it to the locator.
13. $16 \times 0.5 \times (1 + 40/10) = 16 \times 0.5 \times 5 = 40$ threads.
14. Unauthenticated (possibly forged) requests would otherwise consume a real user's quota, enabling a cheap denial of service against that user; also, user identity is not

known until authentication runs.
15. The write publishing the reference can become visible before the constructor's field writes; a thread on the unlocked fast path sees a non-null reference to a partially constructed object.

37.20 Interview questions

Basic

Q1. What is the Strategy pattern? Give a system-design example. Answer. It encapsulates interchangeable algorithms behind one interface, chosen at run time. Examples: load-balancing policies (round robin, least connections) in a proxy, cache eviction policies (LRU, LFU), and retry backoff policies. It keeps the context closed to modification and makes each algorithm testable alone.

Q2. Why is Singleton considered an anti-pattern? Answer. It is global mutable state: dependencies are hidden, tests leak state into one another, two configurations cannot coexist, and it invites contention. It also misleads in distributed systems, being one per process, not per system. Create one instance in the composition root and inject it instead.

Intermediate

Q3. Compare Adapter, Decorator and Proxy. Answer. All wrap another object. Adapter presents a *different* interface to make incompatible code fit; Decorator presents the *same* interface and adds behavior, and decorators stack; Proxy presents the same interface and controls access (lazy creation, permissions, remoteness). Infrastructure analogues: an anti-corruption layer (adapter), a caching or retrying client (decorator), an API gateway or sidecar (proxy).

Q4. How would you make an `OrderService` unit-testable if it currently constructs a database client, an HTTP payment client and calls `datetime.now()`? Answer. Define ports for the repository, payment gateway and clock; implement adapters for production; change `OrderService` to receive them via its constructor; wire them in a composition root; in tests pass an in-memory repository, a fake gateway and a fixed clock. Add contract tests so the fakes match the real adapters.

Advanced

Q5. Design the in-process notification pipeline for a service that sends 2,000 receipts per second at peak through a provider with 100 ms latency and a 1,500 requests/s limit. Answer. Request threads produce Commands into a bounded queue (producer–consumer); a sender pool consumes them. By Little's Law the provider limit al-

lows $1,500 \times 0.1 = 150$ requests in flight, so about 150 sender threads (fewer with an asynchronous client). Because 2,000/s exceeds 1,500/s, the queue grows at 500/s during the peak; bound it by memory (100,000 items ≈ 200 s of peak excess), and beyond that reject or spill to a durable broker. Wrap the client in decorators for retry with jitter and a circuit breaker, and make sends idempotent by order ID.

Q6. A Java service occasionally reads a configuration timeout of 0 under load. The config is lazily created with double-checked locking. Explain and fix. Answer. Without `volatile`, the reference to the config can be published before its constructor's writes are visible; a thread on the unlocked fast path sees a non-null, partially constructed object with default field values. Fix by declaring the field `volatile`, or better, use the initialization-on-demand holder idiom or eager initialization, and make the config's fields `final`.

37.21 Practical exercises

1. Add a `WhatsAppNotifier` to §37.3 by registering it from a separate module at import time. Which files changed?
2. Add a cloud family to the abstract factory in §37.4 with fake network latency, and write one contract test that runs against all three families.
3. Reorder the decorators in §37.10 to `RetryingPriceSource(CachingPriceSource(db))` and predict, then measure, the database call count.
4. Extend the Command example with an `ApplyCoupon` command whose undo restores the previous total, and persist the history to a JSON file.
5. Replace the read-write lock in §37.16.4 with copy-on-write (build a new dictionary, swap a reference) and compare reader throughput with 8 readers.
6. Vary `max_workers` in §37.16.2 from 1 to 64 and plot elapsed time; explain the curve with the sizing formula.

37.22 Design challenges

1. **Pluggable payments.** Design the payment module of a store that supports three processors, per-country routing, retries with idempotency keys, and a test mode. Identify where you would use Adapter, Strategy, Decorator, Abstract Factory and DI, and draw the class diagram.
2. **Collaborative editor backend.** Support undo/redo per user, an audit log, and asynchronous persistence of edits. Decide what the Command objects contain, where they are queued, and how undo interacts with other users' later edits.

Chapter 38 — UML and Low-Level Design

> **Level:** 2–3 · **Track:** A (Traditional) · **Estimated reading time:** 4 h

Chapters 35–37 gave you the vocabulary of object-oriented design: classes and interfaces, the SOLID principles, and the Gang of Four patterns. This chapter teaches you to *draw* a design so that other engineers can check it in minutes, and then to *produce* one under interview conditions. The first half covers the five Unified Modeling Language (UML) diagrams that working engineers actually use (class, sequence, component, state and activity) and the relationships between objects that trip people up most often. The second half is a method for low-level design (LLD) interviews and eight fully worked exercises, from the parking lot to a chess move validator, each with requirements, diagrams, runnable Python, the patterns used and the follow-up questions an interviewer is likely to ask.

Throughout, the diagrams are written in Mermaid, a text-based diagram language. Mermaid's class, sequence and state diagrams are close to UML notation; it has no component or activity diagram, so those two are drawn as flowcharts that approximate UML, and the text says so each time.

38.1 Learning objectives

After this chapter you should be able to:

- Read and draw UML class diagrams with correct visibility, multiplicity and the six relationship kinds (association, aggregation, composition, generalization, realization, dependency).
- Draw sequence diagrams with lifelines, activations, synchronous and asynchronous messages, and `alt` / `opt` / `loop` fragments for a real request flow.
- Draw component, state machine and activity diagrams, and choose the right diagram for a given question.
- Decide between association, aggregation and composition, and between modeling something as an attribute or as a relationship, and express each choice in code.
- Run a 45-minute LLD interview using a nine-step method, and self-assess against a rubric.
- Design, diagram and implement eight classic LLD problems with thread safety and extension points, and defend the patterns you chose.

38.2 Prerequisites

- Classes, encapsulation, inheritance, polymorphism and composition over inheritance — Chapter 35 (UML class diagrams are a notation for exactly these ideas).
- SOLID principles — Chapter 36 (every design review in §38.10 is argued in SOLID terms).
- Design patterns, especially Strategy (§37.7), Observer (§37.8), Decorator (§37.10), Factory (§37.3), State (§37.15) and the concurrency patterns of §37.16 — the exercises apply them.
- Mutexes, race conditions and lock striping — §6.9–§6.10 (thread safety in the exercises).
- Token bucket — §22.4 (the rate limiter exercise wraps it in a class design without re-deriving it).
- LRU and TTL as cache policies — §20.8–§20.9 (the LRU and key-value store exercises implement them).
- Optimistic concurrency — §11.15.3 (the key-value store's transactions use it).

38.3 Class diagrams

38.3.1 What UML is and why it exists

DEFINITION

Definition — Unified Modeling Language (UML). A general-purpose graphical language for specifying, visualizing and documenting software systems, standardized by the Object Management Group (OMG). The current version, UML 2.5.1 (December 2017), defines 14 diagram types divided into *structure* diagrams (what the system is made of) and *behavior* diagrams (what it does over time) [OMG 2017].

First-principles explanation

An architect does not hand a builder a written essay about a house; they hand over a floor plan, an elevation and a wiring diagram, each answering one question with conventions every builder already knows. A solid wall line, a door arc and a socket symbol mean the same thing on every plan. UML plays that role for object-oriented software: a hollow triangle always means "is a kind of", a filled diamond always means "owns and controls the lifetime of". Once both people know the conventions, a picture of 12 classes conveys in 30 seconds what 300 lines of code take 10 minutes to reveal.

Why does this exist?

By the early 1990s there were dozens of competing object-oriented notations. Grady Booch, James Rumbaugh and Ivar Jacobson merged their methods at Rational Software, and OMG adopted the result as UML 1.1 in 1997. UML 2.0 (2005) reworked sequence and activity diagrams substantially, and 2.5 (2015) simplified the specification without changing most notation [OMG 2017; Fowler 2003; Rumbaugh et al. 2004].

Fowler distinguishes three ways people use UML: as a **sketch** (informal, partial diagrams to communicate an idea), as a **blueprint** (complete diagrams that a programmer implements) and as a **programming language** (diagrams compiled to code) [Fowler 2003]. Almost all industry use, and all interview use, is sketching. The goal is not to satisfy the 790-page specification; it is to make the important decisions visible and unambiguous. This chapter follows the standard notation where it matters (relationships, multiplicity, message kinds) and relaxes it where it does not (exact fonts, every adornment).

Table 38.1 — The 14 UML 2.5.1 diagram types and how often you need them.

Family	Diagram	Answers the question	Use in practice
Structure	Class	What types exist and how are they related?	Daily; every LLD interview
Structure	Object	What does one snapshot of instances look like?	Occasionally, to explain a tricky class diagram
Structure	Package	How is the code grouped into modules?	Occasionally
Structure	Component	Which replaceable parts provide and require which interfaces?	Architecture reviews (§38.5)
Structure	Composite structure	What is inside one class at run time?	Rare
Structure	Deployment	Which artifacts run on which nodes?	Usually replaced by infrastructure diagrams
Structure	Profile	How is UML itself extended?	Tool builders only
Behavior	Use case	Which actors want which goals?	Requirements; often a bullet list instead
Behavior	Activity	What is the workflow, including parallel steps?	Business processes, pipelines (§38.7)
Behavior	State machine	How does one object react to events over its lifetime?	Lifecycles, protocols (§38.6)
Interaction	Sequence	Who calls whom, in what order?	Daily; every LLD interview (§38.4)
Interaction	Communication	Same as sequence, laid out by links	Rare
Interaction	Timing	How do states change against a time axis?	Hardware, real-time systems
Interaction	Interaction overview	How do several interactions combine?	Rare

The three interaction diagrams are a sub-family of behavior diagrams, so the split is 7 structure and 7 behavior diagrams. Five of them (class, sequence, component, state machine, activity) cover nearly everything you will draw.

38.3.2 Classes, visibility and multiplicity

DEFINITION

Definition — Class diagram. A structure diagram showing classifiers (classes, interfaces, enumerations), their **attributes** and **operations**, and the **relationships** among them. A class is drawn as a box with up to three compartments: name, attributes, operations.

How it works internally

Each attribute is written `visibility name : Type [multiplicity] = default`, and each operation `visibility name(parameter : Type) : ReturnType`. Mermaid uses the Java-like order `Type name` and `name() ReturnType`, which is also common in hand-drawn sketches; either is fine as long as it is consistent. Abstract classes and operations are written in *italics*; static members are underlined. Stereotypes in guillemets such as «interface», «abstract» or «enumeration» classify a box.

Multiplicity says how many instances may be at the far end of a relationship (or in a multi-valued attribute). It is written as `lower..upper`, where `*` means “unbounded”.

Table 38.2 — Class diagram notation: visibility, multiplicity and adornments.

Notation	Meaning	Python convention	Mermaid syntax
`+`	Public: visible to everyone	`name`	`+name`
`-`	Private: visible only inside the class	`_name` (or `__name`)	`-name`
`#`	Protected: visible to the class and subclasses	`_name` by convention	`#name`
`~`	Package: visible inside the same package or module	module-level, not exported	`~name`
italic	Abstract class or operation	`ABC`, `@abstractmethod`	`<<abstract>>`, `method()*`
underline	Static (class-level) member	class attribute, `@staticmethod`	`name$`
`1`	Exactly one	required reference	`"1"`
`0..1`	Zero or one (optional)	`Optional[X]`	`"0..1"`
`*` or `0..*`	Zero or more	`list[X]`, `dict[K, X]`	`"*"`
`1..*`	One or more	non-empty collection, checked in `__init__`	`"1..*"`
`2..4`	A bounded range	collection with a validated size	`"2..4"`

COMMON MISTAKE

Mistake — putting multiplicity at the wrong end. In `Order "1" --> "1..*" LineItem`, the `1..*` sits next to `LineItem` and is read from the *Order's* point of view: "an order has one or more line items". Students often read it the other way round. Read every association twice, once from each end: "each order has 1..* line items; each line item belongs to exactly 1 order."

38.3.3 The six relationships

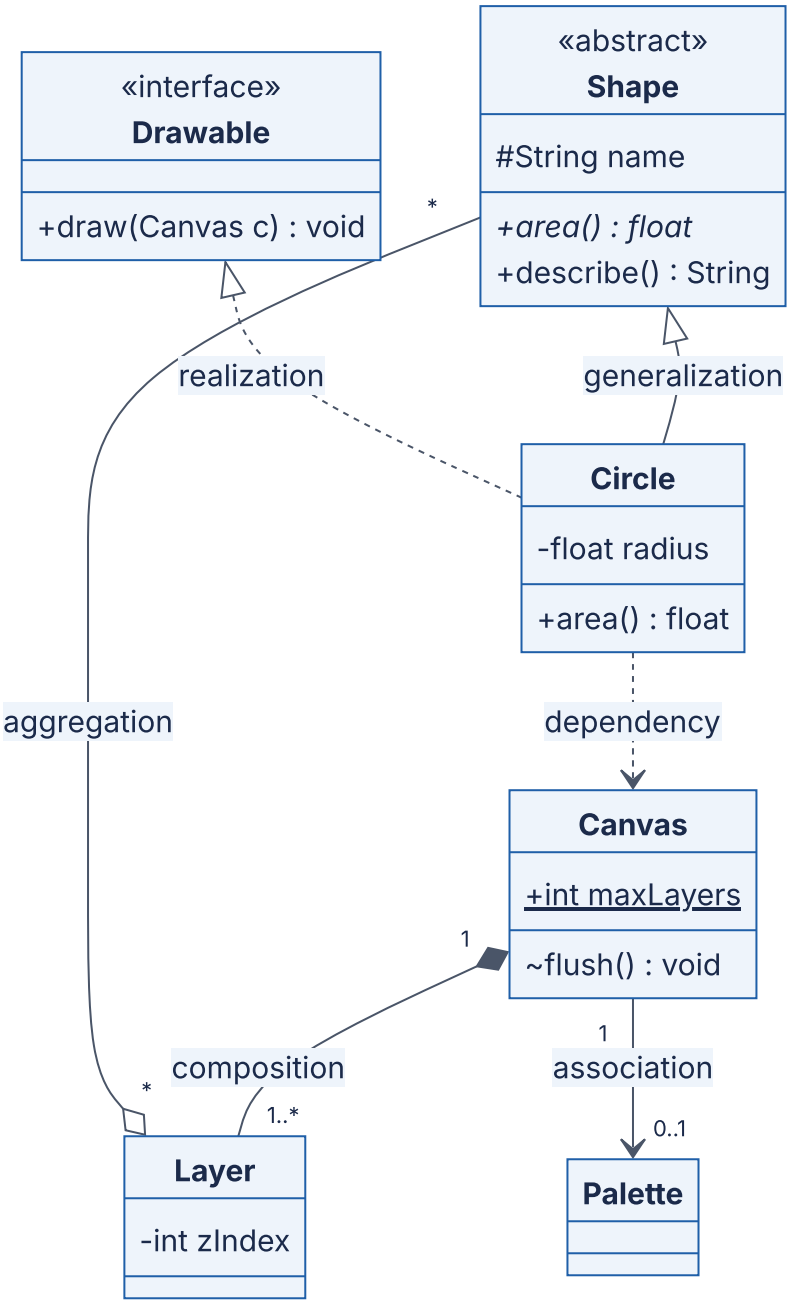
Relationships carry most of the meaning in a class diagram. UML defines more, but six cover practically every design.

Table 38.3 — The six class relationships.

Relationship	Line and end symbol	Meaning	Typical code	Mermaid
Association	Solid line; open arrowhead for navigability	A structural, lasting link: one object holds a reference to the other	Field `self.owner: Customer`	`A --> B`
Aggregation	Solid line, hollow diamond at the whole	Whole–part where the part can be shared and outlives the whole	Field holding objects created elsewhere	`Whole o-- Part`
Composition	Solid line, filled diamond at the whole	Whole–part with exclusive ownership; parts die with the whole	Whole creates parts privately	`Whole *-- Part`
Generalization (inheritance)	Solid line, hollow triangle at the parent	"Is a kind of"; subclass inherits and may override	`class Car(Vehicle)`	`Parent <|-- Child`
Realization	Dashed line, hollow triangle at the interface	A class implements an interface's contract	`class S3Store(BlobStore)` with ABC	`Interface <|.. Impl`
Dependency	Dashed line, open arrowhead	Transient use: a parameter, local variable or return type	`def render(self, c: Canvas)`	`A ..> B`

The relationships form a scale of coupling strength. From weakest to strongest: dependency (uses it for one call), association (remembers it), aggregation (contains it, shared), composition (owns it exclusively), and generalization (*is* it — the strongest coupling of all, which is why §35.8 recommends composition over inheritance). Realization couples only to a contract, so it is the relationship that the Dependency Inversion Principle (§36.7) wants you to draw most often [Martin 2002; Martin 2017].

Figure 38.1 — Class diagram notation: visibility, multiplicity and the six relationships.



Reading the diagram. `Shape` is an abstract class (stereotype and the `*` on `area()` mark it abstract) with a protected `name`; `Circle` inherits from it (solid line, hollow triangle at `Shape`) and also realizes the `Drawable` interface (dashed line, hollow triangle). A `Canvas` *composes* one or more `Layer`s (filled diamond at `Canvas`): layers are created by the canvas and deleted with it. Each `Layer` *aggregates* any number of shapes (hollow diamond), and one shape can appear on several layers, so it is shared. The canvas has a navigable *association* to an optional `Palette` (arrow toward `Palette`, multiplicity `0..1`). `Circle` merely *depends* on `Canvas` (dashed arrow): it receives one as a parameter in `draw` and does not keep it. The static `maxLayers` and package-visible `flush()` show the remaining

adornments. The diagram has no run-time direction or storage; it is a static map of compile-time coupling. If you change `Canvas`, every class with an arrow pointing at it (here `Circle`) may need to change, which is how a class diagram exposes change impact.

Common misconceptions

COMMON MISTAKE

Mistake — drawing every class and every getter. A class diagram that lists 40 classes with all their accessors hides the five decisions that matter. Show the classes that participate in the problem, the operations that define their responsibilities, and every relationship with multiplicity. Omit getters, setters and obvious constructors.

COMMON MISTAKE

Mistake — using inheritance for roles. `Librarian extends Member` looks natural until a librarian borrows a book under a different policy or a member becomes a librarian on Tuesday. Roles that an object can gain or lose are associations to a `Role` object (or a Strategy, §37.7), not subclasses. Generalization is for permanent "kind of" relationships that pass the Liskov test (§36.5).

INDUSTRY EXAMPLE

Diagrams as code on GitHub. Since February 2022 GitHub renders Mermaid code blocks in Markdown files, issues and pull requests, so diagrams can live next to the code and be reviewed as text diffs [GitHub 2022]. A diagram versioned with the code is far more likely to be kept current. *Evidence: Primary* — [GitHub 2022]

38.4 Sequence diagrams

38.4.1 Lifelines, messages and fragments

DEFINITION

Definition — Sequence diagram. An interaction diagram that shows objects or participants as vertical **lifelines** and the **messages** they exchange as horizontal arrows ordered top to bottom in time. **Execution specifications** (activation bars) show when a participant is busy, and **combined fragments** (`alt`, `opt`, `loop`, `par` and others) show conditional, optional, repeated and parallel behavior [OMG 2017].

First-principles explanation

A class diagram is a cast list; a sequence diagram is the script of one scene. It answers "when the user clicks *Buy*, who calls whom, in what order, and what comes back?" Time flows downward, so you can read the diagram like a story. It is the diagram that most often reveals a missing responsibility: if no lifeline can answer a message, a class is missing; if one lifeline receives every message, you have found a God object.

How it works internally

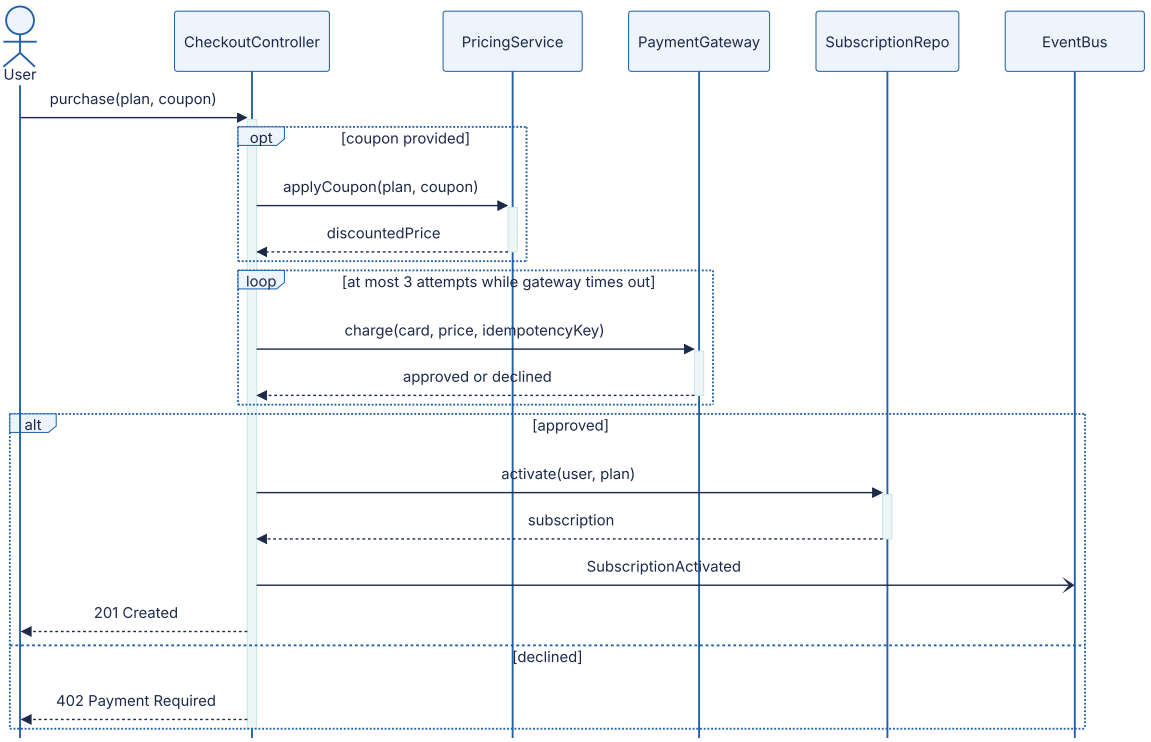
1. Place participants left to right in the order they first act; put the initiator (an actor) on the far left.
2. Draw each message as an arrow from caller to callee, labeled with the operation and key arguments.
3. A **synchronous** message (solid line, filled arrowhead) blocks the caller until the reply; a **reply** is a dashed line with an open arrowhead; an **asynchronous** message (solid line, open arrowhead) lets the caller continue immediately.
4. Activate the callee (a thin bar) while it is processing; nested bars show nested calls.
5. Wrap conditional or repeated sections in combined fragments, each labeled with its operator and a guard in square brackets.

Table 38.4 — Sequence diagram elements and their Mermaid syntax.

Element	UML notation	Meaning	Mermaid
Lifeline	Box with a dashed vertical line	One participant for the scene's duration	`participant X` / `actor U`
Execution (activation)	Thin bar on the lifeline	Participant is executing	`->>+` and `-->>-`, or `activate X`
Synchronous message	Solid line, filled arrowhead	Caller waits for the reply	`A->>B: op()`
Reply	Dashed line, open arrowhead	Return value	`B-->>A: result`
Asynchronous message	Solid line, open arrowhead	Fire and forget	`A-)B: event`
`alt` fragment	Box split by dashed lines, one guard per part	If/else: exactly one operand runs	`alt ... else ... end`
`opt` fragment	Box with one guard	If without else	`opt ... end`
`loop` fragment	Box with a guard or bounds	Repeat while the guard holds	`loop ... end`
`par` fragment	Box split into concurrent operands	Operands run in parallel	`par ... and ... end`
`break` / `critical`	Labeled box	Exit the enclosing interaction / atomic region	`break ... end`, `critical ... end`

UML 2.5.1 defines twelve interaction operators (also `seq`, `strict`, `neg`, `assert`, `ignore` and `consider`), but the six above appear in nearly every real diagram.

Figure 38.2 — Sequence diagram for a PhotoShare Pro purchase with opt, loop and alt fragments.



Reading the diagram. The *User* (an actor) synchronously calls `purchase` on the *CheckoutController*, which stays active for the whole scene. The `opt` fragment runs only when a coupon is supplied: the *PricingService* returns a discounted price. The `loop` fragment retries the *PaymentGateway* charge up to three times on timeout; the idempotency key makes those retries safe (§22.15), which is the most important detail an interviewer will probe. The `alt` fragment splits on the result: on approval the controller persists the subscription through the *SubscriptionRepo* (the storage boundary) and publishes `SubscriptionActivated` *asynchronously* to the *EventBus* (open arrowhead: it does not wait), then replies 201; on decline it replies 402. Failure points are visible as lifelines that can be slow: the external gateway and the repository. Scaling is not shown in a sequence diagram; it describes one request.

INTERVIEW TIP

Tip — draw the unhappy path. Interviewers rarely ask about the path where everything works. One `alt` for “declined” and one `loop` or `break` for “timeout” show that you think about failure, and they take ten seconds to draw.

COMMON MISTAKE

Mistake — one sequence diagram for the whole system. A sequence diagram should cover one use case, one scenario, ideally fewer than 10 lifelines and 25 messages. If it is larger, split it by use case or replace a group of lifelines with one participant (“PaymentSubsystem”) and draw that separately.

38.5 Component diagrams

38.5.1 Components and interfaces

DEFINITION

Definition — Component diagram. A structure diagram that shows **components** (modular, replaceable units that encapsulate their contents) and the **interfaces** they *provide* (offer to others, drawn as a “lollipop” circle) and *require* (need from others, drawn as a “socket” half-circle), connected by **assembly connectors** that wire a required interface to a matching provided one [OMG 2017].

First-principles explanation

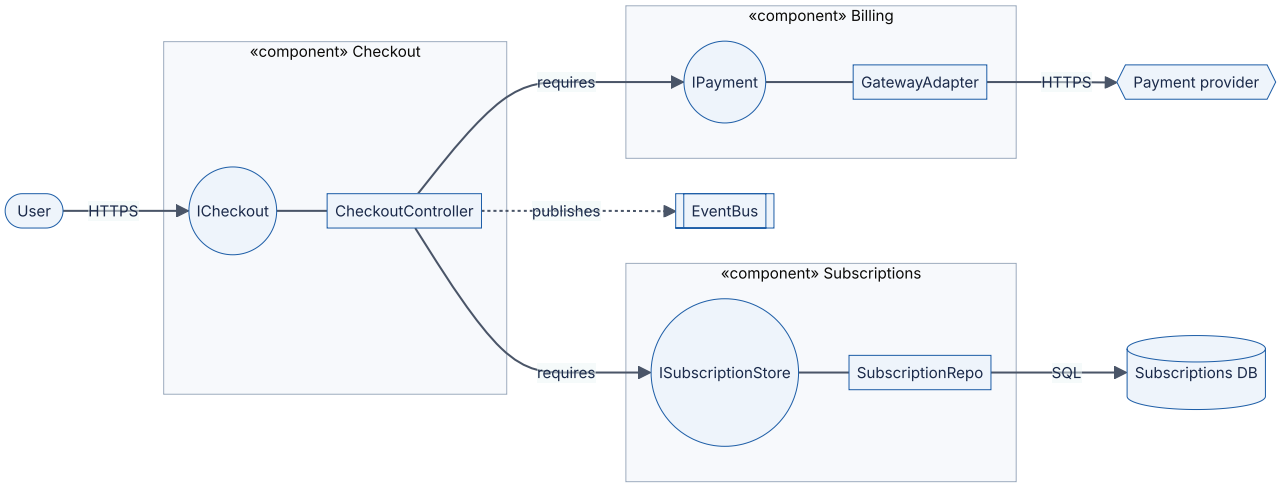
Think of household appliances and wall sockets. The kettle requires “230 V, type G plug”; the wall provides it. You can replace the kettle with any other appliance that requires the same socket, and you can rewire the house without touching the kettle. A component diagram draws software at that granularity: modules, libraries or services, and only the contracts between them, not their internal classes.

Why does this exist?

A class diagram of a 200-class system is unreadable, and a deployment diagram shows machines, not responsibilities. The component diagram sits between them: it shows which parts can be built, tested and replaced independently, which is exactly the question behind modular monoliths (§33.5), hexagonal architecture’s ports and adapters (§33.10) and the Dependency Inversion Principle at the architecture level (§36.8).

Mermaid has no component diagram, so Figure 38.3 approximates UML notation with a flowchart: each `subgraph` is a component, circle nodes are provided interfaces, and edges labeled “requires” are required interfaces wired by an assembly connector.

Figure 38.3 — Component view of the PhotoShare Pro checkout (flowchart approximation of UML component notation).



Reading the diagram. Three components appear as boxes. *Checkout* provides the `ICheckout` interface (circle) to the user over HTTPS and *requires* two interfaces: `IPayment`, provided by the *Billing* component, and `ISubscriptionStore`, provided by *Subscriptions*. The "requires" edges are the assembly connectors. Checkout depends only on the interface circles, never on `GatewayAdapter` or `SubscriptionRepo` directly, so either can be replaced (a different payment provider, a different database) without touching Checkout. Solid edges are synchronous calls; the dotted edge to the *EventBus* is asynchronous publication. Storage and external boundaries are the subscriptions database and the external payment provider, which are also the main failure points. Scaling: each component could be deployed as its own service later, and the interfaces become the service APIs.

RECOMMENDATION

Recommendation — name interfaces after the client's need. `IPayment` with `charge()` and `refund()` describes what Checkout needs; `IStripeClient` describes one vendor's implementation and leaks it into every client. Interfaces owned by the client side are the core of Dependency Inversion (§36.7).

38.6 State diagrams

38.6.1 States, transitions, guards and actions

DEFINITION

Definition — State machine diagram. A behavior diagram that shows the **states** one object (or protocol) can be in and the **transitions** between them. A transition is labeled `trigger [guard] / effect`: the **trigger** is the event, the **guard** a Boolean condition that must be true for the transition to fire, and the **effect** an action executed during the transition. A state may declare **entry**, **exit** and **do** behaviors, run on entering, on leaving, and while inside the state [OMG 2017].

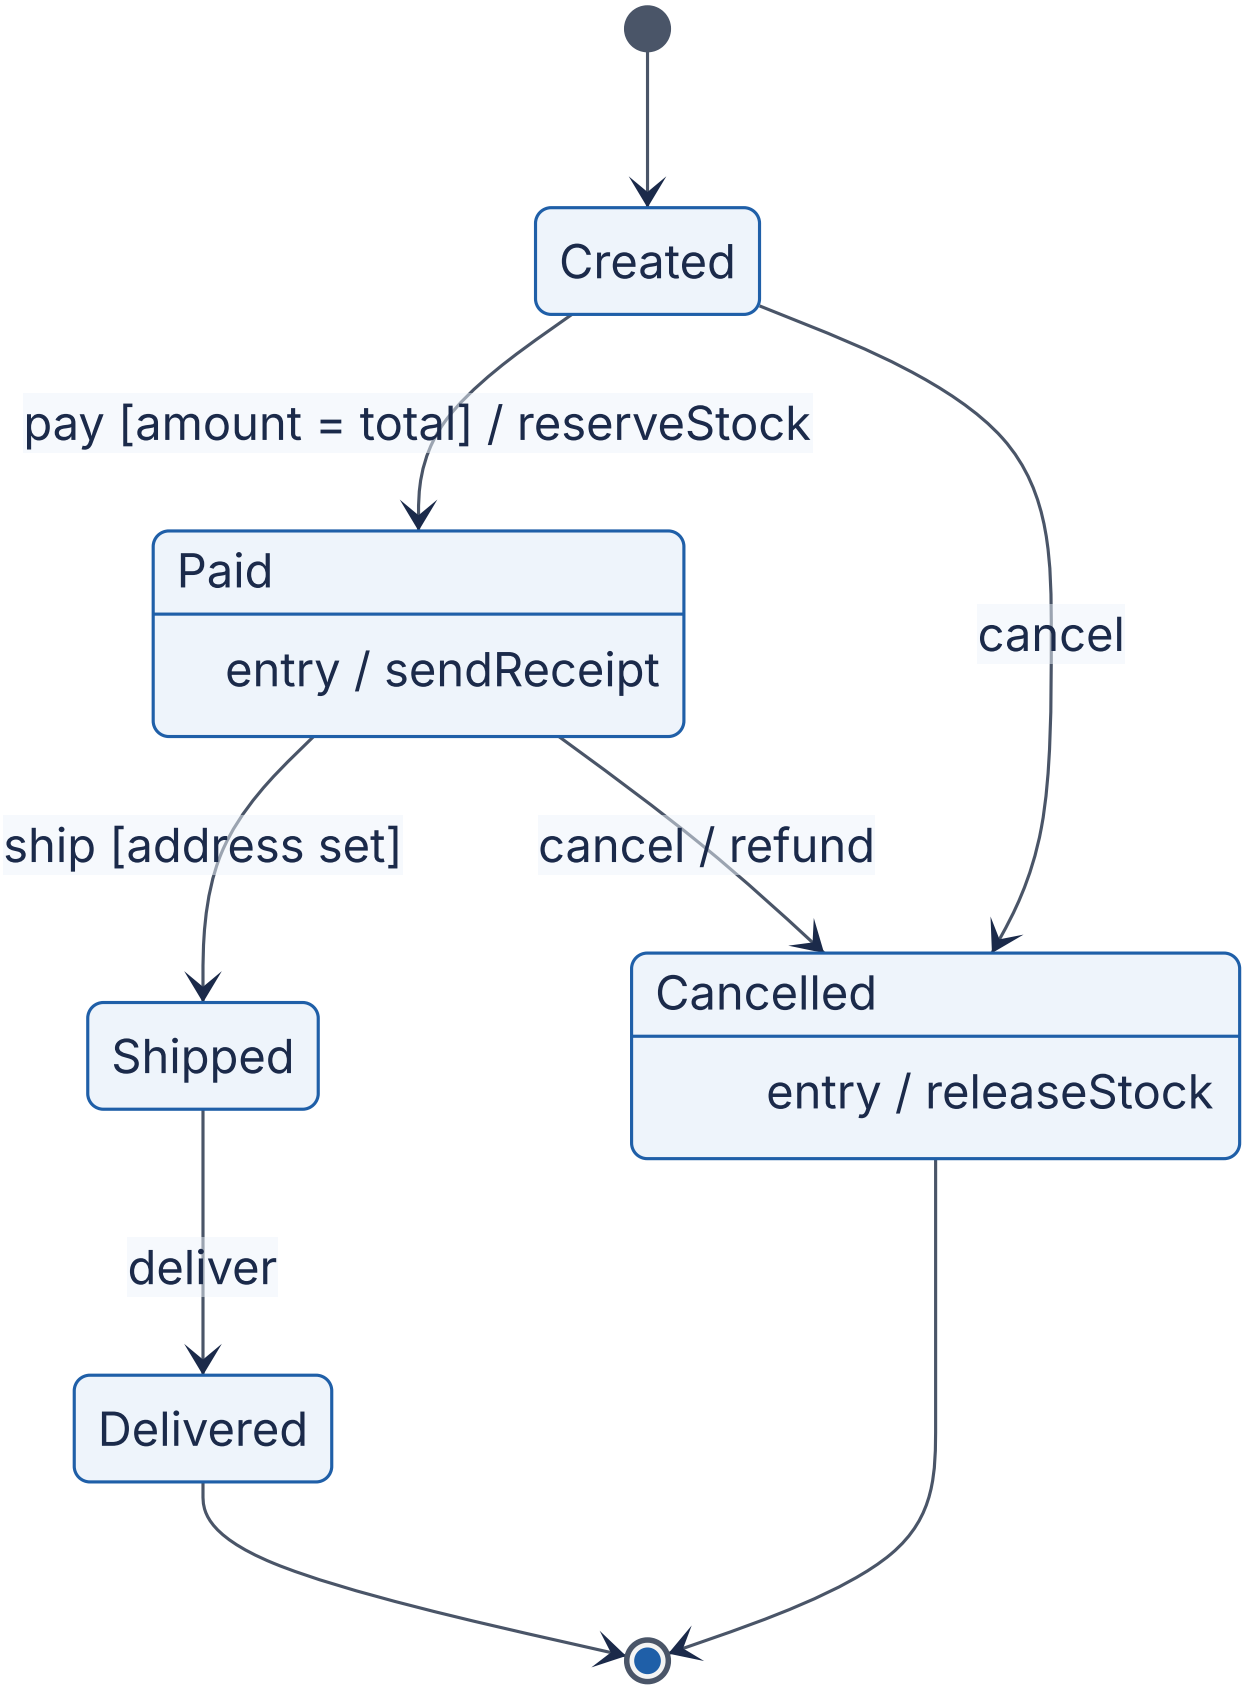
First-principles explanation

A traffic light is a state machine: three states, one event (a timer tick) and a fixed order. A pressed pedestrian button is a guard: "on tick, *if* someone is waiting, go to red". Business objects behave the same way. An order cannot be shipped before it is paid; a refund only makes sense for a paid order. Writing these rules as a diagram makes every illegal combination obvious: if there is no arrow labeled `ship` out of `Created`, shipping an unpaid order is impossible by construction.

How it works internally

1. A filled circle (the **initial pseudostate**) points to the first state; a bullseye is a **final state**.
2. When an event arrives, the machine looks for a transition out of the current state with that trigger.
3. If the guard is false (or no transition matches), the event is ignored or rejected, and the state does not change.
4. Otherwise it runs the current state's exit behavior, then the transition's effect, then the target state's entry behavior.
5. **Composite states** nest a sub-machine (for example, `Shipped` containing `InTransit` and `OutForDelivery`), and a **choice pseudostate** (a diamond) branches on guards after a single trigger.

Figure 38.4 — State machine for an order, with guards, effects and entry actions.



Reading the diagram. An order starts in *Created*. The `pay` event moves it to *Paid* only if the guard `amount = total` holds; the transition's effect reserves stock, and entering *Paid*

sends a receipt. From *Paid* it can be shipped (guarded by a known address) or canceled, and cancellation from *Paid* has a refund effect that cancellation from *Created* does not need. Entering *Canceled* always releases stock. *Delivered* and *Canceled* lead to the final state. Any event without an outgoing arrow is illegal in that state, so “cancel a delivered order” is rejected. There is no network or storage in this diagram; in a real system the state is persisted with the order, and every transition should be a single atomic update (for example `UPDATE ... SET state = 'PAID' WHERE id = ? AND state = 'CREATED'`) so that two concurrent events cannot both fire from the same state.

Code example

A transition table maps directly from the diagram to code, which keeps them in sync:

```
        from enum import Enum, auto

        class S(Enum):
            CREATED = auto()
            PAID = auto()
            SHIPPED = auto()
            DELIVERED = auto()
            CANCELLED = auto()

        class Order:
            # (state, event) -> (guard, next_state, effect); a guard of None means "al-
ways"
            TRANSITIONS = {
                (S.CREATED, "pay"):     (lambda o, amt: amt == o.total, S.PAID,
"reserve_stock"),
                (S.CREATED, "cancel"):  (None, S.CANCELLED, None),
                (S.PAID, "ship"):       (lambda o, _: o.address is not None, S.SHIPPED,
None),
                (S.PAID, "cancel"):     (None, S.CANCELLED, "refund"),
                (S.SHIPPED, "deliver"): (None, S.DELIVERED, None),
            }
            ENTRY = {S.PAID: "send_receipt", S.CANCELLED: "release_stock"}

            def __init__(self, total, address=None):
                self.state, self.total, self.address, self.log = S.CREATED, total, ad-
dress, []

            def fire(self, event, arg=None):
                rule = self.TRANSITIONS.get((self.state, event))
                if rule is None:
                    raise ValueError(f"event {event!r} not allowed in
{self.state.name}")
                guard, target, effect = rule
                if guard is not None and not guard(self, arg):
                    return False                        # guard false: no transition,
state unchanged
                if effect:
                    self.log.append(effect)             # transition effect runs first...
                self.state = target
                if target in self.ENTRY:
                    self.log.append(self.ENTRY[target])  # ...then the target's entry
action
                return True

        if __name__ == "__main__":
            o = Order(total=50, address="1 Main St")
            assert o.fire("pay", 40) is False and o.state is S.CREATED   # guard rejects
            assert o.fire("pay", 50) and o.state is S.PAID
            assert o.fire("ship") and o.fire("deliver")
            try:
                o.fire("cancel")
            except ValueError as e:
```

```
                print("rejected:", e)
            print(o.state.name, o.log)
```

Output: `rejected: event 'cancel' not allowed in DELIVERED`, then `DELIVERED ['reserve_stock', 'send_receipt']`.

What to notice:

- Each row of `TRANSITIONS` is one arrow of Figure 38.4, so reviewing the table against the diagram is mechanical.
- A false guard returns `False` without changing state; an event with no arrow raises. Distinguishing "not now" from "never in this state" helps callers respond correctly.
- The order of actions (exit, transition effect, entry) follows UML's run-to-completion semantics. For behavior that differs a lot per state, the State pattern (§37.15 and the vending machine in §38.10.4) replaces the table with one class per state.

38.7 Activity diagrams

38.7.1 Actions, forks, joins and swimlanes

> DEFINITION
>
> **Definition — Activity diagram.** A behavior diagram that models a workflow as **actions** connected by **control flows**, with **decision** and **merge** nodes for branching, **fork** and **join** bars for concurrency, and **activity partitions** (swimlanes) that assign actions to the participant responsible for them. Its semantics are based on tokens flowing through the graph, similar to a Petri net [OMG 2017].

First-principles explanation

A state diagram follows one object through its life; an activity diagram follows a piece of work through an organization. A recipe is an activity diagram: "boil water" and "chop vegetables" can happen in parallel (fork), both must finish before "add vegetables" (join), and "if the sauce is thick, add water" is a decision. Swimlanes add *who*: the chef chops, the kitchen porter boils.

How it works internally

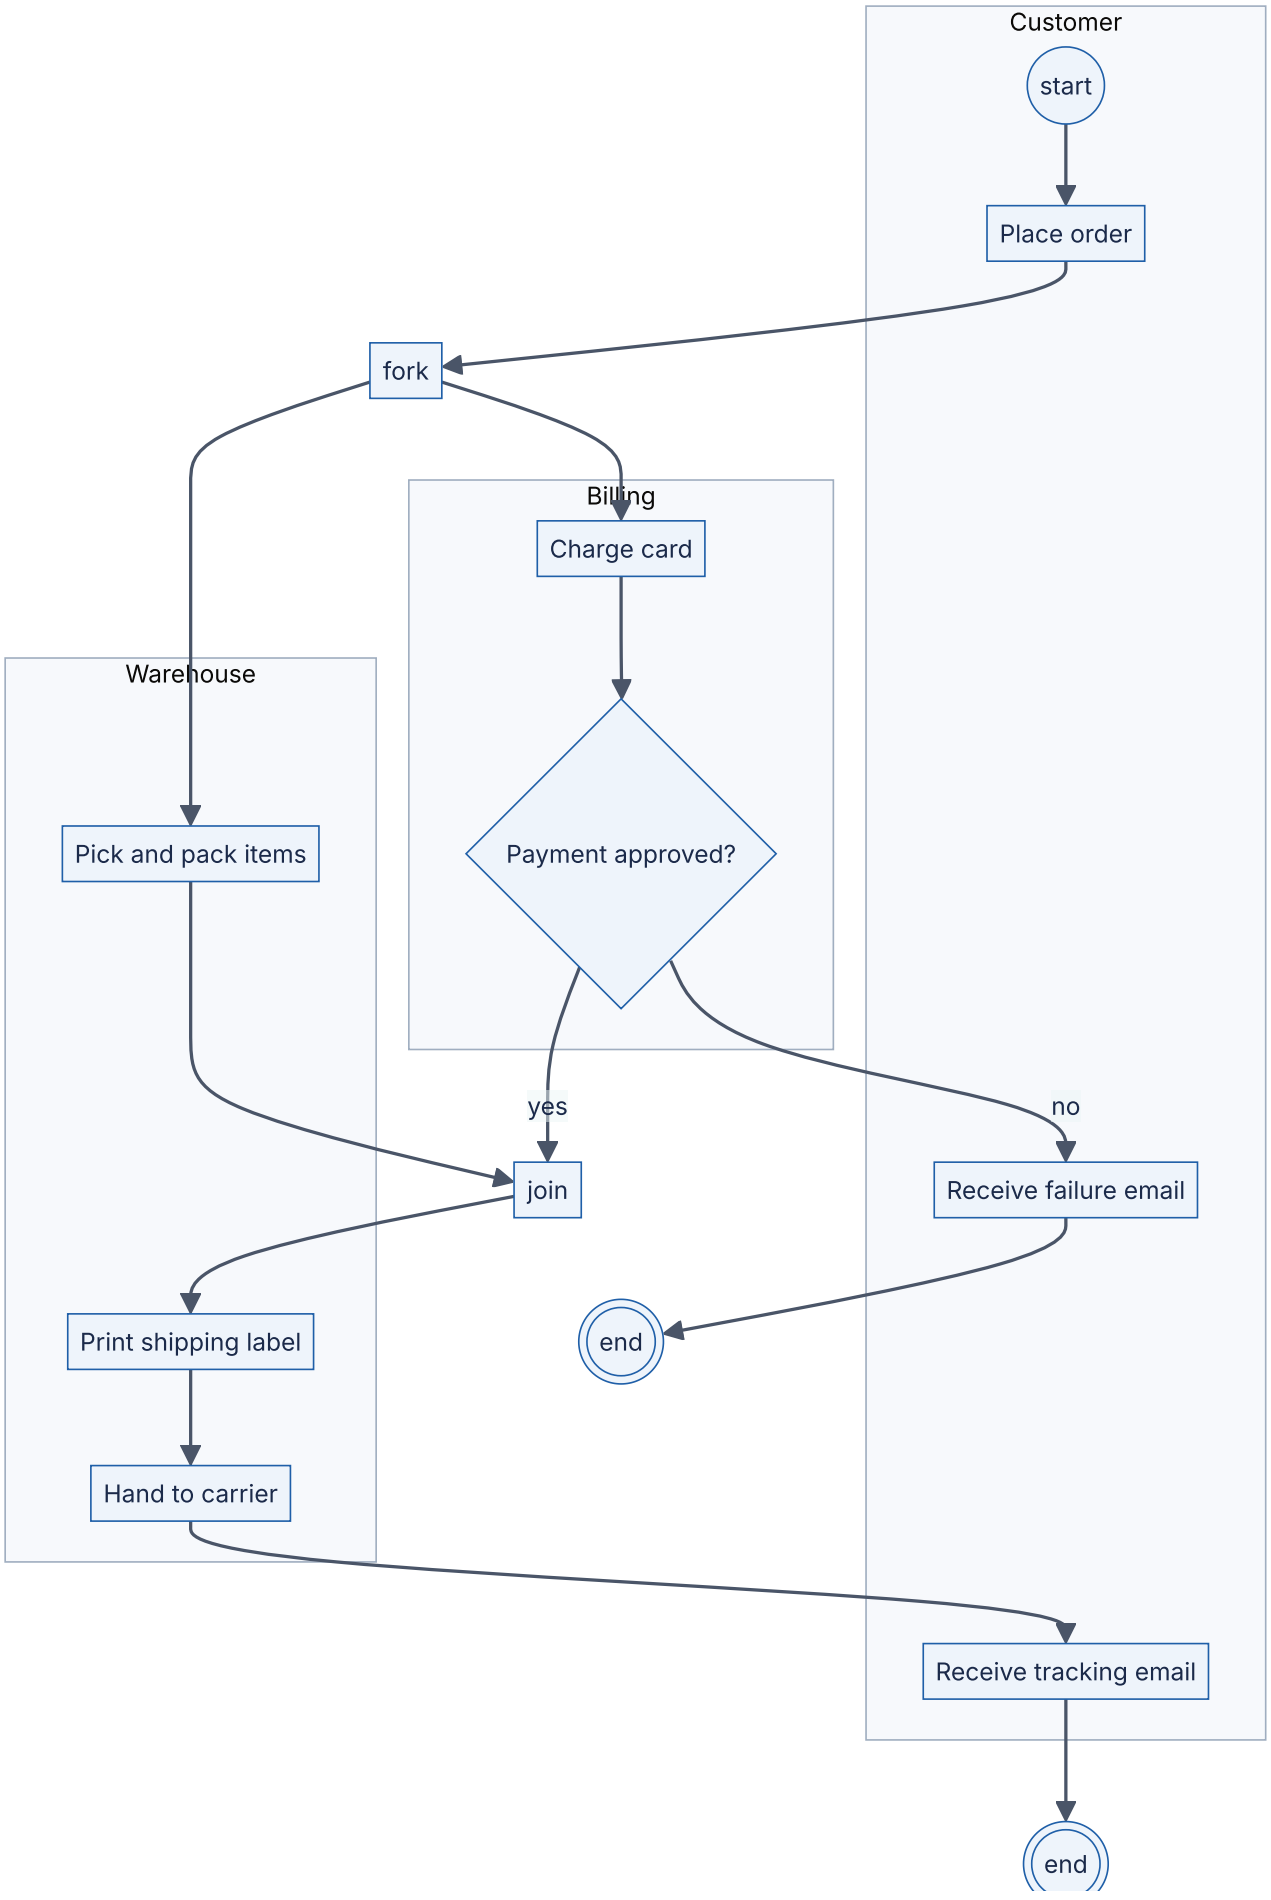
1. An initial node emits one token. Actions run when a token arrives and pass it on when they finish.
2. A **decision** sends the token down exactly one outgoing edge whose guard is true; a **merge** joins alternative paths without waiting.

3. A **fork** copies the token onto every outgoing edge, so those branches run concurrently. A **join** waits until a token has arrived on every incoming edge, then emits one.
4. An **activity final** node ends the whole activity; a **flow final** ends only the branch that reaches it.

Confusing a merge with a join is the classic error: a join after a decision waits forever for the branch that was never taken.

Mermaid has no activity diagram, so Figure 38.5 approximates UML notation with a flowchart: subgraphs are swimlanes, nodes labeled *fork* and *join* stand for the UML bars, and the circles are the initial and final nodes.

Figure 38.5 — Activity diagram for order fulfilment with swimlanes, fork and join (flowchart approximation of UML).



Customer
start
Place order
fork
Billing
Charge card
Payment approved?
Warehouse
Pick and pack items
yes
no
join
Receive failure email
Print shipping label
end
Hand to carrier
Receive tracking email
end

Reading the diagram. Three swimlanes assign responsibility: *Customer*, *Billing* and *Warehouse*. After the customer places the order, the fork starts two concurrent branches: billing charges the card while the warehouse picks and packs. The join waits for both: shipping must not start before payment is approved *and* the parcel is packed. If payment is declined, the decision routes to a failure email and an end node. A strict UML reading notes a subtle bug the diagram exposes: on the decline path the picked items are never returned to the shelf, and the join is never satisfied, so the warehouse branch is left dangling. A real design adds a compensating "restock items" action, which is the same reasoning as a saga's compensation (§32.7). Activity diagrams show no storage or protocols; they show ordering and concurrency, which is where workflow bugs hide.

Table 38.5 — Choosing a diagram for the question being asked.

Question	Diagram	Why not the others
What types exist and how are they coupled?	Class	Behavior diagrams hide structure
What happens, in what order, for one request?	Sequence	Class diagrams have no time axis
What are the replaceable parts and their contracts?	Component	Class diagrams are too fine-grained
Which events are legal for one object, and when?	State machine	Sequence diagrams show one path, not all legal ones
What is the workflow across roles, with parallel steps?	Activity	Sequence diagrams make parallelism and roles awkward
What does the data model look like in the database?	Entity-relationship (§11.17)	UML class diagrams can do it, but ER notation is the database convention

38.8 Object relationships in depth

38.8.1 Association, aggregation and composition

All three are structural links between objects that persist beyond a single method call; they differ in *ownership* and *lifetime*.

DEFINITION

Definition — Association, aggregation, composition. An **association** is a structural relationship in which instances of one class hold links to instances of another. **Aggregation** (UML "shared aggregation") is an association marked as whole–part, in which a part may be shared by several wholes and exists independently of them. **Composition** (UML "composite aggregation") is a whole–part association in which each part belongs to at most one whole at a time, and the whole is responsible for the part's existence: if the composite is deleted, its parts are deleted with it [OMG 2017].

First-principles explanation

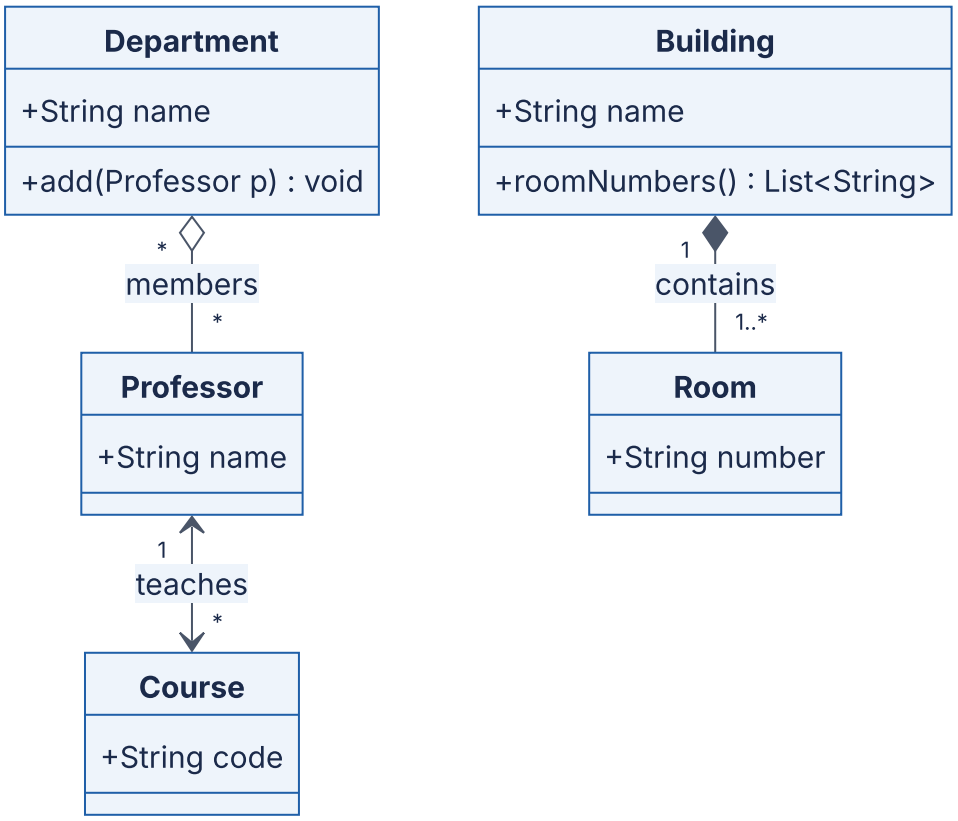
Three tests settle almost every case:

1. **Lifetime test.** If the whole is destroyed, must the part be destroyed too? A room cannot exist without its building: composition. A professor does not vanish when a department closes: not composition.
2. **Sharing test.** Can the part belong to two wholes at once? A professor can be in two departments: aggregation or plain association. A room is in exactly one building: composition.
3. **Creation test.** Who creates the part? If only the whole creates it and nobody outside holds a reference, it is composition. If the part is created elsewhere and handed in, it is aggregation or association.

Why does this matter?

The distinction decides concrete code questions: who constructs the object, whether it can be passed to the outside, whether deleting the parent must cascade (in the database, `ON DELETE CASCADE` for composition, a nullable foreign key or a join table for association), and whether the parent may expose its parts or only copies.

Figure 38.6 — Association, aggregation and composition in one model.



Reading the diagram. *Professor–Course* is a bidirectional **association** (arrowheads at both ends): each course has exactly one lecturer and a professor teaches any number of courses, and both sides can navigate to the other. *Department–Professor* is **aggregation** (hollow diamond at the department): professors are members of departments, may belong to several (multiplicity `*` at the department end), and outlive any department. *Building–Room* is **composition** (filled diamond): a room belongs to exactly one building and is created and destroyed with it. In storage terms the composition maps to a `rooms` table with a non-null `building_id` and `ON DELETE CASCADE`; the aggregation maps to a join table `department_members`. The failure point the diagram highlights is the bidirectional association: two references must be kept consistent, which is a frequent source of bugs.

Code example

```
        from __future__ import annotations

        class Professor:
            """Association: a Professor knows Courses and each Course knows its
Professor."""
            def __init__(self, name: str):
                self.name = name
                self.courses: list[Course] = []

        class Course:
            def __init__(self, code: str, lecturer: Professor):
                self.code = code
                self.lecturer = lecturer          # association end, multiplicity 1
                lecturer.courses.append(self)     # keep both ends consistent

        class Department:
            """Aggregation: professors are shared and outlive the department."""
            def __init__(self, name: str):
                self.name = name
                self.members: list[Professor] = []

            def add(self, p: Professor) -> None:
                self.members.append(p)            # the Professor was created elsewhere

        class Room:
            def __init__(self, number: str):
                self.number = number

        class Building:
            """Composition: the Building creates its Rooms; they never escape it."""
            def __init__(self, name: str, room_count: int):
                self.name = name
                self._rooms = [Room(f"{name}-{i}") for i in range(1, room_count + 1)]

            def room_numbers(self) -> list[str]:
                return [r.number for r in self._rooms]   # expose values, not the parts

        if __name__ == "__main__":
            ada = Professor("Ada")
            db = Course("CS145", ada)
            cs, math = Department("CS"), Department("Math")
            cs.add(ada); math.add(ada)                   # one part, two wholes: shared
            del cs                                       # the department goes away...
            print(ada.name, [c.code for c in ada.courses], len(math.members))  # ...Ada
does not
            hall = Building("Gates", 3)
            print(hall.room_numbers())
```

Output: `Ada ['CS145'] 1`, then `['Gates-1', 'Gates-2', 'Gates-3']`.

What to notice:

- Composition is expressed by *who creates* (`Building.__init__`) and *what escapes* (`room_numbers` returns strings, not `Room` objects). In a garbage-collected language nothing is "deleted"; composition means exclusive ownership and encapsulation.
- The bidirectional association needs code to keep both ends in sync (`lecturer.courses.append(self)`). Prefer one-directional associations unless both directions are genuinely navigated.
- Aggregation looks identical to association in code. The only difference is intent, documented by the diamond.

Table 38.6 — Association, aggregation and composition compared.

Aspect	Association	Aggregation	Composition
What it is	A lasting link between peers	Whole–part, shared part	Whole–part, exclusive part
Part lifetime	Independent	Independent	Bound to the whole
Part shared?	Yes	Yes	No (one whole at a time)
Who creates the part	Anyone	Usually outside the whole	The whole
UML symbol	Plain line or arrow	Hollow diamond at whole	Filled diamond at whole
Database mapping	Foreign key or join table	Join table, no cascade	Child table, `ON DELETE CASCADE`
Example	`Course` → `Professor`	`Playlist` ◇ `Song`	`Order` ◆ `LineItem`
Choose when	Objects collaborate as peers	You want to stress "collection of" without ownership	Part has no meaning outside the whole

NOTE

Note — aggregation is controversial. UML 2.5.1 itself says that the precise semantics of shared aggregation vary by application area and modeler [OMG 2017]. Fowler recommends ignoring aggregation altogether and quotes Jim Rumbaugh describing it as a "modeling placebo" [Fowler 2003]. In interviews, use composition when ownership matters and a plain association otherwise; if you draw a hollow diamond, be ready to say exactly what it adds.

38.8.2 Attribute or relationship?

UML treats an attribute and a navigable association as two notations for the same thing: a property of the class [OMG 2017; Fowler 2003]. `Order` with an attribute `customer :`

`Customer` means the same as a line from `Order` to `Customer`. The choice is about what you want the reader to notice.

1. **Value types are attributes.** Primitive values, enums, dates, and small immutable *value objects* such as `Money`, `Address` or `Coordinates` have no identity of their own (two `Money(5, "USD")` are interchangeable). Write them inside the box.
2. **Entities are relationships.** Classes with identity and their own lifecycle (`Customer`, `Product`, `ParkingSpot`) get a line, so multiplicity and ownership are visible.
3. **Relationships with data become classes.** If the link itself has properties, such as a student's grade in a course or a member's due date for a book, promote the link to an *association class* (`Enrollment`, `Loan`). In code it is always a class; in the database it is the join table.
4. **Collections of entities are always lines.** `items : List<LineItem>` hides the multiplicity and the composition that a filled diamond with `1..*` shows.

COMMON MISTAKE

Mistake — foreign keys in the class diagram. Writing `customerId : int` in `Order` copies the relational schema into the object model and hides the relationship. In a class diagram, draw the association; the identifier is a persistence detail that belongs in the entity-relationship diagram (§11.17).

38.9 The LLD interview method

38.9.1 What is being tested

DEFINITION

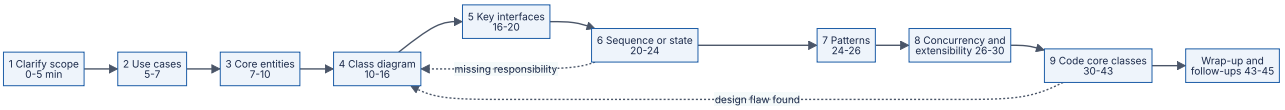
Definition — Low-level design (LLD) interview. A 45–60-minute interview in which you design the classes, interfaces, relationships and key algorithms of a single component or small application (a parking lot, an LRU cache, a rate limiter), usually ending with working or near-working code for the core classes. It is also called an *object-oriented design* or *machine coding* interview. It contrasts with the high-level design interview (§1.5, Chapter 87), which designs a distributed system out of services and data stores.

The interviewer is assessing whether you can turn a vague request into a clean object model, apply the principles of Chapters 35–37 without over-engineering, write correct code, and reason about concurrency and change. There is no single right answer; there are defensible and indefensible ones.

38.9.2 The nine steps

1. **Clarify requirements and scope (3–5 min).** Ask who the users are, which features are in scope, the scale (one lot or a chain of 500; one process or many), and what must *not* be built. Write the agreed functional requirements as a numbered list and two or three non-functional ones (thread safety, extensibility, latency).
2. **List use cases (2 min).** Actor plus verb: “driver parks vehicle”, “attendant views free spots”. Each later sequence diagram corresponds to one use case.
3. **Identify core entities (3 min).** Underline nouns in the requirements and keep those with behavior or identity. Discard synonyms and pure attributes (a “license plate” is an attribute of `Vehicle`, not a class).
4. **Draw relationships as a class diagram (5–7 min).** Add multiplicities and choose composition, association or inheritance deliberately (§38.8). Keep it to the 6–12 classes that matter.
5. **Define key interfaces (3–5 min).** Write the signatures of the public operations and the interfaces at variation points (allocation strategy, fee policy, storage). This is where Dependency Inversion (§36.7) shows.
6. **Sequence the main flows (3–5 min).** One sequence diagram (or a state diagram if the problem is lifecycle-heavy, such as a vending machine) for the most important use case. It validates the class diagram: every message must land on a class that owns that responsibility.
7. **Name the patterns you applied (2 min).** Strategy, State, Observer, Factory, Singleton: say *why* each earns its place and which change it absorbs [Gamma et al. 1994]. Do not add patterns to collect them.
8. **Address concurrency and extensibility (3–5 min).** Identify the shared mutable state, the critical sections and the lock granularity; then walk through two likely changes (a new vehicle type, a new pricing rule) and show which classes change.
9. **Code the core classes (12–15 min).** Write the domain model, the main operation end to end, and one test or driver that exercises it. Prefer correct and readable over complete.

Figure 38.7 — The LLD interview method with a 45-minute time budget.



Reading the diagram. The nine steps run left to right, each with a cumulative time window for a 45-minute slot. The solid arrows are the normal order. The two dotted arrows are feedback loops: drawing the sequence diagram often reveals a responsibility with no owner, and coding often reveals a flaw in the class diagram; in both cases you return briefly to step 4 and say so aloud, which interviewers read as a strength, not a weakness. The main failure points are the two ends: spending 15 minutes on requirements (no time

to code) or starting to code at minute 3 (no design to discuss). For a 60-minute slot, scale steps 4 and 9 most.

Table 38.7 — Time budget for a 45-minute LLD interview.

Minutes	Step	Output on the whiteboard or editor	Typical mistake
0–5	Clarify requirements	Numbered FR list, 2–3 NFRs, out-of-scope list	Assuming scope silently
5–7	Use cases	4–6 “actor verbs object” lines	Skipping, then forgetting a flow
7–10	Core entities	6–12 nouns with one-line responsibilities	Making every noun a class
10–16	Class diagram	Classes, relationships, multiplicities	Inheritance everywhere
16–20	Key interfaces	Signatures of public operations and strategies	Getters and setters only
20–24	Sequence or state diagram	One main flow including one failure branch	Drawing every flow
24–26	Patterns	2–4 named patterns with the reason for each	Pattern bingo
26–30	Concurrency and extensibility	Shared state, lock scope, two change scenarios	“Add a lock” with no scope
30–43	Code	Core classes, main operation, a driver or test	Boilerplate first, logic last
43–45	Wrap-up	Known limitations and next steps	Silence

38.9.3 How you are evaluated

Table 38.8 — LLD interview rubric.

Dimension	Below the bar	Meets the bar	Strong
Requirements	Starts designing immediately	Clarifies scope and lists FRs	Also surfaces NFRs, edge cases and explicit non-goals
Object model	God class or anemic data bags	Cohesive classes, sensible relationships	Clear ownership, value objects vs entities, justified multiplicities
Principles	Tight coupling to concrete classes	Interfaces at obvious variation points	Explains each choice in SOLID terms and avoids speculative generality
Patterns	None, or applied for their own sake	Appropriate pattern for the main variation	Names alternatives and why they lost
Code	Does not run or is mostly scaffolding	Core flow works, readable names	Runs, includes a test, handles failures and edge cases
Concurrency	Not considered	Identifies shared state and locks it	Discusses granularity, contention and atomic operations
Extensibility	Change requires editing many classes	One or two classes per change	Walks through concrete changes and their blast radius
Communication	Silent or unstructured	Explains while working	Drives the session, checks in, manages time

Calibrate by level: a junior candidate who meets the bar on the first five rows usually passes; a senior candidate is expected to be strong on concurrency and extensibility and to lead the discussion.

INTERVIEW TIP

Tip — say the trade-off, then pick. “I could model vehicle types with inheritance or with a `size` enum. Since the only difference is which spots fit, I’ll use the enum and avoid a class hierarchy with no behavior.” That sentence earns more credit than either choice alone.

Table 38.9 — Failure scenarios in an LLD interview.

What goes wrong	Why	Detection	Recovery	Prevention
No code at minute 40	Requirements and diagrams expanded to fill the time	Clock check at minute 25 shows step 6 unfinished	Code the single main operation; describe the rest	Announce the time plan at the start
Class explosion (20+ classes)	Every noun became a class; inheritance for each variant	Diagram no longer fits; many classes without behavior	Collapse variants into enums or strategies	Keep only nouns with behavior or identity
Interviewer asks for a change and many classes must change	Concrete dependencies, switch statements on type	Walking through the change touches 4+ classes	Introduce an interface at that variation point	Ask "what will change?" during step 5
Race condition pointed out	Shared mutable state with check-then-act	Two threads can both see a spot as free	Wrap check and act in one critical section	List shared state explicitly in step 8
Code does not run	Untested edge case or typo	Interviewer traces an example	Walk through a small example by hand	Write a 5-line driver early and grow it

38.10 LLD exercises

Each exercise follows the method of §38.9: requirements, a class diagram, one sequence or state diagram, runnable core code (tested with `python3`), the patterns used, and the extensions and follow-up questions interviewers ask. Exercises 1–4 are worked in full; 5–8 are more compact and focus on the one design decision that makes each problem interesting. All designs run in a single process; turning one into a distributed service is a high-level design question (Part X).

Table 38.10 — The eight exercises at a glance.

#	Problem	Core design decision	Main patterns	Concurrency concern
1	Parking lot	Spot allocation and pricing as pluggable policies	Strategy, Facade	Two cars claiming one spot
2	Elevator system	Dispatch policy separate from car state machine	Strategy, State machine	Hall calls from many panels
3	LRU cache	Hash map plus doubly linked list for O(1)	Interface + implementation	`get` mutates recency order
4	Vending machine	Behavior varies by state	State	Events during dispensing
5	Library system	Title versus physical copy; holds queue	Observer	Two members, one copy
6	Rate limiter	Algorithm behind an interface	Strategy, Decorator, Factory	Per-key atomic update
7	Key-value store	TTL expiry and nested transactions	Command-like write buffers	Commit atomicity, conflicts
8	Chess	Legal-move validation in layers	Polymorphism, Template-like hierarchy	Usually single-threaded

38.10.1 Exercise 1: Parking lot

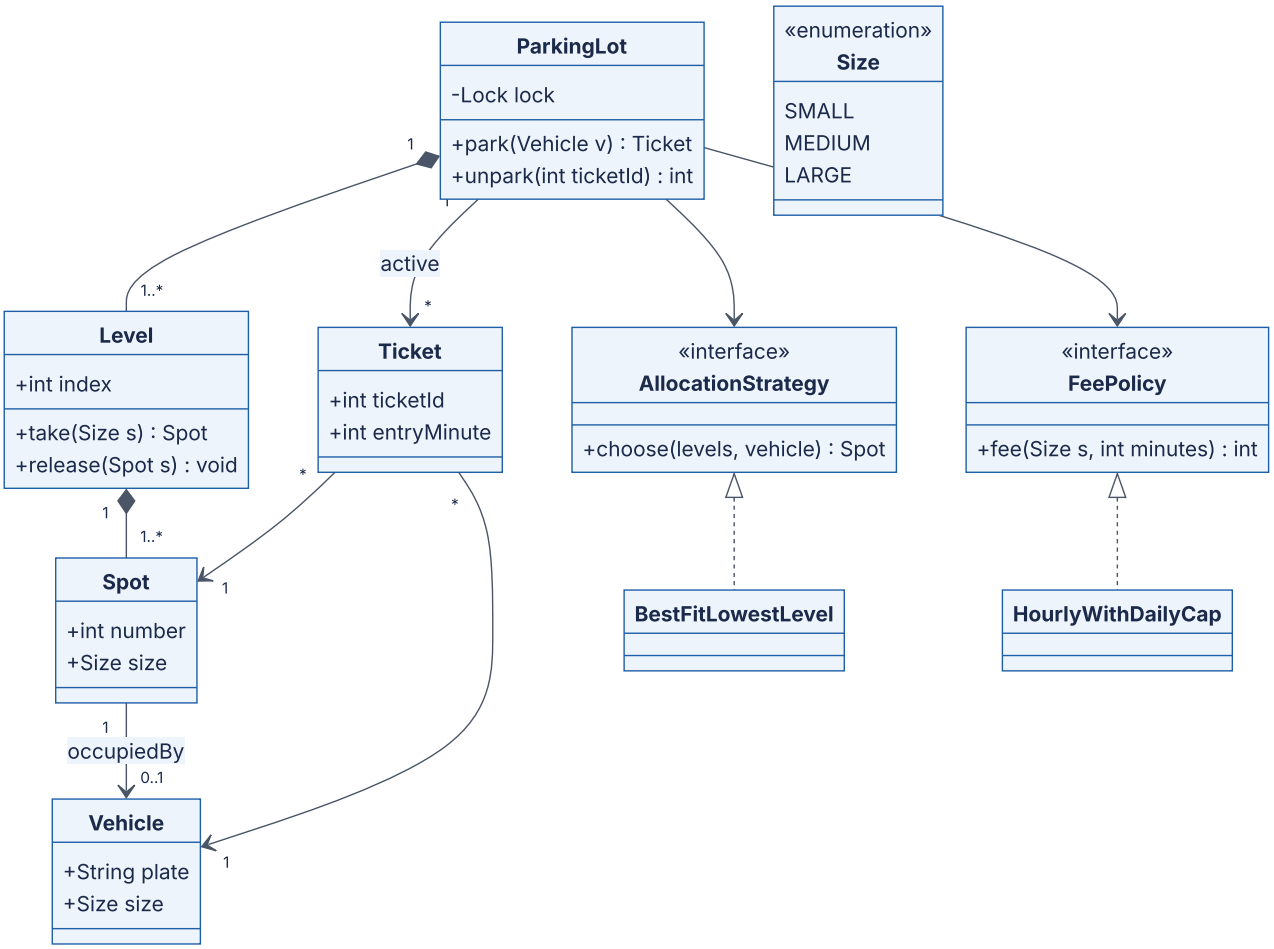
Requirements

Clarified with the interviewer:

1. A lot has several levels; each level has spots of three sizes: small (motorcycles), medium (cars) and large (vans and buses).
2. A vehicle may park in a spot of its size or larger. Choose the smallest fitting size first, then the lowest level, then the lowest spot number.
3. Entry issues a ticket; exit computes a fee from the vehicle size and the duration: an hourly rate with a daily cap.
4. Report “full” when no suitable spot exists. One vehicle (plate) cannot be parked twice.
5. Non-functional: thread safe (several gates operate concurrently); new allocation rules and pricing rules must not require changes to `ParkingLot`.

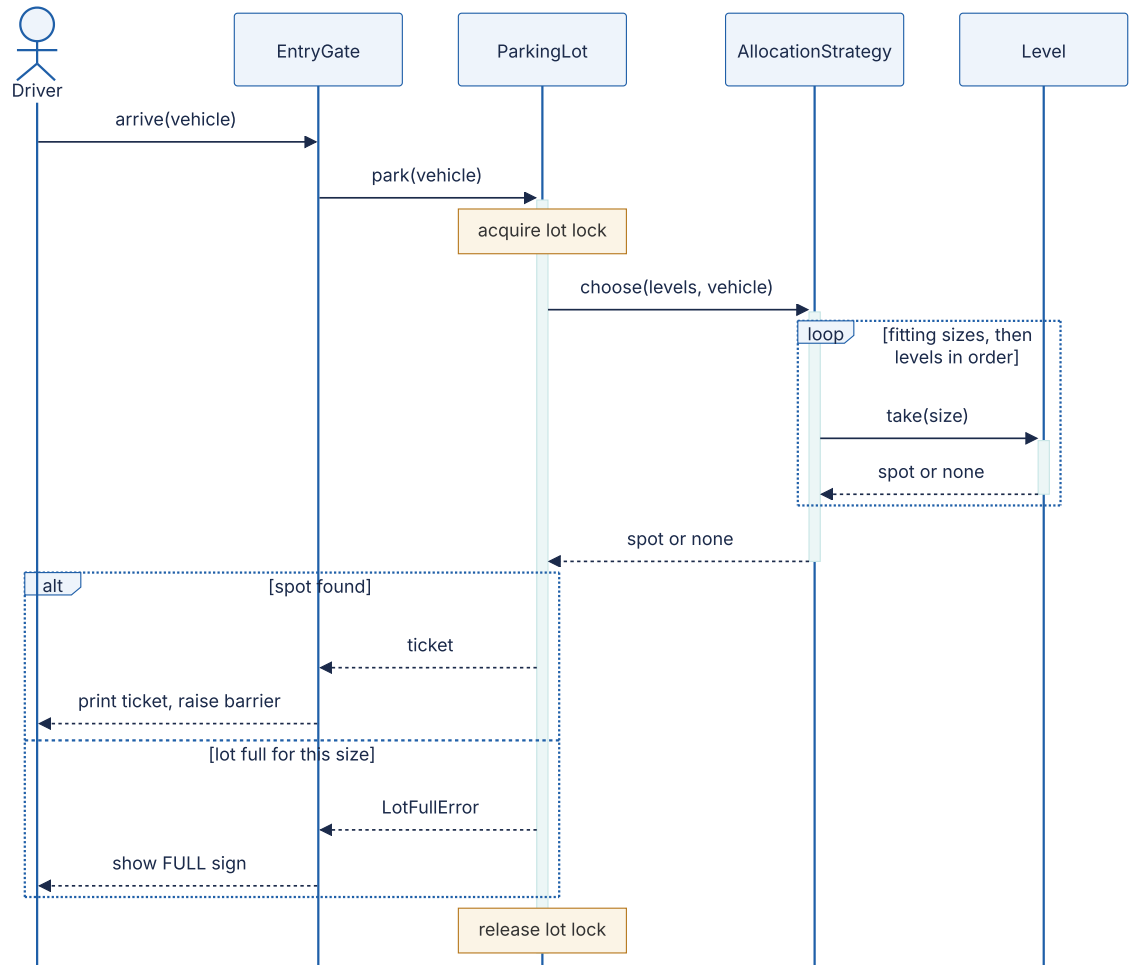
Out of scope: payment processing, reservations, physical sensors.

Figure 38.8 — Parking lot class diagram.



Reading the diagram. `ParkingLot` *composes* its levels and each `Level` composes its spots: they are created with the lot and meaningless without it. Vehicles and tickets are associations: a vehicle exists before and after parking. Each spot is occupied by at most one vehicle (`0..1`). The two interfaces are the variation points named in requirement 5: `AllocationStrategy` decides *which* spot, `FeePolicy` decides *how much*; the lot depends only on the interfaces (Dependency Inversion, §36.7). Vehicle kinds are a `Size` enumeration, not a subclass hierarchy, because the only behavior that differs is which spots fit. The single lock in `ParkingLot` is the concurrency boundary; there is no storage boundary in this in-memory design.

Figure 38.9 — Sequence diagram for parking a vehicle.



Reading the diagram. The entry gate calls `park` synchronously. The lot takes its lock *before* asking the strategy, so the search and the claim of the spot form one critical section: two gates cannot both receive the last medium spot. The strategy loops over fitting sizes and levels, asking each level to `take` a spot (a heap pop, which both finds and removes it). The `alt` fragment covers success (ticket printed) and the full case. The failure point is the lock: a strategy that does slow work (a database call, say) would serialize all gates, so strategies must be fast and in-memory. Scaling to a chain of lots means one `ParkingLot` per site, not one lock for all.

Mathematical foundations

FORMULA

Formula 38.1 — Parking fee with an hourly rate and a daily cap

$$F(t) = \left\lfloor \frac{t}{1440} \right\rfloor C + \min\left(C,\ r\left\lceil \frac{t \bmod 1440}{60} \right\rceil\right)$$

Symbol	Meaning	Units
$F(t)$	Fee charged at exit	dollars
t	Parked duration	minutes
r	Hourly rate for the vehicle size; each started hour is charged in full	dollars/hour
C	Daily cap for the vehicle size, charged for each full 24 hours	dollars/day
1440	Minutes in a day	minutes

WORKED EXAMPLE

Worked example — three exits. Rates: car $r = 4$, $C = 30$; van $r = 8$, $C = 60$.

1. Car, $t = 130$ min: full days $\lfloor 130/1440 \rfloor = 0$; started hours $\lceil 130/60 \rceil = 3$; $F = \min(30, 4 \times 3) = \$12$.
2. Car, $t = 540$ min: $\lceil 540/60 \rceil = 9$ hours; $4 \times 9 = 36 > 30$, so $F = \$30$.
3. Van, $t = 1,565$ min: one full day ($60) plus $1,565 - 1,440 = 125$ min; $\lceil 125/60 \rceil = 3$ hours; $\min(60, 8 \times 3) = 24$; $F = 60 + 24 = \$84$.

Interpretation. For cars the cap binds once $4h > 30$, that is from the 8th started hour (any stay over 420 minutes). **Engineering implication.** Pricing rules change often (weekend rates, grace periods, event pricing). Because they live behind `FeePolicy`, each new rule is a new class tested in isolation, and `ParkingLot` does not change (Open/Closed, §36.4). The code below reproduces all three numbers.

Code

```
        from __future__ import annotations

        import heapq
        import itertools
        import math
        import threading
        from abc import ABC, abstractmethod
        from dataclasses import dataclass
        from enum import IntEnum

        class Size(IntEnum):
            SMALL = 1    # motorcycle
            MEDIUM = 2   # car
            LARGE = 3    # van or bus

        @dataclass(frozen=True)
        class Vehicle:
            plate: str
            size: Size

        @dataclass
        class Spot:

C-7 -> 0 1
concurrent winners: 10
```

What to notice:

- Each level keeps a min-heap of free spot numbers per size, so finding *and* claiming a spot is $O(\log n)$ per level instead of a linear scan of all spots; with S sizes and L levels the search is $O(SL \log n)$, which is constant for a fixed building.
- The check ("is there a free spot?") and the act ("mark it occupied") happen under one lock. Splitting them is the classic check-then-act race (§6.9); the 50-thread test would then occasionally hand one spot to two cars.
- Time comes from an injected `clock`, so fees are testable without waiting hours; tickets are single-use because `unpark` pops them.

Patterns used

Strategy for allocation and pricing (§37.7); **Facade**: `ParkingLot` is the only class the gates talk to; **composition** for lot–level–spot ownership; value objects (`Vehicle`, `Ticket`) are immutable dataclasses.

Extensions and follow-up questions

- *Electric-vehicle spots with chargers?* Add a `features` set to `Spot` and a strategy that prefers matching features; nothing else changes.
- *Reduce lock contention with 20 gates?* Lock per level and let the strategy try levels in a gate-specific order; or keep free counts per level in atomics and lock only the chosen level. Measure first: at a few cars per second, one lock is not a bottleneck.
- *Display free spots per level in real time?* Have `ParkingLot` publish `SpotTaken` / `SpotFreed` events to display boards (Observer, §37.8).
- *Lost ticket?* Look up the active ticket by plate (the `_plates` set becomes a plate→ticket map) and charge per policy.

- *Multiple lots across a city?* That becomes a high-level design: a reservation service with a database per region; the LLD here is the per-lot component.

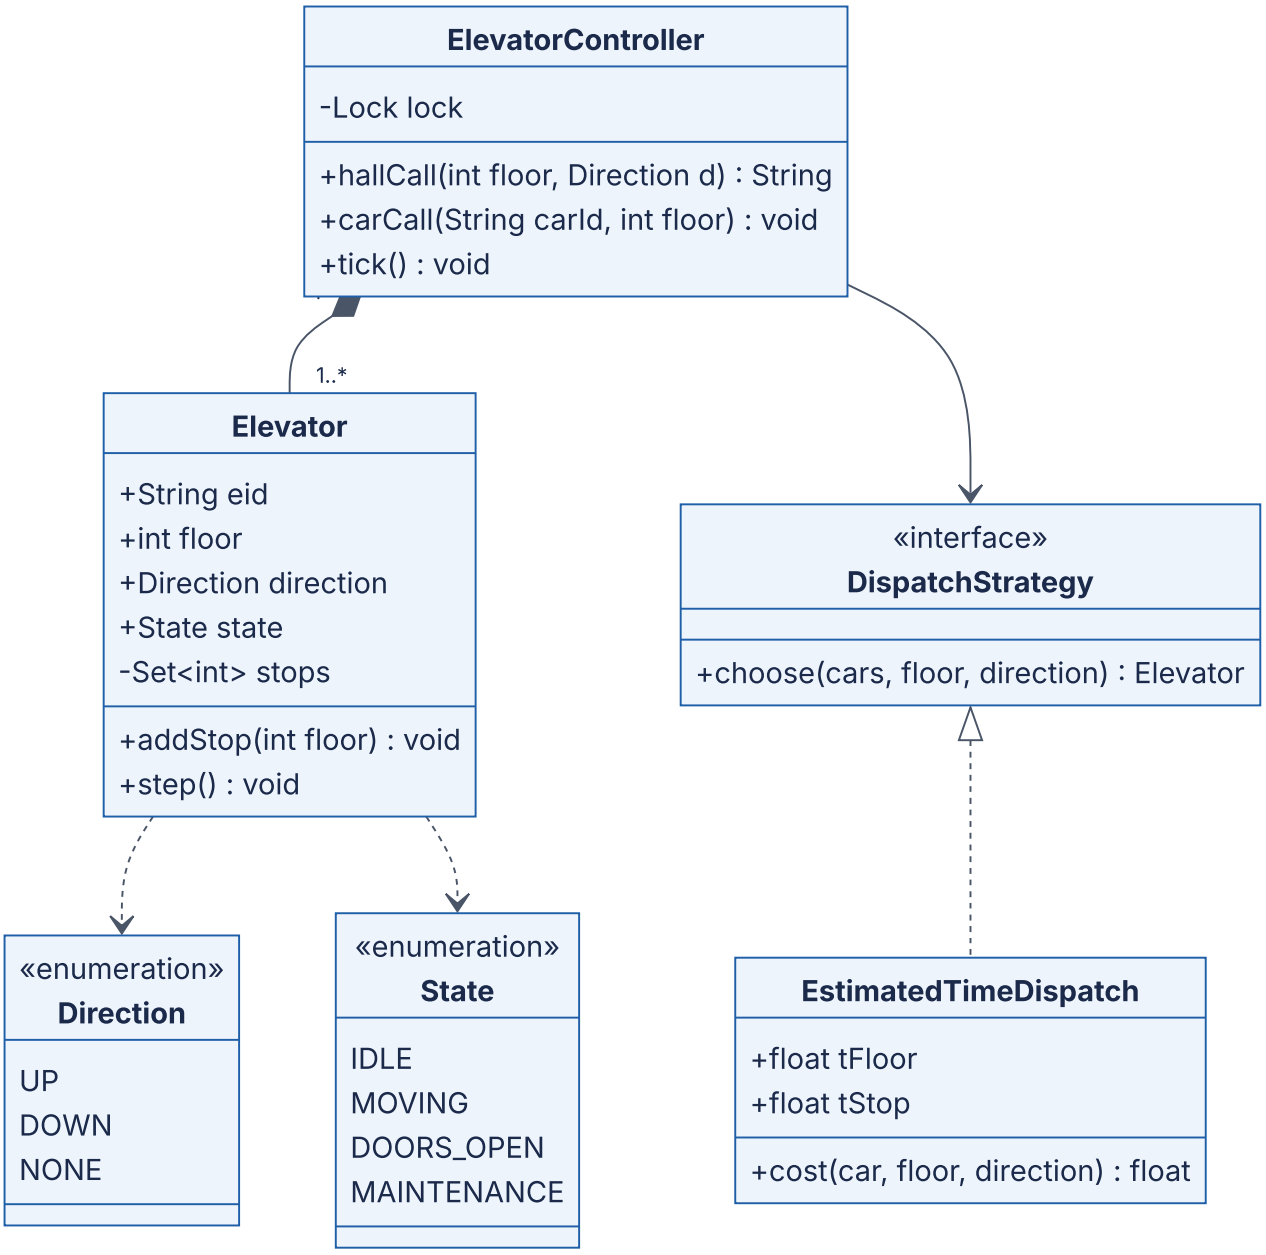
38.10.2 Exercise 2: Elevator system

Requirements

1. A building has *N* floors and *M* cars. Passengers press *hall calls* (floor plus direction) on each floor and *car calls* (destination) inside a car.
2. A dispatcher assigns each hall call to one car; the policy must be replaceable.
3. Each car serves its stops using the LOOK policy: keep moving in the current direction while stops remain ahead, then reverse; idle when there are no stops.
4. A car in maintenance is not dispatched.
5. Non-functional: hall calls arrive concurrently from many panels; the simulation must be deterministic for tests.

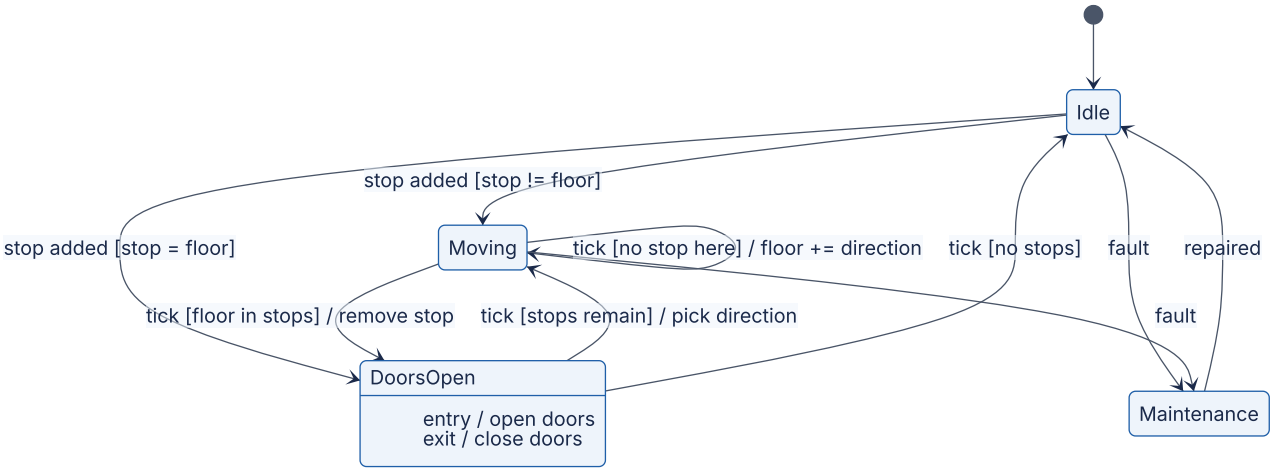
Out of scope: weight sensors, door obstruction, fire mode, energy optimization (all good follow-ups).

Figure 38.10 — Elevator system class diagram.



Reading the diagram. The `ElevatorController` composes the cars and owns the lock that serializes calls and ticks. *Which car* is decided by a `DispatchStrategy` (here `EstimatedTimeDispatch`); *how a car moves* is the car's own state machine (`step`). Keeping the two separate means you can swap in zoning or destination dispatch without touching car movement, and you can test each in isolation. A car's pending work is a set of stop floors. There is no storage boundary; the real-world failure points are a car that stops responding (mark it `MAINTENANCE` so the dispatcher skips it) and the controller itself, which in a real building has a hardware fallback.

Figure 38.11 — State machine of one elevator car.



Reading the diagram. A car starts *Idle*. When a stop is added it either opens its doors (the stop is the current floor) or starts *Moving*. Each tick while moving it either advances one floor or, if the current floor is a stop, removes the stop and enters *DoorsOpen*, whose entry action opens the doors and exit action closes them. Leaving *DoorsOpen* it re-applies LOOK: continue if stops remain, otherwise go *Idle*. A fault from *Idle* or *Moving* sends the car to *Maintenance* until repaired. There is deliberately no transition from *DoorsOpen* to *Moving* without passing the exit action, so a car can never move with open doors, the most important safety property in the whole design. In the code below, the guards are checked in `step()`, and the timed ticks are deterministic so tests do not depend on wall-clock time.

Mathematical foundations

FORMULA

Formula 38.2 — Estimated time for car e to reach a hall call r

$$T(e,r) = d \cdot t_{\text{floor}} + s \cdot t_{\text{stop}}, \qquad d = \begin{cases} |f_e - f_r| & \text{if } e \text{ is idle, or } f_r \text{ is ahead and } e \text{ moves in the call'} \\ |f_e - f_x| + |f_x - f_r| & \text{otherwise} \end{cases}$$

Symbol	Meaning	Units
$T(e,r)$	Estimated time until car e arrives at the caller	s
f_e, f_r	Current floor of the car; floor of the call	floor index
f_x	Farthest pending stop in the car's current direction (where it will turn around)	floor index
d	Floors the car travels before reaching the caller	floors
s	Pending stops on that path before the caller	stops
t_{floor}	Travel time per floor	s/floor
t_{stop}	Time lost per intermediate stop (decelerate, doors, accelerate)	s/stop

WORKED EXAMPLE

Worked example — hall call at floor 7 going up. $t_{\text{floor}} = 2$ s, $t_{\text{stop}} = 10$ s. Three cars:

1. Car A at floor 3, moving up, stops {5, 9}. The call is ahead and in A's direction: $d = |3 - 7| = 4$; stops before 7: {5}, $s = 1$. $T = 4 \times 2 + 1 \times 10 = 18$ s.
2. Car B at floor 10, moving down, stop {2}. B moves *toward* floor 7 but in the wrong direction, so it finishes its sweep first: $f_x = 2$, $d = |10 - 2| + |2 - 7| = 8 + 5 = 13$; $s = 1$ (floor 2). $T = 13 \times 2 + 10 = 36$ s.
3. Car C idle at floor 1: $d = 6$, $s = 0$, $T = 6 \times 2 = 12$ s.

The dispatcher picks C (12 s), even though A is closer (4 floors versus 6). **Interpretation.** Stops cost more than distance: one stop (10 s) equals five floors of travel. **Engineering implication.** "Nearest car" is the wrong heuristic; minimize estimated arrival time instead, and keep the policy behind an interface, because real buildings tune t_{stop} and add penalties (for example for a car that is nearly full).

            print("assigned to:", ctl.hall_call(7, Direction.UP))
            ctl.car_call("A", 2)                          # 2 is behind A: served on the
way back
            for _ in range(40):
                ctl.tick()
            print({car.eid: car.served for car in (a, b, c)})
            assert a.served == [5, 9, 2] and b.served == [2] and c.served == [7]
```

Output:

```
costs for hall call 7 UP: {'A': 18.0, 'B': 36.0, 'C': 12.0}
assigned to: C
{'A': [5, 9, 2], 'B': [2], 'C': [7]}
```

What to notice:

- Car A receives a car call for floor 2 while moving up; LOOK finishes the upward sweep (5, 9) before reversing, which is why it serves `[5, 9, 2]` rather than turning back immediately.
- `cost()` implements Formula 38.2 directly, so the worked example doubles as a unit test.
- The controller lock covers both dispatch and ticks, so a hall call can never be assigned on the basis of a car's half-updated state.

Patterns used

Strategy for dispatch; an explicit **state machine** for each car (an enum plus guarded transitions in `step`; with more states and per-state behavior, refactor to the State pattern of §38.10.4); **composition** of cars in the controller.

Extensions and follow-up questions

- *Hall calls should only be served by a car going the same way.* Store stops as `(floor, direction)` and let a car skip opposite-direction hall stops on the current sweep.
- *Peak-hour zoning.* A `ZonedDispatch` strategy assigns cars to floor bands at 08:30–09:30; select the strategy by time of day (a strategy that delegates to others).
- *Destination dispatch* (passengers enter their destination in the lobby): the dispatcher now sees both ends of each trip and can group passengers by destination; the car model is unchanged.
- *Starvation:* a call that is always outbid by newer calls. Add an age term to the cost or a maximum wait that forces assignment.
- *Real-time control:* replace the discrete tick with an event-driven controller (arrival sensors), keeping the same state machine.

38.10.3 Exercise 3: LRU cache

Requirements

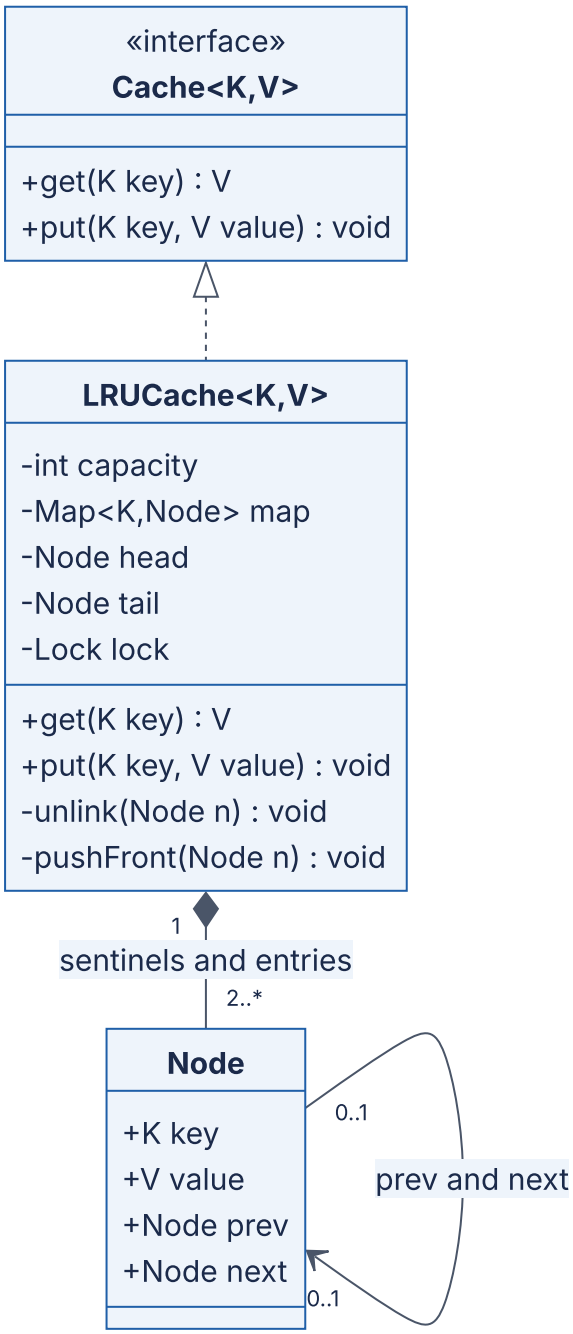
1. `get(key)` returns the value or a miss; `put(key, value)` inserts or updates.
2. Fixed capacity n; when full, `put` of a new key evicts the **least recently used** entry. Both reads and writes count as use.
3. Both operations in $O(1)$ time.
4. Thread safe; expose hit, miss and eviction counts.

The policy itself and its hit-ratio behavior are covered in §20.9; here the question is the data structure and the class design.

Why a hash map plus a doubly linked list

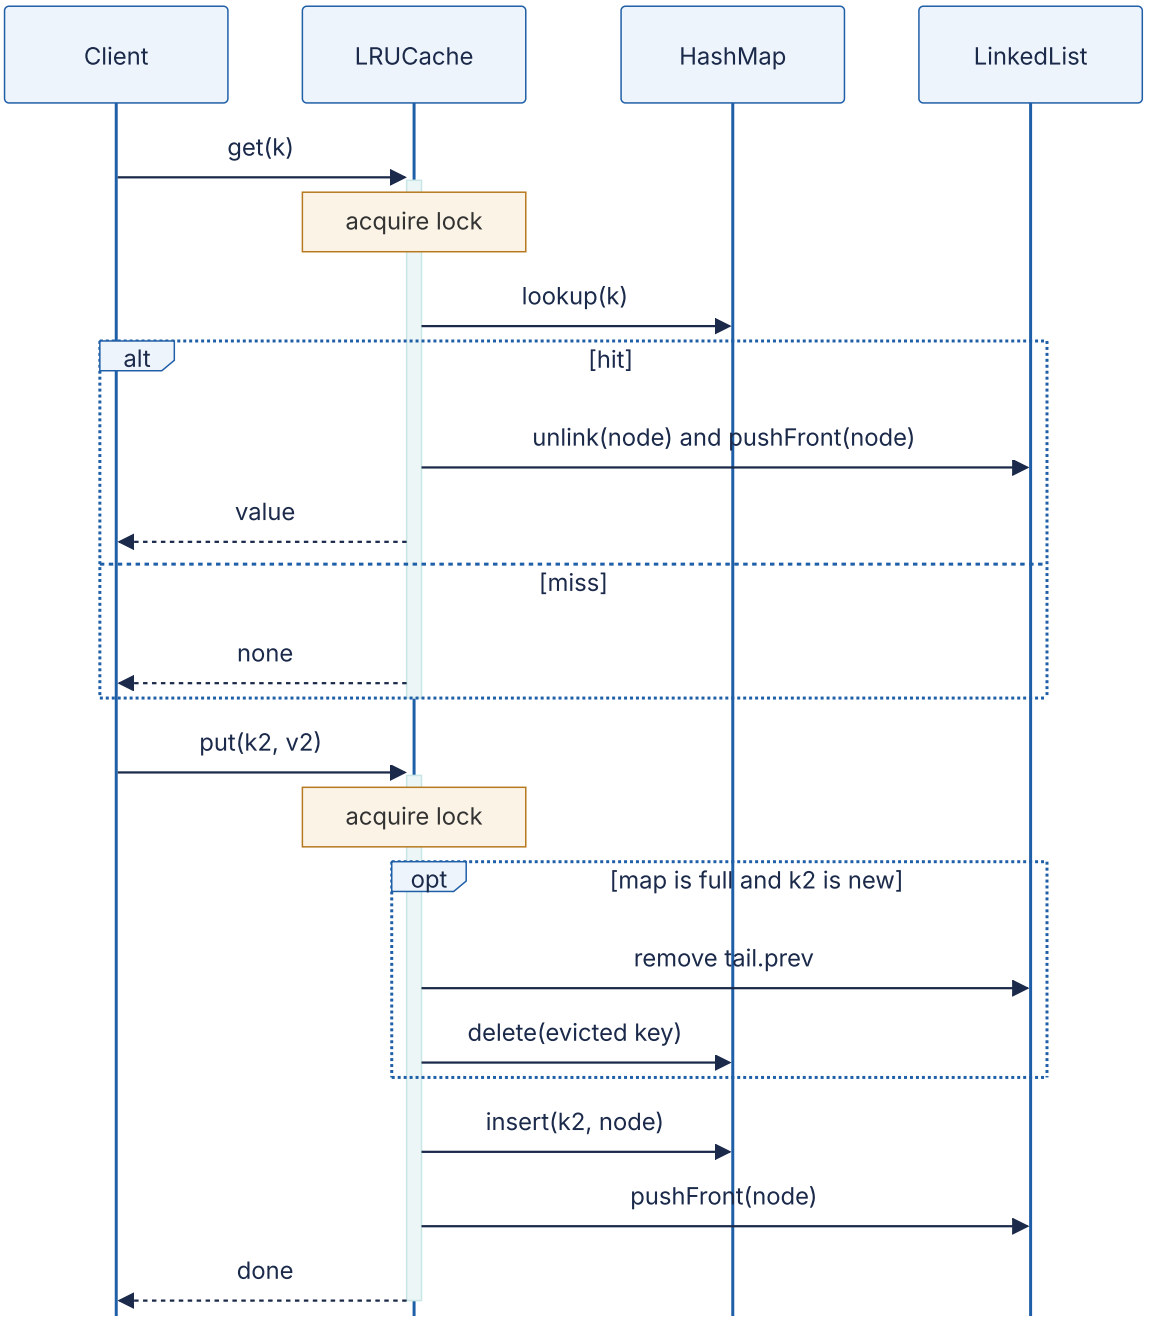
A hash map alone gives $O(1)$ lookup but no order. A list alone keeps order but finding a key is $O(n)$. Combined, the map stores `key → node` and the list keeps nodes in recency order: on each access you unlink the node (constant time, because a *doubly* linked node knows its predecessor) and move it to the front; to evict you remove the node before the tail. Two **sentinel** nodes at head and tail remove every empty-list special case.

Figure 38.12 — LRU cache class diagram.



Reading the diagram. Clients depend on the generic `Cache` interface, so an LFU or TinyLFU implementation (§20.9.3) can replace the LRU without changing them. `LRUCache` composes its nodes (at least the two sentinels, hence `2..*`); nodes are never handed out. Each node links to its neighbors in both directions, which is what makes unlinking $O(1)$. The private `unlink` and `pushFront` are the only list operations, and both assume the lock is held. The single lock is the concurrency boundary; there is no storage boundary, since the cache is in memory.

Figure 38.13 — Sequence diagram for get and put, including eviction.



Reading the diagram. `get` takes the lock, looks the key up in the map and, on a hit, moves the node to the front before returning; a miss changes nothing. `put` of a new key into a full cache first evicts the node before the tail sentinel and deletes its key from the map, then inserts and links the new node. All calls are synchronous and in memory. The failure point the diagram makes visible: `get` *writes* to the list, so it needs the same exclusive lock as `put`; a read-write lock that lets readers share would corrupt the list.

Code

```
        from __future__ import annotations

        import threading
        from abc import ABC, abstractmethod
        from typing import Generic, Hashable, Optional, TypeVar

        K = TypeVar("K", bound=Hashable)
        V = TypeVar("V")

        class Cache(ABC, Generic[K, V]):                    # the interface clients de-
pend on
            @abstractmethod
            def get(self, key: K) -> Optional[V]: ...
            @abstractmethod

                with self._lock:
                    out, n = [], self._head.next
                    while n is not self._tail:
                        out.append(n.key)
                        n = n.next
                    return out

        if __name__ == "__main__":
            c = LRUCache[str, int](3)
            for k, v in [("a", 1), ("b", 2), ("c", 3)]:
                c.put(k, v)
            c.get("a")                                      # a becomes most recent
            c.put("d", 4)                                   # evicts b, the least re-
cent
            print(c.keys_mru_to_lru(), c.get("b"))
            assert c.keys_mru_to_lru() == ["d", "a", "c"] and c.get("b") is None

            # Stress: 8 threads x 20,000 mixed operations; invariants must hold after-
wards.
            import random
            big = LRUCache[int, int](100)
            def worker(seed):
                rng = random.Random(seed)
                for _ in range(20_000):
                    k = rng.randrange(300)
                    if rng.random() < 0.7:
```

```
                        big.get(k)
                    else:
                        big.put(k, k * k)
            ts = [threading.Thread(target=worker, args=(s,)) for s in range(8)]
            for t in ts: t.start()
            for t in ts: t.join()
            order = big.keys_mru_to_lru()
            assert len(order) == len(big._map) == 100 and set(order) == set(big._map)
            assert all(big._map[k].value == k * k for k in order)
            total = big.hits + big.misses
            print(f"ops={total} hit ratio={big.hits / total:.2f} evictions={big.evic-
tions}")
```

Output: `['d', 'a', 'c'] None`, then a line such as `ops=111952 hit ratio=0.33 evictions=32220` (`ops` counts only the `get` calls, about 70% of the 160,000 operations; the exact numbers vary with thread scheduling, while the invariants are asserted).

What to notice:

- Every operation does a constant number of map operations and pointer swaps: $O(1)$ time. Memory is one node per entry plus a map slot, roughly 100–200 bytes of overhead per entry in CPython, which matters when n reaches millions.
- The stress test checks *structural* invariants after 160,000 concurrent operations: the list and the map hold the same 100 keys and every value is intact. Without the lock, two threads can interleave the pointer assignments of `_unlink` and `_push_front` and lose or duplicate nodes; CPython's global interpreter lock makes this rare but does not prevent it, and free-threaded builds make it likely.
- The hit ratio of about 0.33 is what theory predicts for uniformly random keys: capacity 100 over 300 keys. Real workloads are skewed and do much better (§20.3.3).

Concurrency options

One lock serializes all operations, which is fine up to a few million operations per second in a compiled language and far beyond what one CPython process can issue. Beyond that, **lock striping** splits the cache into k independent LRU segments keyed by `hash(key) mod k`, each with its own lock (approximate global LRU, near-linear scaling). Libraries such as Caffeine avoid locking on reads entirely by recording accesses in buffers and replaying them under a lock in batches. Neither changes the class design: both are new implementations of `Cache`.

INDUSTRY EXAMPLE

Standard-library LRU implementations. CPython's `functools.lru_cache` (pure-Python fallback in `Lib/functools.py`) uses exactly this structure: a dictionary from key to link and a circular doubly linked list with a root sentinel, guarded by a lock. Java's `LinkedHashMap` constructed with `accessOrder = true` maintains entries in access order, and its documentation recommends overriding `removeEldestEntry` to build an LRU cache. *Evidence: Primary* — [Python Software Foundation: functools source; Oracle: LinkedHashMap]

Extensions and follow-up questions

- *Use `OrderedDict`?* Yes in production Python (`move_to_end`, `popitem(last=False)`); the interviewer usually wants the underlying structure first.
- *Add TTL.* Store an expiry in each node and treat expired entries as misses (lazy expiry); combine with Exercise 7's sweeper.
- *Evict by size in bytes rather than count.* Track a running byte total and evict from the tail until the new entry fits.
- *Prevent one scan from flushing the cache.* Segmented LRU or W-TinyLFU (§20.9.3), behind the same interface.

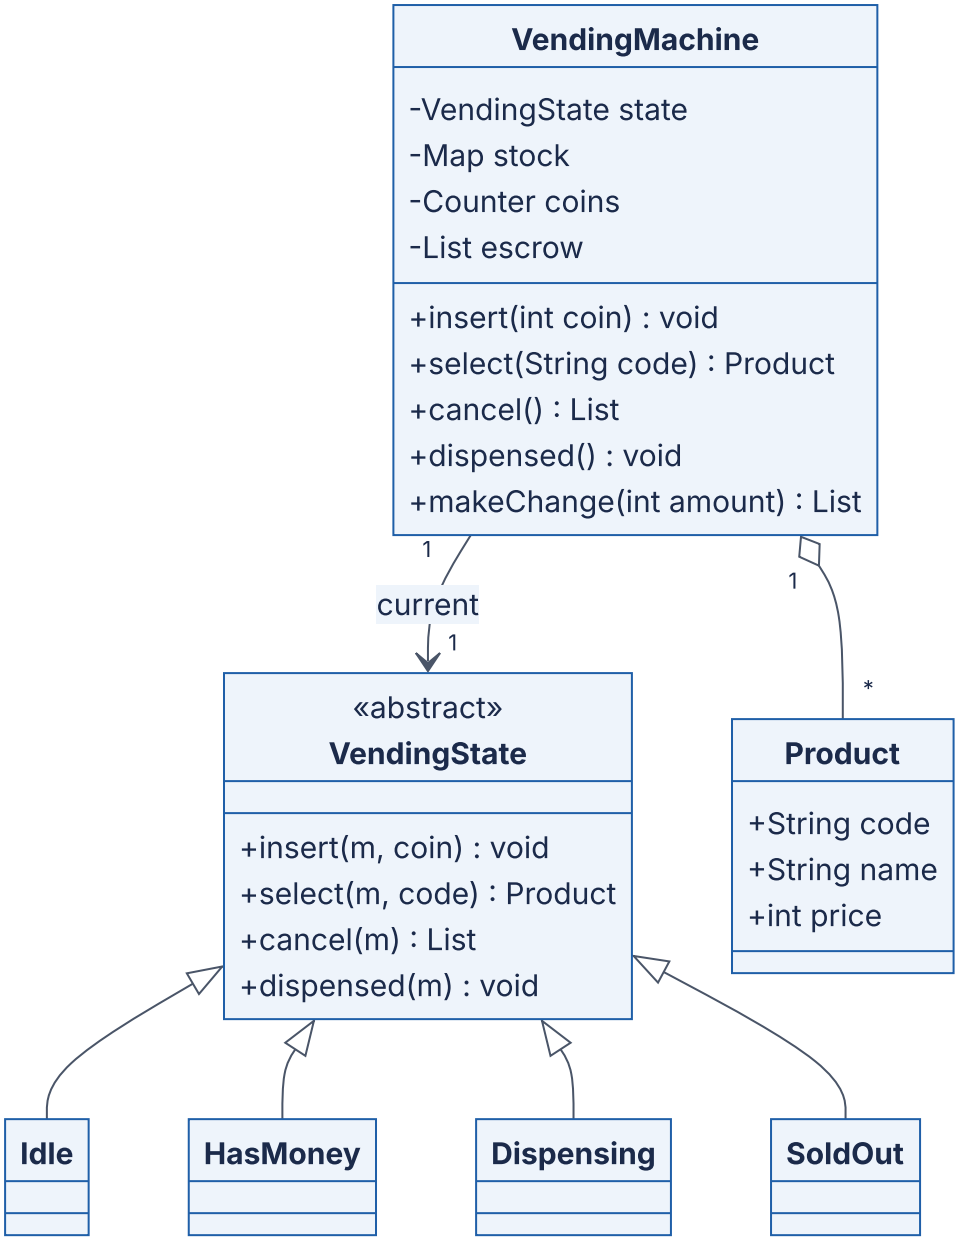
38.10.4 Exercise 4: Vending machine

Requirements

1. Customers insert coins (5, 10, 25 and 100 cents), select a product by slot code, receive the product and change, or cancel for a full refund.
2. A selection fails with a clear message if the slot is empty, the balance is short, or the machine cannot make change.
3. While the motor is dispensing, all input is rejected; when every slot is empty the machine is *sold out*.
4. Extensible: adding a state (for example *maintenance*) must not require editing every method of the machine.

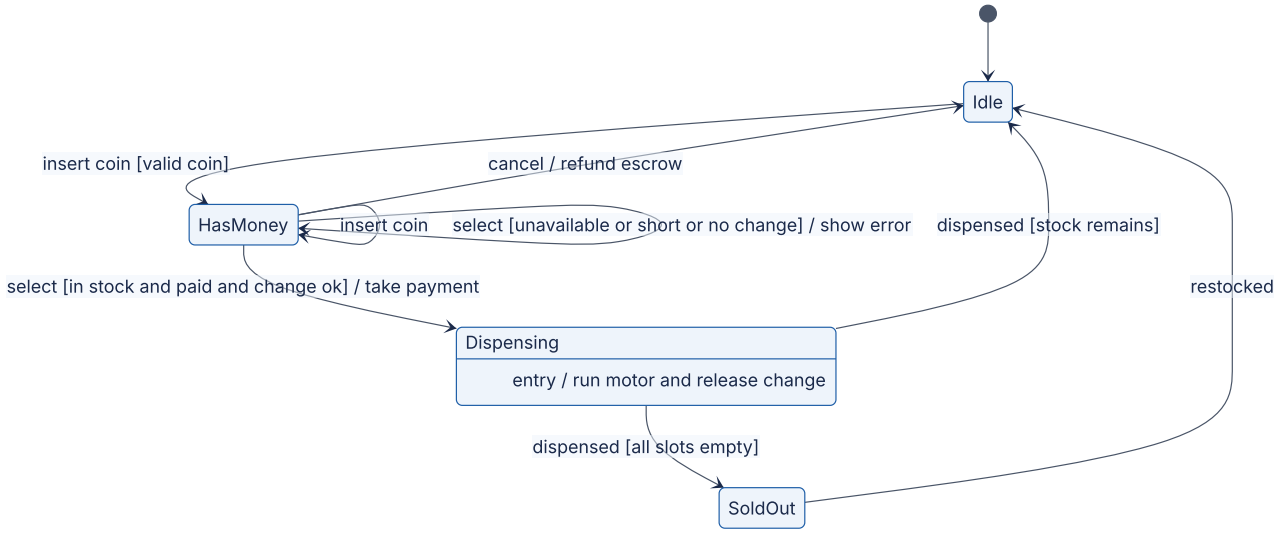
The fourth requirement is the reason for the **State pattern** (§37.15). Behavior depends heavily on state, and the naive implementation, one `if state == ...` chain in every method, grows with states × events and scatters each state's rules across the class.

Figure 38.14 — Vending machine class diagram (State pattern).



Reading the diagram. `VendingMachine` is the pattern's *Context*: its public methods forward every event to the current `VendingState` object. The abstract state rejects every event by default; each concrete state overrides only the events that are legal in it and decides the next state. Adding *Maintenance* means one new subclass and the transitions into it. Products are aggregated (the catalog is configured from outside). The coin box and escrow (coins inserted for the current purchase) are the machine's money state, and keeping escrow separate from the coin box is what makes `cancel` a simple refund.

Figure 38.15 — Vending machine state diagram.



Reading the diagram. From *Idle*, a valid coin moves the machine to *HasMoney*, where more coins accumulate. A selection that fails one of its guards leaves the state unchanged and shows an error; a successful one takes payment and enters *Dispensing*, whose entry action drives the motor and returns change. Only the `dispensed` event from the motor sensor leaves *Dispensing*, so coins or selections made mid-vend are rejected. When the last item is sold the machine goes to *SoldOut* until restocked. The failure point is the motor: if `dispensed` never arrives, the machine is stuck, so a real controller adds a timeout transition to a *Fault* state with a refund.

            product, change = vm.select("A1")                # 100 - 65 = 35 -> 25 + 10
            print(product.name, "change", change, "state", vm.state.name)
            try:
                vm.insert(25)
            except InvalidAction as e:
                print("dispensing:", e)
            vm.dispensed()
            print("state", vm.state.name, "coin box", dict(vm.coins))
            assert change == [25, 10] and vm.state.name == "sold_out"
```

Output:

```
idle: cannot select while idle
idle: nothing is being dispensed while idle
balance 100 state has_money
has_money: B2 unavailable
Water change [25, 10] state dispensing
dispensing: cannot insert coins while dispensing
state sold_out coin box {25: 1, 10: 1, 5: 2, 100: 1}
```

What to notice:

- `VendingMachine` contains no conditionals on state; each rule lives in exactly one state class (Single Responsibility per state, Open/Closed for new states).
- `make_change` may use the coins just inserted, which matters when the coin box is nearly empty.
- Greedy change-making is optimal for unlimited US-style coins but can fail with *limited* coins: to return 30 cents from {one 25, three 10s}, greedy takes the 25 and then cannot make 5, although 10 + 10 + 10 works. A dynamic-programming search over available counts fixes it; the interface does not change.

Patterns used

State (§37.15) for behavior by state; the machine is the Context; states are stateless and could be shared singletons.

Extensions and follow-up questions

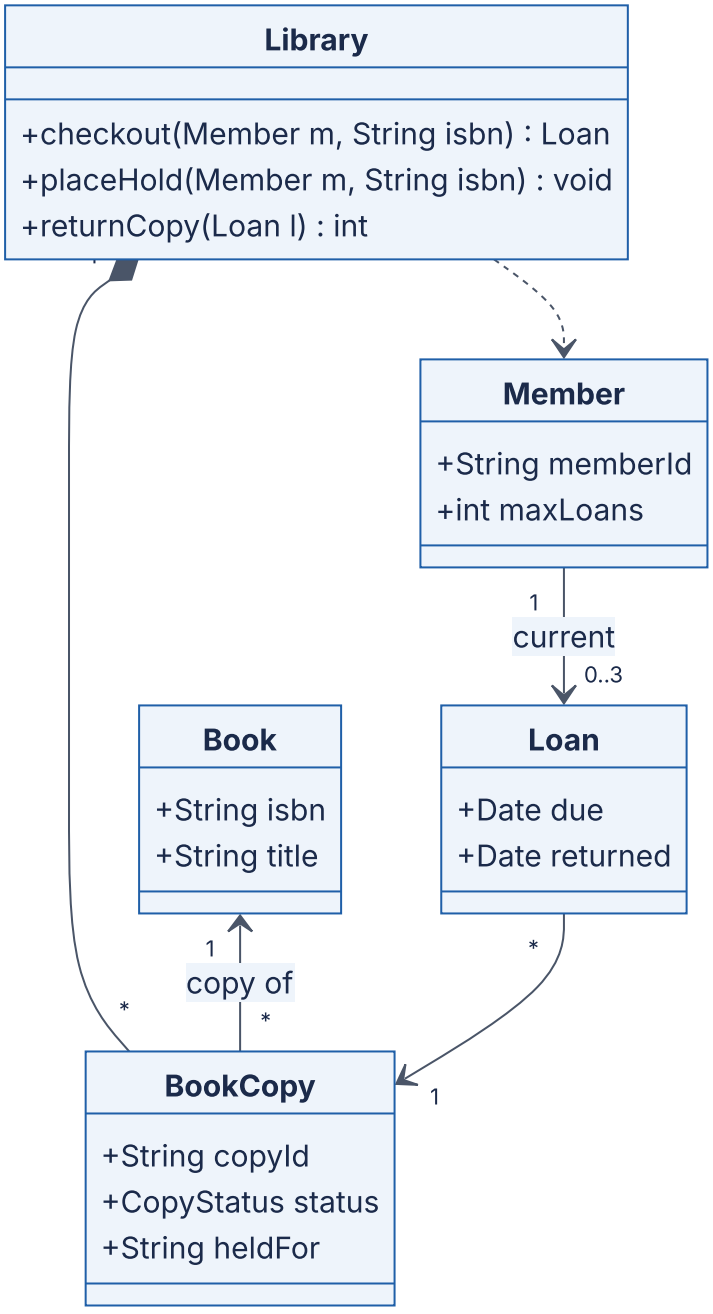
- *Card payments?* A `PaymentMethod` strategy; the *HasMoney* state becomes *Authorized* for cards.
- *Concurrency?* A physical machine has one user, but its controller receives events from buttons, the coin mechanism and the motor; serialize them through one event queue rather than locks in every state.
- *Remote telemetry and restocking alerts?* Observer on stock changes.
- *Why not the transition table of §38.6?* A table suits uniform behavior; the State pattern suits states with substantially different logic. Both are defensible; say which and why.

38.10.5 Exercise 5: Library management system

Requirements. Members borrow and return physical copies of books (21-day loans, at most 3 at a time); a late return is fined 25 cents per day, capped at $10; when no copy is available a member places a hold, and the next returned copy is set aside for the first member in the queue, who is notified.

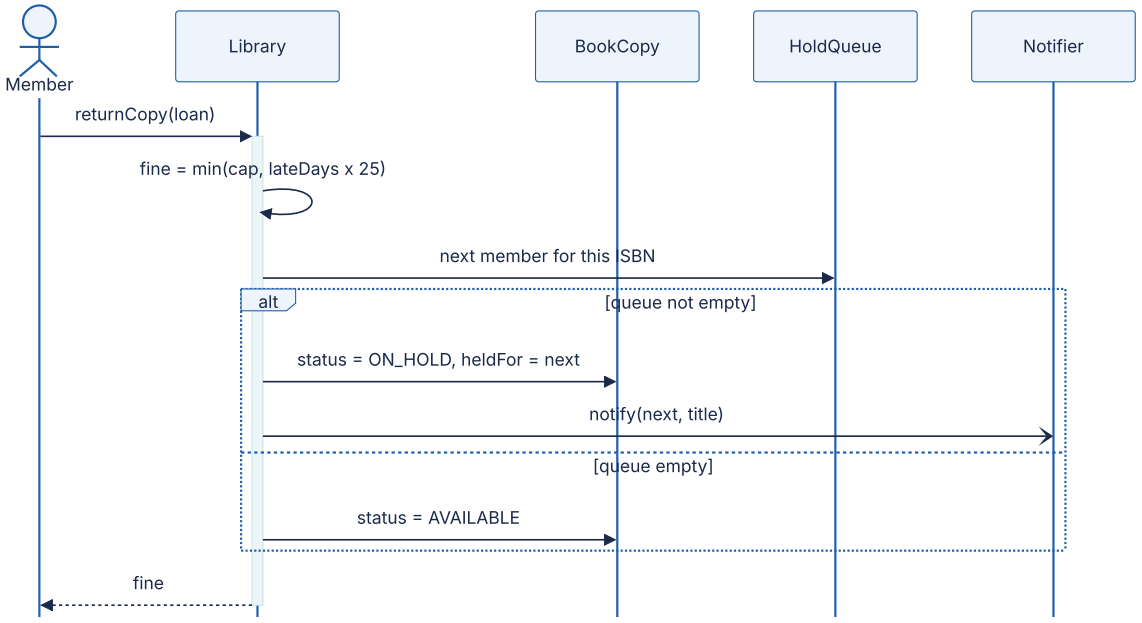
The key modeling decision is separating the *title* (`Book`, one per ISBN) from the *physical item* (`BookCopy`, many per title). Candidates who merge them cannot express "the library owns four copies of this book, two are on loan", and the hold queue belongs to the title, not to a copy. Librarians call the same distinction *manifestation* versus *item* [IFLA 1998]. `Loan` is an association class (§38.8.2) between member and copy that carries the due date.

Figure 38.16 — Library class diagram.



Reading the diagram. Each `BookCopy` refers to one `Book`; one book has many copies. A `Member` has at most three current `Loan`s, and each loan refers to exactly one copy. The library owns its copies and the hold queues (a FIFO of member IDs per ISBN, kept as an attribute in the code). In a database this becomes `books`, `copies`, `members`, `loans` and `holds` tables; the concurrency hazard is two checkouts of the last copy, solved with a conditional update on the copy's status.

Figure 38.17 — Sequence diagram for returning a copy that has a waiting hold.



Reading the diagram. Returning computes the fine, then checks the title's hold queue. If someone is waiting, the copy is set aside for them and a notification is sent *asynchronously* (an e-mail must not block the return desk); otherwise the copy becomes available. A later checkout by anyone other than the holder is refused.

            except LookupError as e:
                print("cat:", e)
            print("bob gets", lib.checkout(bob, sicp.isbn).copy.copy_id)
```

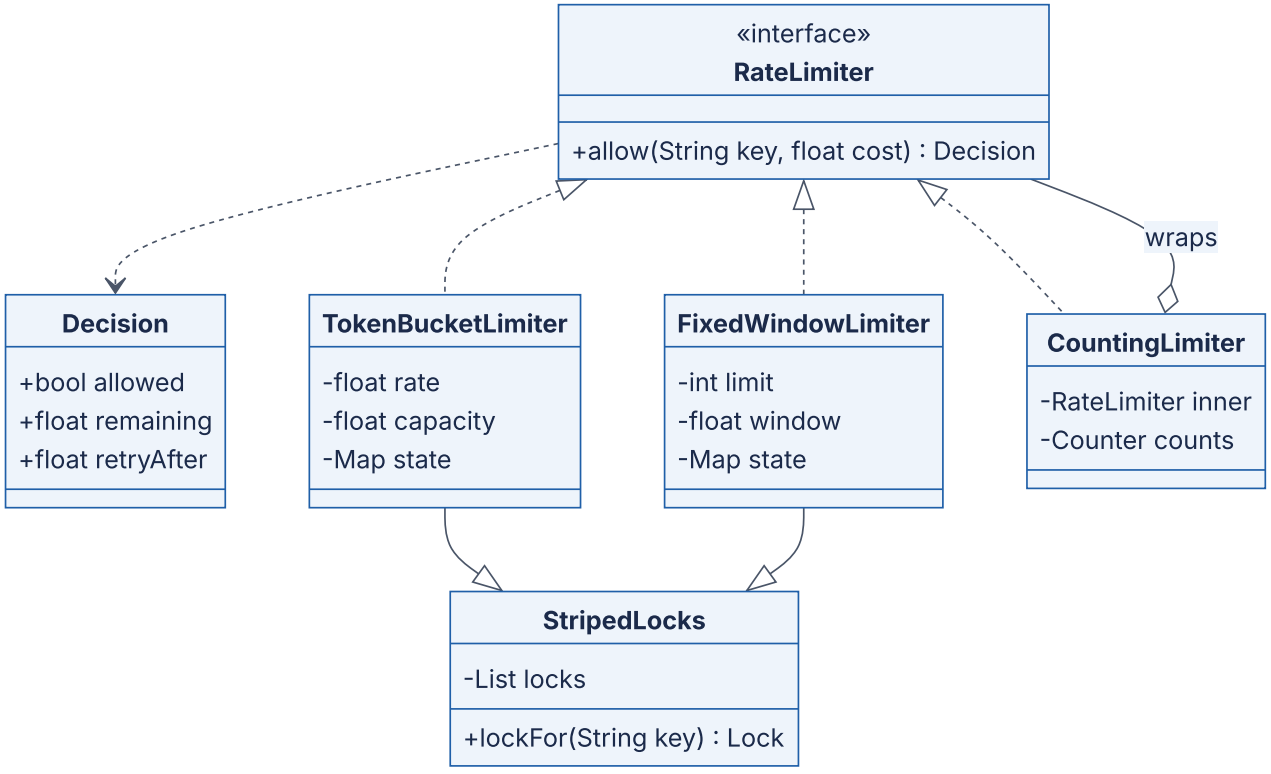
Output: `bob: no copy available; place a hold`, `notify bob: 'SICP' is ready for pickup`, `fine (cents): 150` (6 days × 25), `cat: no copy available; place a hold`, `bob gets c1`.

Patterns and follow-ups. Listeners implement **Observer** (§37.8) so e-mail, SMS and push channels can be added without touching `Library`. Typical follow-ups: hold expiry (a copy on hold for more than 3 days passes to the next member, needing a scheduled sweep like Exercise 7's); different loan policies per member type (a `LoanPolicy` strategy, not `StudentMember` subclasses); search by title or author (an index from words to ISBNs, or a search engine, §16); and concurrent checkouts across branches (a database transaction with `UPDATE copies SET status = 'ON_LOAN' WHERE copy_id = ? AND status = 'AVAILABLE'`, checking the affected row count).

38.10.6 Exercise 6: Rate limiter class design

Requirements. Offer `allow(key, cost)` returning a decision (allowed, remaining, retry-after); support at least two algorithms selected by configuration; be safe under concurrent calls; let operators add metrics without modifying algorithms. The token bucket algorithm itself, its formula and its parameter choices are in §22.4, and distributed enforcement is in §22.8; this exercise is about the *class design* around them.

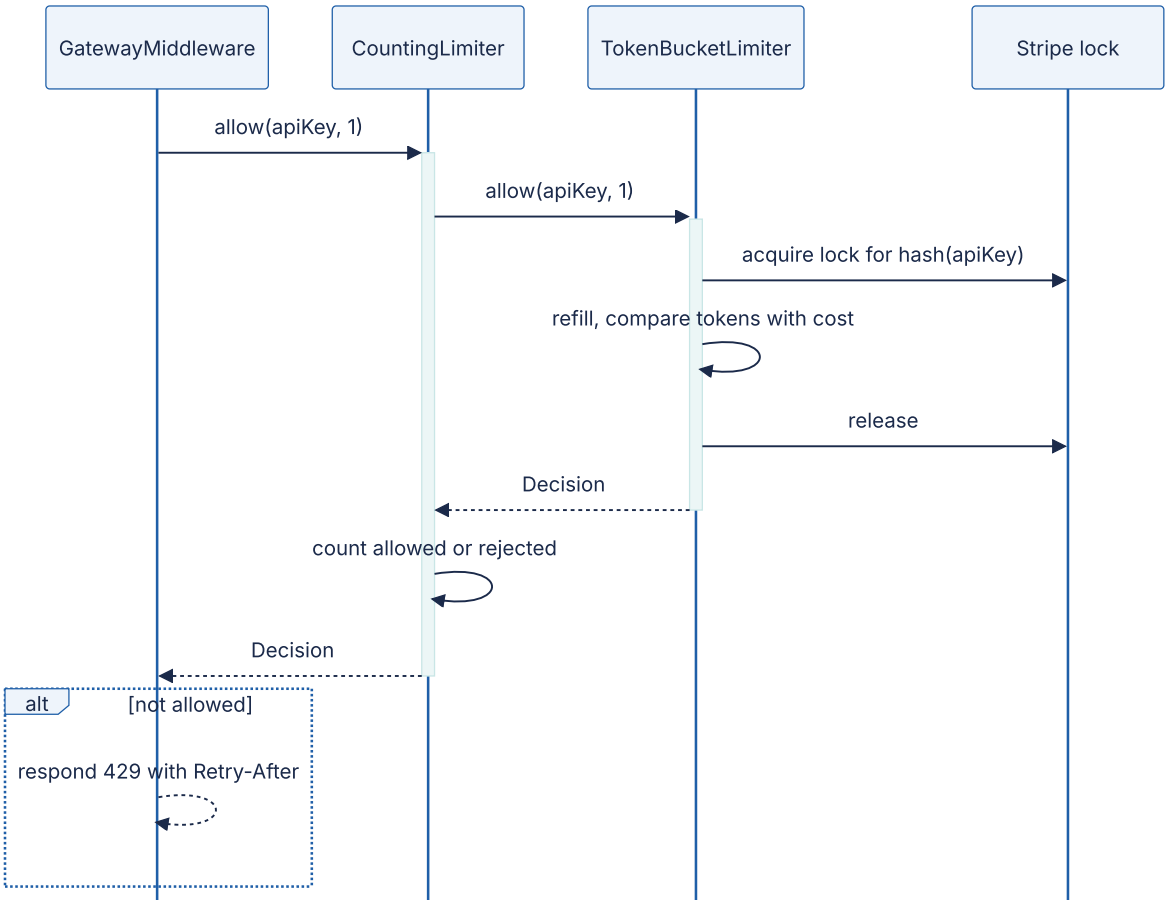
Figure 38.18 — Rate limiter class diagram.



Reading the diagram. Callers (gateway middleware) depend only on `RateLimiter` and the immutable `Decision` value object. Two algorithms realize the interface; `CountingLimiter` is a **Decorator** (§37.10) that also realizes it and wraps any other limiter

to add metrics. Both algorithms inherit lock striping, a fixed array of locks indexed by key hash, so unrelated keys rarely contend while operations on one key stay atomic. A factory (`build_limiter`) builds the right object from configuration.

Figure 38.19 — Sequence diagram for one admission decision.



Reading the diagram. The middleware calls the decorator, which delegates to the token bucket. The bucket takes only its key’s stripe lock, refills lazily and decides, so the read-modify-write is atomic per key. The decorator counts the outcome; the middleware turns a rejection into HTTP 429 with `Retry-After` from the decision (§22.3.4). Everything is in process; in a fleet, the same interface would be implemented by a Redis-backed class (§22.8.2) and callers would not change.

Output:

```
20 allowed; retry after 0.1 s; {'allowed': 20, 'rejected': 5}
after 1 s: 10 allowed
other key: True
fixed window: [True, True, True, True, True, False] retry 59.0
concurrent admits: 20
```

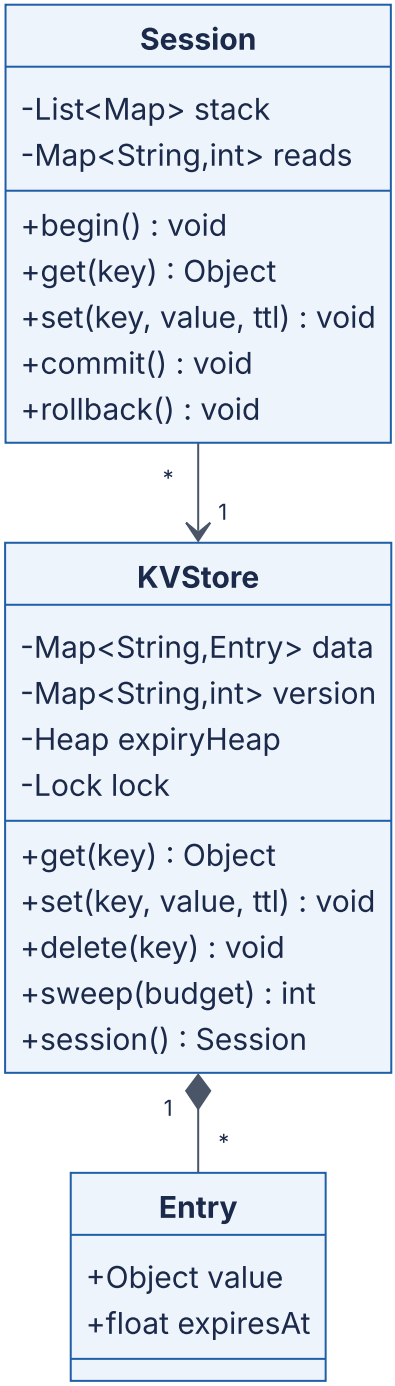
Patterns and follow-ups. Strategy (algorithms behind one interface), **Decorator** (metrics, logging, a "shadow mode" that logs but never rejects), **Factory** (configuration to object). The 16-thread test admits exactly 20 requests with the clock frozen, which proves per-key atomicity. Follow-ups: idle keys accumulate forever (evict with an LRU of keys, Exercise 3, or a TTL); hierarchical limits (a `CompositeLimiter` that must check all buckets *before* debiting any, or debit and refund on rejection); and fail-open versus fail-closed when a remote store is unreachable (§22.8.5), which is another decorator.

38.10.7 Exercise 7: In-memory key-value store with TTL and transactions

Requirements. `get`, `set(key, value, ttl)` and `delete`; keys with a time to live (TTL) disappear when it elapses; clients can `begin`, `commit` and `rollback` transactions, nested to any depth, and see their own uncommitted writes; a commit is all-or-nothing and fails if another client changed a key that this transaction read.

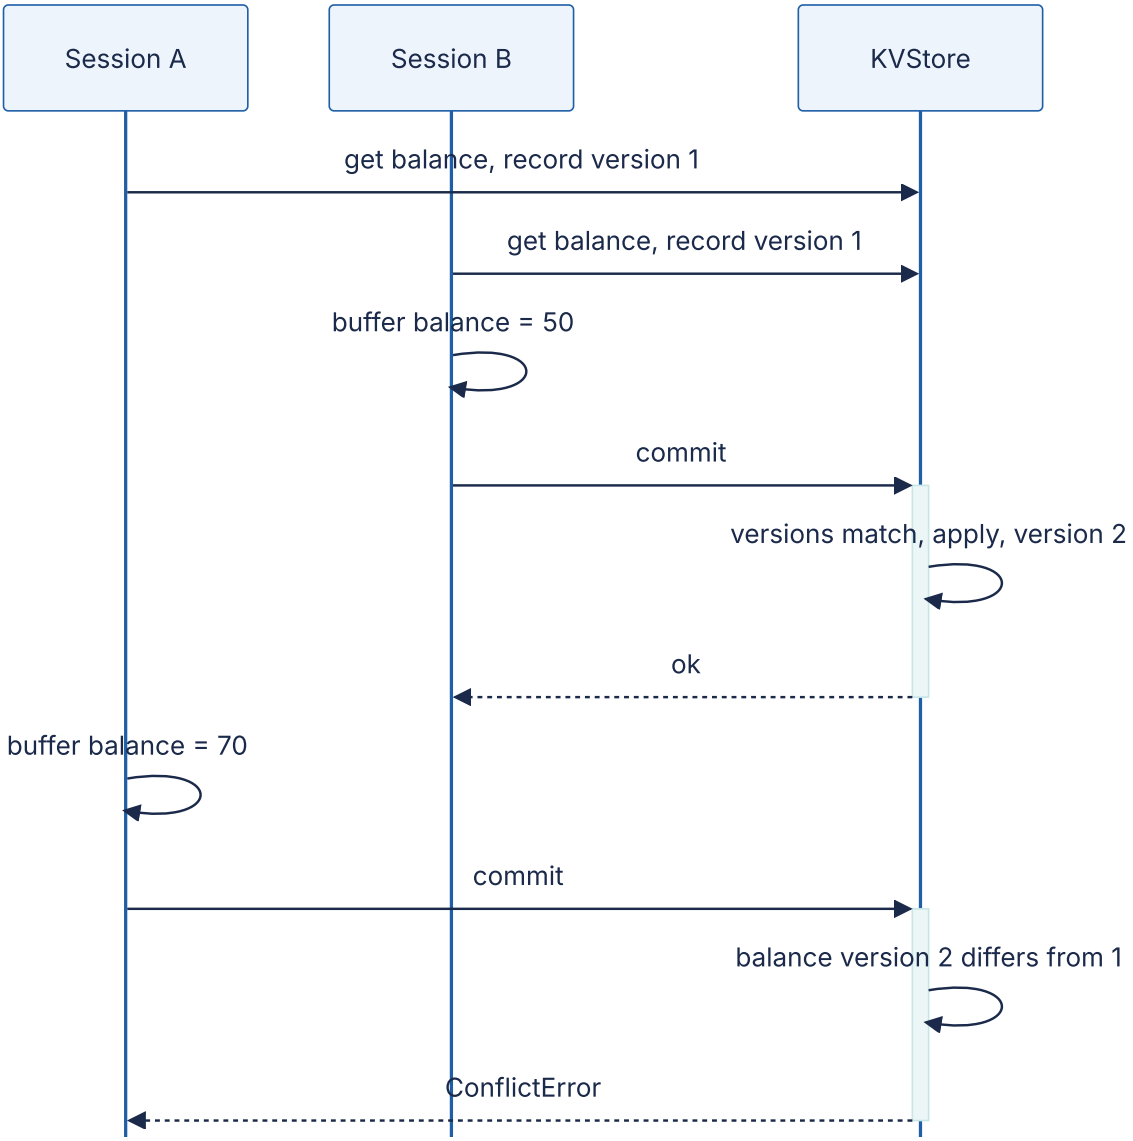
Design. Expiry uses two mechanisms, like Redis [Redis Docs: EXPIRE]: **lazy** expiry on every read (an expired key is deleted when touched) and an **active** sweep from a min-heap of `(expires_at, key)` with a work budget, so memory is reclaimed even for keys nobody reads. Transactions live in a per-client `Session` holding a stack of write buffers: `begin` pushes, `rollback` pops, an inner `commit` merges into the level below, and the outermost `commit` validates and applies the buffer under the store lock. Validation is **optimistic concurrency** (§11.15.3): the session records the version of each key it read, and the commit fails if any version changed.

Figure 38.20 — Key-value store class diagram.



Reading the diagram. The store composes its entries and keeps a version counter per key that increases on every write, delete or expiry. Many sessions share one store. Each session’s buffers and read-set are private, so uncommitted writes are invisible to other clients (no dirty reads). The store lock is the only synchronization point, and commits hold it for validation and application together.

Figure 38.21 — Sequence diagram for two conflicting transactions.



Reading the diagram. Both sessions read `balance` at version 1 and buffer their writes locally. B commits first; validation passes and the write bumps the version to 2. A's commit then finds a changed version and fails instead of silently overwriting B's debit (a lost update, §11.13.1). A retries the whole transaction with fresh reads.

```

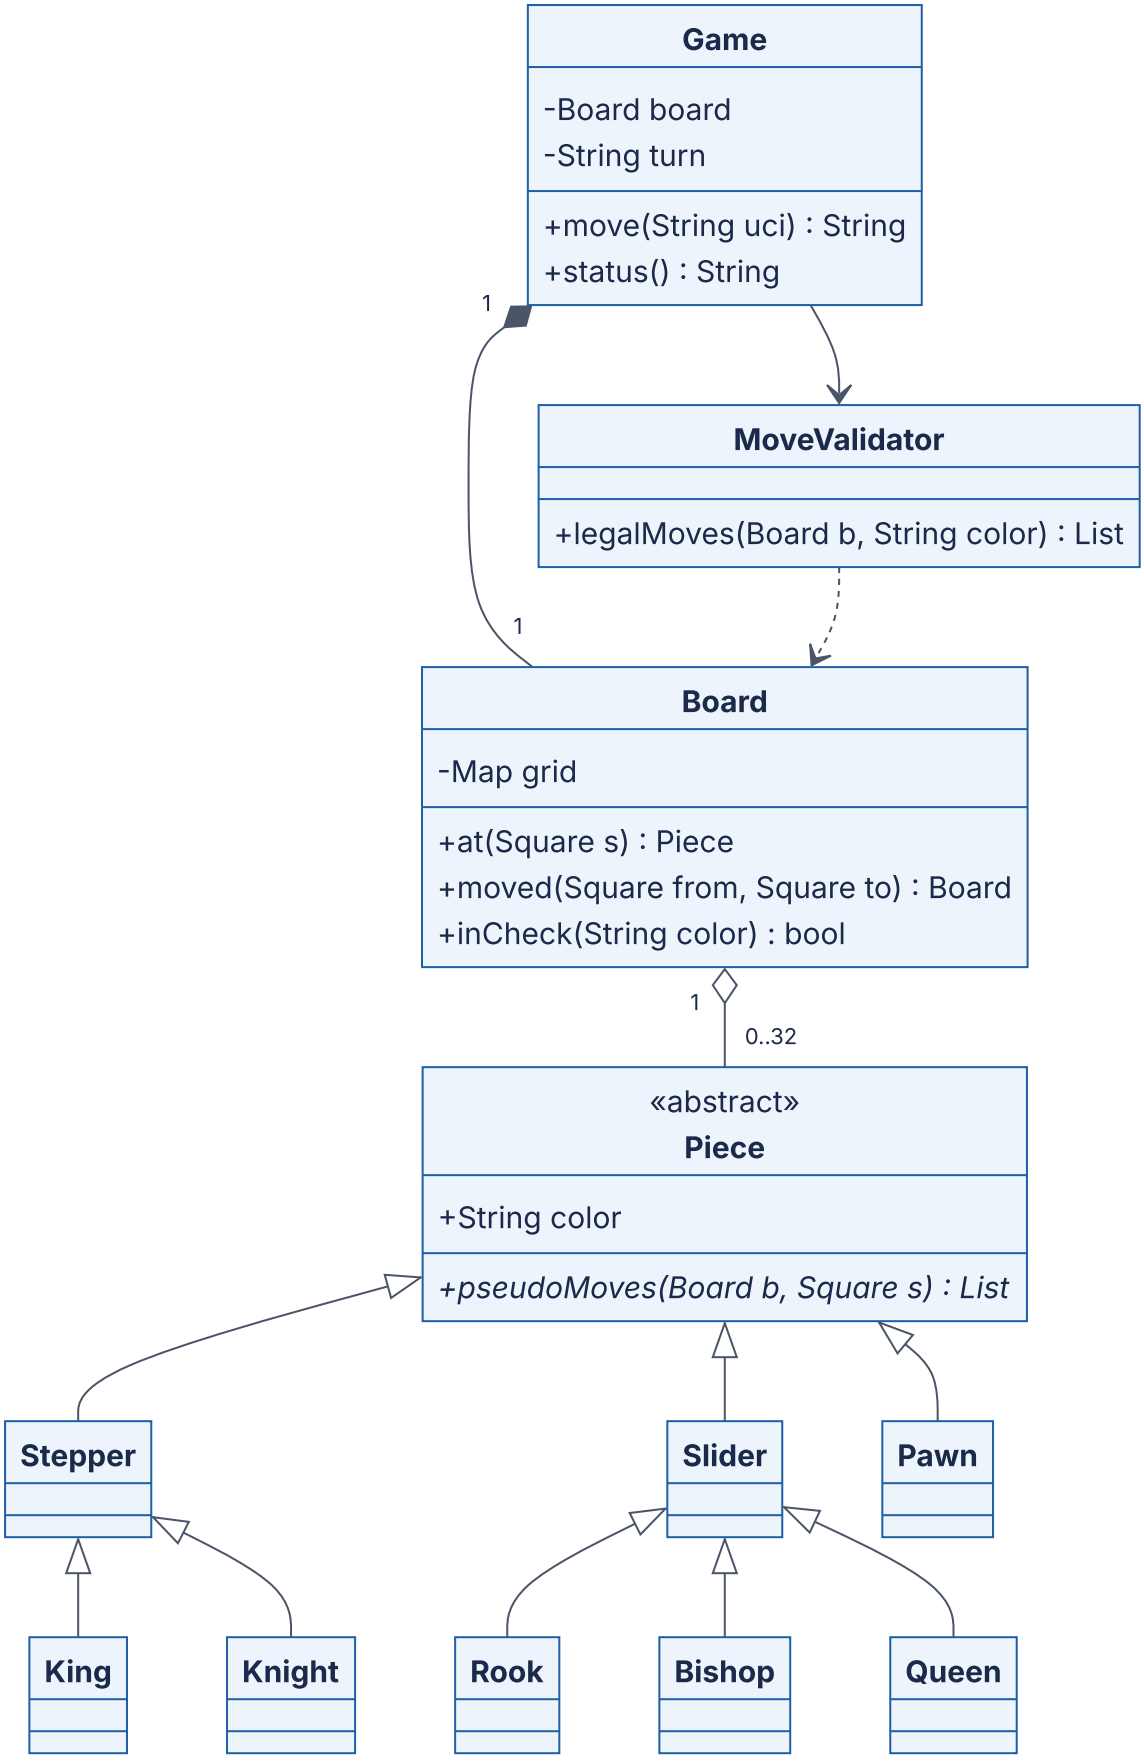
Patterns and follow-ups. Write buffers are a form of the **Command** pattern (recorded operations applied later, §37.12); the session-per-client design is a **Unit of Work**. A TTL inside a transaction counts from commit time, which you should state. Follow-ups: durability (an append-only log of committed buffers, fsync policy per §6.14); isolation level (every read is validated at commit under the store lock, so committed transactions are serializable in commit order, but a transaction can *observe* a mix of old and new values before it aborts, because reads do not come from a snapshot; MVCC snapshots, §11.14, fix that); memory limits (evict with LRU, Exercise 3); and why Redis transactions differ: `MULTI` / `EXEC` queue commands and run them without interleaving but do not roll back a failed command, while `WATCH` provides the same optimistic check-and-set as this design [Redis Docs: Transactions].

38.10.8 Exercise 8: Chess (move validation)

Requirements. Two players alternate moves on a standard board; the system rejects illegal moves, reports check, checkmate and stalemate. Out of scope for the first pass: castling, en passant, promotion, draw rules (all follow-ups).

The key design decision is validating moves in two layers. Each piece knows only its own geometry and produces **pseudo-legal** moves (moves that follow the piece's movement rules and do not land on a friendly piece). A separate `MoveValidator` filters them to **legal** moves by applying each one to a copy of the board and rejecting it if the mover's king is attacked afterwards. This keeps check logic, which concerns the whole position, out of every piece class, and is the same split that the python-chess library exposes as `pseudo_legal_moves` and `legal_moves` [python-chess docs].

Figure 38.22 — Chess class diagram.



Game

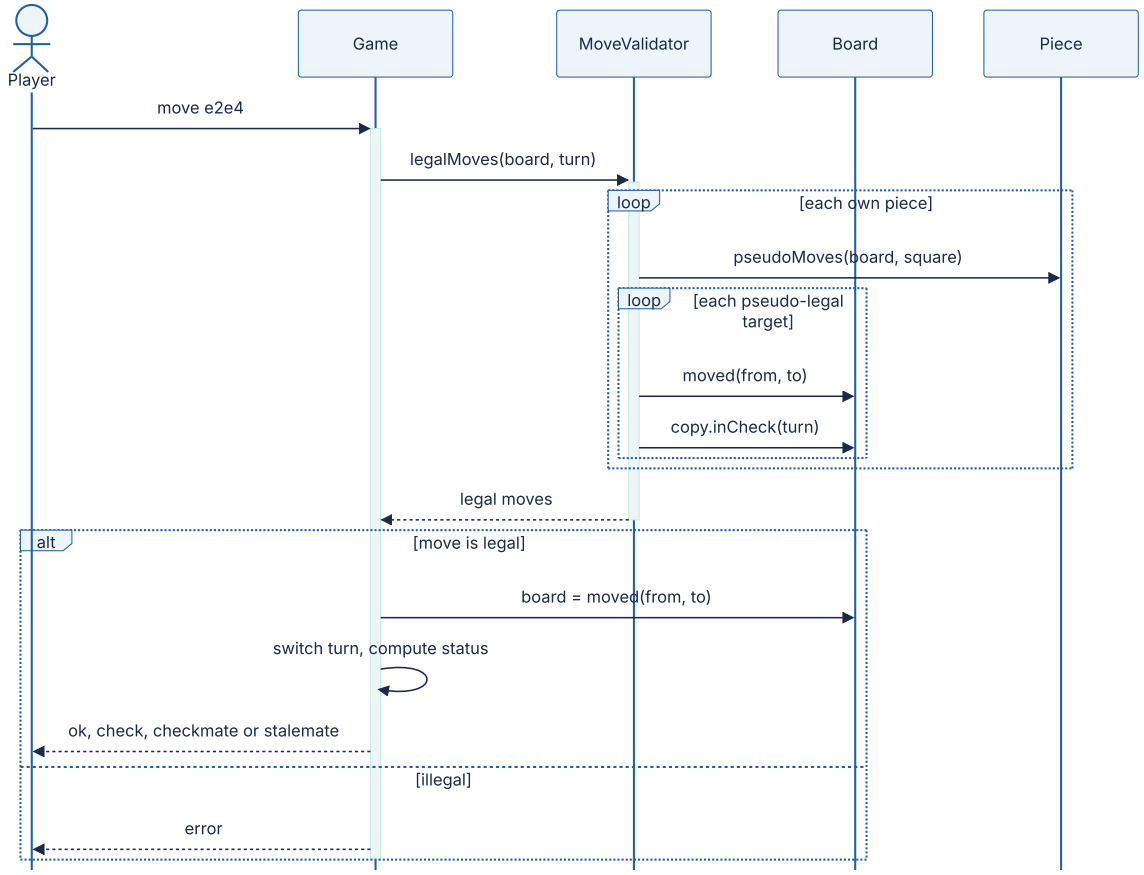
0..32
«abstract»
Piece
+String color
+pseudoMoves(Board b, Square s) : List
Stepper
Slider
Pawn
King
Knight
Rook
Bishop
Queen

Reading the diagram. `Game` owns the board and the turn and delegates legality to `MoveValidator`. The piece hierarchy is a justified use of inheritance: behavior genuinely differs by kind and every subclass is substitutable for `Piece` (Liskov, §36.5). The two intermediate classes remove duplication: a `Stepper` hops by fixed offsets (king, knight); a `Slider` follows rays until blocked (rook, bishop, queen), so a queen is just "a slider with eight rays". Pieces are immutable and shared between board copies; `Board.moved` returns a new board, which removes all undo bugs from validation.

Figure 38.23 — Sequence diagram for validating and applying a move.



Reading the diagram. For every own piece, the validator asks for pseudo-legal targets, builds the resulting board, and keeps the move only if the mover's king is not attacked. `Game` applies a legal move, switches the turn and computes the status by generating the opponent's legal moves: none plus check is checkmate, none without check is stalemate. The cost is visible as two nested loops; about 20–40 moves per position, each needing an attack test, is trivial for a game server but too slow for an engine searching millions of positions, which uses bitboards and incremental updates instead.

```

Patterns and follow-ups. Polymorphism over a small class hierarchy; validation as a separate policy object (it could become a chain of rules for variants such as Chess960). The 20 opening moves match the known count for the initial position, a quick correctness check. Follow-ups: castling and en passant need *history* (has the king moved? what was the last move?), so the board state grows into a `Position` with castling rights and an en-passant square; promotion turns a move into a value object with an optional piece; undo and replay come from storing moves as **Commands** (§37.12); draw by threefold repetition needs a position hash (Zobrist hashing); and online play turns `Game` into a server-side aggregate whose moves are validated on the server, never trusted from the client.

SUMMARY

- **UML is a sketching language for design decisions.** UML 2.5.1 defines 14 diagram types; class, sequence, component, state machine and activity diagrams cover nearly all practical needs. Draw only what carries a decision.
- **Class diagrams:** visibility `+ - # ~`; multiplicity `1`, `0..1`, `*`, `1..*` read from the opposite end; six relationships from weakest to strongest coupling: dependency (dashed arrow), association (line), aggregation (hollow diamond), composition (filled diamond), and generalization (hollow triangle); realization (dashed line, hollow triangle) couples only to a contract.
- **Sequence diagrams** show one scenario over time: lifelines, activations, synchronous calls (filled arrowhead), replies (dashed), asynchronous messages (open arrowhead), and `alt` / `opt` / `loop` / `par` fragments. Always draw one unhappy path.
- **Component diagrams** show replaceable parts and their provided and required interfaces; **state machines** show legal events per state with `trigger [guard] / effect` and entry/exit actions; **activity diagrams** show workflows with decisions, forks, joins and swimlanes. Mermaid approximates component and activity notation with flowcharts.
- **Composition** means exclusive ownership and shared lifetime; **aggregation** is a shared whole–part link of debated value; **association** is a lasting peer link. Value types are attributes; entities are relationships; links with data become association classes.
- **LLD interview method:** clarify → use cases → entities → class diagram → interfaces → sequence or state diagram → patterns → concurrency and extensibility → code, in about 45 minutes with code starting by minute 30.
- **Exercise lessons:** put variation behind interfaces (allocation, pricing, dispatch, rate-limit algorithm); keep check-then-act inside one critical section; separate title from copy, pseudo-legal from legal, car movement from dispatch; use the State pattern when behavior differs per state; LRU is a hash map plus a doubly linked list with sentinels; TTL needs lazy plus active expiry; transactions need private write buffers and atomic, validated commits.

38.12 Knowledge checkpoint

1. What do `#` and `~` mean in front of a class member, and how is a static member shown?
2. In `Order "1" --> "1..*" LineItem`, how many line items can an order have, and how many orders can a line item belong to?

3. Give the line and end symbol for realization and for dependency.
4. What three tests distinguish composition from aggregation?
5. When should a relationship between two classes become a class of its own?
6. In a sequence diagram, how do synchronous and asynchronous messages differ in notation and meaning?
7. What is the difference between `alt` and `opt`?
8. In a state machine, what happens when an event arrives and the guard is false?
9. Why does a join after a decision node deadlock an activity?
10. In the LLD method, by what minute should you normally be coding in a 45-minute interview, and why?
11. Why does the LRU cache need a *doubly* linked list, and why must `get` take an exclusive lock?
12. Using Formula 38.2 with $t_{\text{floor}} = 2$ s and $t_{\text{stop}} = 10$ s, an idle car is 9 floors away and another car moving toward the caller in the right direction is 3 floors away with 2 stops in between. Which is dispatched?
13. Why is `Book` separate from `BookCopy` in the library design?
14. Why is the vending machine a better fit for the State pattern than for a transition table?
15. What are pseudo-legal moves, and why validate legality on a copy of the board?

Answers

1. `#` is protected (class and subclasses), `~` is package visibility. Static members are underlined (Mermaid: a trailing `$`).
2. One or more line items per order; exactly one order per line item. Multiplicity is written at the far end and read from the near class.
3. Realization: dashed line with a hollow triangle at the interface. Dependency: dashed line with an open arrowhead at the used class.
4. Lifetime (does the part die with the whole?), sharing (can the part belong to two wholes?), creation (does only the whole create it and keep it private?). Yes, no, yes means composition.
5. When the link has data of its own, such as a due date or a grade; it becomes an association class (`Loan`, `Enrollment`).
6. Synchronous: solid line, filled arrowhead; the caller waits for the reply (dashed line). Asynchronous: solid line, open arrowhead; the caller continues without waiting.
7. `alt` has two or more guarded operands, exactly one of which runs (if/else); `opt` has one operand that runs or not (if without else).
8. The transition does not fire; the object stays in its current state, and no exit, effect or entry behavior runs.
9. Only one branch receives a token after a decision, but a join waits for tokens on all incoming edges, so it never fires. Use a merge instead.

10. Around minute 30; the last 13–15 minutes are needed to write and exercise working code, which is part of the evaluation.
11. Unlinking a node in $O(1)$ needs its predecessor, which only a doubly linked node stores. `get` moves the node to the front, which mutates the list, so concurrent `get`s would race.
12. Idle car: $9 \times 2 = 18$ s. Moving car: $3 \times 2 + 2 \times 10 = 26$ s. The idle car (18 s) is dispatched.
13. A title has many physical copies with different statuses; loans attach to copies, holds attach to titles. Merging them cannot represent either correctly.
14. Its states differ substantially in behavior (accepting coins, computing change, ignoring input while dispensing); one class per state keeps each set of rules cohesive and makes adding a state a local change.
15. Moves that follow a piece's movement rules without considering whether the own king is left in check. Applying the move to a copy and testing for check handles pins, discovered checks and king moves uniformly without undo logic.

38.13 Interview questions

Basic

Q1. Explain the difference between aggregation and composition, with an example in code. Answer. Both are whole–part associations. In composition the whole exclusively owns its parts and controls their lifetime: an `Order` creates its `LineItem`s, never shares them, and deleting the order deletes them (filled diamond; `ON DELETE CASCADE`). In aggregation the parts exist independently and may be shared: a `Playlist` references `Song`s that exist in the catalog and in other playlists (hollow diamond). In code, composition shows as the whole constructing the parts privately and exposing values or copies; aggregation as references passed in from outside. Many practitioners model aggregation as a plain association because its semantics are loosely defined.

Q2. Which diagrams would you draw to explain a checkout flow to a new team member? Answer. A sequence diagram of the purchase scenario, including the payment-declined `alt` branch and the retry loop with an idempotency key; a state machine for the order lifecycle so they know which transitions are legal; and, if they are joining one module of several, a component diagram showing which interfaces their module provides and requires. A class diagram of the order aggregate helps if they will change the domain model.

Intermediate

Q3. Design a parking lot. How do you keep two entry gates from assigning the same spot? Answer. Follow §38.10.1: a `ParkingLot` facade composing levels and spots, `Size` enum for vehicles and spots, `AllocationStrategy` and `FeePolicy` interfaces, im-

mutable `Ticket`s. Finding a spot and marking it occupied must be one critical section; otherwise both gates can see the same spot as free (check-then-act). Use one lock for the lot, or a lock per level with the strategy claiming atomically within that level. In a database-backed design, claim with a conditional update (`WHERE occupied = false`) and check the row count.

Q4. Implement an LRU cache with O(1) operations. How would you scale it to many threads? Answer. Hash map from key to node plus a doubly linked list in recency order with head and tail sentinels; `get` moves the node to the front; `put` inserts at the front and evicts the node before the tail when full. A single lock is correct because `get` also mutates. To scale, stripe the cache into k independent segments by key hash (approximate global LRU), or use buffered access recording and batched reordering as high-performance libraries do; keep all of them behind one `Cache` interface.

Advanced

Q5. Design an elevator system for a 40-floor building with 6 cars. How do you choose which car answers a hall call, and how do you test it? Answer. Separate the dispatcher (a Strategy) from each car's state machine (Idle, Moving, DoorsOpen, Maintenance with guarded transitions; the doors can never be open while moving). Dispatch by minimum estimated arrival time (Formula 38.2), not nearest car, because stops cost more than travel; add an age term against starvation and a zoning strategy for the morning peak. Make the controller deterministic with a discrete tick and injected time, so the worked cost example and full sweeps (LOOK ordering) become unit tests; simulate traffic to compare average and p95 waiting time between strategies.

Q6. Design an in-memory key-value store with TTL and transactions. What isolation do you provide? Answer. Entries with an optional TTL; lazy expiry on read plus an active sweep driven by a min-heap with a per-run budget. Per-client sessions hold a stack of write buffers for nested transactions with read-your-writes; outermost commit validates the read-set versions and applies all writes atomically under the store lock (optimistic concurrency), raising a conflict otherwise. Committed transactions are serializable in commit order; reads inside a transaction are not from a snapshot, so add MVCC if transactions must observe consistent data before commit. Discuss durability (append-only log), memory limits (eviction), and why Redis `MULTI`/`EXEC` has no rollback but `WATCH` provides the same optimistic check.

38.14 Practical exercises

1. Draw the class diagram of a codebase you know (8–12 classes) and mark every relationship as dependency, association, aggregation, composition, generalization or realization. Find one inheritance that should be composition.

2. Add a `Maintenance` state to the vending machine that only an operator key can enter and leave; confirm that no existing state class changes except the transitions into it.
3. Add direction-aware hall stops to the elevator code (`(floor, direction)` pairs) and write a test where a car moving up passes a floor with a pending *down* call without stopping.
4. Replace the vending machine's greedy change-making with a dynamic-programming version that respects coin counts, and test the {one 25, three 10s} → 30 cents case.
5. Extend the chess code with castling: add castling rights to the board state and verify that castling through an attacked square is rejected.

38.15 Design challenges

1. **Food-delivery order lifecycle.** Design the classes, state machine and two sequence diagrams for an order that moves through placement, restaurant acceptance, courier assignment, pickup, delivery and refunds, with partial cancellations of individual items. Show where the state is persisted and how concurrent events (customer cancels while courier picks up) are resolved.
2. **Meeting-room booking system.** Rooms, recurring bookings, conflict detection, waitlists and calendar notifications for 2,000 rooms across 30 offices. Deliver the class diagram, the conflict-detection algorithm and its complexity, the concurrency strategy for two people booking the same slot, and three extension scenarios with their blast radius.

38.17 Open verification items

- Exact wording and clause number in UML 2.5.1 stating that shared-aggregation semantics vary by application area and modeler; and the 790-page length of the specification PDF (approximate).
- Fowler’s quotation of Rumbaugh’s “modeling placebo” remark on aggregation (*UML Distilled*, 3rd ed.), page reference not checked.
- GitHub Mermaid announcement: exact publication date (believed 14 February 2022) and URL.
- Current implementation details of CPython’s `lru_cache` (C accelerator versus pure-Python fallback) and the per-entry memory overhead estimate of 100–200 bytes.
- Redis expiry and transaction behavior as documented in 2026.

Part VIII — Production Infrastructure and Operations

Chapter 39 — Reliability and Resilience

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

Earlier chapters added mechanisms that keep a system working when something breaks: replicas and failover (Chapters 26–27), and timeouts, retries, circuit breakers and load shedding (Chapter 22). This chapter is about the *operating discipline* that decides how much of that machinery you need, tells you whether it works, and limits the damage when it does not: how reliable to be and how to measure it as users experience it; how to build and degrade so failures stay small; how to recover data and service after a disaster; and how people respond to incidents and learn from them without blame.

Chapter 4 already gave you the arithmetic of nines, series and parallel composition, MTBF and MTTR, and durability (§4.14–§4.16). Here we *apply* that arithmetic to targets, alerts, budgets and recovery plans, and we do not re-derive it. QuickBite, the food-delivery platform of Chapter 2, is the running example: order placement must be available 99.95% per 30-day month, browsing 99.9%, and a confirmed order must survive the loss of any node or zone (Table 2.5).

39.1 Learning objectives

After this chapter you should be able to:

- Distinguish availability, reliability, durability and resilience; compute time- and request-based availability.
- Choose a redundancy scheme across failure domains and quantify how correlated failures erode it.
- Design graceful degradation and compute the availability a fallback buys.
- Choose SLIs per journey, specify an API’s SLO, derive an SLA, and compute a composite SLO.
- Compute error budgets, write an error-budget policy, and derive burn-rate alert thresholds, detection times and time to exhaustion.
- Select a disaster-recovery strategy by comparing the cost of each tier with the expected cost of its RTO and RPO.
- Design backups with point-in-time recovery and restore tests, and compute restore duration.
- Plan a chaos experiment with a steady-state hypothesis and a bounded blast radius.
- Run an incident with defined roles and write a blameless postmortem.

39.2 Prerequisites

- Nines, downtime budgets, series/parallel/k-of-n composition — §4.14 (applied here, not re-derived).
- MTBF, MTTR and reliability $R(t)$; durability and correlated failures — §4.15, §4.16.
- Percentiles and tail latency — §4.8.
- Headroom, N+k and zone-level static stability — §18.11.2.
- Timeouts, retries, circuit breakers, bulkheads and load shedding — §22.9–§22.14 (cross-referenced, not re-taught).
- Failure detection, failover and recovery — §27.10–§27.12; split brain and fencing — §26.12, §26.13.
- Write-ahead logging and checkpoints — §13.5 (the basis of point-in-time recovery).
- QuickBite requirements and capacity — §2.5, §2.11.

39.3 Availability versus reliability

39.3.1 Four words that are often confused

> DEFINITION
>
> **Definition — Availability, reliability, durability, resilience. Availability** is the fraction of time, or of valid requests, for which a system serves correctly (§4.14). **Reliability** is the probability that the system performs its required function correctly over a stated period, $R(t)$ (§4.15); in SRE usage the word is also used broadly for "the system does what users need", of which availability is the most-measured part [Beyer et al. 2016]. **Durability** is the probability that acknowledged data is not lost (§4.16). **Resilience** is the ability to absorb a fault, keep delivering an acceptable (possibly degraded) service, and recover to full service.

First-principles explanation

Think of a city bus service. *Availability* asks: when you walk to the stop, how often is a bus running? *Reliability* asks: once you board, how likely is it that you arrive without a breakdown? *Durability* asks: if you leave your bag on the bus, will it still exist at the depot tomorrow? *Resilience* asks: when one bus breaks down, does the company send a replacement, shorten the route, or abandon everyone? A service can score well on one and badly on another. A system that is up but returns yesterday's prices is available and unreliable. A database that is down for an hour but loses nothing is unavailable and durable.

A useful vocabulary separates cause from effect [Avizienis et al. 2004]. A **fault** is a defect or event (a disk sector goes bad, a bug ships, a cable is cut). An **error** is the incorrect internal state the fault produces (a corrupted page, a wrong pointer). A **failure** is the mo-

ment the delivered service deviates from what users should get. Resilience engineering works on the gaps: stop faults becoming errors (validation, checksums), and stop errors becoming failures (redundancy, fallbacks, retries).

Why does this exist?

Teams that say “the service was up” while users saw errors, or page engineers when one node dies although users saw nothing, are measuring the wrong thing. Precise definitions decide what “good” means before you spend money on it.

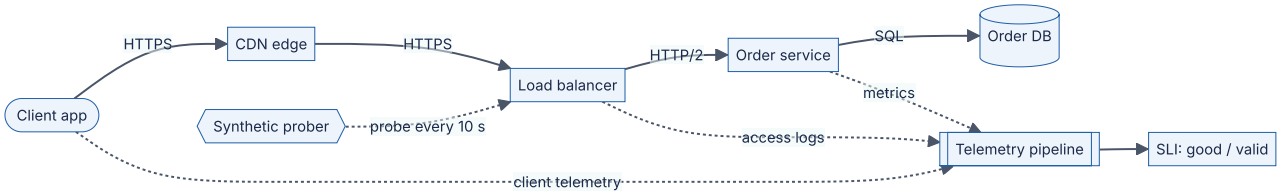
39.3.2 Measuring availability: time-based versus request-based

There are two ways to turn “serves correctly” into a number.

Time-based availability divides the period into small intervals (usually minutes) and classifies each one as good or bad, typically by a probe or by whether the error ratio in that minute exceeded a threshold. Availability is the fraction of good intervals. It matches how contracts and status pages talk (“we were down for 12 minutes”) and works even when traffic is low.

Request-based (aggregate) availability counts outcomes: the fraction of *valid* requests that succeeded. The SRE book recommends it for distributed services, because a globally distributed system is rarely “all up” or “all down”; it is usually partly degraded, and counting requests captures exactly how many users were hurt [Beyer et al. 2016].

Figure 39.1 — Where availability can be measured.



Reading the diagram. A request flows synchronously (solid arrows) from the client app through the CDN and load balancer to the order service and its database, the storage boundary. Four measurement points feed the telemetry pipeline asynchronously (dotted). *Server metrics* are precise but blind to failures upstream of the service (DNS, CDN, load balancer). *Load-balancer logs* see every request that arrived. *Client telemetry* sees what users saw, including network failures, but is noisy and delayed. The *synthetic prober* sends known-good requests, useful when real traffic is low, and yields a time-based measure. Most teams compute the SLI at the load balancer and validate it against client data; scaling the pipeline is a Chapter 40 topic.

FORMULA

Time-based and request-based availability

$$A_{\text{time}} = \frac{\text{good intervals}}{\text{total intervals}} \qquad A_{\text{req}} = \frac{\text{good requests}}{\text{valid requests}}$$

Symbol	Meaning	Units
good intervals	Intervals (e.g. minutes) whose error ratio stayed below a threshold, or whose probe succeeded	count
total intervals	All intervals in the measurement window	count
good requests	Valid requests served correctly (right status, within any latency bound in the definition)	count
valid requests	Requests that count toward the SLI; excludes, for example, client errors (4xx) and health checks	count
A_{time} , A_{req}	Availability under each definition	dimensionless

WORKED EXAMPLE

Worked example — One month, two availabilities. QuickBite's order API receives 500,000 place-order requests per day, 15,000,000 in a 30-day month (43,200 minutes). Two incidents occur: (a) a 40-minute total outage at 03:00, when traffic is 1% of the daily volume per hour; (b) a 90-minute partial outage at the 19:00 peak, when 10% of the daily volume arrives per hour and 20% of requests fail. A minute counts as bad if more than 5% of its requests fail.

1. *Time-based:* incident (a) gives 40 bad minutes; incident (b) has a 20% error ratio, above the 5% threshold, so all 90 minutes are bad.
   $A_{\text{time}} = 1 - 130/43,200 = 1 - 0.00301 = 99.699\%$.
2. *Request-based, incident (a):* requests in 40 minutes at 1% of 500,000 per hour: $5,000 \times 40/60 = 3,333$ failed.
3. *Incident (b):* $50,000$ requests per hour $\times 1.5$ h $= 75,000$ requests, 20% failed $= 15,000$.
4. $A_{\text{req}} = 1 - (3,333 + 15,000)/15,000,000 = 1 - 0.00122 = 99.878\%$.

Interpretation. By time, the night outage costs 31% of the bad minutes; by requests, it costs 18% of the failures. Time-based measurement overweights quiet periods and counts a 20% partial failure as a full outage. Request-based measurement weights by user impact. **Engineering implication.** Use request-based availability for high-traffic services, and either a time-based measure or synthetic traffic for low-traffic ones, where a single failed request among ten would swing a request ratio wildly. Neither measure, on its own, says whether a few unlucky users suffered all the failures; per-user measures such as Google's windowed "user-uptime" address that [Hauer et al. 2020].

Table 39.1 — Time-based versus request-based availability.

Aspect	Time-based	Request-based
Unit	Good minutes / total minutes	Good requests / valid requests
Weighting	Every minute equal	Weighted by traffic
Partial outages	Binary per minute (threshold)	Proportional
Low traffic	Works (with probes)	Noisy; needs synthetic traffic
Pitfall	Threshold choice hides partial failure	Hides concentrated harm to a few users

Common misconceptions

COMMON MISTAKE

Mistake — "The service returned 200, so it was available." Availability means *correct* service. A 200 with an empty menu, a stale price or an error message in the body is a failure from the user's point of view (§8.6.4). Define "good" by what the user needed, and add correctness checks (for example, probes that verify response content) where silent wrong answers are possible.

39.4 Fault tolerance and redundancy

39.4.1 Redundancy across failure domains

DEFINITION

Definition — Fault tolerance, redundancy and failure domain. Fault tolerance is the ability to keep providing correct service despite faults in some components. **Redundancy** is extra capacity or extra copies that make this possible. A **failure domain** is a set of components that can fail together because they share something: a power feed, a rack switch, a zone, a region, a software version, a configuration system or an operator.

First-principles explanation

A spare tire helps only if it is not flat for the same reason as the first one. Carrying two spare tires inside the same trunk does nothing if the trunk is what catches fire. Redundancy therefore has two parts: *how many* spares (N+1, N+2, 2N) and *how independent* they are (different racks, zones, regions, versions, people).

The common schemes, with N the number of units needed to carry peak load:

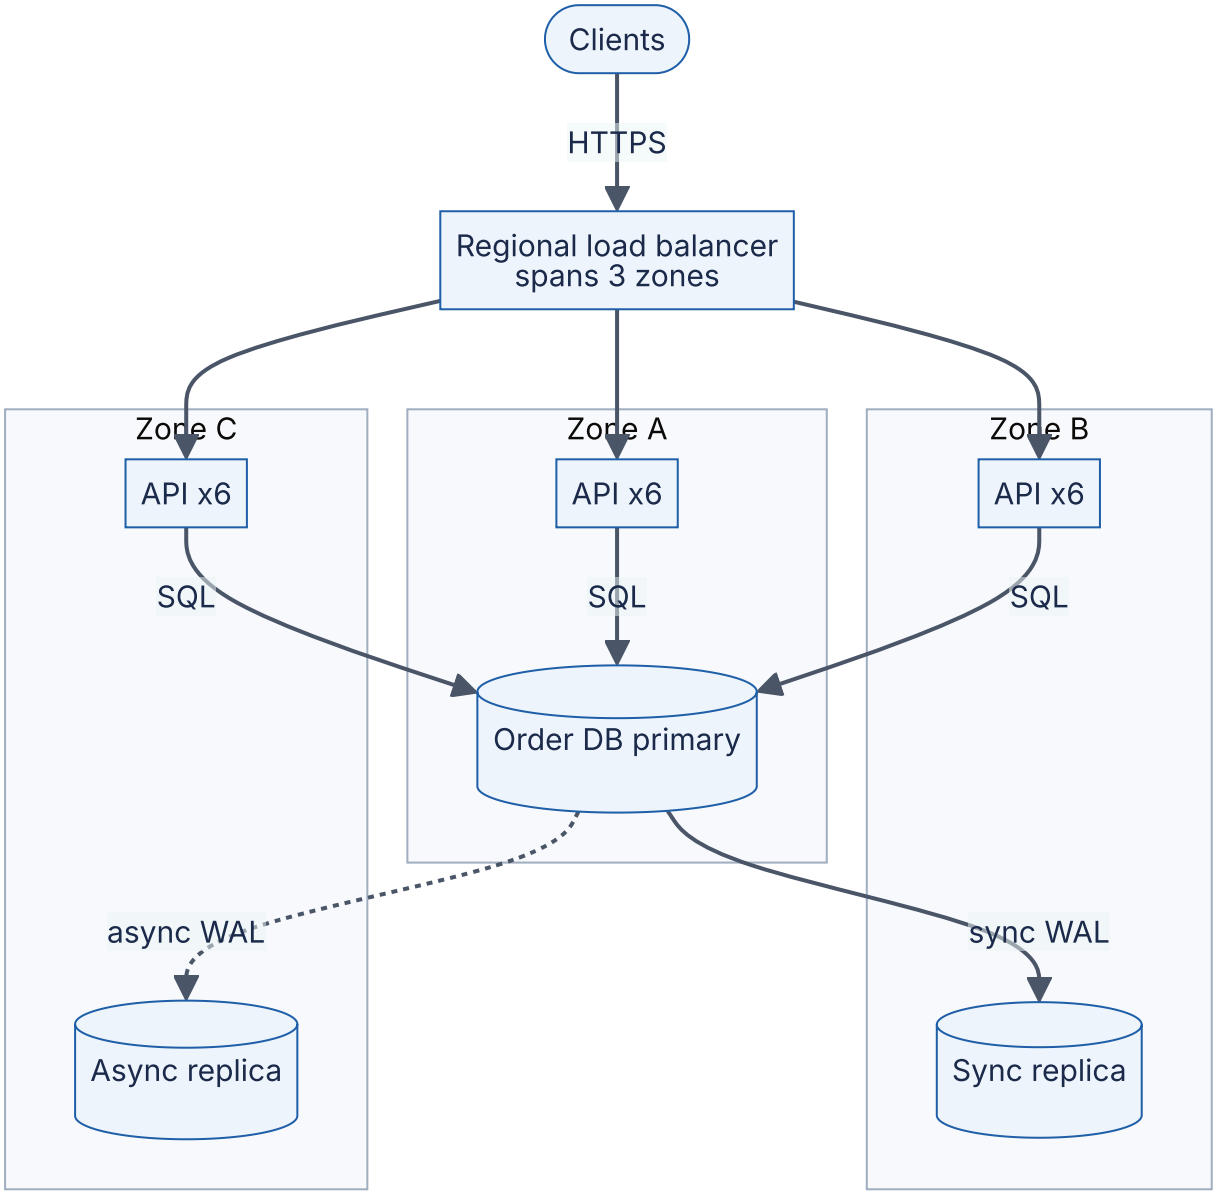
- **N** — no redundancy; any failure loses capacity.
- **N+1** — one spare: survives one unit failure.
- **N+2** — two spares: survives a failure while another unit is down for maintenance or a deploy, the usual default for services [Beyer et al. 2016].
- **2N** — a full duplicate, often in another failure domain: survives the loss of half the fleet, for example a whole zone of two.
- **Zone-level static stability** — enough capacity in the surviving zones to carry peak *without scaling action* after losing a zone [Weiss and Furr 2020].

Chapter 18 already computes the cost: for QuickBite, N+2 needs 14 API nodes and zone-safe provisioning across three zones needs 18 (§18.11.2). We do not repeat that arith-

metic here; we focus on where the spares live and what can still take them all out at once.

Redundancy also comes in temperatures: **active–active** units all serve traffic, so they are known to work; a **hot standby** runs and replicates but its readiness is unproven until used; **warm** and **cold** standbys need start-up or restoration first. Failover has its own hazards (fencing, split brain; §26.12, §27.11).

Figure 39.2 — QuickBite across three zones with zone-level static stability.



Reading the diagram. Clients reach a zone-redundant regional load balancer, which spreads HTTPS requests over three groups of six stateless API nodes; any two groups carry peak load (§18.11.2). All API nodes send SQL synchronously to the primary in Zone A, which ships each commit synchronously to Zone B before acknowledging it, so a zone loss loses no confirmed order (N3, RPO = 0), and asynchronously to Zone C. The cylin-

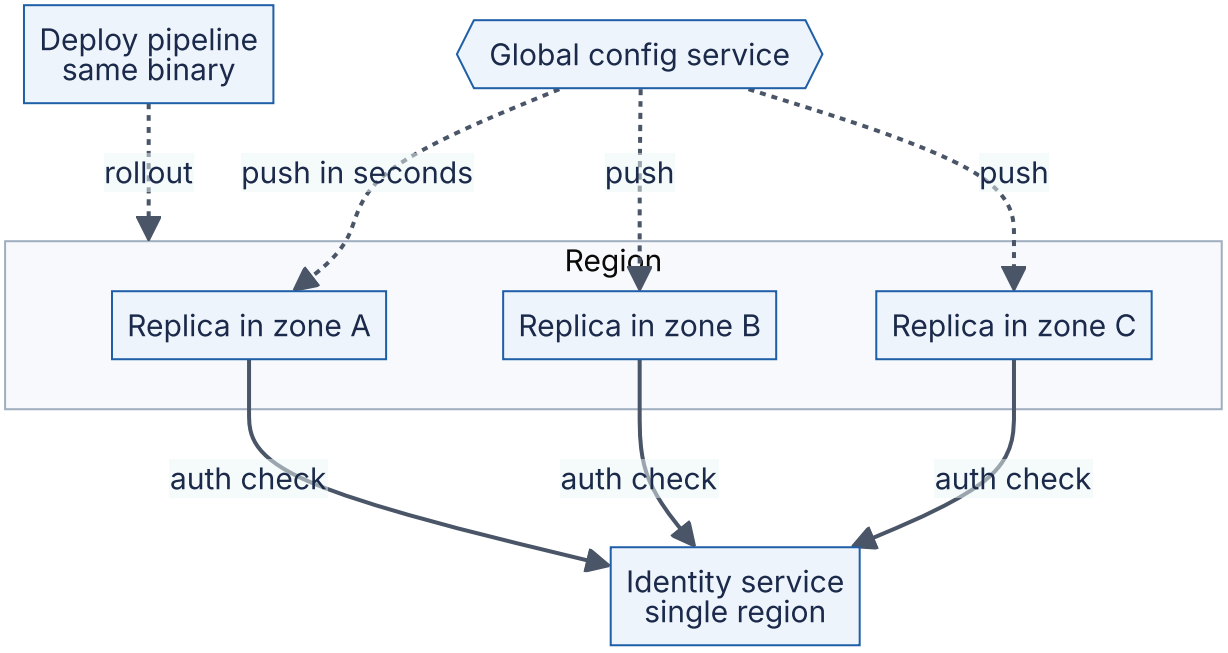
ders are the storage boundary. Failure points: losing Zone A forces a failover to Zone B (§27.11), with seconds of failed writes; losing Zone B stalls commits unless Zone C becomes the synchronous replica. Scaling: add API nodes evenly per zone; the single write primary is the limit (Chapter 14).

39.4.2 Independence assumptions and correlated failures

All the redundancy arithmetic of §4.14 multiplies probabilities, which is valid only if failures are independent. Real failures are often correlated: Ford et al. found that failures in Google's storage fleet frequently arrive in bursts that independence-based models underestimate by orders of magnitude [Ford et al. 2010]. The causes fall into a short list:

1. **Shared infrastructure** — power, cooling, top-of-rack switches, a zone's network.
2. **Shared software** — every replica runs the same binary, so the same input (a leap second, a malformed record) crashes all of them.
3. **Shared configuration and control planes** — one global configuration push, DNS change or feature-flag flip reaches every zone in seconds.
4. **Shared dependencies** — every "independent" replica calls the same identity, DNS or metadata service.
5. **Shared load** — when one replica fails, its traffic moves to the others, which then overload: a **cascading failure** (§22.9).
6. **Shared people and process** — the same operator, runbook or automation acting on every unit.

Figure 39.3 — Redundant replicas with hidden shared fate.



Reading the diagram. Three replicas in three zones look independent. Dotted arrows are asynchronous pushes: a global configuration service sends the same configuration to all three within seconds, and the deploy pipeline ships the same binary. Solid arrows are synchronous per-request calls to a single identity service. Each is a failure point that defeats zone redundancy, and adding replicas does not help; the shared state is configuration, not data. What helps is staging global changes zone by zone, caching identity decisions to ride out short identity outages, and letting each replica run on its last known good configuration (§39.5).

FORMULA

Common-cause (beta-factor) model for a redundant pair

$$U_{\text{pair}} \approx \beta U + ((1-\beta)U)^2 \qquad A_{\text{pair}} = 1 - U_{\text{pair}}$$

Symbol	Meaning	Units
U	Unavailability of one unit, $1 - A$	dimensionless
β	Fraction of a unit's failures that are common-cause, hitting both units at once	dimensionless (0–1)
U_{pair}	Probability both units are down	dimensionless
A_{pair}	Availability of the redundant pair	dimensionless

The model, borrowed from safety engineering, splits each unit's unavailability into a common-cause part βU, which takes both units down, and an independent part $(1-\beta)U$, which must happen to both units at the same time. The approximation drops a small cross term.

WORKED EXAMPLE

Worked example — How 10% shared fate costs two nines. Two zones, each 99.9% available ($U = 0.001$).

1. *Independent ($\beta = 0$):* $U_{pair} = (0.001)^2 = 10^{-6}$, $A = 99.9999\%$, about 2.6 s of downtime per 30 days.
2. *With $\beta = 0.1$:* common part $0.1 \times 0.001 = 1.0 \times 10^{-4}$; independent part $(0.9 \times 0.001)^2 = 8.1 \times 10^{-7}$; total 1.008×10^{-4}.
3. $A_{pair} = 1 - 0.0001008 = 99.990\%$, about 4.4 min per 30 days.

Interpretation. If only one failure in ten is shared, the pair is about 100 times less available than the independent model predicts, and the common-cause term dominates completely. **Engineering implication.** Once you have two zones, adding a third buys little; removing shared fate buys a lot. Stage configuration and binary rollouts per failure domain, avoid synchronous global dependencies, and test zone evacuation. Treat any availability estimate that multiplies independent probabilities as an upper bound.

INDUSTRY EXAMPLE

Meta, 4 October 2021. During maintenance, a command meant to assess backbone capacity disconnected all of Meta's data centers from the backbone; an audit tool that should have blocked it had a bug. Meta's DNS servers, designed to withdraw their BGP advertisements when they cannot reach the data centers, all withdrew at once and became unreachable. Recovery was slow because out-of-band access also depended on the backbone and engineers had to work on site. Redundant DNS sites failed together because they shared one health rule and one backbone. *Evidence: Primary* — [Janardhan 2021]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
All zones crash on one bad config	Global push, shared code path	Error SLI spikes in every zone at once	Roll back config; serve last known good	Staged per-zone rollout, config validation, canaries (Chapter 43)
Survivors overload after zone loss	Sized N+2, not zone-safe	Utilization and latency jump	Shed non-critical load (§22.9)	Static stability (§18.11.2)
Failover never completes	Standby untested; replica lag	Failover runbook times out	Manual promotion	Regular failover drills (§39.11)
Two primaries after network split	Detector fails over a live primary	Conflicting writes	Fence the old primary	Quorum, leases, fencing tokens (§26.12–§26.13)

COMMON MISTAKE

Mistake — "We are multi-zone, so we are highly available." Zones protect against zone-scoped faults: power, cooling, local network. They do nothing against a bad deploy, an expired certificate, a global configuration error or a regional control-plane failure, which together cause a large share of real outages. Ask, for each redundant set, "what single change could break all of these at once?"

39.5 Graceful degradation

39.5.1 Degrade instead of failing

DEFINITION

Definition — Graceful degradation. A design property in which, under failure or overload, a system keeps delivering its most important functions, possibly with reduced quality (staler data, fewer features, simpler results), instead of failing completely.

First-principles explanation

When a restaurant's oven breaks, a good kitchen does not close; it switches to the cold menu and tells guests. That requires a decision made in advance: which dishes matter most, and what the cold alternative is. Software is the same. You decide, before the incident, which features are critical, which are nice to have, and what each one falls back to.

Why does this exist?

Composition punishes long dependency chains: a page that needs ten 99.9% services in series is at most 99.0% available (§4.14.2). Most of those dependencies, however, are not essential to the user's goal. If the recommendation carousel fails, a customer can still order. Graceful degradation turns hard dependencies into **soft dependencies**: their failure lowers quality but not availability of the critical journey.

How it works internally

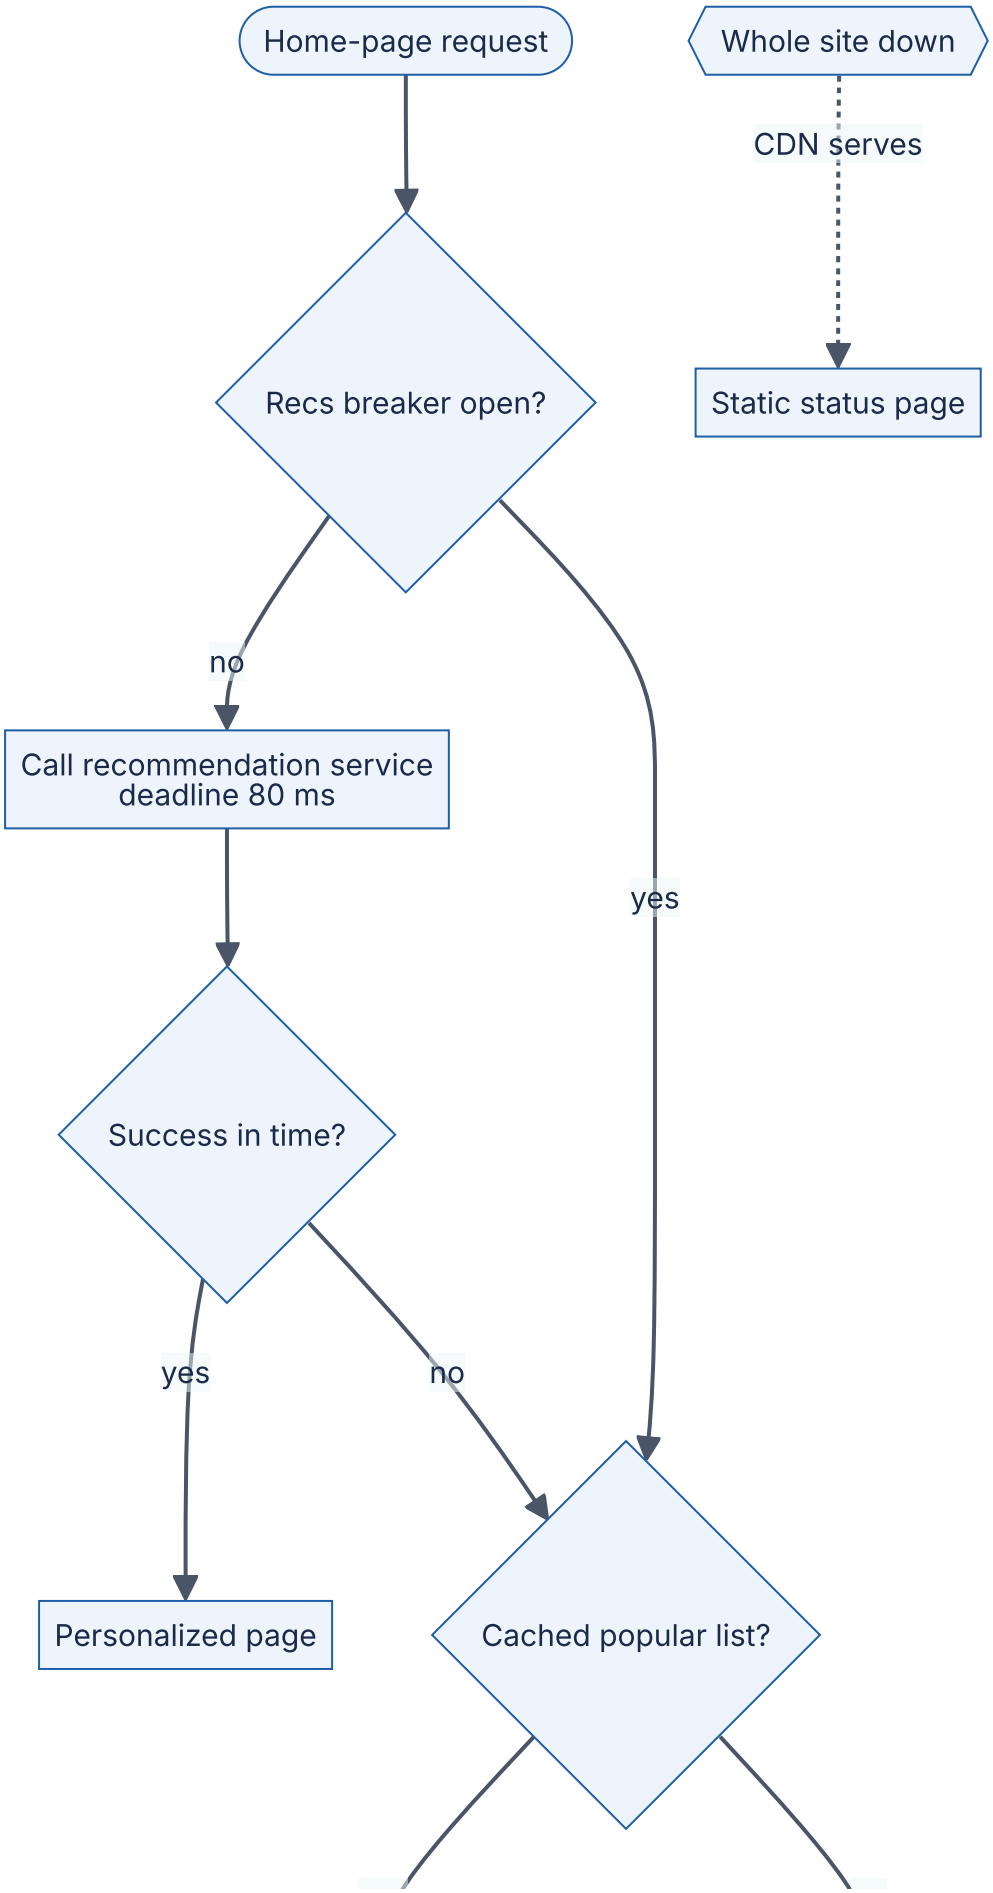
1. **Tier the features.** Classify each feature by business criticality. Table 39.2 shows QuickBite's tiers.
2. **Define a fallback for each non-critical call.** Options, from best to worst: a cached or stale value (stale-if-error, §20.11.3); a simpler computation (popular items instead of personalized ones); a static default; omitting the feature.

3. **Bound the wait.** A fallback is useless if the caller first waits 30 s for the dependency. Combine fallbacks with deadlines and circuit breakers (§22.11, §22.13), so the fallback is chosen within milliseconds once a dependency is known to be failing.
4. **Shed or switch off load deliberately** when the system is overloaded: drop lower tiers first (§22.9).
5. **Keep a static fallback page.** For a total outage, serve a static page from the CDN or object storage that says what is happening and what still works, so users see a clear message instead of a browser error.
6. **Make degraded modes visible** in metrics and in the UI, and test them: a fallback that is never exercised tends to be broken when needed.

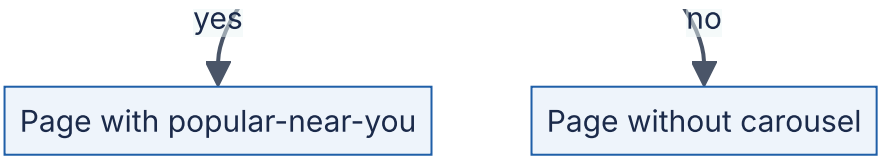
Table 39.2 — QuickBite feature tiers and fallbacks.

Tier	Features	On dependency failure	Shed under overload
0 — critical	Place order, payment, order status	Retry within deadline; secondary payment provider; fail clearly	Never (last to go)
1 — important	Search, menus, courier tracking	Cached menus (≤ 60 s stale); last known courier position	After tier 2 and 3
2 — enhancing	Personalized recommendations, ETA model	Popular-near-you list; static ETA range	Early
3 — optional	Reviews, promotions banner, analytics beacons	Hide the widget; drop beacons	First

Figure 39.4 — Choosing a response for one request under failure.



Home-page request
Whole site down
CDN serves
Recs breaker open?
Static status page
no
Call recommendation service
deadline 80 ms
yes
Success in time?
yes
no
Personalized page
Cached popular list?



Reading the diagram. The home-page request first checks the recommendation service's circuit breaker (§22.13). If closed, it makes a synchronous call with an 80 ms deadline; success yields the personalized page. A timeout, error or open breaker leads to the fallback: a cached "popular near you" list built asynchronously by a batch job (the cache is the storage boundary, not drawn), or a page without the carousel. The dotted path is the last defense: if the origin is down, the CDN serves a static page. Failure points: a fallback that calls a failing dependency, a breaker that never closes. Degraded mode is cheaper than the primary path, so it *reduces* load and helps recovery.

Brownouts

A **brownout** is degradation used as a control mechanism, not only as a failure response. Klein et al. proposed marking parts of a response as optional and serving them only with a probability called the **dimmer**; a controller lowers the dimmer when response time rises above its target and raises it when there is headroom, so the application keeps latency bounded under overload at the cost of fewer optional features [Klein et al. 2014]. The same idea can be used on purpose: deliberately switching off optional features for a small share of traffic in a game day proves that the fallbacks work.

Mathematical foundations

FORMULA

Effective success with a fallback

$$A_{\text{eff}} = A_d + (1 - A_d)\,A_f \qquad Q = A_d \cdot 1 + (1 - A_d)\,A_f\,q_f$$

Symbol	Meaning	Units
A_d	Availability of the primary dependency within its deadline	dimensionless
A_f	Availability of the fallback, given the primary failed	dimensionless
A_{eff}	Probability the caller gets some acceptable answer	dimensionless
q_f	Relative quality (or value) of the fallback answer, 1 = as good as primary	dimensionless (0–1)
Q	Expected quality per request	dimensionless

WORKED EXAMPLE

Worked example — What the popular-items fallback is worth. QuickBite's recommendation service meets its 80 ms deadline 99.5% of the time ($A_d = 0.995$). The cached popular list is available 99.99% of the time *when the recommendation service is failing* ($A_f = 0.9999$) and, from A/B tests, produces 70% of the click-through of personalized results ($q_f = 0.7$).

1. Without a fallback, the carousel is missing for $1 - 0.995 = 0.5\%$ of page views; if the page *required* it, the home page would be only 99.5% available.
2. With the fallback: $A_{\text{eff}} = 0.995 + 0.005 \times 0.9999 = 0.995 + 0.0049995 = 0.9999995$.
3. Expected quality: $Q = 0.995 + 0.005 \times 0.9999 \times 0.7 = 0.995 + 0.0034997 = 0.9985$.

Interpretation. The fallback lifts the carousel from 99.5% to six nines of "something useful", at a cost of 0.15% of recommendation quality. **Engineering implication.** The independence of A_f from the primary failure is the critical assumption: if the popular list is stored in the same cache cluster that is failing, A_f collapses. Keep fallbacks on different infrastructure, and measure A_f by exercising the fallback regularly.

Real-world industry applications

INDUSTRY EXAMPLE

Amazon on the risks of fallback. The Amazon Builders' Library argues that fallback logic is hard to test, is exercised only during rare failures, and can make an outage worse: for example, a fallback that shifts load onto a different, smaller system that then also fails. Amazon's guidance prefers making the primary path more reliable, keeping systems statically stable, and using fallbacks only when they are simple and exercised continuously, for example by pushing data proactively so the "fallback" is the normal path. *Evidence: Primary* — [Gabrielson 2019]

Advantages and disadvantages

Graceful degradation raises the availability of critical journeys cheaply and reduces load during incidents. Its costs are more code paths, more test cases, user-visible inconsistency (stale menus, missing features) and the risk of a fallback that silently stays on. Keep degraded modes observable: a "degraded responses" metric per feature, alerted when it stays high.

COMMON MISTAKE

Mistake — Degrading the critical path. Serving a cached price when placing an order, or skipping fraud checks under load, trades a small availability gain for financial loss. Degradation applies to tiers 1–3; tier 0 either succeeds correctly or fails clearly and safely.

39.6 SLI, SLO and SLA

39.6.1 Three layers of a reliability promise

DEFINITION

Definition — SLI, SLO, SLA. A **service level indicator (SLI)** is a carefully defined quantitative measure of some aspect of the service as users experience it, best expressed as the ratio of good events to valid events. A **service level objective (SLO)** is a target for an SLI over a time window, for example "99.95% of valid place-order requests succeed, over a rolling 28 days". A **service level agreement (SLA)** is a contract with a customer that states objectives and the consequences, usually financial service credits, of missing them [Beyer et al. 2016].

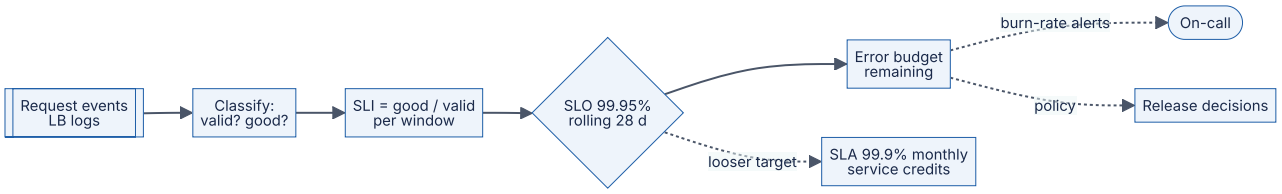
First-principles explanation

A parcel company measures the fraction of parcels delivered by the promised day: that measurement is the SLI. Internally it aims for 99%: the SLO. In the contract with a large shop it promises 97%, with a refund if it misses: the SLA. The internal target is stricter than the contract so that the company notices and reacts long before it owes money. The same layering applies to software.

Why does this exist?

Without an agreed SLO, every incident becomes an argument ("is this bad?") and every release decision is a negotiation between developers who want speed and operators who want stability. An SLO turns "reliable enough" into a number that product, engineering and operations agreed on in advance, and the error budget of §39.7 turns that number into a decision rule.

Figure 39.5 — From raw events to SLI, SLO, error budget and SLA.



Reading the diagram. Request events from load-balancer logs are classified as valid or not (health checks and client errors excluded) and good or bad; the SLI is their ratio per window. The SLO compares it with the target over a rolling window, yielding the remaining error budget, which two asynchronous consumers use: burn-rate alerts page the on-call engineer (§39.7.3), and the error-budget policy gates releases. The SLA is derived with a looser target and a calendar-month window. The storage boundary is the event store; its failure point is a broken pipeline that makes the SLI read 100% while users suffer, so alert on missing data too.

39.6.2 Choosing SLIs per user journey

Start from **user journeys**, not from components: “a customer places an order”, “a restaurant receives a new order”. For each journey, ask what the user would notice and pick a small number of SLIs, usually from a standard menu [Beyer et al. 2016; Beyer et al. 2018]:

Table 39.3 — SLI menu by kind of system.

System kind	SLI types	QuickBite example
Request-driven (APIs, web)	Availability, latency, quality (degraded answers)	Place-order success ratio; p99 latency below 800 ms
Pipeline (batch, streaming)	Freshness, correctness, coverage	Courier position at most 10 s old (F2)
Storage	Durability, availability, latency of reads/writes	Confirmed orders never lost (N3)
Asynchronous delivery	End-to-end delay, delivery ratio	New order on restaurant tablet within 5 s (F3)

Rules: measure as close to the user as practical (Figure 39.1); exclude requests that are not the service’s fault (4xx) but include 429s caused by its own overload; use ratios of events so SLIs compose into budgets; keep one to three SLIs per journey; and pick thresholds users care about (if users abandon checkout after 2 s, a 10 s threshold measures nothing).

39.6.3 Percentile SLIs

Latency is a distribution, and SLOs are about its tail (§4.8). The robust way to express “p99 below 800 ms” as an SLI is to *count* requests faster than the threshold:

FORMULA

Latency SLI as a ratio

$$\mathrm{SLI}_{\mathrm{lat}} = \frac{\#\{\text{valid requests with latency} \le \tau\}}{\#\{\text{valid requests}\}} \qquad \text{SLO: } \mathrm{SLI}_{\mathrm{lat}} \ge p$$

Symbol	Meaning	Units
τ	Latency threshold	ms
p	Target fraction of fast requests (0.99 for a "p99" objective)	dimensionless
$\mathrm{SLI}_{\mathrm{lat}}$	Fraction of valid requests at or below the threshold	dimensionless

Stating the SLO this way makes "p99 < 800 ms" and "99% of requests ≤ 800 ms" the same statement, but the ratio form can be summed across servers and time windows, while percentiles cannot be averaged (§40.5.2). In a histogram-based metrics system, make τ a bucket boundary so the count is exact.

WORKED EXAMPLE

Worked example — Is the latency SLO met, and how much budget is left? QuickBite's place-order SLO is "99% of valid requests complete within 800 ms over 28 days". In the first 14 days the order API served 7,000,000 valid requests; the 800 ms histogram bucket counted 6,941,000 at or below 800 ms. The daily p99 values, read from dashboards, ranged from 610 ms to 1,150 ms.

1. $\mathrm{SLI}_{\mathrm{lat}} = 6,941,000/7,000,000 = 0.99157$, i.e. 99.157% ≥ 99%: so far, met.
2. Slow requests allowed so far: $1\% \times 7,000,000 = 70,000$; slow requests observed: $59,000$, so $59,000/70,000 = 84\%$ of the half-window allowance is spent.
3. Projected over 28 days (about 14,000,000 requests): allowance 140,000; spent 59,000, i.e. 42% of the full-window latency budget in half the window.

Interpretation. The ratio answers the question directly and composes; averaging daily p99 values (here somewhere near 800 ms) would answer nothing. **Engineering implication.** Store latency as histograms with a bucket at every SLO threshold, compute latency SLIs as counts, and treat the latency budget exactly like the availability budget.

39.6.4 A worked SLO specification for an API

An SLO is only useful if it is precise enough that two engineers computing it from the same logs get the same number. The SRE Workbook recommends writing a short SLO

document per service with the SLI specification, its implementation, the window and the rationale [Beyer et al. 2018].

Table 39.4 — SLO specification for QuickBite's `POST /v1/orders`.

Field	Value
Journey	Customer places an order
Valid events	All `POST /v1/orders` requests at the regional load balancer, excluding 4xx other than 429, health checks and synthetic load tests
Availability SLI	Responses with status 2xx, or 409 for a duplicate idempotency key (§22.15), divided by valid events
Latency SLI	Valid requests completed within 800 ms at the load balancer, excluding payment-provider time reported in a response header
Availability SLO	99.95% over a rolling 28-day window
Latency SLO	99% within 800 ms over a rolling 28-day window
Error budget	0.05% of valid requests (about 7,000 failed orders per 28 days at 500,000 orders/day)
Measurement source	Load-balancer access logs, cross-checked weekly with client telemetry
Rationale	Negotiated in Chapter 2 (N1, N2); users retry once, so brief failures cost little

39.6.5 SLAs and service credits

An SLA differs from an SLO in three ways: a looser target, usually a calendar-month window, and definitions (downtime, exclusions, claims) written for contracts. Public cloud SLAs typically commit to a monthly uptime percentage and pay tiered service credits, a percentage of the monthly bill that grows as availability falls; for example, AWS's compute SLA commits to 99.99% region-level monthly uptime with credits starting at 10% below that level (as of 2025) [AWS Compute SLA]. Credits are small compared with customers' own losses: an SLA signals confidence; it is not insurance.

WORKED EXAMPLE

Worked example — Setting the SLA below the SLO. QuickBite sells a restaurant-chain API with an SLA (illustrative) of 99.9% monthly availability: 10% credit below 99.9%, 25% below 99.5%. A chain pays $40,000 per month. The internal SLO is 99.95% over 28 days.

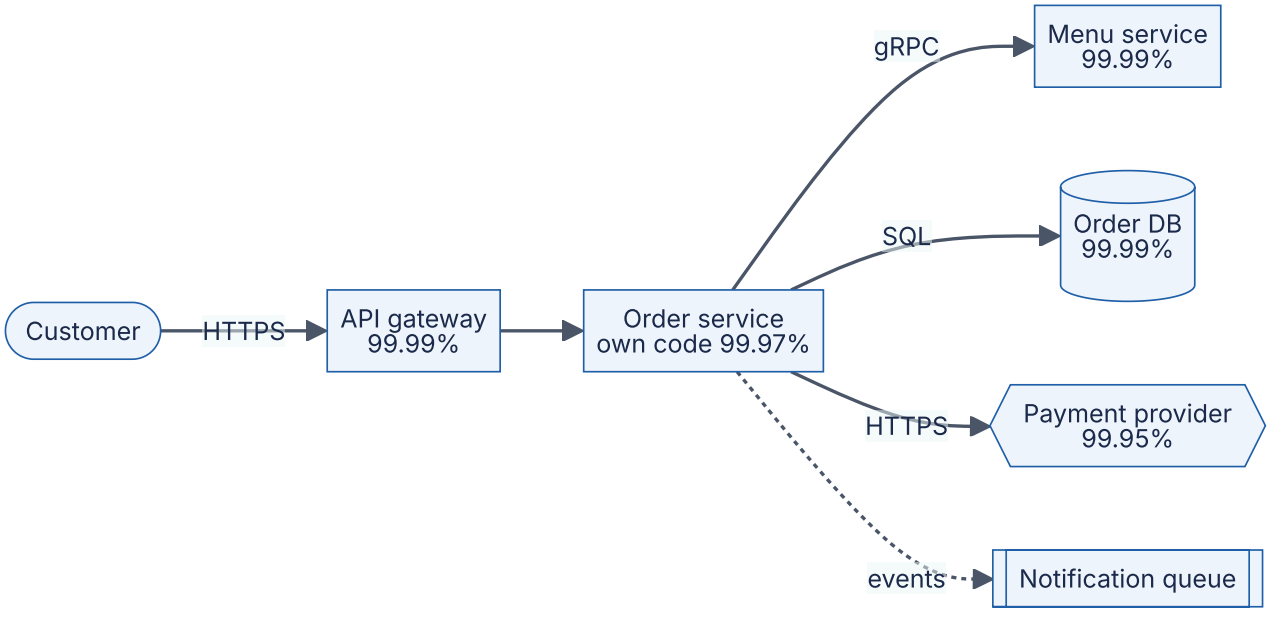
1. SLA allowance per 30-day month: $0.001 \times 43,200 = 43.2$ min. SLO allowance per 28 days: $0.0005 \times 40,320 = 20.2$ min.
2. To breach the SLA, the service must fail at twice its SLO's allowed rate, by which point the error-budget policy (§39.7.2) has frozen releases.
3. A month at 99.8% availability costs $0.10 \times 40,000 = \$4,000$ in credits; at 99.4%, $\$10,000$.

Interpretation. The SLO–SLA gap is a safety margin measured in minutes. **Engineering implication.** Set the SLA at or below the level you have *achieved* historically, and make SLA exclusions match the SLI's definition of valid events.

39.6.6 The composite SLO of dependent services

A service cannot be more available than the dependencies it calls *synchronously and without fallback*. Treynor et al. turned this into a design rule: each critical dependency should be roughly an order of magnitude more available than the service that depends on it ("the rule of the extra 9"), or the service must be designed to tolerate its failures [Treynor et al. 2017].

Figure 39.6 — Dependencies of the place-order journey.



Reading the diagram. A customer's HTTPS request passes the API gateway to the order service, which synchronously checks the menu over gRPC, writes the order to the database (the storage boundary) and authorizes payment with an external provider over HTTPS. Each synchronous hop is in series and is a failure point. Notifications are published asynchronously to a queue (dotted), so their failure does not fail the order. Scaling each service does not change the composition; changing which calls are synchronous does.

FORMULA

Composite availability of a service with dependencies

$$A_{\text{journey}} \le A_{\text{own}} \times \prod_{i \in \text{hard deps}} A_i \qquad A_i^{\text{soft}} = 1 - (1 - A_i)(1 - A_{f,i})$$

Symbol	Meaning	Units
A_{own}	Availability of the service's own code and infrastructure	dimensionless
A_i	Availability of hard (synchronous, no fallback) dependency i	dimensionless
$A_{f,i}$	Availability of the fallback for dependency i when it is made soft	dimensionless
A_i^{soft}	Effective availability of dependency i with an independent fallback	dimensionless
A_{journey}	Upper bound on availability of the journey	dimensionless

The product is the series rule of §4.14.2 applied to a dependency graph; the soft form is the parallel rule, and both assume independence (§39.4.2).

WORKED EXAMPLE

Worked example — Can place-order meet 99.95%? Use Figure 39.6's numbers.

1. *As drawn:* $0.9999 \times 0.9997 \times 0.9999 \times 0.9999 \times 0.9995 = 0.99890$, i.e. 99.890%, about 47.5 min of failure per 30 days against a 21.6-min budget. The SLO is unreachable.
2. *Add a second payment provider* used on failure ($A_f = 0.999$): $A_{\text{pay}}^{\text{soft}} = 1 - 0.0005 \times 0.001 = 0.9999995$. Journey: $0.9999 \times 0.9997 \times 0.9999 \times 0.9999 \times 0.9999995 = 0.99940$, still short.
3. *Make the menu check soft* by validating against a local menu cache refreshed every 60 s, with prices re-checked at commit from the database, so $A_{\text{menu}} \approx 0.999999$: $0.9999 \times 0.9997 \times 0.999999 \times 0.9999 \times 0.9999995 = 0.99950$ (0.999499 before rounding), a hair below target with no margin.
4. *Raise own availability* to 99.98% through safer deployments (canaries, Chapter 43): $0.9999 \times 0.9998 \times 0.999999 \times 0.9999 \times 0.9999995 = 0.99960$, which leaves about 20% of the budget as margin.

Interpretation. A 99.95% journey cannot be built on a 99.95% hard dependency; every hard dependency spends budget, and the service's own code usually spends the most. **Engineering implication.** Draw the dependency graph of each critical journey, compute the product, and fix the shortfall by making dependencies soft (fallbacks, caches, asynchrony) or by obtaining a better-than-target dependency, not by hoping. The same calculation tells you which SLO to *ask* of an internal dependency.

COMMON MISTAKE

Mistake — Setting the SLO to the current measured availability, or to 100%. An SLO equal to today's performance turns every bad day into a violation and freezes improvement; 100% leaves no budget for change and is unachievable because users' own networks are less reliable [Beyer et al. 2016]. Start from user need and business cost, check feasibility with the composite calculation, and revisit quarterly.

39.7 Error budgets

39.7.1 The budget

DEFINITION

Definition — Error budget. The amount of unreliability an SLO permits over its window: $1 - \text{SLO}$, expressed as a number of bad requests or bad minutes. While budget remains, the team may spend it on risk (releases, experiments, migrations); when it is exhausted, reliability work takes priority [Beyer et al. 2016].

First-principles explanation

A household budget does not say “never spend money”; it says how much you may spend so that you can choose what to spend it on. An error budget does the same for failures. It ends the false choice between “ship faster” and “be stable”: both sides agree on the SLO, and the remaining budget decides, with data, whether the next risky release goes out this week.

FORMULA

Error budget for a window

$$B_{\text{req}} = (1 - \text{SLO}) \times N_{\text{valid}} \qquad B_{\text{time}} = (1 - \text{SLO}) \times T$$

Symbol	Meaning	Units
SLO	Target fraction of good events	dimensionless
N_{valid}	Valid events expected in the window	requests
T	Window length	minutes
B_{req}	Budget in bad requests	requests
B_{time}	Budget in minutes of total outage (equivalently, bad-request-minutes at 100% error)	minutes

WORKED EXAMPLE

Worked example — QuickBite’s budgets for 28- and 30-day windows.

1. 30 days = 43,200 min; 28 days = 40,320 min.
2. Browsing, 99.9%: $0.001 \times 43,200 = 43.2$ min; $0.001 \times 40,320 = 40.3$ min.
3. Place order, 99.95%: $0.0005 \times 43,200 = 21.6$ min; $0.0005 \times 40,320 = 20.2$ min.
4. Requests, place order over 28 days: $500,000 \times 28 = 14,000,000$ valid requests; $B_{\text{req}} = 0.0005 \times 14,000,000 = 7,000$ failed orders.
5. One incident failing 30% of orders for 45 minutes at average traffic: $0.30 \times 45 = 13.5$ full-outage-equivalent minutes, $13.5/20.2 = 67\%$ of the 28-day budget.

Interpretation. One moderate incident can consume two thirds of a month’s budget for a 99.95% service. **Engineering implication.** A 28-day rolling window always contains exactly four of each weekday, so weekly traffic patterns do not distort it, and it never “resets” at month end; calendar months suit SLAs and reporting. Choose rolling windows for operational decisions.

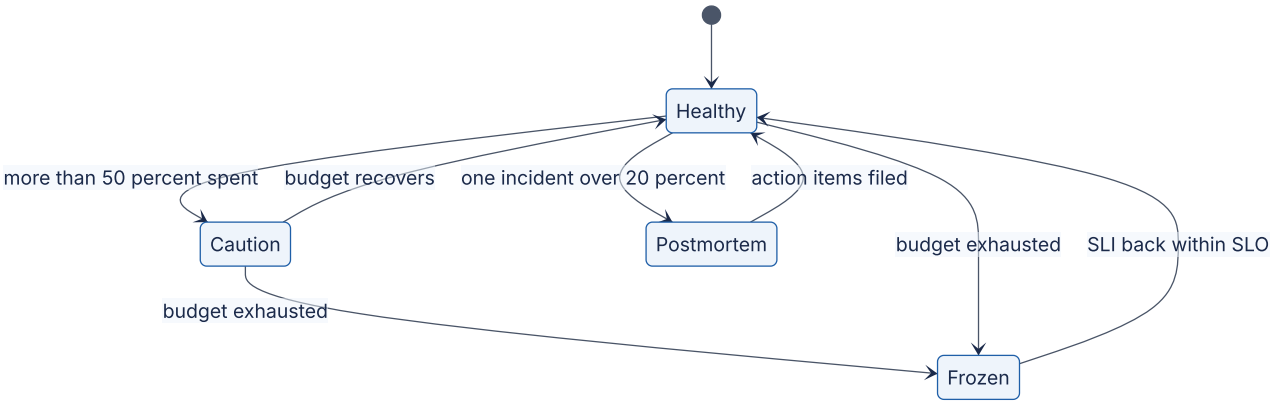
Table 39.5 — Error budget by SLO and window.

SLO	28 days (min)	30 days (min)	Per week (min)	Bad requests per 10^6
99%	403.2	432.0	100.8	10,000
99.5%	201.6	216.0	50.4	5,000
99.9%	40.3	43.2	10.1	1,000
99.95%	20.2	21.6	5.0	500
99.99%	4.0	4.3	1.0	100

39.7.2 The error-budget policy

A budget without consequences is a dashboard. An **error-budget policy** is a document, agreed by product and engineering leadership, that states what happens as the budget is spent. The SRE Workbook's example policy says, in essence, that if the service has exceeded its error budget for the preceding four-week window, all changes and releases other than P0 issues or security fixes are halted until the service is back within its SLO; that a single incident consuming more than 20% of the budget over four weeks requires a postmortem; and that disagreements are escalated to a named executive [Beyer et al. 2018].

Figure 39.7 — An error-budget policy as a state machine.



Reading the diagram. States describe the team's release posture, driven by the rolling-window budget; there is no data flow. In **Healthy**, normal releases proceed. In **Caution** (an illustrative intermediate state many teams add), risky changes need extra review and canaries run longer. When the budget is exhausted, the team enters **Frozen**: only fixes and security patches ship and engineering time moves to reliability work until the SLI is back within the SLO for the window. Independently, any single incident that consumed more than 20% of the budget triggers a mandatory postmortem (§39.12). The failure point of any policy is enforcement: write it down in advance and have leadership sign it, so it is applied in the heat of a deadline.

39.7.3 Burn rate and multiwindow, multi-burn-rate alerting

Why simple alerts fail

Alerting on “error ratio > 0.1% over 10 minutes” for a 99.9% SLO pages on every short blip that uses a tiny fraction of the budget (poor **precision**), while a steady 0.08% error ratio, which never trips it, quietly consumes 80% of the budget (poor **recall**). The SRE Workbook evaluates several designs against four properties, precision, recall, **detection time** and **reset time**, and recommends alerting on the *rate at which the budget is being consumed* over two windows at once [Beyer et al. 2018].

FORMULA

Burn rate, alert threshold and time to exhaustion

$$b = \frac{e}{1 - \text{SLO}} \qquad b_{\text{alert}} = \frac{f \times P}{W} \qquad t_{\text{exhaust}} = \frac{(1 - s)P}{b} \qquad t_{\text{detect}} = \frac{(1 - \text{SLO})\, b_{\text{alert}}\, W}{e}$$

Symbol	Meaning	Units
e	Observed error ratio over a window	dimensionless
b	Burn rate: multiple of the sustainable consumption rate (1 = budget lasts exactly the period)	dimensionless
P	SLO period	hours
f	Fraction of the period’s budget that may be consumed before the alert fires	dimensionless
W	Long alert window	hours
b_{alert}	Burn-rate threshold for the alert	dimensionless
s	Fraction of the budget already spent	dimensionless
t_{exhaust}	Time until the budget is gone at burn rate b	hours
t_{detect}	Time for a constant error ratio e to trip the long window, starting from a clean window ($e \geq (1 - \text{SLO})\, b_{\text{alert}}$)	hours

Derivation. At error ratio e, budget is consumed at $e/(1 - \text{SLO})$ times the sustainable rate, which is b. Consuming fraction f of the budget in window W means $b \times W/P = f$, so $b_{\text{alert}} = fP/W$. With $1 - s$ of the budget left and burn rate b, the remaining budget lasts $(1 - s)P/b$. The long window’s average error ratio reaches the alert level $(1 - \text{SLO})\, b_{\text{alert}}$ after t hours of error ratio e when $e\,t/W = (1 - \text{SLO})\, b_{\text{alert}}$.

WORKED EXAMPLE

Worked example — Recomputing the Workbook's 14.4, 6 and 1. The SRE Workbook recommends three alerts for a 30-day SLO: page if 2% of the budget is consumed in 1 hour, page if 5% is consumed in 6 hours, and open a ticket if 10% is consumed in 3 days, each with a short window of one twelfth of the long one [Beyer et al. 2018].

1. $P = 30 \times 24 = 720$ h.
2. Fast page: $b = 0.02 \times 720/1 = 14.4$. Slow page: $b = 0.05 \times 720/6 = 6$. Ticket: $b = 0.10 \times 720/72 = 1$.
3. As error ratios for a 99.9% SLO: $14.4 \times 0.001 = 1.44\%$, $6 \times 0.001 = 0.6\%$, $1 \times 0.001 = 0.1\%$.
4. Time to exhaustion from a full budget: $720/14.4 = 50$ h; $720/6 = 120$ h (5 days); $720/1 = 720$ h (30 days). A total outage, $e = 100\%$, burns at $b = 1/0.001 = 1,000$ and exhausts the budget in $720/1,000 = 0.72$ h $= 43.2$ min.
5. Detection time of the fast page for a total outage: $0.001 \times 14.4 \times 60 \text{ min}/1.0 = 0.864$ min ≈ 52 s. For a 5% error ratio: $0.001 \times 14.4 \times 60/0.05 = 17.3$ min, by which time $0.05 \times 17.28/43.2 = 2\%$ of the budget has gone, exactly the design fraction.
6. For a 28-day window, $P = 672$ h: the same fractions give 13.44, 5.6 and 0.93. Using 14.4 unchanged on a 28-day window pages at $14.4/672 \times 1 = 2.14\%$ consumption instead of 2%, a negligible difference.

Interpretation. Each alert fires when a fixed share of the budget is gone, whatever the error ratio: severe incidents are detected in about a minute, mild ones only when they matter. **Engineering implication.** Pick f and W by asking "how much budget may we lose before a human must act, and how fast?", then derive b; do not copy 14.4 without knowing what it encodes.

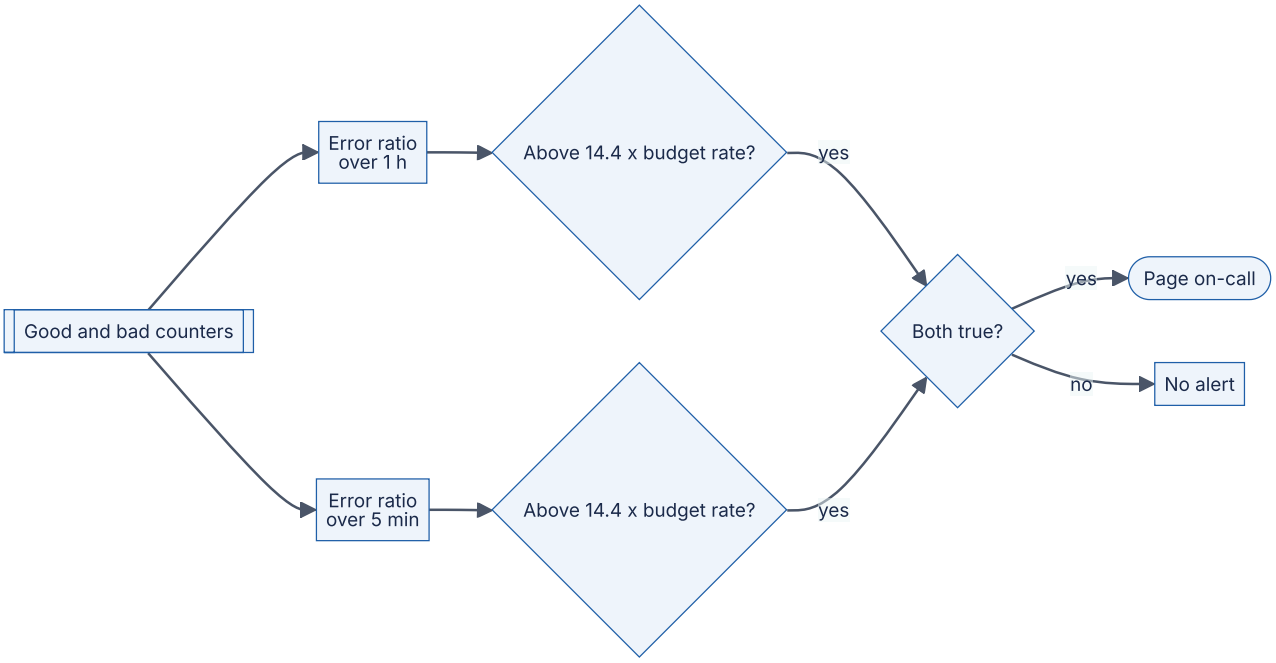
Two windows per alert

A long window alone has a slow **reset time**: after a one-hour total outage ends, the 1-hour window still averages above 1.44% for most of the next hour, so the alert keeps firing after the fix. Requiring the *short* window (here 5 minutes) to exceed the same burn rate as well makes the alert stop within about 5 minutes of recovery while barely delaying detection.

Table 39.6 — Multiwindow, multi-burn-rate alerts for a 99.9%, 30-day SLO.

Severity	Budget consumed	Long window	Short window	Burn rate	Error ratio	Detection at 100% errors
Page	2%	1 h	5 min	14.4	1.44%	52 s
Page	5%	6 h	30 min	6	0.6%	2.2 min
Ticket	10%	3 d	6 h	1	0.1%	4.3 min

Figure 39.8 — Evaluating one multiwindow burn-rate alert.



Reading the diagram. Good and bad request counters, stored as time series (the storage boundary), are evaluated over two windows every evaluation interval, typically 30–60 s. Each window's error ratio is compared with the same threshold, $14.4 \times (1 - \text{SLO})$. The page fires only if both comparisons are true: the long window proves the problem is significant, and the short window proves it is still happening. The same structure is repeated for each row of Table 39.6, so a single SLO has three rules. The failure points are missing data (counters stop, ratios become undefined: alert on absence separately) and very low traffic, where a few errors produce huge ratios. Prometheus recording rules for this pattern are shown in §40.10.

Code example: a burn-rate calculator

The program below derives the thresholds and then replays a synthetic incident minute by minute to show when each alert fires and how much budget is gone by then.

```
        """Error-budget and multiwindow, multi-burn-rate calculator (minute resolu-
tion)."""
        from dataclasses import dataclass

        @dataclass
        class AlertRule:
            name: str
            budget_fraction: float  # share of the period's budget spent before alerting
            long_min: int           # long window, minutes
            short_min: int          # short window, minutes (about long/12)
            action: str

        def burn_rate_threshold(rule, period_min):
            """Burn rate that spends `budget_fraction` of the budget in `long_min`."""
            return rule.budget_fraction * period_min / rule.long_min

        def window_ratio(bad, total, end, width):
            """Error ratio over the `width` minutes ending at minute `end` (inclu-
sive)."""
            start = max(0, end - width + 1)
            b, t = sum(bad[start:end + 1]), sum(total[start:end + 1])
            return b / t if t else 0.0

        def first_fire(rule, slo, period_min, bad, total):
            """First minute at which both windows burn faster than the threshold."""
            limit = burn_rate_threshold(rule, period_min) * (1 - slo)  # as an error ra-
tio
            for m in range(len(total)):
                if (window_ratio(bad, total, m, rule.long_min) >= limit and
                        window_ratio(bad, total, m, rule.short_min) >= limit):
                    return m
            return None

        SLO, PERIOD = 0.999, 30 * 24 * 60          # 99.9 % over 30 days, in minutes
        RULES = [AlertRule("fast page", 0.02, 60, 5, "page"),
                 AlertRule("slow page", 0.05, 360, 30, "page"),
                 AlertRule("ticket", 0.10, 4320, 360, "ticket")]

        print(f"Budget: {(1 - SLO) * PERIOD:.1f} bad minutes per 30 days")
        for r in RULES:
            br = burn_rate_threshold(r, PERIOD)
            print(f"{r.name:9s} burn rate {br:5.1f}  error ratio >= {br * (1 -
SLO):.3%}  "
                  f"budget gone in {PERIOD / br / 60:6.1f} h  -> {r.action}")

        # Synthetic traffic: 1,000 requests/minute; 4 quiet days (longer than the
        # 3-day ticket window), then a 90-minute incident at a 5 % error ratio.
        RPM, QUIET, INCIDENT = 1000, 4 * 24 * 60, 90
        total = [RPM] * (QUIET + INCIDENT + 120)
        bad = [RPM * 0.0002] * len(total)   # 0.02 % background errors (expected counts)
        for m in range(QUIET, QUIET + INCIDENT):
            bad[m] = RPM * 0.05

        budget_requests = (1 - SLO) * RPM * PERIOD   # budget in requests for the period
        for r in RULES:
            m = first_fire(r, SLO, PERIOD, bad, total)
```

```
            if m is None:
                print(f"{r.name:9s} did not fire")
                continue
            spent = sum(bad[QUIET:m + 1]) / budget_requests
            print(f"{r.name:9s} fired {m - QUIET + 1:3d} min into the incident; "
                  f"incident has spent {spent:.2%} of the 30-day budget")
```

Output (`python3`):

```
Budget: 43.2 bad minutes per 30 days
fast page burn rate  14.4  error ratio >= 1.440%  budget gone in   50.0 h  -> page
slow page burn rate   6.0  error ratio >= 0.600%  budget gone in  120.0 h  -> page
ticket    burn rate   1.0  error ratio >= 0.100%  budget gone in  720.0 h  -> ticket
fast page fired  18 min into the incident; incident has spent 2.08% of the 30-day budget
slow page fired  42 min into the incident; incident has spent 4.86% of the 30-day budget
ticket    fired  70 min into the incident; incident has spent 8.10% of the 30-day budget
```

What to notice:

- `burn_rate_threshold` is the formula fP/W; nothing else in the program is specific to 14.4.
- `first_fire` requires *both* windows to exceed the threshold, exactly as in Figure 39.8.
- The fast page fires at minute 18, matching the hand calculation of 17.3 min, with about 2% of the budget spent: the alert is tuned to budget, not to error ratio.
- The slow page and ticket fire slightly *before* their nominal 5% and 10%, because the 0.02% background errors already fill part of their long windows.
- The quiet period exceeds the 3-day window on purpose: a partly empty long window fires early, a real effect for new services.

WARNING / TRADE-OFF

Warning — Burn-rate alerts on low-traffic services. At 10 requests per minute, the 5-minute window holds 50 requests, so one failure is a 2% error ratio and trips a 14.4× alert on a 99.9% SLO. Options: generate synthetic traffic, aggregate several small services into one SLO, require a minimum number of failures before alerting, or lengthen windows and accept slower detection [Beyer et al. 2018].

COMMON MISTAKE

Mistake — Treating the error budget as a quota to spend down to zero. The budget is permission, not an obligation, and it is computed on a rolling window, so spending it all early leaves no room for the outage you did not plan. Equally, a budget that is never spent suggests the SLO is too strict or the team is too cautious.

39.8 Disaster recovery, RTO and RPO

39.8.1 Recovery objectives

DEFINITION

Definition — Disaster recovery, RTO, RPO. Disaster recovery (DR) is the set of plans and mechanisms for restoring service and data after an event that redundancy within the normal deployment cannot absorb: loss of a region, mass data corruption, ransomware, a destructive operator error. The **recovery time objective (RTO)** is the maximum acceptable time from disruption to restored service. The **recovery point objective (RPO)** is the maximum acceptable amount of data loss, measured as time before the disruption whose writes may be lost [AWS 2021].

First-principles explanation

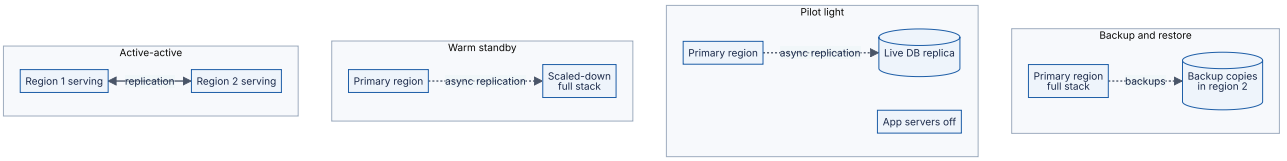
If your house floods, two questions matter: how long until you can live somewhere again (RTO), and how many of your recent photos are gone because the last copy you kept elsewhere is from last month (RPO). Fault tolerance (§39.4) keeps the lights on through small events; DR is the plan for the flood. RPO is set by how often data leaves the failure domain (backup frequency or replication lag); RTO is set by how much of the recovery environment already exists and how much is automated.

How it works internally: four strategies

The AWS DR whitepaper describes four strategies of increasing cost and decreasing RTO/RPO [AWS 2021]:

1. **Backup and restore.** Data is backed up to another region; infrastructure is recreated from code only after a disaster. RPO and RTO in hours.
2. **Pilot light.** Data is replicated continuously to the recovery region and core infrastructure (databases) runs there, but application servers are switched off; they are started and scaled on failover. RPO in seconds to minutes, RTO in tens of minutes.
3. **Warm standby.** A scaled-down but fully functional copy runs in the recovery region and can take traffic at once, then scales up. RTO in minutes.
4. **Multi-site active–active.** Two or more regions serve production traffic simultaneously; losing one shifts traffic to the others. RTO near zero; RPO near zero or zero depending on the replication model (Chapter 44).

Figure 39.9 — The four DR strategies.



Reading the diagram. Each box is one strategy, primary region on the left and recovery region on the right. Dotted arrows are asynchronous data movement: periodic backups, continuous replication into a database with no application servers (pilot light), or into a smaller complete stack (warm standby). In active–active, both regions serve and replicate to each other, which needs conflict handling or per-record write ownership (Chapter 44). The storage boundary is wherever the recovery copy lives; its age is the RPO. Failure points: restore speed (backup and restore), scaling up during a regional event when other tenants do the same (pilot light, warm standby), and spare capacity in surviving regions (active–active, §18.11.2).

Table 39.7 — DR strategies: cost versus RTO and RPO.

Strategy	Typical RPO	Typical RTO	Standing cost (vs. production)	Main risk
Backup and restore	Hours (backup interval)	Hours to a day	Storage only, a few %	Restore never tested; too slow
Pilot light	Seconds–minutes	Tens of minutes	Database replica, ~10–20%	Scale-up fails under pressure
Warm standby	Seconds–minutes	Minutes	Scaled-down stack, ~30–50%	Standby drifts from production
Active–active	Near zero to zero	Near zero	100%+ plus complexity	Conflicts; correlated global faults

The cost percentages are rough planning figures for illustration; the RPO/RTO ranges follow the AWS whitepaper’s characterization [AWS 2021].

Mathematical foundations

FORMULA

Expected annual cost of a DR strategy

$$C_{\text{total}} = C_{\text{DR}} + p(\text{RTO} \times c_{\text{down}} + \text{RPO} \times c_{\text{loss}})$$

Symbol	Meaning	Units
C_{DR}	Standing annual cost of the strategy (infrastructure, licenses, drills)	$/year
p	Expected number of disasters per year that require DR	events/year
RTO	Achieved recovery time	hours
c_{down}	Cost of one hour of full outage (lost revenue, penalties)	$/hour
RPO	Achieved data-loss window	hours
c_{loss}	Cost of losing one hour of writes (refunds, re-entry, trust)	$/hour of data
C_{total}	Expected annual cost	$/year

WORKED EXAMPLE

Worked example — Choosing QuickBite's regional DR tier (illustrative numbers). Assume $p = 0.1$ region-scale events per year, $c_{\text{down}} = \$50,000$/h and $c_{\text{loss}} = \$200,000$ per hour of lost orders.

1. *Backup and restore* (RTO 10 h, RPO 1 h, $C_{\text{DR}} = \$8$k): $0.1 \times (10 \times 50\text{k} + 1 \times 200\text{k}) = 0.1 \times 700\text{k} = \$70$k; total \$78k.
2. *Pilot light* (RTO 1.5 h, RPO 3 min = 0.05 h, \$40k): $0.1 \times (75\text{k} + 10\text{k}) = \$8.5$k; total \$48.5k.
3. *Warm standby* (RTO 15 min, RPO 36 s = 0.01 h, \$120k): $0.1 \times (12.5\text{k} + 2\text{k}) = \$1.45$k; total \$121.5k.
4. *Active–active* (RTO ≈ 1 min, RPO ≈ 0, \$350k): $0.1 \times 1\text{k} = \$0.1$k; total \$350.1k.

Interpretation. Pilot light minimizes expected cost here. Backup and restore looks cheap until a disaster happens: one event costs \$700k, which may be unsurvivable for a start-up even if the long-run average is acceptable. **Engineering implication.** Expected value is a starting point, not the answer: add the worst single-event loss, regulatory RTO/RPO requirements and reputational effects, and note that DR tiers can differ per data set (pilot light for orders, backup and restore for analytics). Also note what this does *not* cover: QuickBite's RPO = 0 for orders applies to node and zone failures, achieved by synchronous replication within the region (Figure 39.2); cross-region replication is asynchronous, so region loss still risks seconds of orders.

COMMON MISTAKE

Mistake — "Replication is our backup." Replication copies mistakes as faithfully as data: a `DELETE` without a `WHERE`, a corrupting bug or ransomware encryption reaches every replica in seconds. DR needs at least one copy that is *delayed or immutable* (backups, snapshots with retention locks, delayed replicas), so you can go back to a point before the damage.

39.9 Backup strategies

39.9.1 Full, incremental and differential backups

DEFINITION

Definition — Backup types. A **full backup** copies the entire data set. An **incremental backup** copies what changed since the *previous backup of any type*. A **differential backup** copies what changed since the *last full backup*. A **snapshot** is a point-in-time image, usually copy-on-write, taken by the storage layer.

Restore needs a **chain**: a full backup plus every incremental since it, or a full backup plus the latest differential. Incrementals are small and fast to take, but restore needs every link to be present and valid; differentials grow through the week but restore from two pieces.

WORKED EXAMPLE

Worked example — Weekly full with daily incrementals or differentials. A 4 TB database changes 200 GB of distinct blocks per day (assume no block changes twice in a week, the worst case for differentials). Full backup on Sunday.

1. *Incremental:* six daily backups of 200 GB; weekly storage $4 + 6 \times 0.2 = 5.2$ TB; Saturday restore = full + 6 incrementals = 7 pieces, 5.2 TB read.
2. *Differential:* day k holds $0.2k$ TB; storage $4 + 0.2(1 + 2 + \ldots + 6) = 4 + 4.2 = 8.2$ TB; Saturday restore = full + 1 differential = 2 pieces, $4 + 1.2 = 5.2$ TB read.

Interpretation. Differentials cost 58% more storage here to cut the restore chain from 7 pieces to 2; with overlapping changes the differentials shrink. **Engineering implication.** Long incremental chains multiply the chance that one corrupt or missing piece breaks the restore; many systems therefore take periodic synthetic fulls (merging incrementals into a new full) to keep chains short.

Table 39.8 — Backup approaches compared.

Approach	Backup time and size	Restore	Best for
Incremental	Fast, smallest	Longest chain	Frequent backups of large data
Differential	Grows until next full	Two pieces	Middle ground
Storage snapshot	Seconds, copy-on-write	Fast, but often same failure domain	Short-term rollback; copy elsewhere for DR
Logical dump (e.g. `pg_dump`)	Slow for large DBs	Portable across versions	Migrations, small DBs
Base backup + WAL archive	Continuous	Any point in time	Databases needing low RPO

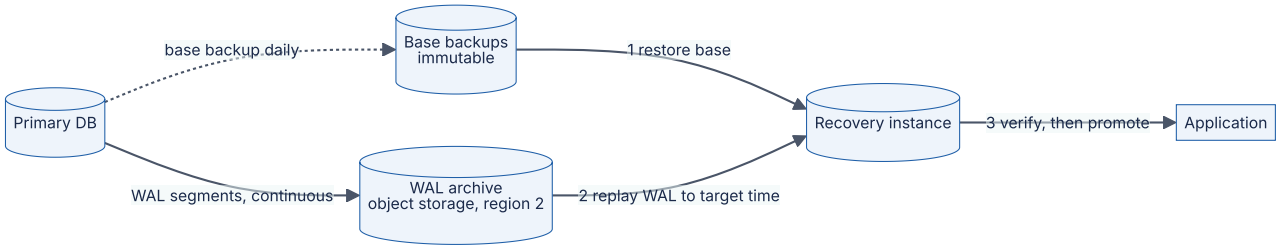
39.9.2 The 3-2-1 rule

A widely used rule of thumb: keep at least **3** copies of data, on **2** different kinds of media or storage systems, with **1** copy off site. Modern practice adds that one copy should be **immutable or offline** (object lock, separate account with no delete permission), so that an attacker or a buggy automation holding production credentials cannot delete it, and that restores are tested regularly (Chapter 10 discusses ransomware threats).

39.9.3 Point-in-time recovery with WAL archiving

A database's write-ahead log already records every change in order (§13.5). **Point-in-time recovery (PITR)** combines a periodic **base backup** (a physical copy of the data files) with a continuous **archive** of WAL segments. To recover to 14:32:10, you restore the latest base backup taken before that time and replay archived WAL up to the target time, stopping just before the `DROP TABLE` that caused the disaster [PostgreSQL Docs: PITR]. The RPO is the age of the newest archived WAL segment, often under a minute; the RTO is dominated by copying the base backup and replaying WAL.

Figure 39.10 — Base backups plus WAL archive enable point-in-time recovery.



Reading the diagram. The primary continuously ships each completed WAL segment to an archive in another region, and writes a daily base backup to immutable storage (dotted). Recovery is synchronous: restore the latest base backup before the target time onto a new instance, replay archived WAL to the target, verify, then promote. The three stores sit in different failure domains. Failure points: a gap in the WAL archive makes every later point unreachable, so monitor archive lag and continuity; restores need compatible database versions. Replay is largely single-threaded, so frequent base backups bound replay time.

FORMULA

Restore duration

$$T_{\text{restore}} = T_{\text{prov}} + \frac{S}{r_{\text{copy}}} + \frac{V_{\text{WAL}}}{r_{\text{replay}}} + T_{\text{verify}} \qquad V_{\text{WAL}} \le w \times I_{\text{base}}$$

Symbol	Meaning	Units
T_{prov}	Time to provision the recovery instance	hours
S	Size of the base backup	bytes
r_{copy}	Effective restore throughput from backup storage	bytes/s
V_{WAL}	WAL volume to replay since the base backup	bytes
r_{replay}	WAL replay rate	bytes/s
w	WAL generation rate	bytes/hour
I_{base}	Interval between base backups	hours
T_{verify}	Integrity checks and application smoke tests	hours

WORKED EXAMPLE

Worked example — Does QuickBite’s order database meet a 4-hour RTO? Database $S = 4$ TB; daily base backup at 00:00; WAL generated at 30 GB/h; disaster at 18:00. Restore from object storage at 400 MB/s; replay at 100 MB/s; provisioning 15 min; verification 30 min. (Decimal units: 1 TB = 10^{12} bytes.)

1. Copy: $4 \times 10^{12} / 4 \times 10^{8} = 10,000$ s = 2.78 h.
2. WAL: $18 \times 30 = 540$ GB; $540 \times 10^{9} / 10^{8} = 5,400$ s = 1.5 h.
3. Total: $0.25 + 2.78 + 1.5 + 0.5 = 5.03$ h: the 4-hour RTO is missed.
4. Fix: base backups every 6 h ($V_{\text{WAL}} \le 180$ GB, 0.5 h) and parallel restore at 1 GB/s (1.11 h): $0.25 + 1.11 + 0.5 + 0.5 = 2.36$ h.

Interpretation. Restore time is dominated by bytes moved and WAL replayed, both of which grow silently as the business grows. **Engineering implication.** Compute RTO from measured restore drills, not vendor throughput figures, re-run the calculation as data grows, and if no backup schedule fits the RTO, move up a DR tier (a standby replica that is already restored).

39.9.4 Restore testing

A backup that has never been restored is a hypothesis. Automate restore tests (for example weekly: restore the latest backup into an isolated environment, run integrity and row-count checks, record the duration as the measured RTO) and run periodic DR drills with people following the runbook. As the SRE book puts it, users need recovery, not backups [Beyer et al. 2016].

INDUSTRY EXAMPLE

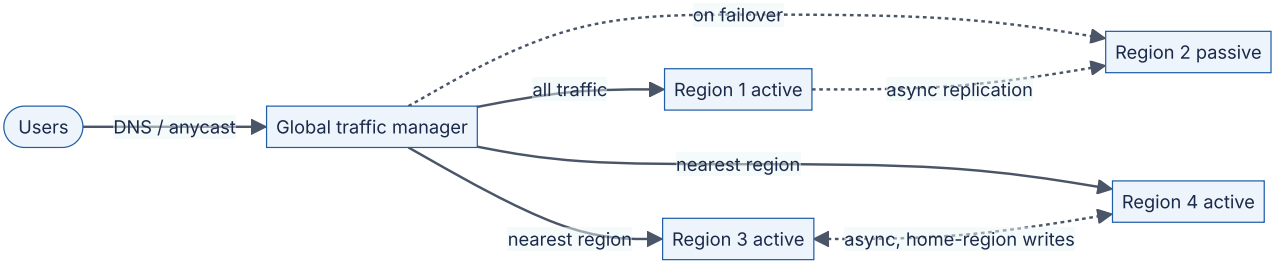
GitLab.com, 31 January 2017. While fighting a replication problem under load, an engineer ran a directory removal intended for the secondary database server on the primary, deleting roughly 300 GB of production data. The team then found that their regular `pg_dump` backups had been silently failing (a database version mismatch, with failure notifications lost to email rejection) and that other backup mechanisms were not enabled for the database. They restored from a copy taken about six hours earlier for staging, losing about six hours of database changes on GitLab.com; the restore itself took many hours because of slow disks. GitLab published a detailed, blameless postmortem and live-streamed the recovery. *Evidence: Primary* — [GitLab 2017]

What goes wrong	Why	Detection	Recovery	Prevention
Backups silently failing	Job errors not alerted	Restore test fails or none exists	Take a fresh backup now	Alert on backup age and size; automated restore tests
Backups deleted with production	Same credentials and account	Audit logs	None if no other copy	Immutable, cross-account copy (3-2-1)
Restore exceeds RTO	Data growth; slow replay	Drill timings trend upward	Use standby instead	Re-run restore math quarterly
PITR target unreachable	Gap in WAL archive	Archive continuity check	Restore to last contiguous point	Monitor archive lag and gaps

39.10 Multi-region architecture (introduction)

A **region** is a geographic area containing several isolated zones (§41.4). Multiple regions protect against region-wide failures and bring service closer to distant users, at the price of cross-region latency (tens to hundreds of milliseconds, §4.17) and harder consistency. The basic choice is between **active–passive**, where one region serves and another stands by (the pilot-light and warm-standby tiers of §39.8), and **active–active**, where all regions serve and data replication must handle concurrent writes, either by giving each record a home region or by conflict resolution (§27.14).

Figure 39.11 — Active–passive versus active–active regions.



Reading the diagram. Users resolve the service through a global traffic manager (DNS or anycast, §19.9). On the left, active–passive: Region 1 takes all traffic and replicates asynchronously to Region 2, which receives traffic only on failover, a decision with RPO and split-brain implications (§26.12). On the right, active–active: users go to the nearest region, which replicate to each other asynchronously, each record written in its home region to avoid conflicts. Each region's databases are storage boundaries; the global traffic manager and any global control plane are shared fate (§39.4.2). Chapter 44 covers global traffic management, data residency and cell architecture in depth.

39.11 Chaos engineering

> DEFINITION
>
> **Definition — Chaos engineering.** "The discipline of experimenting on a system in order to build confidence in the system's capability to withstand turbulent conditions in production" [Principles of Chaos Engineering].

39.11.1 Experiments, not breakage

First-principles explanation and why it exists

Fire drills exist because the first real fire is a bad time to discover that the exit is locked. Redundancy, failover and fallbacks are claims; chaos engineering tests them deliberately, at a time you choose, with the blast radius you choose. Netflix's Chaos Monkey, which randomly terminates production instances during business hours, forced every service to tolerate instance loss [Izrailevsky and Tseitlin 2011]. Basiri et al. later formalized the practice: it is *experimentation*, not random breakage [Basiri et al. 2016].

How it works

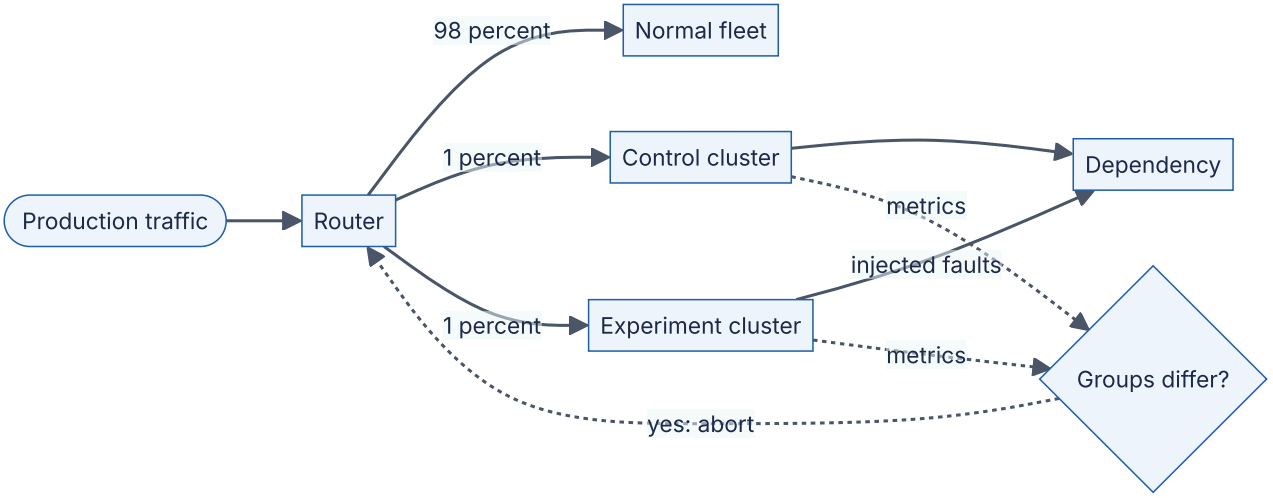
The principles describe an experiment in five steps [Principles of Chaos Engineering; Basiri et al. 2016]:

1. **Define steady state** as a measurable business output, not internal metrics. Netflix uses stream starts per second, which follows a predictable daily pattern.

2. **Hypothesize** that steady state continues in both a control group and an experimental group.
3. **Introduce real-world events**: instance and zone loss, latency, errors from a dependency, clock skew, full disks.
4. **Try to disprove the hypothesis** by comparing the two groups. A difference reveals a weakness.
5. **Minimize the blast radius** and automate: start small, abort automatically, run continuously.

Netflix's Chaos Automation Platform (ChAP) applies this to microservices: it routes a small share of traffic to a control cluster and an equal share to an experiment cluster in which failures are injected into calls to one dependency, compares their key metrics, and stops the experiment automatically if they diverge too much [Basiri et al. 2019].

Figure 39.12 — A chaos experiment with control and experiment groups.



Reading the diagram. A router sends most production traffic to the normal fleet and two equal small shares to a control and an experiment cluster running the same version. Calls from the experiment cluster to one dependency receive injected failures or latency. Both groups' steady-state metrics flow asynchronously to a comparator, which stops the experiment's traffic if the groups diverge. There is no new storage boundary; the failure points are the abort path and side effects that escape the slice (shared caches, queues, databases). Grow the slice only after it passes at small size.

FORMULA

Error-budget cost of an experiment

$$B_{exp} = s \times e_{max} \times t$$

Symbol	Meaning	Units
s	Fraction of traffic in the experiment group	dimensionless
e_{max}	Worst-case error ratio in the experiment group before abort	dimensionless
t	Experiment duration	minutes
B_{exp}	Worst-case budget consumed, in full-outage-equivalent minutes	minutes

WORKED EXAMPLE

Worked example — Is a 30-minute experiment affordable? QuickBite injects payment-provider timeouts into 1% of checkout traffic for 30 minutes. Worst case, every experiment request fails.

1. $B_{exp} = 0.01 \times 1.0 \times 30 = 0.3$ min.
2. Place-order budget per 28 days: 20.2 min; share: $0.3/20.2 = 1.5\%$.
3. With automatic abort after 2 minutes of divergence, the realistic worst case is $0.01 \times 1.0 \times 2 = 0.02$ min, 0.1% of the budget.

Interpretation. A well-bounded experiment costs a small, predictable slice of the budget. **Engineering implication.** Budget experiments explicitly, pause them when the error-budget policy is in Caution or Frozen, and grow the slice only after the hypothesis holds at small scale.

Game days are scheduled, human-run exercises: a team deliberately fails a zone, a primary or a dependency and practices detection, runbooks and communication, testing people as much as software. They are the natural place to rehearse DR (§39.8) and restores (§39.9.4).

39.12 Incident management and blameless postmortems

39.12.1 Running an incident

DEFINITION

Definition — Incident. An unplanned event that degrades or threatens a service's SLOs, security or data and requires a coordinated response. **Incident management** is the process of detecting, coordinating, mitigating and learning from incidents.

The SRE book's incident-management chapter, drawing on emergency-services practice, separates roles so nobody both fixes and coordinates [Beyer et al. 2016]:

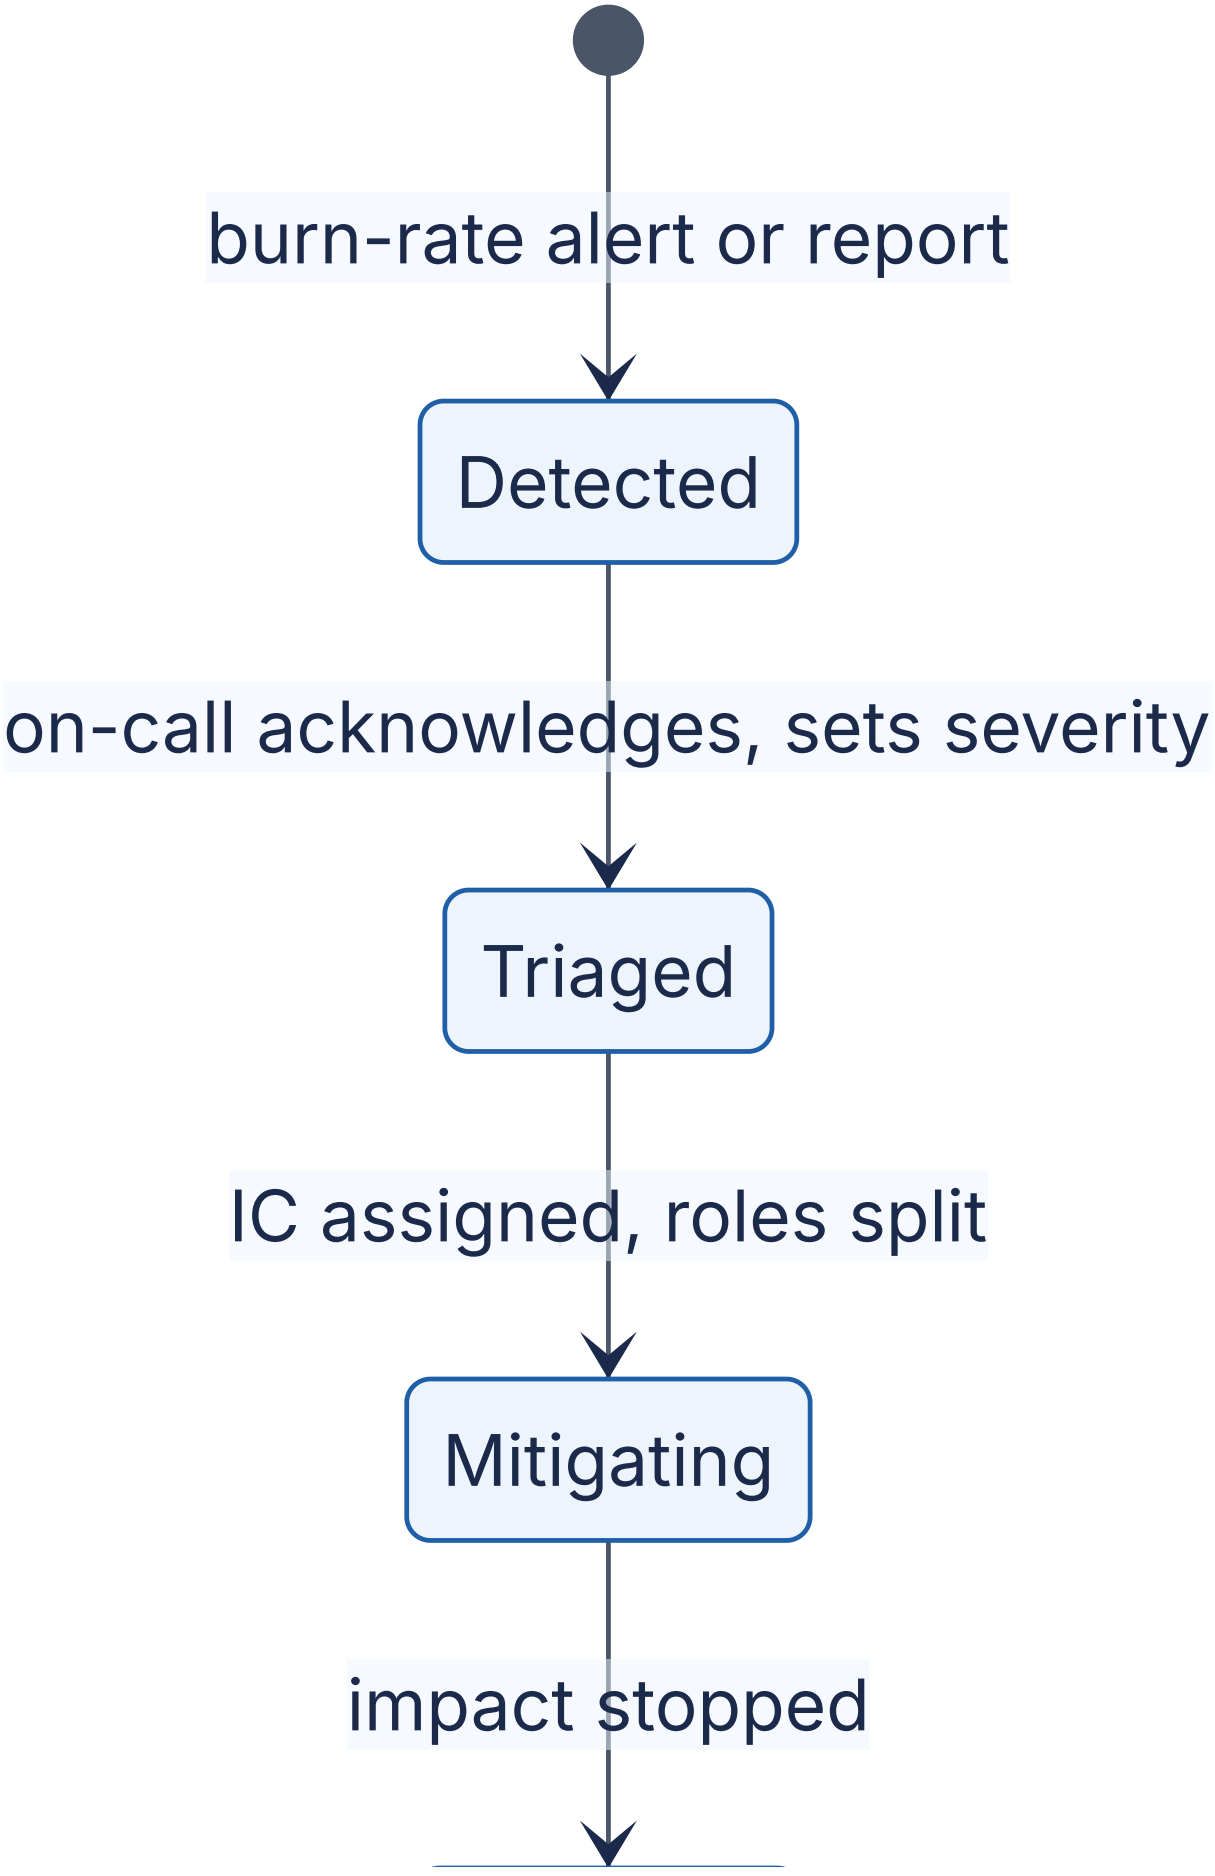
- **Incident commander (IC)** — owns the incident: sets priorities, assigns roles, decides; does not debug.
- **Operations lead** — the only person (or team) changing production.
- **Communications lead** — posts regular status updates to stakeholders and users.
- **Planning lead / scribe** — keeps the timeline, records decisions, files follow-up tickets, arranges hand-offs.

Mitigation comes before diagnosis: roll back, fail over, shed load or disable a feature first, find the cause later.

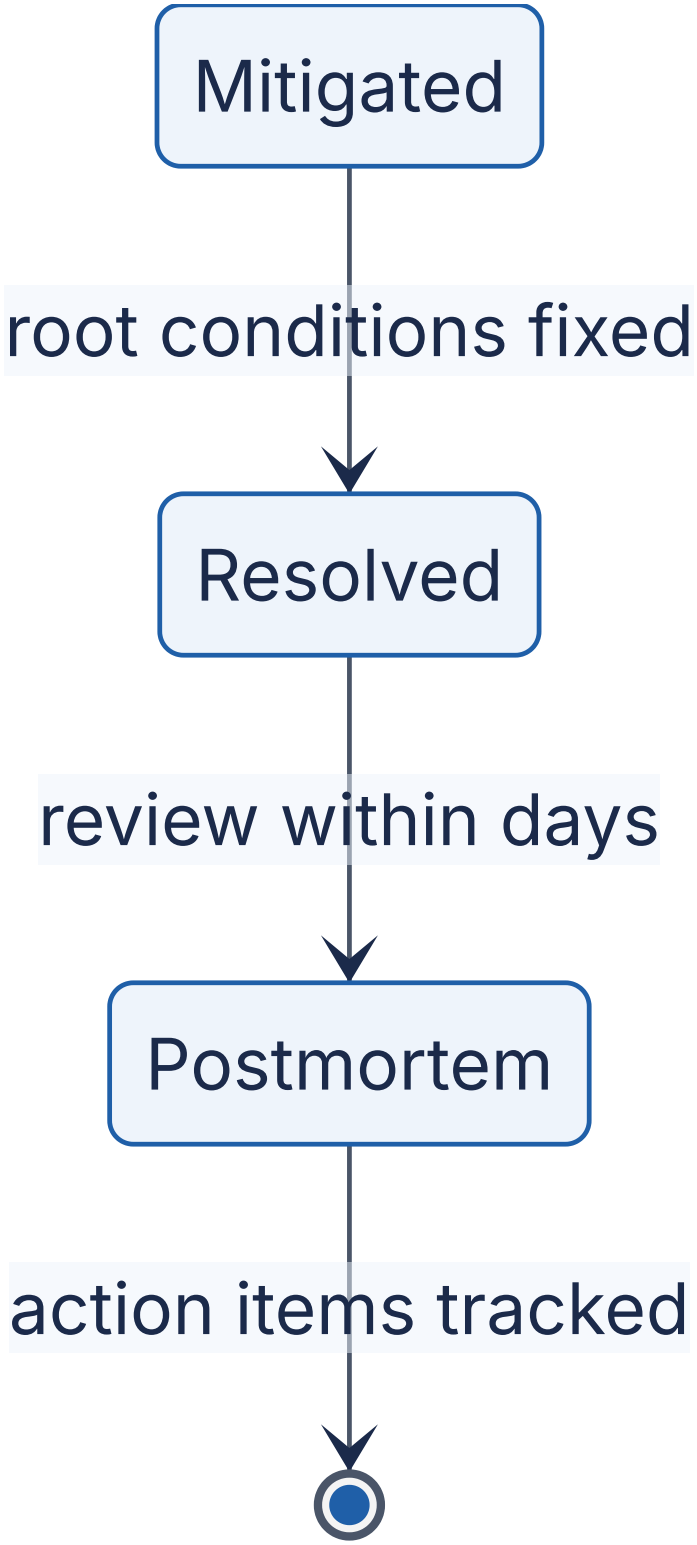
Table 39.9 — Severity levels (an illustrative scheme).

Severity	Definition	Response
SEV1	Critical journey down or data loss/security breach	Page immediately, IC assigned, public status updates every 30 min, postmortem required
SEV2	Major degradation or fast budget burn (page alerts)	Page, IC assigned, postmortem required
SEV3	Minor degradation, workaround exists (ticket alerts)	Business hours; postmortem optional

Figure 39.13 — Incident lifecycle.



burn-rate alert or report
Detected
on-call acknowledges, sets severity
Triaged
IC assigned, roles split
Mitigating
impact stopped



Reading the diagram. States are phases of one incident, with no data flow. An alert or report moves it to Detected; acknowledgment and a severity make it Triaged; the IC splits roles and the operations lead mitigates. The intervals give time to detect, acknowledge and mitigate, which sum to the user-visible duration (the MTTR of §4.15). Mitigated is not Resolved: a rollback stops impact long before the defect is fixed. The failure point is hand-offs, especially across time zones; a written timeline and explicit role transfers address it.

39.12.2 Blameless postmortems

A **postmortem** is a written record of an incident: impact, timeline, contributing factors and action items. It is **blameless** when it assumes everyone acted reasonably given the information they had, and asks why the system made the harmful action easy and the problem hard to see. Allspaw argued that blaming and punishing people makes engineers hide information, which destroys the learning the organization needs; engineers who can describe their actions without fear give the most accurate accounts [Allspaw 2012]. Cook's "How Complex Systems Fail" supplies the theory: complex systems always run with latent flaws, catastrophe needs several failures to combine, "post-accident attribution to a 'root cause' is fundamentally wrong", and hindsight bias makes the right action look obvious afterwards [Cook 1998; Dekker 2014].

Table 39.10 — Five whys versus contributing-factors analysis.

Aspect	Five whys	Contributing-factors analysis
Shape	One linear causal chain	A network of conditions that combined
Ends at	A single “root cause”, often a person	Several factors: technical, process, organizational
Strength	Quick, easy to teach	Matches how complex systems fail
Risk	Stops at “operator error”; misses latent conditions	Takes longer; needs a skilled facilitator

Good action items are specific, owned, dated and tracked, and they are a mix of **prevent** (validate configuration), **mitigate** (feature flags, kill switches), and **detect** (better SLIs and alerts). “Be more careful” is not an action item.

INDUSTRY EXAMPLE

Google Cloud, 12 June 2025. Google’s incident report describes a quota-policy feature added on 29 May 2025 to Service Control, which checks authorization and quota for Google Cloud APIs. The new code path had no feature flag and inadequate error handling, and was not exercised during rollout because only a specific policy triggered it. On 12 June, a policy change containing blank fields was inserted into the regional Spanner tables that Service Control reads; Spanner replicated it globally within seconds, and the null pointer crashed Service Control binaries in every region. Engineers identified the cause and prepared a “red-button” to disable the path within minutes, and smaller regions recovered first; in large regions such as us-central1, restarting tasks without randomized exponential backoff created a herd effect on the underlying Spanner infrastructure, prolonging recovery. Remediation includes making Service Control fail open, feature-flagging critical changes, propagating global metadata gradually, and better error handling and backoff. The contributing factors map onto this chapter: global configuration as shared fate (§39.4.2), an untested path without a kill switch (§39.5), and retries without jitter (§22.12). *Evidence: Primary* — [Google Cloud 2025]

COMMON MISTAKE

Mistake — Ending the postmortem at “human error”. Human error is where the investigation starts, not where it ends [Dekker 2014]. Ask what made the action possible, why safeguards did not stop it and why recovery took as long as it did.

39.13 Summary and revision notes

SUMMARY

- Availability is correct service over time or requests; reliability is correct operation over a period; durability is not losing data; resilience is absorbing faults and recovering. Measure request-based availability for busy services, time-based or synthetic for quiet ones.
- Redundancy only helps if failures are independent; common-cause failures ($U_{\text{pair}} \approx \beta U$) dominate. Stage global changes per failure domain and avoid shared synchronous dependencies.
- Graceful degradation tiers features and gives each a fallback; $A_{\text{eff}} = A_d + (1 - A_d)A_f$ only if the fallback is independent and exercised. Brownouts use optional content as a control knob.
- SLIs are good/valid ratios per user journey; latency SLIs count requests under a threshold. SLOs are targets over windows; SLAs are looser contracts with credits. A journey is bounded by the product of its hard dependencies (rule of the extra 9).
- Error budget $= (1 - \text{SLO}) \times$ window; a policy turns it into release decisions. Burn rate $b = e/(1 - \text{SLO})$; threshold $b = fP/W$ gives 14.4, 6 and 1 for 2%/1 h, 5%/6 h, 10%/3 d on 30 days; pair each long window with a short one.
- DR strategies trade standing cost for RTO/RPO: backup and restore, pilot light, warm standby, active–active. Compare $C_{\text{DR}} + p(\text{RTO}\, c_{\text{down}} + \text{RPO}\, c_{\text{loss}})$ and the worst single event.
- Backups: full, incremental, differential; 3-2-1 with an immutable copy; PITR = base backup + WAL archive; restore time = provision + copy + replay + verify; test restores automatically.
- Chaos engineering is experimentation: steady state, hypothesis, real-world events, small blast radius, automatic abort.
- Incidents need roles (IC, operations, communications, planning), severity levels and mitigation first; postmortems are blameless and look for contributing factors, not one root cause.

39.14 Knowledge checkpoint

1. Give an example of a system that is available but unreliable.
2. Two zones are each 99.95% available with $\beta = 0.2$. Estimate the pair's unavailability.
3. A dependency is 99.0% available within its deadline and its fallback 99.9%. What is A_{eff}?
4. Why express a p99 latency objective as a ratio of fast requests?
5. Compute the error budget in minutes for 99.95% over 28 days.

6. What burn rate corresponds to a 0.5% error ratio on a 99.9% SLO, and when is the budget exhausted from full?
7. Derive the burn-rate threshold for consuming 5% of a 30-day budget in 6 hours.
8. Why does a multiwindow alert need the short window?
9. A journey depends synchronously on services at 99.99%, 99.95% and 99.9%. What is its maximum availability?
10. Distinguish RTO from RPO and give the lever that controls each.
11. Why is replication not a backup?
12. A 2 TB base backup restores at 500 MB/s and 90 GB of WAL replays at 100 MB/s; provisioning and checks take 30 min. What is the restore time?
13. What are the five principles of chaos engineering?

Answers

1. A service that is up but returns stale or wrong results, such as yesterday's prices.
2. $0.2 \times 0.0005 + (0.8 \times 0.0005)^2 = 1.0 \times 10^{-4} + 1.6 \times 10^{-7} \approx 1.0 \times 10^{-4}$, i.e. about 99.99%.
3. $0.99 + 0.01 \times 0.999 = 0.99999$.
4. Counts can be summed across servers and windows; percentiles cannot be averaged.
5. $0.0005 \times 40,320 = 20.2$ min.
6. $b = 0.005/0.001 = 5$; $720/5 = 144$ h $= 6$ days.
7. $0.05 \times 720/6 = 6$.
8. Without it, the alert keeps firing long after recovery because the long window still averages the incident (slow reset).
9. $0.9999 \times 0.9995 \times 0.999 = 0.99840$.
10. RTO is time to restore service (lever: how much recovery infrastructure already runs, automation); RPO is data lost (lever: backup frequency or replication lag).
11. Replication copies deletions and corruption to every replica; a backup is a separate, older, ideally immutable copy.
12. $2 \times 10^{12}/5 \times 10^{8} = 4,000$ s $= 1.11$ h; $90 \times 10^{9}/10^{8} = 900$ s $= 0.25$ h; total $1.11 + 0.25 + 0.5 = 1.86$ h.
13. Hypothesize about steady state; vary real-world events; run in production; automate continuously; minimize blast radius.

39.15 Interview questions

Basic

Q1. What is the difference between an SLO and an SLA? Answer. An SLO is an internal target for an SLI over a window, used to make engineering decisions. An SLA is an external contract with consequences, usually service credits. The SLA is looser than the SLO so the team reacts before money is owed, and its definitions must match the SLI's.

Q2. What is an error budget used for? Answer. It quantifies allowed unreliability, $1 - \text{SLO}$, and a policy uses it to balance release velocity and reliability: release freely while budget remains, freeze risky changes and invest in reliability when it is spent.

Intermediate

Q3. Design alerting for a 99.9% availability SLO. Answer. Alert on budget burn, not raw errors: page at burn rate 14.4 over 1 h and 5 min, and at 6 over 6 h and 30 min; ticket at 1 over 3 d and 6 h. Explain that each fires at a fixed budget fraction (2%, 5%, 10%), detection is under a minute for total outages, the short window gives fast reset, and low-traffic services need synthetic traffic or minimum counts.

Q4. How would you choose a DR strategy for an order database? Answer. Get RTO/RPO from the business, compute standing cost plus expected loss for each tier, consider the worst single event and regulation, and check feasibility: restore-time math for backup and restore, scale-up risk for pilot light. Typically: synchronous replication across zones for RPO 0 on zone loss, pilot light or warm standby across regions, plus immutable PITR backups against corruption. Test with drills.

Advanced

Q5. Your service must meet 99.99% but depends on a 99.95% dependency. What do you do? Answer. Show the product bound makes it impossible as a hard dependency. Make it soft: cache, fallback provider, asynchronous processing, or degrade the feature; or negotiate a better dependency SLO. Recompute with independence caveats and add the dependency's SLI to dashboards.

Q6. After a global outage caused by a configuration push, what should the postmortem conclude? Answer. Avoid "the engineer pushed bad config". Contributing factors: no validation, instant global propagation, no canary per region, code path without a feature flag, crash-on-bad-input instead of failing safe, recovery slowed by retry storms. Action items: staged rollouts with automatic rollback, config validation, fail-static behavior, kill switches, jittered backoff, each with an owner and date.

39.16 Practical exercises

1. Write the SLO specification (as in Table 39.4) for QuickBite's courier-tracking freshness SLI, and compute its error budget for 28 days.
2. Extend the burn-rate program to compute reset time for each alert after the incident ends, and to handle a 28-day period.
3. Restore your own development database from a backup to a point in time, measure each term of the restore formula, and compare with your RTO.

4. Run a game day in a staging environment: terminate one zone's instances and record detection, mitigation and recovery times.

39.17 Design challenges

1. **Payments platform DR.** Design DR for a payments ledger with RPO = 0 and RTO = 5 min across regions; justify the replication model and estimate the latency cost per commit.
2. **SLOs for a streaming pipeline.** Define freshness, correctness and coverage SLIs for a clickstream pipeline, its burn-rate alerts and its error-budget policy.
3. **Degradation plan.** For a ride-hailing app, tier all features, define fallbacks, and compute the availability of "request a ride" with and without them.

39.19 Open verification items

- Google Cloud 12 June 2025 report: exact red-button and per-region recovery timings, and the exact remediation list wording (sources not fetchable in this session).
- AWS Compute SLA credit tiers below 99.0% in the current version.
- GitLab 2017: data volume deleted (~300 GB) and the approximate six-hour loss window.
- Origin of the 3-2-1 backup rule (commonly attributed to Peter Krogh).
- SRE Workbook example policy wording (20% single-incident threshold; escalation path).
- Cost percentages in Table 39.7 are illustrative planning figures, not sourced.

Chapter 40 — Observability

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

At 19:40 on a Friday, QuickBite's checkout error rate climbs from 0.1% to 9%. The infrastructure dashboards are green: CPU, memory and request rate all look normal. One engineer greps logs on three machines, another restarts the payment service, and a third posts screenshots in chat. Forty minutes later someone notices that every failing order comes from the newest Android app version paying with one card network. Nothing in the dashboards could have shown that, because nobody had thought to chart "errors by app version by card network" in advance.

This chapter is about building systems that can answer questions nobody thought to ask. It covers the three classic telemetry signals (logs, metrics and traces) and what each costs, then the tools that dominate practice in 2026: OpenTelemetry for instrumentation, Prometheus for metrics, Grafana for dashboards and Alertmanager for routing alerts. It ends with the workflow that ties them together: alert, dashboard, trace, logs and profile. The chapter owns the deep treatment of distributed tracing; §34.9 gave only an introduction. QuickBite, the food-delivery platform of Chapter 2, is the running example, and all QuickBite numbers are assumptions made for teaching.

40.1 Learning objectives

After this chapter you should be able to:

- Distinguish monitoring from observability, and explain why high-cardinality, wide events answer questions that predefined dashboards cannot.
- Design a structured-logging pipeline with correlation IDs, buffering, tiered storage, sampling and PII redaction, and estimate its volume and monthly cost.
- Choose between counters, gauges, histograms and summaries; explain why percentiles cannot be averaged; and compute the series count and memory of a labeled metric.
- Explain spans, trace trees and W3C `traceparent` propagation, and compare head and tail sampling with volume, buffer and capture-probability arithmetic.
- Describe the OpenTelemetry API, SDK, Collector and OTLP, and state the stability of each signal as of 2026.
- Write PromQL `rate` and `histogram_quantile` queries and recording rules, and choose a long-term storage design (federation, Thanos, Cortex or Mimir).

- Design dashboards and symptom-based alerts with routing, deduplication, inhibition and runbooks, avoiding alert fatigue and dashboard sprawl.
- Debug an incident from alert to dashboard to trace to logs to profile, using exemplars, and explain when continuous profiling helps.

40.2 Prerequisites

- Percentiles, histograms and fan-out tail latency — §4.8 (the arithmetic of p99 is used throughout).
- USE, RED and the four golden signals — §23.3 (summarized here, not repeated).
- Profiling, flame graphs and off-CPU analysis — §23.4 (§40.12 extends them to fleets).
- Time-series databases and Gorilla compression — §12.8 (storage internals behind Prometheus).
- Microservices and the introduction to tracing — §34.8, §34.9.
- Message brokers and Kafka as a buffer — Chapters 30 and 31.
- SLIs, SLOs, error budgets and burn rates — §39.6, §39.7 (burn-rate alerts build on them).

40.3 Monitoring versus observability

40.3.1 Two definitions

DEFINITION

Definition — Monitoring. Collecting, aggregating and displaying predefined measurements of a system, and alerting when they cross thresholds, so that operators learn about *known* failure modes. The Google SRE book defines it as “collecting, processing, aggregating, and displaying real-time quantitative data about a system” [Beyer et al. 2016, ch. 6].

DEFINITION

Definition — Observability. A property of a system and its telemetry: how well you can understand *any* internal state the system gets into, including states never seen before, by asking new questions of the data it already emits, without shipping new code [Majors, Fong-Jones and Miranda 2022]. The term comes from control theory, where a system is observable if its internal state can be inferred from its outputs.

First-principles explanation

Think of a car. The dashboard warning lights are monitoring: each light was designed in advance for a known problem (low oil, high temperature). They are cheap, reliable and essential. But when the car makes a strange noise only on left turns above 60 km/h in the rain, no light exists for it. A mechanic plugs in a diagnostic tool that records hundreds of sensor values with timestamps and slices them: "show me wheel speed when steering angle is left and speed is over 60". The diagnostic recording makes the car *observable*: it supports questions the designers never anticipated.

Why does this exist?

A monolith on three servers fails in a few familiar ways, and a dozen dashboards cover them. A system of 80 microservices, 6 app versions, 4 card networks, 30 cities and daily deployments fails in combinations. The number of possible "slices" is the product of all those dimensions, far too many to chart in advance. Most production incidents in such systems are novel: if a failure mode had been seen before, it would usually have been fixed. You therefore need data rich enough to slice by *any* dimension after the fact.

40.3.2 Known-unknowns and unknown-unknowns

Monitoring answers **known-unknowns**: you know which question to ask ("is the error rate above 1%?") but not today's answer. Observability targets **unknown-unknowns**: you do not even know which question to ask until you start exploring ("which attribute do the failing requests share?").

Table 40.1 — Monitoring versus observability.

Aspect	Monitoring	Observability
Question type	Predefined: known-unknowns	Exploratory: unknown-unknowns
Typical data	Pre-aggregated metrics, fixed dashboards	Wide structured events, traces, high-cardinality fields
Answers	"Is something wrong?"	"What is different about the requests that are wrong?"
Cost driver	Number of time series	Volume of events stored and scanned
Failure mode	Green dashboards during a real outage	Expensive storage and slow queries if undisciplined

The two are complements: cheap, reliable metrics *detect* problems; rich events and traces *explain* them.

KEY CONCEPT

Concept — The "three pillars" and their limits. Logs, metrics and traces are often called the three pillars of observability. The framing is useful for tooling but misleading as a goal: three disconnected stores, each queried in a different language, do not make a system observable. What matters is that signals share identifiers (trace ID, service name, deployment version) so that you can pivot from one to another, and that at least one store keeps raw, high-cardinality context about each request [Majors, Fong-Jones and Miranda 2022].

40.3.3 High-cardinality, wide events

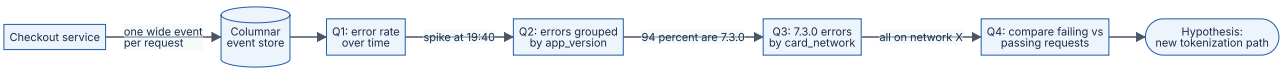
DEFINITION

Definition — Cardinality and dimensionality. The **cardinality** of a field is the number of distinct values it takes: `http.method` has about 5, `user_id` may have millions. **Dimensionality** is the number of fields attached to each event. A **wide event** (also called a canonical log line) is one structured record per unit of work, typically per request per service, carrying dozens to hundreds of fields.

How it works internally

1. At the start of a request, the service creates an empty event and adds fields as it learns them: route, user ID, app version, cart size, card network, feature-flag states, downstream call timings, cache hits.
2. At the end of the request, it adds the outcome (status, error class, duration) and emits the event once.
3. A columnar event store ingests the events. Columnar storage makes "group by any field" cheap because a query reads only the referenced columns.
4. An engineer filters and groups interactively: errors grouped by `app_version`, then by `card_network`, then compared with successful requests (Figure 40.1).

Figure 40.1 — From a symptom to a cause by slicing wide events.



Reading the diagram. The checkout service emits one wide event per request asynchronously to a columnar event store, the storage boundary. Each subsequent box is an interactive query, and each edge label is what the previous answer revealed, narrowing the population. No query was planned in advance; the investigator chose `app_version` and `card_network` while exploring, and the final step ranks field values over-represented among failures. Failure points: with only pre-aggregated counters Q2 and Q3 are impossi-

ble; without `card_network` on the event the trail goes cold. Scaling: event volume grows with traffic, so stores sample routine successes and keep all failures (§40.6.3).

Metrics systems cannot store `user_id` or `trace_id` as a label, because every distinct value creates a new time series (§40.5.3). Event stores can, because each event is a row and a new value costs only its bytes. This is the fundamental trade: **metrics are cheap per request but expensive per dimension; events are cheap per dimension but expensive per request.**

Real-world industry applications

INDUSTRY EXAMPLE

Facebook Scuba. Facebook built Scuba, an in-memory database that ingests millions of rows per second and lets engineers slice recent operational data by arbitrary columns with interactive query latency. It was used for performance monitoring, bug investigation and ad-hoc analysis, and is a direct ancestor of the wide-event approach later popularized by Honeycomb, whose founders had used Scuba at Facebook after it acquired Parse, where they worked. *Evidence: Primary* — [Abraham et al. 2013]; [Majors, Fong-Jones and Miranda 2022]

Advantages and disadvantages

Wide events give arbitrary slicing, precise counts and a natural link to traces (a span is a wide event with a parent). They cost more storage than metrics, need a columnar store with fast group-by, and require discipline: fields must be consistently named, and personal data must be controlled (§40.4.5).

COMMON MISTAKE

Misconception — "We have logs, metrics and traces, so we are observable." Observability is measured by the questions you can answer during an incident, not by the products you run. Test it: pick a past incident and ask whether the telemetry you have *today* would show the cause within ten minutes, without a code change.

40.4 Logs

40.4.1 Structured logging and levels

DEFINITION

Definition — Log and structured log. A **log** is a time-ordered record of discrete events emitted by a program. A **structured log** encodes each event as a set of named fields (usually JSON, or key–value pairs), so that machines can filter and aggregate by field instead of parsing free text with regular expressions.

First-principles explanation

A ship's captain who writes "rough night, lost some cargo" in a diary has written an unstructured log. A cargo manifest with columns for time, container ID, weight and status is a structured log. Both record the same night, but only the manifest answers "how many tonnes did we lose between 02:00 and 04:00?" without a human reading every line.

Why does this exist?

Free-text lines such as `Payment failed for order 991 after 3 retries` force every consumer to write a parser that breaks silently when the message is rephrased. At hundreds of gigabytes per day (§40.4.4) machines, not people, read logs.

```
{"ts":"2026-10-30T19:42:07.118Z","level":"ERROR","service":"payment",
 "service.version":"4.12.0","env":"prod","event":"payment.authorize.failed",
 "order_id":"o-991","card_network":"X","attempt":3,"duration_ms":2004,
 "error.type":"ProviderTimeout","trace_id":"4bf92f3577b34da6a3ce929d0e0e4736",
 "span_id":"00f067aa0ba902b7"}
```

What to notice:

- `event` is a stable, machine-friendly name; the human message, if any, is secondary.
- `trace_id` and `span_id` link this line to its trace (§40.6), which is what makes logs navigable during an incident.
- Resource fields (`service`, `service.version`, `env`) are identical across logs, metrics and traces, so you can pivot between them.
- Durations carry their unit in the field name; timestamps are UTC in ISO 8601 with milliseconds.

Table 40.2 — Log levels and how to use them.

Level	Meaning	Production default	Example
TRACE / DEBUG	Developer detail for diagnosing code paths	Off, or sampled; enable per service at runtime	Cache key computed, SQL text
INFO	Normal, noteworthy lifecycle events	On, but not one line per loop iteration	Order created, service started
WARN	Unexpected but handled; may need attention	On	Retry succeeded on attempt 2
ERROR	An operation failed and a user or job was affected	On, never sampled away	Payment authorization failed
FATAL	The process cannot continue	On	Cannot bind port; exiting

Syslog (RFC 5424) defines eight numeric severities from 0 (Emergency) to 7 (Debug), and OpenTelemetry's log data model maps all common schemes to a `SeverityNumber` from 1 to 24 [IETF RFC 5424; OpenTelemetry Specification: Logs Data Model]. Whatever scheme you use, decide what each level means for your organization and make the level changeable at runtime, so that you can turn on DEBUG for one service during an incident without a redeploy.

40.4.2 Correlation IDs

> DEFINITION
>
> **Definition — Correlation ID.** An identifier generated at the edge of the system for each incoming request (or taken from the client) and attached to every log line, span and downstream call made on that request's behalf, so that all records of one request can be retrieved together. When distributed tracing is in place, the **trace ID** serves as the correlation ID.

Without one, finding the 14 log lines of one failed order among 9 MB/s of logs means guessing by timestamp. With one, it is a single indexed lookup. Generate the ID at the first hop, propagate it on every outbound call and queued message, and inject it into log records automatically from the logging context rather than by hand. OpenTelemetry's logging bridges do this: records emitted inside an active span carry its trace and span IDs [OpenTelemetry Docs: Logs].

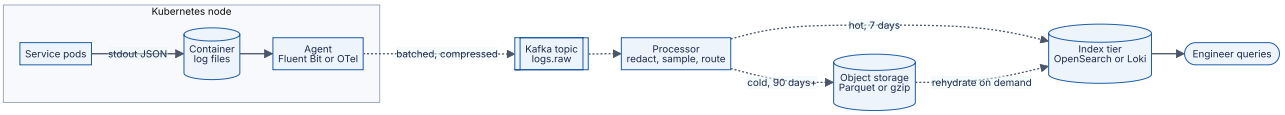
40.4.3 Log pipelines

A log pipeline moves records from thousands of processes to storage that engineers can query, without slowing the processes and without losing data when a downstream component stalls.

How it works internally

1. **Emit.** The application writes structured lines to standard output or a local file, never synchronously to a remote server: a slow log backend must not become request latency.
2. **Collect.** A node-level **agent** (Fluent Bit, Vector, the OpenTelemetry Collector or Filebeat, typically a Kubernetes DaemonSet) tails the files, adds metadata (pod, node, namespace), parses and batches.
3. **Buffer.** The agent ships batches to a durable buffer, usually a Kafka topic (Chapter 31), which absorbs bursts and lets the indexing tier be restarted or upgraded without losing data.
4. **Process.** Stream processors consume the buffer to redact personal data, drop or sample noisy events, enrich (geo-IP, team ownership) and route.
5. **Store.** Records go to two tiers: a **hot** searchable tier (Elasticsearch/OpenSearch with a full-text inverted index, Grafana Loki with a label-only index, or a columnar store such as ClickHouse) for days to weeks, and a **cold** tier of compressed files in object storage (§15.4, §15.9) for months to years, queried rarely or rehydrated on demand.

Figure 40.2 — A buffered, tiered log pipeline.



Reading the diagram. Services write JSON to standard output; the container runtime persists it to local files on the node, the first storage boundary, which survives brief agent restarts. The agent tails the files and ships compressed batches asynchronously (dotted) to a Kafka topic, the second storage boundary and the main shock absorber: if the index tier falls behind, lag grows in Kafka instead of logs being dropped. Processors consume, redact and sample, then write to the hot index for interactive search and to object storage for cheap retention; rehydration copies cold data back into an index when an investigation needs it. Only the engineer's query is synchronous. Failure points: a full node disk, Kafka retention shorter than an index outage, and mapping explosions from unbounded field names. Scaling: add Kafka partitions and consumers; shard the index by time and tenant.

Table 40.3 — Log storage back ends compared (as of 2026).

Aspect	Elasticsearch / OpenSearch	Grafana Loki	Columnar store (ClickHouse)
What it indexes	Every field and full text (inverted index, Chapter 16)	Only a small set of labels; content is scanned	Columns, with sparse primary index and optional skip indexes
Query strength	Fast full-text and field search	Cheap ingestion; “grep at scale” within labeled streams	Fast aggregations and group-by over wide events
Storage cost	Highest: index often comparable to raw size	Low: compressed chunks in object storage	Low to medium: high compression on columns
Weakness	Cost and mapping management at high volume	Slow for needle-in-haystack queries over broad label sets	Full-text search weaker than an inverted index
Choose when	Security and free-text search dominate	Most queries start from service and time, then filter	Logs are wide events and you aggregate a lot

[Elastic Docs; Grafana Loki Docs; ClickHouse Docs]

40.4.4 Volume, sampling and cost

Logging is usually the most expensive telemetry signal per useful bit, because every request produces several lines and every line is stored and often indexed.

FORMULA

Log volume and monthly cost

$$V_{\text{day}} = R \times n \times b \times 86,400 \qquad C_{\text{month}} = 30\, V_{\text{day}}\, c_{\text{hot}} + \frac{V_{\text{day}}\, T_{\text{cold}}}{\rho}\, c_{\text{cold}}$$

Symbol	Meaning	Units
V_{day}	Raw log volume per day	bytes/day
R	Average request rate across all services	requests/second
n	Log lines emitted per request (all services)	lines/request
b	Average size of one structured line	bytes/line
c_{hot}	Price to ingest, index and keep one GB in the hot tier for its retention	$/GB
T_{cold}	Cold-tier retention	days
ρ	Compression ratio in the cold tier	dimensionless
c_{cold}	Object storage price	$/GB-month
C_{month}	Monthly cost (30-day month)	$/month

WORKED EXAMPLE

Worked example — QuickBite's log bill. Assumptions (illustrative, not any vendor's price list): $R = 3,000$ requests/s across services, $n = 6$ lines per request (1 access log, 3 INFO, 2 DEBUG), $b = 500$ bytes, $c_{\text{hot}} = \$0.50$/GB for 7-day hot retention, cold retention 90 days at $\rho = 10$ and $c_{\text{cold}} = \$0.023$/GB-month. GB means 10^9 bytes.

1. Bytes per second: $3,000 \times 6 \times 500 = 9,000,000$ B/s $= 9$ MB/s.
2. Per day: $9 \times 10^6 \times 86,400 = 7.776 \times 10^{11}$ B $=$ **777.6 GB/day** (about 23.3 TB per month).
3. Hot tier: $30 \times 777.6 \times 0.50 = \$11,664$ per month.
4. Cold tier: $777.6 \times 90/10 = 6,998$ GB stored; $6,998 \times 0.023 = \$161$ per month.
5. Now drop DEBUG in production and sample successful-request INFO lines at 10%, keeping every access line, WARN and ERROR: lines per request fall from 6 to $1 + 3 \times 0.1 = 1.3$, i.e. 21.7% of the original volume, or 168.5 GB/day.
6. New hot cost: $30 \times 168.5 \times 0.50 = \$2,528$ per month, saving about $9,100 per month.

Interpretation. The hot, indexed tier is about 98% of the bill; cold object storage is nearly free by comparison. Volume is driven by lines per request, not by the number of servers. **Engineering implication.** Control what enters the hot tier: drop DEBUG, sample routine successes, never sample errors, and keep everything (compressed) in object storage if compliance needs it. Put a per-service volume budget on the dashboard so a chatty deployment is caught on the day it ships.

WARNING / TRADE-OFF

Warning — Sample by request, not by line. If each service independently keeps 10% of its INFO lines, the chance that all five services kept the lines of the *same* request is $0.1^5 = 10^{-5}$: you get fragments of many requests and the full story of none. Make the sampling decision once per request (for example from the trace ID, as in §40.6.3) and honor it everywhere, and always keep every line of requests that failed.

40.4.5 Personal data and redaction

Logs are where personal data most often leaks: developers log whole request objects while debugging, and the lines land in a widely readable store with long retention. Under laws such as the EU GDPR, a log store holding names, emails, card data or locations becomes a regulated data store.

Defend in layers:

1. **At the source.** Log identifiers, not contents: `user_id` rather than email, the last four card digits rather than the number. Use typed log fields with an allowlist, and

mark sensitive types (`Email`, `CardNumber`) so the logger refuses or masks them.
2. **In the pipeline.** Run a redaction processor (for example the OpenTelemetry Collector's `redaction` or `transform` processors, or a stream job) that masks patterns such as card numbers, emails and tokens. Treat it as a safety net: regular expressions miss things.
3. **At rest.** Restrict index access by role, encrypt, keep hot retention short, and where you must keep an identifier for joins, replace it with a keyed hash (HMAC) so the raw value cannot be recovered without the key.

Never log secrets: passwords, session tokens, API keys or `Authorization` headers. A leaked token in a log is a credential leak to everyone with log access (§10.8).

Failure scenarios

Table 40.4 — Logging failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Request latency rises when the log backend is slow	Synchronous remote logging on the request path	Latency correlates with log back-end latency	Switch to local file or stdout plus agent	Never log synchronously over the network
Logs missing for the incident window	Node disk full or rotation faster than the agent ships	Gaps per node; agent lag metric	Replay from Kafka if retained	Buffer in Kafka; alert on agent lag
Index cluster overloaded, ingestion stalls	A deploy logs a new field per user (mapping explosion) or a hot loop	Field-count and ingest-rate alerts	Drop the offending stream in the processor	Schema allowlists; per-service quotas
Personal data exposed to all engineers	Request bodies logged during debugging	Pattern scanners on the stream	Purge, rotate any leaked secrets, notify per policy	Typed fields, redaction, short retention
Cannot reconstruct one request	No correlation ID, or per-line sampling	Investigations stall at service boundaries	Correlate manually by time	Propagate trace IDs; sample per request

COMMON MISTAKE

Misconception — "Logs are free; disk is cheap." Disk is cheap; indexing, replication and querying are not. In the worked example the hot tier cost about 72 times as much as cold storage. Logging every request in detail at every hop is a design decision with a five-figure monthly price.

40.5 Metrics

DEFINITION

Definition — Metric. A numeric measurement aggregated over time and identified by a name plus a set of **labels** (key–value pairs). Each unique combination of name and label values is one **time series**, a sequence of `(timestamp, value)` samples. For example, `http_requests_total{service="checkout", method="POST", status="500"}` is one series.

Metrics are the cheapest signal per request: a counter costs the same whether it counts ten requests or ten million. That makes them the right basis for dashboards and alerts. The price is that aggregation throws away the individual request, and every label multiplies the number of series.

40.5.1 Counters, gauges, histograms and summaries

Table 40.5 — Metric types.

Type	What it records	Operations that make sense	Example
Counter	A monotonically increasing total; resets to 0 on restart	Rate of increase; sum across instances	`http_requests_total`, `bytes_sent_total`
Gauge	A value that goes up and down; a snapshot	Current value, min, max, average over time	`queue_depth`, `memory_bytes`, `in_flight_requests`
Histogram	Counts of observations in configured buckets, plus their sum and count	Rates per bucket; aggregate across instances; estimate quantiles	`http_request_duration_seconds`
Summary	Quantiles computed inside each process over a sliding window, plus sum and count	Read the precomputed quantile for that one process	`rpc_duration_seconds{quantile="0.99"}`

[Prometheus Docs: Metric types; Histograms and summaries]

Counters store totals rather than rates because a total survives missed scrapes: if one scrape is lost, the next one still shows the cumulative count and the rate over the window is correct. Query functions treat a decrease as a restart and compensate (§40.8.2).

A **histogram** maps each observation into a bucket. In Prometheus a histogram with bucket upper bounds $b_1 < b_2 < \ldots < b_k$ exposes $k + 1$ cumulative series `_bucket{le="b_i"}`

(including `le="+Inf"`), plus `_sum` and `_count`. Because the buckets are just counters, histograms from 60 pods can be **added** to give a fleet-wide distribution. A **summary** computes p99 inside each process; there is no correct way to combine 60 per-process p99 values into a fleet p99. Use histograms whenever you need to aggregate [Prometheus Docs: Histograms and summaries].

40.5.2 Why percentiles cannot be averaged

A percentile is a property of a whole distribution; the average of two p99 values is not the p99 of anything. If pod A serves 90,000 fast requests and pod B 10,000 slow ones, the fleet p99 is set by the slowest 1,000 requests, all from pod B, while averaging weights the pods equally. In the program below the mean of per-pod p99s is 453 ms; the true fleet p99 is 585 ms.

The same program answers a second question: how accurate is a quantile estimated from histogram buckets? PromQL's `histogram_quantile` finds the bucket containing the target rank and **interpolates linearly** inside it, assuming observations are spread evenly across the bucket [Prometheus Docs: Functions]. The true value can be anywhere in the bucket.

FORMULA

Error bound of a bucketed quantile

$$|\hat{q} - q| \le u - l \qquad \frac{|\hat{q} - q|}{q} \le \frac{u - l}{l} \qquad \text{exponential buckets } (u = \gamma l)\text{: } \frac{|\hat{q} - q|}{q} \le \gamma - 1$$

Symbol	Meaning	Units
q	True quantile of the observations	seconds
$\hat{q}$	Estimate from linear interpolation inside the bucket	seconds
l, u	Lower and upper bounds of the bucket containing the target rank	seconds
γ	Growth factor between consecutive bucket bounds	dimensionless

WORKED EXAMPLE

Worked example — Default buckets versus the SLO. The Prometheus client libraries' default buckets are 5, 10, 25, 50, 100, 250, 500 ms and 1, 2.5, 5, 10 s. QuickBite's checkout p99 is near 900 ms and its p99.9 near 1.45 s.

1. p99 falls in the bucket (0.5, 1] s: the error bound is $u - l = 0.5$ s, or up to $0.5/0.5 = 100\%$ relative to the lower bound.
2. p99.9 falls in (1, 2.5] s: bound 1.5 s, up to 150% relative.
3. With custom buckets every 0.1–0.2 s around the latency thresholds (a 300 ms target, and the 800 ms place-order SLO of Table 39.4) and up to 1.5 s, the bucket containing p99 is (0.8, 1.0] s: bound 0.2 s, about 25%.
4. A Prometheus **native histogram** with schema 3 uses exponential buckets with $\gamma = 2^{2^{-3}} = 2^{0.125} \approx 1.0905$, so the relative error is at most about 9% everywhere, with no bucket layout to choose [Prometheus Docs: Native histograms].

Interpretation. The bound is a worst case; the simulation below shows typical errors of a few percent when buckets are dense and tens of percent when the quantile lands in a wide bucket. **Engineering implication.** Put bucket boundaries where your SLO thresholds and expected percentiles lie, or use native or exponential histograms; and alert on "fraction of requests slower than the SLO threshold" with a bucket boundary exactly at the threshold, which is exact rather than estimated.

```
import math
import random

# Prometheus client default buckets (seconds); +Inf is implicit.
DEFAULT_BUCKETS = [0.005, 0.01, 0.025, 0.05, 0.1, 0.25, 0.5, 1, 2.5, 5, 10]
# Buckets chosen around 300 ms and 800 ms latency thresholds.
SLO_BUCKETS = [0.025, 0.05, 0.075, 0.1, 0.125, 0.15, 0.2, 0.25, 0.3,
               0.4, 0.6, 0.8, 1.0, 1.5, 2.5]

def latencies(n, rng):
    """Mostly log-normal around 80 ms, plus a 2% slow mode near 900 ms."""
    out = []
    for _ in range(n):
        if rng.random() < 0.02:
            out.append(rng.lognormvariate(math.log(0.9), 0.3))
        else:
            out.append(rng.lognormvariate(math.log(0.08), 0.5))
    return out

def true_quantile(sorted_xs, q):
    """Nearest-rank quantile of the raw samples."""
    k = max(1, math.ceil(q * len(sorted_xs)))
    return sorted_xs[k - 1]

def observe(xs, bounds):
    """Cumulative bucket counts, like Prometheus *_bucket{le=...} series."""
    cum = [sum(1 for x in xs if x <= b) for b in bounds]
    return cum + [len(xs)]                      # last entry is le="+Inf"

def histogram_quantile(q, bounds, cum):
    """Linear interpolation inside the target bucket, as PromQL does."""
    total = cum[-1]
    rank = q * total
    for i, c in enumerate(cum):
        if c >= rank:
            if i == len(bounds):                # rank falls in +Inf bucket
                return bounds[-1]
            lower = 0.0 if i == 0 else bounds[i - 1]
            prev = 0 if i == 0 else cum[i - 1]
            in_bucket = c - prev
            return lower + (bounds[i] - lower) * (rank - prev) / in_bucket
    return float("nan")

rng = random.Random(42)
xs = latencies(100_000, rng)
s = sorted(xs)
print(f"{'q':>6} {'true ms':>8} {'default ms':>11} {'err %':>7} "
      f"{'slo ms':>8} {'err %':>7}")
for q in (0.5, 0.9, 0.99, 0.999):
    t = true_quantile(s, q)
    d = histogram_quantile(q, DEFAULT_BUCKETS, observe(xs, DEFAULT_BUCKETS))
```

```
            b = histogram_quantile(q, SLO_BUCKETS, observe(xs, SLO_BUCKETS))
            print(f"{q:>6} {t*1000:8.1f} {d*1000:11.1f} {100*(d-t)/t:7.1f} "
                  f"{b*1000:8.1f} {100*(b-t)/t:7.1f}")

        # Why you cannot average percentiles: two instances, unequal traffic.
        fast = sorted(rng.lognormvariate(math.log(0.05), 0.3) for _ in range(90_000))
        slow = sorted(rng.lognormvariate(math.log(0.4), 0.3) for _ in range(10_000))
        avg_p99 = (true_quantile(fast, 0.99) + true_quantile(slow, 0.99)) / 2
        fleet_p99 = true_quantile(sorted(fast + slow), 0.99)
        print(f"mean of per-instance p99s: {avg_p99*1000:.0f} ms; "
              f"true fleet p99: {fleet_p99*1000:.0f} ms")
```

Output (Python 3.13, fixed seeds):

```
     q  true ms  default ms   err %   slo ms   err %
   0.5    81.0        83.8     3.4     82.0     1.2
   0.9   160.8       216.7    34.7    166.3     3.4
  0.99   915.5       904.5    -1.2    923.5     0.9
 0.999  1453.7      2303.7    58.5   1486.1     2.2
mean of per-instance p99s: 453 ms; true fleet p99: 585 ms
```

What to notice:

- `histogram_quantile` reproduces PromQL's rule: the lowest bucket starts at 0, interpolation is linear, and a rank in the `+Inf` bucket returns the highest finite bound, because nothing is known above it.
- With default buckets, p90 is 35% high (it lands in the wide 100–250 ms bucket) and p99.9 is 58% high; p99 happens to be close only because the true value sits near the 1 s boundary. Accuracy depends on luck unless you choose buckets.
- SLO-aligned buckets cut every error to under 4% with 15 buckets, a few more series per label combination than the 11 defaults.
- The last line shows averaging per-pod p99s understates the fleet p99 by about 130 ms. Always aggregate bucket counts first (`sum by (le)`) and compute the quantile last.

40.5.3 Cardinality explosion

FORMULA

Series count and head memory of one metric

$$N_{\max} = \prod_{i=1}^{m} |L_i| \qquad N = \phi N_{\max} (B + 2) \qquad M = N \times s$$

Symbol	Meaning	Units
$\|L_i\|$	Number of distinct values of label i	values
$N_{\max}$	Upper bound on label combinations	combinations
ϕ	Fraction of combinations that actually occur	dimensionless
B	Bucket series per histogram, including `+Inf`; for a counter or gauge replace $(B + 2)$ by 1	series
N	Active time series	series
s	Memory per active series in the TSDB head (index, labels, open chunk)	bytes/series
M	Head memory for this metric	bytes

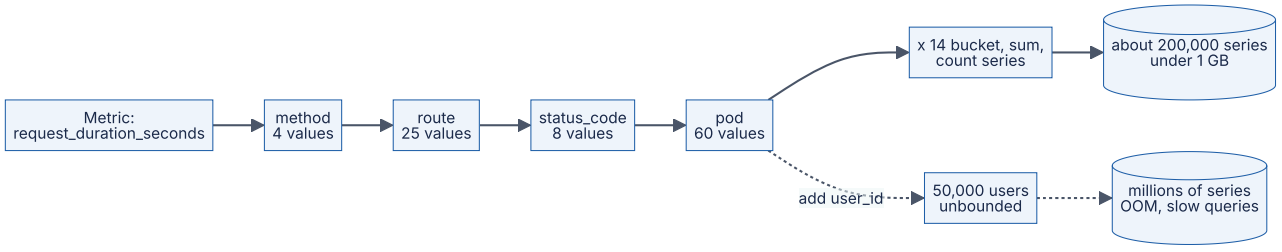
WORKED EXAMPLE

Worked example — One innocent label. QuickBite records `http_server_request_duration_seconds` with labels `method` (4 values), `route` (25), `status_code` (8 seen) and `pod` (60), using the 11 default buckets plus `+Inf`, so $B + 2 = 14$. Assume $\phi = 0.3$ (most routes accept one method and see few status codes) and $s = 4$ KB per series, a planning figure: measure your own with the TSDB status page.

1. $N_{\max} = 4 \times 25 \times 8 \times 60 = 48,000$ combinations.
2. $N = 0.3 \times 48,000 \times 14 = 201,600$ series.
3. $M = 201,600 \times 4$ KB ≈ 806 MB of head memory for one metric.
4. A developer adds `user_id` to debug one customer. Each of 50,000 active users per hour touches about 5 method/route/status combinations on one pod: $50,000 \times 5 \times 14 = 3.5$ million series, about **14 GB**, and new users keep creating new series.
5. Remedy instead: replace `status_code` with `status_class` (2xx, 3xx, 4xx, 5xx: 4 values) and drop the label combinations that never occur: $N_{\max} = 4 \times 25 \times 4 \times 60 = 24,000$; at $\phi = 0.4$, $N = 0.4 \times 24,000 \times 14 = 134,400$ series, about 538 MB.

Interpretation. Series count is multiplicative: one unbounded label turns a manageable metric into an outage of the monitoring system itself. **Engineering implication.** Labels must have small, bounded value sets. Identifiers such as user, order, trace or request IDs belong in logs, traces and exemplars (§40.11.2), never in metric labels. Enforce it with per-target `sample_limit` and series limits, and review new labels in code review.

Figure 40.3 — How labels multiply into series.



Reading the diagram. Read left to right as multiplication: each label stage multiplies the number of distinct series by its value count, and the histogram multiplies by 14 series per combination. The solid path ends in a manageable TSDB head (the storage boundary, in memory plus write-ahead log). The dotted branch shows the failure mode: an unbounded label creates series as fast as new users arrive, until the Prometheus process runs out of memory or queries time out. This is not a request path; it is a growth path

that happens at write time. Scaling options are to cut labels, aggregate before storage (recording rules or Collector processors) or shard the TSDB, in that order of preference.

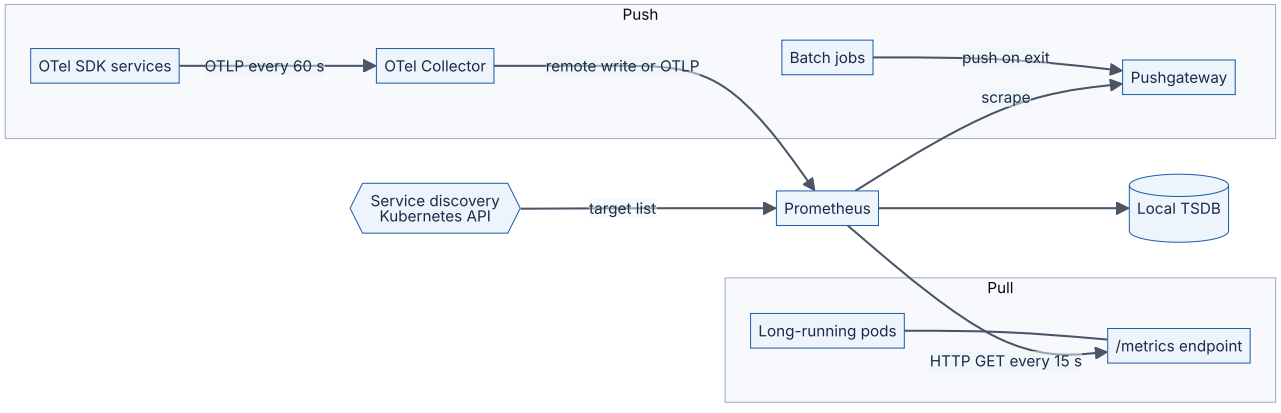
40.5.4 Pull versus push

Table 40.6 — Pull and push collection compared.

Aspect	Pull (scrape)	Push
How it works	Monitoring server fetches `/metrics` from each target on an interval	Targets send metrics to a receiver (OTLP, StatsD, remote write)
Target discovery	Server must know targets (service discovery)	Receiver learns targets from what arrives
Liveness signal	Free: a failed scrape sets `up = 0`	Silence is ambiguous: dead, or idle?
Short-lived jobs	Poor: the job may end before a scrape	Natural
Through firewalls and NAT	Server needs network access to every target	Targets need access to one endpoint
Back-pressure	Server controls load by interval	Receiver must protect itself (rate limits, queues)
Typical systems	Prometheus	OpenTelemetry OTLP, StatsD, Graphite, cloud agents

Prometheus pulls, getting a free health check, and offers the **Pushgateway** only for batch jobs that finish before a scrape [Prometheus Docs: When to use the Pushgateway]. OpenTelemetry SDKs push OTLP, and Prometheus 3 can receive OTLP itself. Most platforms run both.

Figure 40.4 — Pull and push paths into one metrics store.



Reading the diagram. Prometheus learns its targets from service discovery, then issues synchronous HTTP GET scrapes to each pod's `/metrics` endpoint every 15 s. Batch jobs push to the Pushgateway on exit, and Prometheus scrapes the gateway; the gateway keeps the last value forever unless deleted, so use it only for jobs. OTel-instrumented ser-

vices push OTLP to a Collector, which forwards it. All paths end in the local TSDB, the storage boundary. Failure points: a timed-out scrape marks the target down; a Collector outage loses pushed metrics unless it buffers. Scaling: shard scraping across Prometheus servers (§40.8.4).

40.5.5 Time-series storage

Section 12.8 explains time-series storage: an inverted label index, a write-ahead log, two-hour blocks, retention by deleting blocks, and Gorilla compression at about 1.37 bytes per sample [Pelkonen et al. 2015]. Two consequences matter here. First, storage per sample is tiny, so **sample rate is rarely the limit; series count is**, because each active series needs index entries and an open chunk in memory. Second, **downsampled rollups cannot reproduce percentiles**: keep histogram buckets in long-term storage if you need p99 from last quarter.

40.6 Traces and distributed tracing

Section 34.9 introduced traces, spans and context propagation. This section is the book's deep treatment: the data model, the W3C header format, sampling and its arithmetic, and storage.

40.6.1 Spans and trace trees

DEFINITION

Definition — Trace and span (data model). A **span** records one timed operation: a trace ID (16 bytes), a span ID (8 bytes), a parent span ID (empty for the **root span**), a name such as `POST /checkout`, a **kind** (server, client, producer, consumer or internal), start and end timestamps, a status, key–value **attributes**, timestamped **events** (for example an exception) and optional **links** to spans in other traces. A **trace** is the set of spans sharing one trace ID; parent pointers turn it into a tree rooted at the first instrumented operation [OpenTelemetry Specification: Tracing API; Sigelman et al. 2010].

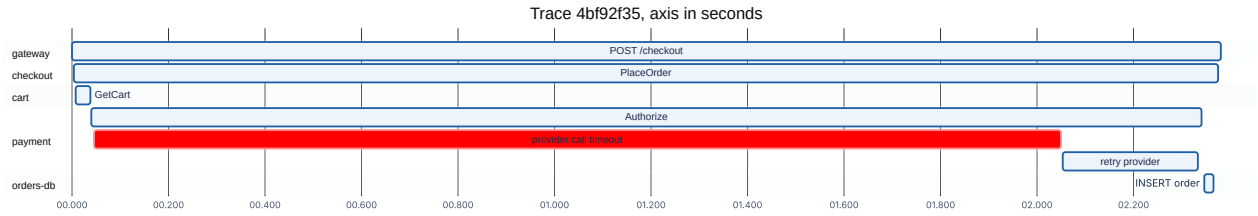
First-principles explanation

A parcel crosses a sorting hub, a truck, a depot and a courier's van. Each handler scans the barcode and records when the parcel arrived and left. The barcode is the trace ID; each scan pair is a span; "handed to me by the depot" is the parent pointer. Collect the scans and you can draw the parcel's journey and see that it sat in the depot for two days. Without the barcode, each handler's records exist but cannot be joined.

Why does this exist?

Metrics tell you the checkout p99 rose; per-service logs give each service's view. Neither tells you that *this* slow request spent 2.0 of its 2.4 seconds waiting for one payment-provider call that then retried. Google built Dapper because engineers could not tell which of many services caused a slow web search; its design goals were low overhead, transparency to application developers (instrumentation lives in shared RPC, threading and control-flow libraries) and continuous deployment across the fleet [Sigelman et al. 2010]. Twitter's Zipkin (2012) and Uber's Jaeger (2015, later a CNCF graduated project) brought the same design to open source, and OpenTelemetry (§40.7) standardized it.

Figure 40.5 — A slow checkout trace as a waterfall.



Reading the diagram. Each bar is a span; rows are grouped by service, and the horizontal axis is time from the root span's start. Nesting is shown by containment: the gateway's server span (0–2,380 ms) contains checkout's `PlaceOrder`, which contains the cart and payment calls, all synchronous request/response. The highlighted span is the payment provider call that hit a 2 s client timeout (2,004 ms) before a retry succeeded in 280 ms, so 2.3 s of the 2.38 s total is spent in payment; the database insert (20 ms) is irrelevant to latency. Gaps between bars are time no span covers, itself a clue. Failure points: a dependency timeout longer than the caller can afford, and retries on the critical path. Spans are exported asynchronously, so the waterfall appears in the trace store seconds later.

The waterfall answers the question every latency investigation starts with: **where did the time go?** The **critical path** is the chain of spans that determined the end time; shortening anything off it does not help.

40.6.2 Trace context propagation

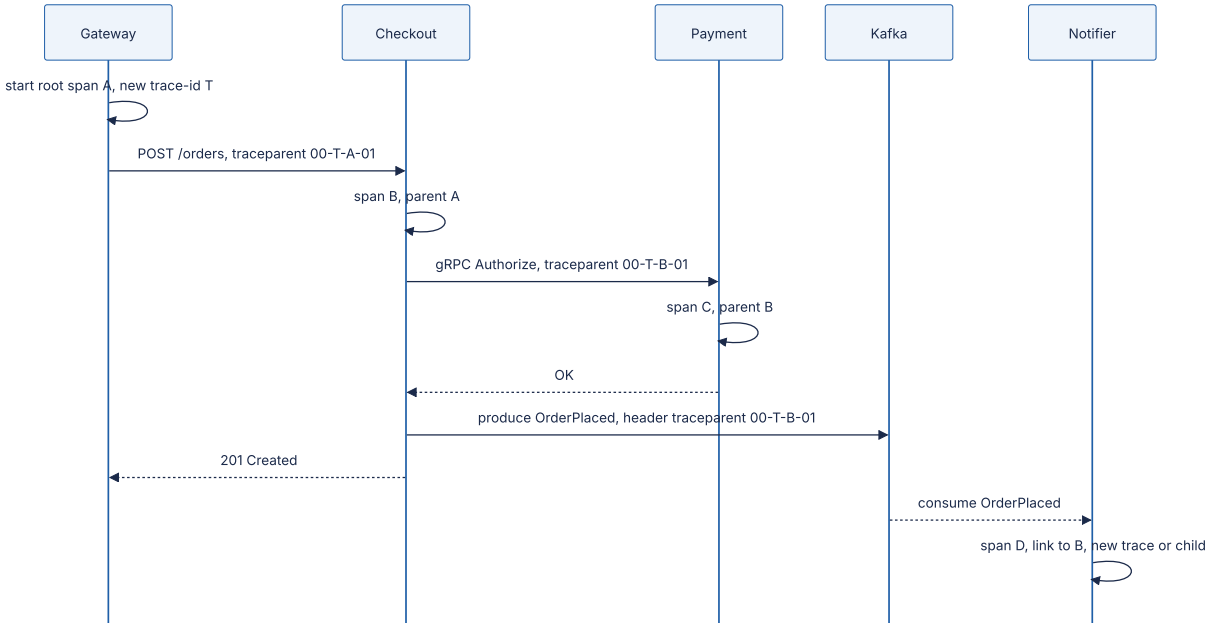
For spans in different processes to join one tree, every outbound call must carry the trace ID and the caller's span ID. The **W3C Trace Context** Recommendation standardizes this for HTTP with two headers, so that services instrumented by different vendors' libraries interoperate [W3C Trace Context].

```
traceparent: 00-4bf92f3577b34da6a3ce929d0e0e4736-00f067aa0ba902b7-01
             |  |                                |                |
             |  trace-id: 16 bytes, 32 hex       parent-id:       trace-flags:
             version: 00                         8 bytes, 16 hex  01 = sampled
tracestate:  vendorA=t61rcWkgMzE,ot=th:c
```

What to notice:

- **version** is `00`; `ff` is invalid. **trace-id** and **parent-id** must not be all zeros. The parent-id is the span ID of the *caller's* span; the callee creates a new span whose parent is that ID.
- **trace-flags** bit 0 (`01`) is the **sampled** flag: the caller recorded this trace, so downstream services should too. Level 2 of the specification adds a bit (`02`) declaring that the trace ID's rightmost 7 bytes are random, which sampling algorithms rely on.
- **tracestate** carries vendor-specific key–value pairs (up to 32 entries) alongside the standard header without breaking interoperability; OpenTelemetry uses the `ot` key for its consistent-sampling threshold.
- A separate W3C **Baggage** header carries application key–value pairs (for example `tenant=acme`) to every downstream service. Baggage is visible to every hop and to third parties you call, so never put secrets or personal data in it.

Figure 40.6 — Propagating trace context across HTTP and a queue.



Reading the diagram. The gateway, the first instrumented hop, creates trace ID T and root span A, makes the sampling decision and writes the `traceparent` header. Each synchronous call (solid arrows: HTTP, then gRPC metadata) carries the current span ID as the parent, so Checkout's span B is a child of A and Payment's span C is a child of B. Checkout also writes the context into the Kafka record headers; the notifier consumes

asynchronously (dotted), possibly minutes later, and starts span D either as a child or, more commonly for batch consumers, in a new trace with a **span link** to B so that one consumer span can reference many producer spans. Storage boundaries are the Kafka log and the trace store. Failure points: any proxy, thread pool or queue client that drops the header fragments the tree; clock skew can make a child appear to start before its parent.

Inside a process, the current span is held in a **context** object stored in thread-local or async-local storage. Work handed to a thread pool or callback must carry that context explicitly, or the new work starts an orphan trace. This is the most common reason traces "break" in otherwise instrumented services.

40.6.3 Head sampling and tail sampling

Tracing every request is usually unaffordable. At 1,000 requests per second with 25 spans each, a trace store ingests 25,000 spans per second. Sampling chooses which traces to keep.

> DEFINITION
>
> **Definition — Head and tail sampling. Head sampling** decides at the root span, before the request runs, usually with a probability applied to the trace ID; the decision propagates in the sampled flag so that the whole trace is kept or dropped consistently. **Tail sampling** decides after the trace completes, when its duration, errors and attributes are known, by buffering all spans of each trace in a collector until a decision timer expires [OpenTelemetry Docs: Sampling].

Dapper's first production version used uniform head sampling at 1 in 1,024 traces and later added adaptive rates, because for high-volume services this still captured plenty of examples of common behavior [Sigelman et al. 2010]. Head sampling is cheap and simple, but blind: the rare request you need, the one that failed or took 9 seconds, is kept with the same small probability as every boring success.

FORMULA

Sampling volume, capture probability and tail-sampler buffer

$$V = R\,p_{\text{eff}}\,S\,b \qquad P_{\text{capture}} = 1 - (1-p)^{k} \qquad p_{\text{eff}}^{\text{tail}} = f_{\text{int}} + (1 - f_{\text{int}})\,p \qquad M_{\text{buf}} = R\,w\,S\,b_{\text{mem}}$$

Symbol	Meaning	Units
R	Root traces started	traces/second
p	Head sampling probability, or tail baseline probability	dimensionless
p_{eff}	Fraction of traces stored	dimensionless
S	Mean spans per trace	spans/trace
b	Stored bytes per span	bytes/span
V	Stored trace volume	bytes/second
k	Occurrences of a rare event in the time window	occurrences
P_{capture}	Probability head sampling keeps at least one of them	dimensionless
f_{int}	Fraction of “interesting” traces (errors or slow) kept by tail policies	dimensionless
w	Tail-sampling decision wait	seconds
b_{mem}	In-memory bytes per buffered span	bytes/span
M_{buf}	Collector memory needed to buffer pending traces	bytes

WORKED EXAMPLE

Worked example — Tracing QuickBite's checkout. $R = 1,000$ traces/s, $S = 25$, $b = 500$ B stored, $b_{\text{mem}} = 1.5$ KB in the collector. Errors are 0.3% and slow (> 1 s) requests 0.9% of traffic, so $f_{\text{int}} \approx 0.012$.

1. Keep everything: $1,000 \times 25 \times 500 = 12.5$ MB/s **= 1.08 TB/day**.
2. Head sampling at 5%: $0.05 \times 1.08 = 54$ GB/day.
3. A bug fails 20 requests per hour. Probability that 1% head sampling captures at least one in an hour: $1 - 0.99^{20} = 1 - 0.818 = 18.2\%$. At 5%: $1 - 0.95^{20} = 64.2\%$.
4. Tail sampling, keeping all errors and slow traces plus a 1% baseline: $p_{\text{eff}} = 0.012 + 0.988 \times 0.01 = 0.0219$, i.e. 0.0219×1.08 TB ≈ 23.6 GB/day, and **100%** of the failing requests are captured.
5. Price of tail sampling: the collectors must receive all 25,000 spans/s, and with $w = 10$ s they buffer $1,000 \times 10 \times 25 \times 1.5$ KB $= 375$ MB of pending spans, plus headroom for traffic spikes.

Interpretation. Tail sampling stores less than half of 5% head sampling yet keeps every interesting trace. **Engineering implication.** Use head sampling when shipping every span is unaffordable; use tail sampling (often after a generous head rate) when the traces you need are rare. Budget collector CPU, network and memory for 100% of spans, and route all spans of a trace to the same collector.

The simulation below checks these numbers on 200,000 synthetic traces, comparing head sampling at 5% and 1% with a tail policy that keeps errors, slow traces and a 1% baseline.

```
        import math
        import random
        from dataclasses import dataclass

        @dataclass
        class Trace:
            trace_id: int
            duration_s: float
            error: bool
            spans: int

        def generate(n, rng):
            """Synthetic traffic: 0.3% errors, ~1% slower than 1 s."""
            traces = []
            for i in range(n):
                slow_mode = rng.random() < 0.01
                mu = math.log(1.6) if slow_mode else math.log(0.12)
                duration = rng.lognormvariate(mu, 0.4)
                error = rng.random() < 0.003
                traces.append(Trace(rng.getrandbits(64), duration, error,
                                    spans=rng.randint(10, 40)))
            return traces

        def head_sample(t, rate):
            """Decided at the root from trace-ID bits, before the outcome is known."""
            return t.trace_id < rate * 2**64

        def tail_sample(t, rate, slow_s=1.0):
            """Decided after the whole trace is buffered: policies run in order."""
            if t.error:
                return "error"
            if t.duration_s > slow_s:
                return "slow"
            if t.trace_id < rate * 2**64:              # consistent probabilistic
                return "baseline"
            return None

        def report(name, kept, traces):
            errors = [t for t in traces if t.error]
            slow = [t for t in traces if t.duration_s > 1.0]
            k_err = sum(1 for t in kept if t.error)
            k_slow = sum(1 for t in kept if t.duration_s > 1.0)
            spans = sum(t.spans for t in kept)
            print(f"{name:<22} kept {len(kept):>6} traces
({100*len(kept)/len(traces):5.2f}%)"
                  f"  spans {spans:>8}  errors {k_err:>3}/{len(errors)}"
                  f"  slow {k_slow:>4}/{len(slow)}")

        rng = random.Random(7)
        traces = generate(200_000, rng)
```

```
        report("head 5%", [t for t in traces if head_sample(t, 0.05)], traces)
        report("head 1%", [t for t in traces if head_sample(t, 0.01)], traces)
        tail = [(t, tail_sample(t, 0.01)) for t in traces]
        kept = [t for t, why in tail if why]
        report("tail err+slow+1%", kept, traces)
        for why in ("error", "slow", "baseline"):
            print(f"  kept by {why:<8}: {sum(1 for _, w in tail if w == why)}")
```

Output:

```
head 5%               kept   9926 traces ( 4.96%)  spans   248020  errors  33/618  slow
94/1741
head 1%               kept   2027 traces ( 1.01%)  spans    51072  errors   7/618  slow
22/1741
tail err+slow+1%      kept   4352 traces ( 2.18%)  spans   109555  errors 618/618  slow
1741/1741
  kept by error   : 618
  kept by slow    : 1736
  kept by baseline: 1998
```

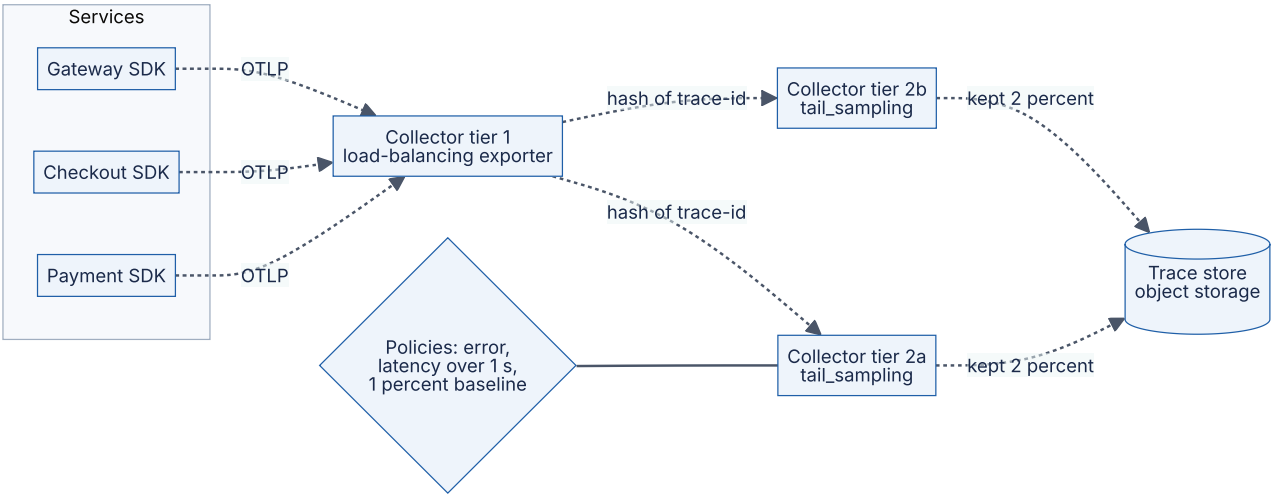
What to notice:

- Head sampling keeps errors and slow traces in proportion to its rate (33 of 618 errors at 5%): it is unbiased, which is good for estimating averages and bad for debugging.
- The tail policy stores 2.18% of traces, matching $p_{\text{eff}} \approx 0.012 + 0.988 \times 0.01$, yet keeps all 618 errors and all 1,741 slow traces.
- Policies are evaluated in order and the first match labels the reason; record that reason as a span attribute so analysts know which traces are a biased sample and which baseline traces can be used for statistics.
- Both samplers compare the trace ID with a threshold rather than calling a random number generator, so every service and collector that sees the same trace ID makes the same decision. This is why the W3C random-trace-ID flag matters.

Table 40.7 — Head and tail sampling compared.

Aspect	Head sampling	Tail sampling
Decision point	Root span, before work	Collector, after trace completes
Information used	Trace ID, route, maybe caller	Duration, status, any attribute of any span
Keeps rare failures	Only with probability p	Yes, by policy
Network and CPU cost	Unsampled spans never leave the process	Every span shipped to collectors
Infrastructure	None beyond the SDK	Stateful collector tier, trace-ID-aware routing, buffering
Statistical bias	Unbiased sample	Biased toward interesting traces; weights needed for rates
Choose when	Very high volume, uniform traffic, tight budgets	Debugging rare errors and tail latency matters most

Figure 40.7 — Tail sampling with trace-ID-aware routing.



Reading the diagram. Services export spans asynchronously over OTLP to a stateless first collector tier. Its load-balancing exporter hashes each span's trace ID and forwards it, so all spans of one trace, which come from different services, reach the same second-tier collector. Second-tier collectors buffer spans per trace for the decision wait, evaluate the policies in the diamond, and write only kept traces to the trace store, the storage boundary. Every arrow is asynchronous; no request waits for tracing. Failure points: rescaling the second tier changes the hash ring and splits in-flight traces; a crash loses undecided traces; late spans need a decision cache or are dropped. Scaling: add second-tier collectors and size memory with M_{buf}.

40.6.4 Span storage and analysis

Trace stores see very high write rates, no updates, and reads that fetch every span of one trace or search by service, duration and attributes. Dapper stored each trace as one

Bigtable row with one column per span [Sigelman et al. 2010]. Jaeger uses Cassandra or Elasticsearch/OpenSearch with secondary indexes. Grafana Tempo stores traces as Apache Parquet blocks in object storage with no attribute index, relying on trace-ID lookup and a column-scanning query language, TraceQL [Grafana Tempo Docs]: cheap storage, slower ad hoc search.

Beyond single traces, aggregate analysis turns spans into metrics: **span metrics** (request rate, errors and duration histograms per service and operation, derived from spans before sampling) and **service graphs** (who calls whom, with rates and error counts). Compute them in the Collector before sampling, otherwise rates are distorted by the sampling bias.

Real-world industry applications

> INDUSTRY EXAMPLE
>
> **Google Dapper.** Dapper instrumented Google's common RPC and threading libraries so that applications needed no changes, sampled traces (1 in 1,024 initially) to keep overhead low, collected spans asynchronously from local logs into Bigtable, and exposed an API on which teams built latency analysis tools. Its paper defined the vocabulary (trace trees, spans, annotations) used by Zipkin, Jaeger and OpenTelemetry. *Evidence: Primary* — [Sigelman et al. 2010]

> INDUSTRY EXAMPLE
>
> **Facebook Canopy.** Canopy traces requests from browsers and mobile apps through back-end services, models the raw traces and extracts features into datasets that engineers query in aggregate: the move from "look at one trace" to "analyze millions of traces". *Evidence: Primary* — [Kaldor et al. 2017]

Failure scenarios

Table 40.8 — Tracing failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Traces split into fragments	A hop (proxy, thread pool, queue client) drops context	Many root spans in non-edge services	Patch the hop to propagate context	Shared instrumentation; propagation tests
Incomplete traces	Services disagree on sampling (no parent-based sampler)	Spans with missing parents	Use parent-based sampling everywhere	Standard SDK configuration
Rare errors never sampled	Head sampling at low rate	Error metrics exist but no matching traces	Raise rate temporarily	Tail sampling for errors and latency
Collector out of memory	Tail-sampling buffer sized for average, not peak	Collector restarts, dropped spans	Scale out; reduce decision wait	Size M_{buf} for peak; memory limiter
Trace store cost overrun	High-cardinality attributes and full payloads on spans	Bytes per span trend	Drop attributes in the Collector	Attribute allowlist; span size limits

COMMON MISTAKE

Misconception — "Tracing adds latency to every request." Span creation costs on the order of microseconds or less, and export happens asynchronously in batches off the request path. The real costs are CPU and network for exporting spans and the storage behind them, which is what sampling controls. Do not trace synchronously to a remote server, and do not attach megabyte payloads as attributes.

40.7 OpenTelemetry

DEFINITION

Definition — OpenTelemetry (OTel). A vendor-neutral, open-source framework of APIs, SDKs, a wire protocol (OTLP), semantic conventions and a Collector for generating, collecting and exporting traces, metrics, logs and (newer) profiles. It was formed in 2019 by merging the OpenTracing and OpenCensus projects and is hosted by the Cloud Native Computing Foundation [OpenTelemetry Docs].

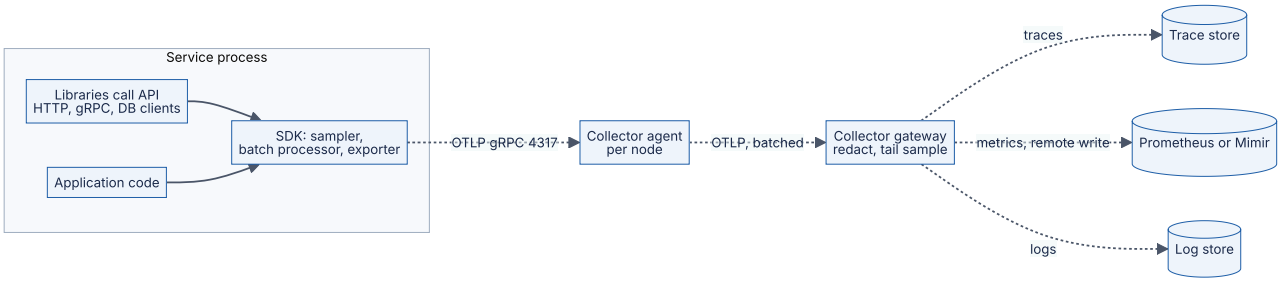
Before OpenTelemetry, switching tracing vendors meant re-instrumenting every service with a new proprietary library. OpenTelemetry separates **instrumentation** (done once, against a stable API) from **destination** (any back end that accepts OTLP, chosen in configuration).

40.7.1 API, SDK and Collector

1. **API.** The interfaces that libraries and applications call: get a tracer, start a span, record a counter. With no SDK installed it is a no-op, so library authors can instrument without forcing a dependency on users.
2. **SDK.** The implementation the *application owner* installs: samplers, span processors (batching), metric readers and aggregation, resource detection (service name, version, host, Kubernetes pod) and exporters.
3. **Collector.** A separate process that receives telemetry, processes it and exports it. Each **pipeline** is built from **receivers** (OTLP, Prometheus scrape, file logs, and others), **processors** (memory limiter, batch, attributes, redaction, tail sampling) and **exporters** (OTLP, Prometheus remote write, vendor formats); **connectors** join pipelines, for example turning spans into span metrics.

The Collector runs in two common roles: as an **agent** next to the workload (a DaemonSet or sidecar) that offloads batching and retries from the application, and as a **gateway** tier that centralizes sampling, redaction, routing and credentials.

Figure 40.8 — OpenTelemetry from API to back ends.



Reading the diagram. Inside the process, instrumented libraries and application code call only the API; the SDK samples, batches and exports. Export is asynchronous (dotted) over OTLP to a per-node agent, which forwards batches to a gateway tier that applies organization-wide processing before fanning out to separate trace, metric and log back ends, the storage boundaries. Back ends change in gateway configuration, not in services. Failure points: a full SDK export queue drops telemetry rather than blocking requests (by design); put the memory-limiter processor first so gateways shed load instead of crashing. Scaling: agents scale with nodes, stateless gateways horizontally.

40.7.2 OTLP and semantic conventions

OTLP (OpenTelemetry Protocol) encodes telemetry as Protocol Buffers and transports it over gRPC (default port 4317) or HTTP (default port 4318, with protobuf or JSON payloads) [OpenTelemetry Specification: OTLP]. Each batch groups data by **resource** (the entity producing it: service, version, host, pod) and by **instrumentation scope** (the library that produced it), so shared attributes are sent once per batch.

Semantic conventions standardize attribute names so that dashboards and queries work across languages and vendors: `service.name` and `service.version` on the resource; `http.request.method`, `http.route` and `http.response.status_code` on HTTP spans and metrics; `error.type` on failures. The HTTP conventions were declared stable in 2023 [OpenTelemetry Semantic Conventions]. Following them is what lets a pre-built "HTTP service" dashboard work for a Java service and a Go service alike.

A minimal SDK configuration uses standard environment variables, identical across languages:

```
        export OTEL_SERVICE_NAME=checkout
        export
OTEL_RESOURCE_ATTRIBUTES=service.version=4.12.0,deployment.environment.name=prod
        export OTEL_EXPORTER_OTLP_ENDPOINT=http://otel-agent:4317
        export OTEL_TRACES_SAMPLER=parentbased_traceidratio
        export OTEL_TRACES_SAMPLER_ARG=0.10
```

What to notice: `parentbased_traceidratio` makes a new root trace sampled with probability 0.10 derived from the trace ID, but always follows the parent's sampled flag for non-root spans, so traces stay complete across services.

40.7.3 Auto-instrumentation

Auto-instrumentation (zero-code instrumentation) needs no source changes: the Java agent rewrites framework bytecode at class-load time, Python's `opentelemetry-instrument` and the Node.js and .NET equivalents patch libraries at startup, and eBPF-based tools observe compiled binaries from the kernel. It yields HTTP, RPC, database and messaging spans plus RED metrics on day one, but cannot know your business: add **manual** attributes for domain fields (`payment.card_network`, `app.version`), which are what solve incidents like this chapter's opening.

40.7.4 Signal status (as of 2026)

Table 40.9 — OpenTelemetry signals (as of 2026; check the project's status page for each language).

Signal	Specification status	Notes
Traces	Stable	Stable API and SDK in all major languages
Metrics	Stable	Stable in most major languages; exponential histograms supported
Logs	Stable data model, bridge API and SDK	Usually fed from existing logging libraries through bridges and Collector receivers
Baggage	Stable	Propagated with W3C Baggage
Profiles	Alpha / development	OTLP profiles data model and Collector support were maturing in 2025–2026

Status differs by language SDK and by component, so treat the table as a starting point, not a guarantee [OpenTelemetry Docs: Status].

40.8 Prometheus

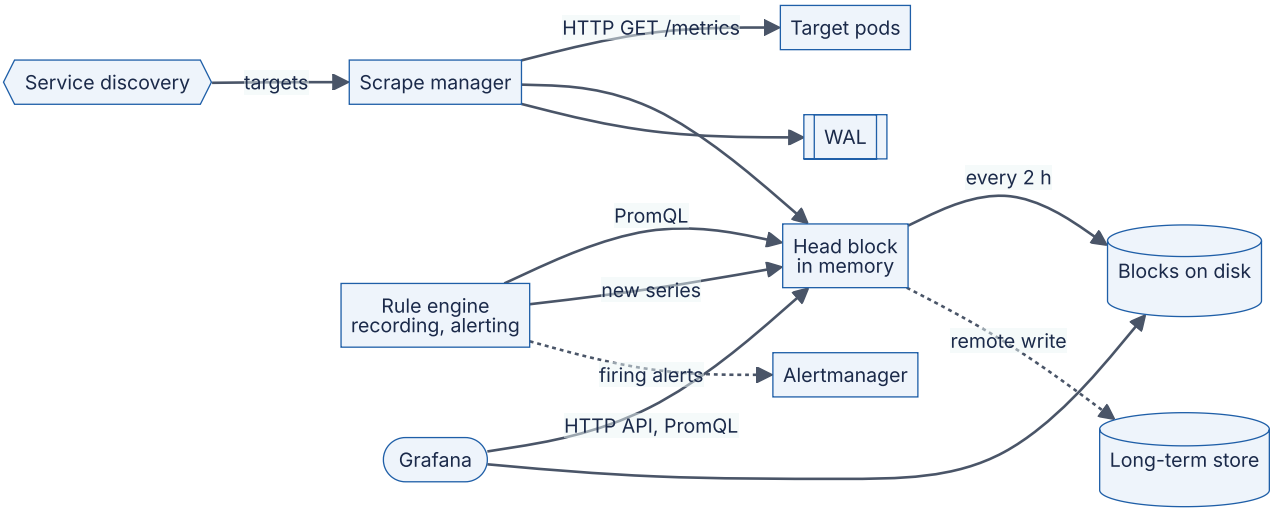
DEFINITION

Definition — Prometheus. An open-source monitoring system and time-series database, started at SoundCloud in 2012 and a graduated CNCF project since 2018, that scrapes metrics over HTTP, stores them locally, evaluates recording and alerting rules, and is queried with PromQL [Prometheus Docs: Overview].

40.8.1 The scrape model and architecture

1. **Discover.** Service discovery (Kubernetes, Consul, cloud APIs, files) produces the target list; **relabeling** rules filter targets and rewrite labels before scraping.
2. **Scrape.** Every scrape interval (commonly 15–60 s), Prometheus issues `GET /metrics` to each target and parses the text exposition format (or OpenMetrics, or protobuf for native histograms). It records `up` and `scrape_duration_seconds` for every target.
3. **Store.** Samples are appended to the in-memory head block and the write-ahead log; every two hours the head is cut into an immutable block, which is later compacted; blocks older than the retention (15 days by default) are deleted (§12.8.1).
4. **Evaluate.** Recording rules precompute expensive queries into new series; alerting rules evaluate PromQL conditions and send firing alerts to Alertmanager.
5. **Serve.** Grafana and other clients query through the HTTP API; remote write streams samples to long-term storage.

Figure 40.9 — Prometheus architecture.



Reading the diagram. Service discovery feeds the scrape manager, which pulls from targets synchronously over HTTP and appends samples to the head block and the write-ahead log (WAL); the WAL is replayed after a crash. Blocks on local disk are the main storage boundary. The rule engine evaluates PromQL on a schedule, writes recording-rule results back as new series and sends firing alerts asynchronously to Alertmanager. Grafana queries the head and blocks through the HTTP API. Remote write copies samples asynchronously to a long-term store. Failure points: a single node's disk, cardinality-driven memory exhaustion (§40.5.3) and scrapes slower than the interval. Scaling: identical pairs for availability; shard targets by function or hash.

40.8.2 PromQL: rate and histogram_quantile

Three queries cover most dashboards.

```
# 1. Request rate per route: per-second increase of a counter over 5 minutes.
sum by (route) (rate(http_server_requests_total{service="checkout"}[5m]))

# 2. Error ratio.
  sum(rate(http_server_requests_total{service="checkout", status_class="5xx"}[5m]))
/ sum(rate(http_server_requests_total{service="checkout"}[5m]))

# 3. Fleet p99 latency: add bucket rates across pods FIRST, then estimate.
histogram_quantile(0.99,
  sum by (le) (rate(http_server_request_duration_seconds_bucket{service="checkout"}
[5m])))
```

What to notice:

- `rate()` computes the per-second average increase over the window, handles counter resets after restarts, and needs at least two samples in the window; make the window at least four times the scrape interval so one missed scrape does not create gaps.

- Always `rate` first, then `sum`. Summing raw counters across pods and then taking the rate turns every pod restart into a huge negative jump that `rate` misreads.
- In query 3, `sum by (le)` keeps the bucket label so that buckets from all pods are added before `histogram_quantile` interpolates, which is the correct aggregation shown in §40.5.2. Averaging per-pod quantiles would be wrong.

40.8.3 Recording rules

A dashboard that computes query 3 over 201,600 bucket series (§40.5.3) on every refresh does a lot of repeated work. A **recording rule** evaluates the expensive part once per interval and stores the result as a new, small series.

FORMULA

Samples read by a range query

$$W = N_{\text{series}} \times \frac{\Delta}{\tau} \times P$$

Symbol	Meaning	Units
N_{series}	Series selected by the query	series
Δ	Range-vector window (e.g. `[5m]`)	seconds
τ	Scrape or rule interval	seconds
P	Evaluation steps (points on the graph)	count
W	Samples read per query	samples

WORKED EXAMPLE

Worked example — A p99 panel with and without a recording rule. 201,600 bucket series, $\Delta = 300$ s, $\tau = 15$ s, a 24-hour graph at 1-minute steps, so $P = 1,440$.

1. Raw: $201,600 \times 20 \times 1,440 = 5.81 \times 10^{9}$ samples per panel load.
2. Recording rule `route:http_server_request_duration_seconds_bucket:rate5m = sum by (route, le) (rate(...[5m]))` produces $25 \times 12 = 300$ series, one sample per 15 s.
3. The panel then reads $300 \times 1,440 = 432,000$ samples (an instant selection per step), about 13,000 times fewer.

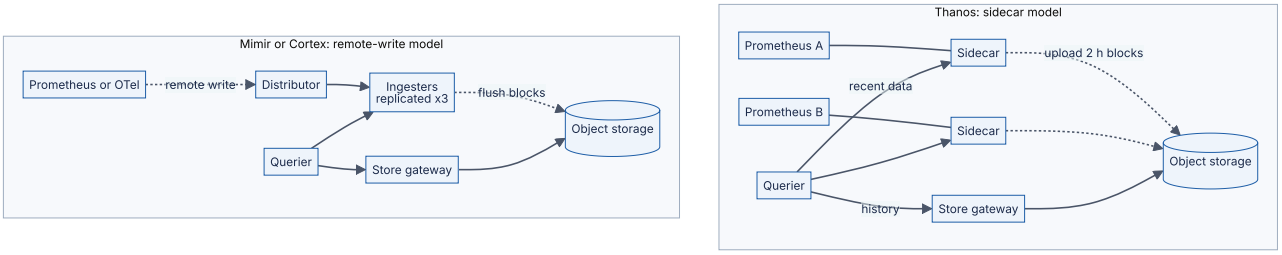
Interpretation. Recording rules trade a small, steady evaluation cost for orders-of-magnitude cheaper reads. **Engineering implication.** Record every aggregation used by dashboards and alerts, name them `level:metric:operations` as the Prometheus documentation recommends, and alert on recorded series.

40.8.4 Federation and long-term storage

A single Prometheus server keeps weeks of data for one set of targets. Organizations need global views across clusters and regions, months or years of retention and high availability.

- **Federation.** A higher-level Prometheus scrapes selected, usually pre-aggregated, series from lower-level servers via their `/federate` endpoint. Simple, but it copies only what you select and adds another single node.
- **Thanos.** A **sidecar** next to each Prometheus uploads two-hour blocks to object storage and serves recent data; a **querier** fans out PromQL across sidecars and **store gateways** (which read object storage) and deduplicates HA pairs; a **compactor** compacts and downsamples blocks in the bucket [Thanos Docs].
- **Cortex and Grafana Mimir.** Prometheus servers (or OTel Collectors) **remote-write** to a horizontally scalable, multi-tenant cluster: distributors shard series to replicated ingesters, which periodically flush blocks to object storage; queriers and store gateways read both. Mimir began in 2022 as a fork of Cortex by Grafana Labs [Cortex Docs; Grafana Mimir Docs].

Figure 40.10 — Two long-term storage designs.



Reading the diagram. In the Thanos design, each Prometheus keeps writing locally and its sidecar uploads finished blocks asynchronously to object storage; the querier answers PromQL by fanning out synchronously to sidecars for recent data and store gateways for history, deduplicating replicas. In the Mimir/Cortex design, Prometheus or OTel Collectors stream samples by remote write to distributors, which shard and replicate them to ingesters; ingesters flush blocks to object storage; queriers merge ingester and store-gateway results. Object storage is the durable boundary in both. Failure points: in Thanos, up to about two hours of not-yet-uploaded data lives only on the Prometheus disk; in Mimir, losing a majority of an ingester replica set loses unflushed samples. Scaling: Thanos grows with Prometheus servers; Mimir scales each component horizontally and is multi-tenant.

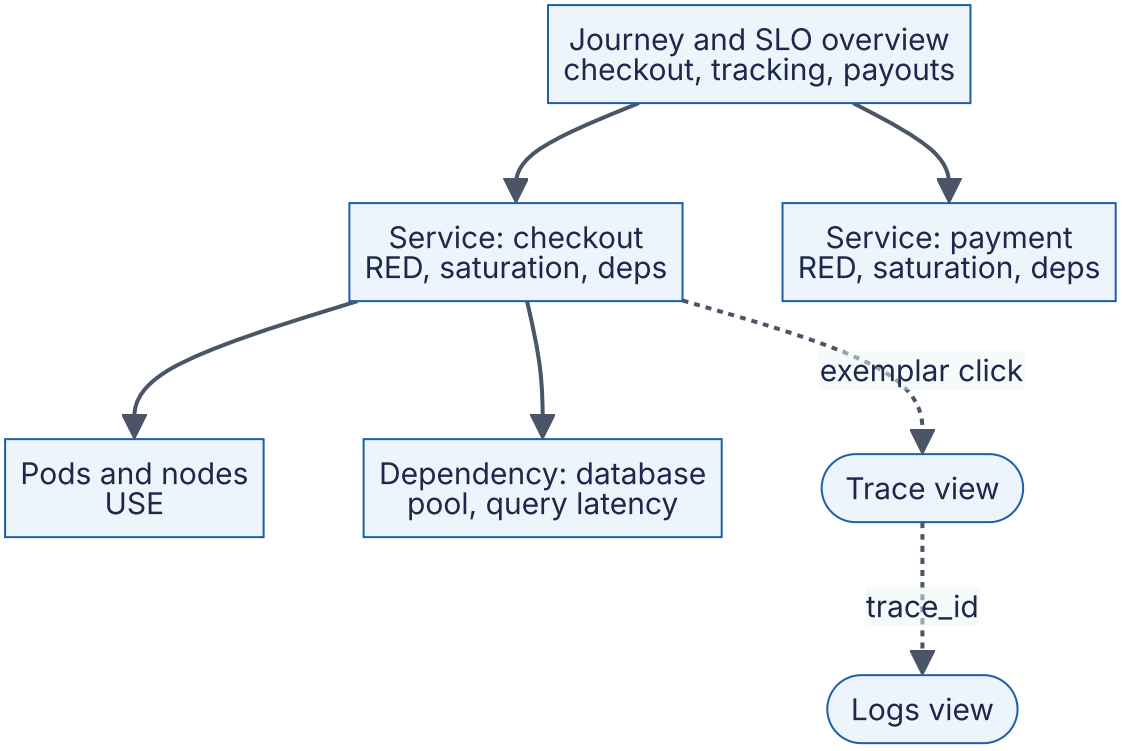
40.9 Grafana

Grafana is an open-source visualization platform that queries many **data sources** (Prometheus, Loki, Tempo, Elasticsearch, SQL databases, cloud monitoring APIs) and renders **dashboards** of **panels**. **Variables** (for example `$service`, `$cluster`) make one dashboard serve many services; **annotations** overlay events such as deployments on graphs; and links and exemplars let a user jump from a latency graph to a trace or from a trace to its logs [Grafana Docs].

Design guidelines that consistently pay off:

1. **One question per dashboard.** "Is this service healthy, and if not, where?": RED or golden signals on top, then saturation (USE), then dependencies (§23.3).
2. **Hierarchy and drill-down.** A small set of top-level dashboards (business journeys and SLOs) links to service dashboards, which link to instance and dependency views, traces and logs (Figure 40.11). People should not search for dashboards during an incident.
3. **Consistent visual language.** Same units and time ranges, latency as percentiles (never averages alone), SLO thresholds drawn, deploy annotations everywhere.
4. **Dashboards as code.** Version-control dashboards (provisioned JSON, Jsonnet or Terraform), review changes and generate per-service dashboards from a template.

Figure 40.11 — A dashboard hierarchy for drill-down.



Reading the diagram. Each box is a dashboard, and solid arrows are links a responder follows from the general to the specific: a journey overview that shows SLO status, a templated service dashboard with RED, saturation and dependency panels, and resource-level USE views. Dotted arrows leave dashboards entirely: an exemplar on a latency panel opens a trace, and the trace's ID opens the matching logs. Separate stores are joined by shared labels and IDs. Failure point: hand-made service dashboards that differ from one another cost responders time; the structure scales by templating, not by hand.

Dashboard sprawl is the opposite: thousands of unowned, near-duplicate, often broken dashboards. Grafana's guidance describes maturing from sprawl, through methodical templates and RED/USE, to version-controlled, reviewed dashboards [Grafana Docs: Dashboard best practices]. Counter it with owners, deletion of dashboards unviewed for 90 days, and a curated "start here" folder.

COMMON MISTAKE

Misconception — "More dashboards mean better visibility." During an incident, a responder has minutes. Fifty dashboards that each show a slightly different view slow them down. Dashboards are for answering known questions quickly; exploration of unknown-unknowns belongs in query tools over events and traces (§40.3).

40.10 Alerting

40.10.1 Symptom-based and cause-based alerts

DEFINITION

Definition — Symptom-based alert. An alert on something users experience (errors, latency, unavailability, correctness), ideally expressed against an SLO. A **cause-based** alert fires on a suspected cause (high CPU, a full disk queue, a replica down) that may or may not hurt users [Beyer et al. 2016, ch. 6].

A hospital monitor alarms when a patient's oxygen saturation drops, not on each possible cause; the doctor then investigates. Paging works the same way. CPU at 90% with healthy latency is efficiency; CPU at 30% with a deadlocked pool is an outage that a CPU alert misses. The SRE book's rules are that every page must be urgent, actionable and require human intelligence, and that you should page on symptoms and use causes to debug [Beyer et al. 2016, ch. 6].

Table 40.10 — Symptom-based versus cause-based alerts.

Aspect	Symptom-based	Cause-based
Example	Checkout 5xx ratio burning error budget 14× too fast	Node CPU > 90% for 5 min
Catches unknown causes	Yes	Only the anticipated cause
False positives	Low: users are affected by definition	High: many causes are harmless
Best use	Paging	Tickets, dashboards, and imminent-exhaustion cases (disk full in 4 h, certificate expiring)

Alert fatigue follows when pages are noisy: responders learn to ignore or silence them, and the real page is missed. Measure it: track the fraction of pages that led to action (precision) and pages per on-call shift. The SRE book suggests at most about two incidents per 12-hour shift so that each can be handled thoroughly and followed up with a postmortem [Beyer et al. 2016, ch. 11]. Delete or demote any alert that repeatedly fires without action.

40.10.2 Burn-rate alerts

A threshold such as “error ratio > 1% for 5 minutes” is either too sensitive for brief blips or too slow for total outages. **Burn-rate alerts**, derived in §39.7.3, page when the error budget is being consumed much faster than the SLO allows.

FORMULA

Burn rate and budget consumed

$$\beta = \frac{e}{1 - \mathrm{SLO}} \qquad \text{budget consumed in time } t = \frac{\beta\, t}{T}$$

Symbol	Meaning	Units
e	Observed error ratio over the alert window	dimensionless
SLO	Target success ratio	dimensionless
β	Burn rate; 1 spends the budget exactly over the SLO period	dimensionless
T	SLO period	hours
t	Duration of the burn	hours

WORKED EXAMPLE

Worked example — The 14.4× page. Checkout's SLO is 99.9% over 30 days (T = 720 h), a round figure used in all of this chapter's alerting examples; at QuickBite's negotiated 99.95% for placing orders (Table 39.4) every error-ratio threshold below halves, while the burn rates stay the same. The error ratio over the last hour is 1.44%.

1. $\beta = 0.0144/0.001 = 14.4$.
2. One hour at this rate consumes $14.4 \times 1/720 = 2\%$ of the monthly budget; the whole budget would last $720/14.4 = 50$ hours.
3. The Site Reliability Workbook pairs this long window (1 h) with a short window (5 min) at the same burn rate, so the alert fires only if the problem is still happening, and resets quickly after recovery [Beyer et al. 2018, ch. 5].

Interpretation. A 1.44% error ratio sounds small, but it would empty a month's budget in about two days. **Engineering implication.** Page on fast burns (for example 14.4× over 1 h and 6× over 6 h) and open tickets on slow burns (1× over 3 days); §39.7.3 derives these thresholds and their detection times.

40.10.3 Alertmanager: routing, deduplication and inhibition

Prometheus evaluates alerting rules; **Alertmanager** decides who hears about them. An alert moves from *inactive* to *pending* when its condition is true, and to *firing* once it has stayed true for the rule's `for` duration, which filters blips.

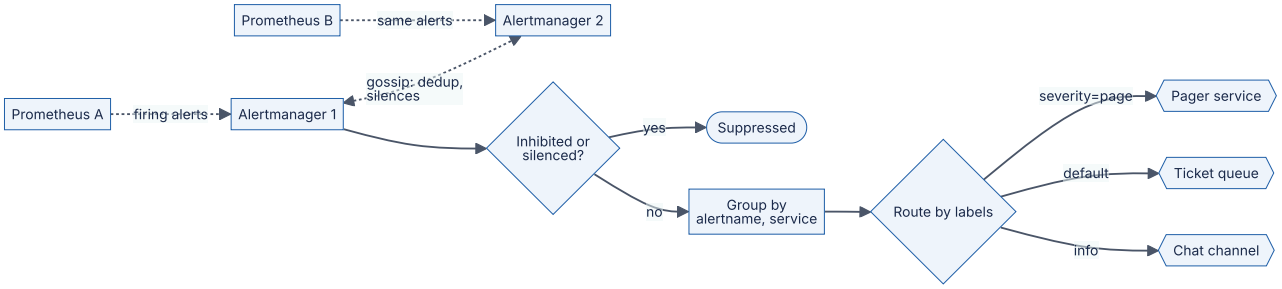
```
        # Prometheus rules file: record error ratios over two windows, then alert
        groups:
        - name: checkout-slo
          rules:
          - record: service:slo_errors_per_request:ratio_rate5m
            expr: |
              sum by (service) (rate(http_server_requests_total{status_class="5xx"}
[5m]))
              / sum by (service) (rate(http_server_requests_total[5m]))
          - record: service:slo_errors_per_request:ratio_rate1h
            expr: |
              sum by (service) (rate(http_server_requests_total{status_class="5xx"}
[1h]))
              / sum by (service) (rate(http_server_requests_total[1h]))
          - alert: CheckoutErrorBudgetFastBurn
            expr: |
              service:slo_errors_per_request:ratio_rate1h{service="checkout"} > (14.4 *
0.001)
              and
              service:slo_errors_per_request:ratio_rate5m{service="checkout"} > (14.4 *
0.001)
            for: 2m
            labels: {severity: page, team: payments}
            annotations:
              summary: "Checkout is burning its 30-day error budget 14x too fast"
              runbook_url: "https://runbooks.example.internal/checkout/error-budget-
burn"
        ---
        # Alertmanager configuration (alertmanager.yml)
        route:
          receiver: default-tickets
          group_by: [alertname, service]
          group_wait: 30s
          group_interval: 5m
          repeat_interval: 4h
          routes:
          - matchers: [severity="page", team="payments"]
            receiver: payments-pager
        inhibit_rules:
        - source_matchers: [alertname="RegionUnreachable"]
          target_matchers: [severity="page"]
          equal: [region]
```

What to notice:

- Two recording rules (§40.8.3) compute the error ratio over 5 minutes and 1 hour; the alert requires both to exceed 14.4 times the budget rate, and `runbook_url` travels with the alert.
- `for: 2m` adds up to two minutes to the detection times of Table 39.6 (52 s for a total outage becomes about 3 minutes); the short window already filters blips, so keep `for` short or omit it.

- `group_by` collapses 60 pods' identical alerts into one notification; `group_wait` waits 30 s to gather the group, `group_interval` throttles updates and `repeat_interval` re-notifies an unresolved alert every 4 hours (these three values are Alertmanager's defaults) [Prometheus Docs: Alertmanager configuration].
- The routing tree sends pages for the payments team to its pager and everything else to a ticket queue.
- The inhibition rule suppresses service pages in a region while a `RegionUnreachable` alert is firing for that same region, so responders see the cause, not 40 symptoms.

Figure 40.12 — An alert's path through Alertmanager.



Reading the diagram. Two Prometheus replicas evaluate the same rules and send the same alerts asynchronously to a clustered pair of Alertmanagers, which gossip to deduplicate notifications and share silences, so the redundant pair does not double-page. Each alert is checked against inhibition rules and silences, grouped, and routed by its labels down the routing tree to a receiver: a pager for urgent symptoms, tickets for slow burns and causes, chat for information. Failure points: if Alertmanager is down nothing pages, so run a **dead man's switch**, an always-firing alert whose *absence* an external service detects; a routing mistake can send a page to a ticket queue. Scaling: one small cluster serves a large organization.

40.10.4 Runbooks

Every page links to a **runbook**: what the alert means, its user impact, the dashboards and queries to open first, safe mitigations (roll back, fail over, shed load) and escalation contacts. A runbook turns a 3 a.m. page from research into execution. Keep it beside the alert definition in version control, and review it in every postmortem (§39.12). If a runbook's steps are fully mechanical, automate them and remove the page.

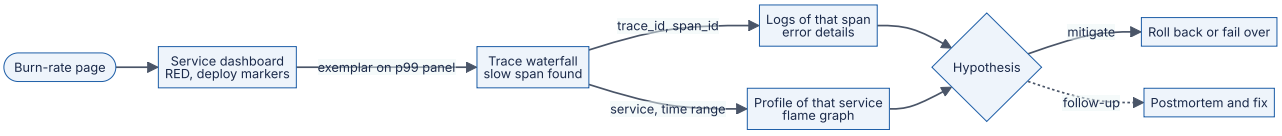
40.11 Root cause analysis

40.11.1 The debugging workflow

An investigation moves from broad to narrow, switching signals as the question changes: **metrics** say *that* something is wrong and *when*; **traces** say *where* in the call graph; **logs**

and wide events say *what* happened in that place; **profiles** say *which code* consumed the resources (Figure 40.13). Section 23.3.4 described the methodology (RED, then USE, then profile); this section adds the tooling that makes each hop take seconds.

Figure 40.13 — From alert to root cause across signals.



Reading the diagram. The page opens a service dashboard, where deployment annotations answer “what changed?”. An **exemplar** on the latency panel jumps straight to a trace that contributed to the spike; the trace’s slow span gives the service and operation; its IDs retrieve the exact log lines; and the service and time range select a continuous profile. Each solid arrow is an interactive query against a different store (metrics, traces, logs, profiles); the dotted arrow is asynchronous follow-up work. Failure point: missing shared identifiers (no trace ID in logs, inconsistent service names) break the chain and force correlation by timestamp.

40.11.2 Exemplars

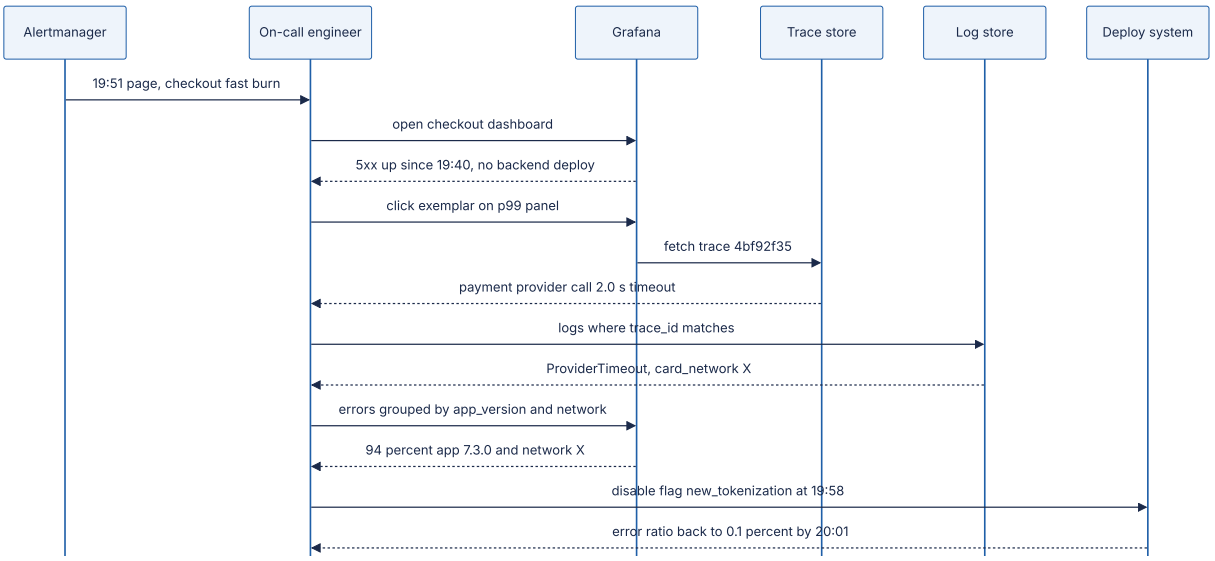
> DEFINITION
>
> **Definition — Exemplar.** A reference from an aggregated metric sample to an individual event that contributed to it, typically a trace ID attached to one histogram bucket observation, with its value and timestamp [OpenMetrics; Prometheus Docs: Exemplars].

A histogram bucket tells you that 37 requests took between 1 and 2.5 s in the last minute; an exemplar adds “for example, trace `4bf92f35…`, which took 2.38 s.” Exemplars bridge the cardinality gap of §40.5.3: the trace ID never becomes a label (no new series), but the metric still points to a concrete request. OpenTelemetry SDKs attach exemplars automatically when a measurement is recorded inside a sampled span; Prometheus stores them when exemplar storage is enabled, and Grafana draws them as dots on the graph. Exemplars should point to *sampled* traces, which is another reason to keep all slow and failed traces (§40.6.3).

40.11.3 Worked incident walkthrough

This replays the chapter’s opening incident with the tooling in place. All times and numbers are illustrative.

Figure 40.14 — Incident timeline.



Reading the diagram. Messages run top to bottom in time. The burn-rate page (asynchronous notification) reaches the on-call engineer eleven minutes after errors start: the 5-minute window exceeds 1.44% almost at once, but the 1-hour average needs t minutes of 9% errors, where $(0.09\,t + 0.001\,(60 - t))/60 = 0.0144$, so $t \approx 9$ (§39.7.3), plus the rule's 2-minute `for`. Each subsequent exchange is a synchronous query: the dashboard rules out a backend deploy; an exemplar leads to one failing trace; the trace's ID retrieves its logs, which carry `card_network`; a grouped query over wide events or span attributes shows the failures concentrate in one app version and one card network. The mitigation is a feature-flag change, not a deploy (§43.7); nobody restarted healthy services or grepped machines.

WORKED EXAMPLE

Worked example — What the incident cost. Checkout serves 60 orders/s at the Friday dinner peak (§2.11) and about 15 million orders per 30-day month (500,000 per day, §39.3.2); errors ran at 9% instead of 0.1% from 19:40 to 20:01 (21 minutes, 1,260 s). SLO 99.9% over 30 days.

1. Requests in the window: $60 \times 1,260 = 75,600$.
2. Excess failures: $75,600 \times (0.09 - 0.001) = 6,728$ orders.
3. Monthly budget: $15,000,000 \times 0.001 = 15,000$ allowed failures; this incident used $75,600 \times 0.09 / 15,000 = 45\%$ of it. Counted in full-outage-equivalent minutes instead, $21 \times 0.09 = 1.89$ of 43.2 minutes is only 4.4%: an incident at peak costs about ten times its share of the clock, because peak traffic is about ten times the average (§18.11.3).
4. Burn rate during the incident: $0.09/0.001 = 90$; a whole month's budget would last $720/90 = 8$ hours.
5. Without the tooling (40 minutes to mitigate as in the opening), excess failures would have been roughly $60 \times 2,400 \times 0.089 = 12,816$.

Interpretation. Twenty-one minutes at peak cost 45% of the monthly budget and thousands of orders; halving time to mitigate roughly halved the damage.
Engineering implication. Mean time to mitigate is dominated by investigation, and investigation time is what linked signals buy. Measure detection and mitigation times in every postmortem.

40.12 Profiling in production

Section 23.4 explained sampling profilers, flame graphs and off-CPU analysis on one machine. **Continuous profiling** runs a low-rate sampling profiler on every instance all the time, ships the aggregated stacks to a central store and makes them queryable by service, version, region and time, like metrics.

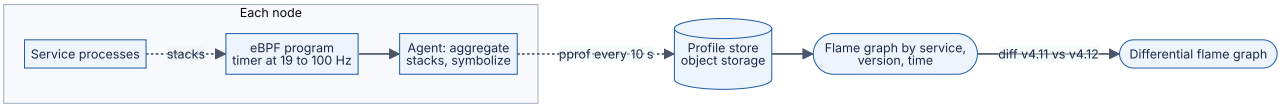
40.12.1 Continuous profiling and eBPF

Why does this exist?

Many performance problems depend on production data, traffic mix and hardware and do not reproduce on a laptop. With continuous profiling the incident window's profile *already exists*, and fleet-wide aggregation shows which functions cost the most CPU across thousands of machines. Google-Wide Profiling described this approach at datacenter scale, sampling machines and periods to keep overhead negligible [Ren et al. 2010].

eBPF makes it nearly zero-touch: a kernel program attached to a CPU timer event (for example 19–100 Hz per CPU) captures stacks for every process on the node without changing applications or restarting them; user space aggregates identical stacks and uploads them every few seconds. Interpreted and JIT-compiled runtimes need symbol information (frame pointers, perf maps or runtime-specific unwinders) for readable stacks. Open-source systems include Grafana Pyroscope and Parca; profiles are commonly stored in pprof format, and OpenTelemetry's profiles signal aims to standardize transport (Table 40.9).

Figure 40.15 — Continuous profiling with eBPF.



Reading the diagram. On each node an eBPF program samples the stacks of all processes (dotted: passive observation, no change to services); the agent aggregates identical stacks, symbolizes them and uploads compressed profiles asynchronously to a central store backed by object storage, the storage boundary. Engineers query flame graphs by service, version and time window, and **differential** flame graphs compare two versions to show what a deployment made more expensive. Failure points: missing symbols give unreadable frames; short-lived processes may be missed. Cost grows with nodes and unique stacks, not request rate, typically around 1% CPU or less at low frequencies (measure yours).

Some profilers tag samples with the active span ID, linking a slow span to its CPU profile. Use continuous profiling for cost reduction, deploy regressions and CPU-bound incidents; use off-CPU profiles and traces for latency dominated by waiting (§23.4.3).

40.13 Summary and revision notes

SUMMARY

- Monitoring answers known questions with predefined metrics and alerts; observability lets you ask new questions of existing telemetry. High-cardinality wide events make unknown-unknowns answerable.
- Logs: structured JSON with stable event names, levels and trace IDs; ship via agent → Kafka → processors → hot index plus cold object storage. Volume is $R \times n \times b$; the hot tier dominates cost; sample per request, never errors; redact personal data in layers.
- Metrics: counters, gauges, histograms, summaries. Aggregate histogram buckets, never percentiles. Quantile error is bounded by bucket width; align buckets with SLOs or use native histograms. Series count is the product of label cardinalities; identifiers never become labels.
- Traces: spans with parent pointers form a tree; W3C `traceparent` carries version, trace ID, parent span ID and flags. Head sampling is cheap and unbiased; tail sampling keeps rare errors and slow traces but needs trace-ID-aware, buffering collectors.
- OpenTelemetry separates instrumentation (API) from implementation (SDK) and destination (Collector, OTLP). Traces, metrics and logs are stable; profiles were alpha as of 2026.
- Prometheus pulls, stores locally and evaluates rules; `rate` then `sum`, `sum by (le)` then `histogram_quantile`; record expensive queries; use Thanos, Cortex or Mimir for global views and long retention.
- Grafana dashboards should be hierarchical, templated and version-controlled; sprawl slows incidents.
- Page on symptoms (burn-rate alerts), not causes; route, group, deduplicate and inhibit in Alertmanager; every page needs a runbook.
- Debug alert → dashboard → exemplar → trace → logs → profile; shared identifiers make each hop fast. Continuous eBPF profiling keeps the incident's profile on hand.

40.14 Knowledge checkpoint

1. Give one question monitoring answers and one only observability answers.
2. Why can an event store hold `user_id` cheaply when a metrics store cannot?
3. Compute daily log volume for 2,000 requests/s, 4 lines per request, 400 bytes per line.
4. Why must log sampling be decided per request?
5. Pods A and B report p99 values of 100 ms and 500 ms. What is the fleet p99?

6. p99 falls in the bucket (0.25, 0.5] s. What is the maximum error of the estimate?
7. A counter has labels with 3, 20 and 50 values; 50% of combinations occur. How many series? As a 12-bucket histogram?
8. Decode `00-0af7651916cd43dd8448eb211c80319c-b7ad6b7169203331-01`.
9. A bug produces 10 failing requests per hour. Probability that 2% head sampling captures one in an hour?
10. Errors are 0.5%, slow requests 1%, baseline 1%. What fraction does tail sampling store?
11. Why does tail sampling need a load-balancing exporter?
12. Why `rate` then `sum`, rather than `sum` then `rate`?
13. What do `group_by`, inhibition and silences each do in Alertmanager?
14. Error ratio 0.6% against a 99.9% SLO. What is the burn rate, and how long does a 30-day budget last?
15. What is an exemplar, and why does it not cause cardinality explosion?

Answers

1. Monitoring: “Is checkout’s error ratio above 1%?” Observability: “What do the failing checkouts have in common?”
2. Each event is a row; a new value costs only its bytes. In a TSDB each new value creates a series with index entries and an in-memory chunk.
3. $2,000 \times 4 \times 400 \times 86,400 = 2.76 \times 10^{11}$ B ≈ 276 GB/day.
4. Independent per-line or per-service sampling keeps fragments of many requests and the full story of almost none.
5. It cannot be computed from those numbers; it depends on traffic and the full distributions. Add the histograms, then compute.
6. 0.25 s, i.e. up to 100% of the lower bound.
7. $3 \times 20 \times 50 \times 0.5 = 1,500$ series; as a histogram $1,500 \times (12 + 2) = 21,000$.
8. Version 00; trace ID `0af7651916cd43dd8448eb211c80319c`; parent span ID `b7ad6b7169203331`; flags 01, sampled.
9. $1 - 0.98^{10} = 1 - 0.817 = 18.3\%$.
10. $f_{\text{int}} \approx 0.015$; $0.015 + 0.985 \times 0.01 = 2.49\%$.
11. A trace’s spans come from many services; a sampler can only judge the whole trace if all spans reach the same collector, so routing hashes the trace ID.
12. `rate` detects counter resets per series; summing first hides resets, which then look like huge decreases.
13. Grouping merges related alerts into one notification; inhibition mutes alerts while a related, more causal alert fires; silences mute matching alerts for a set time.
14. $\beta = 0.006/0.001 = 6$; $30/6 = 5$ days.
15. A trace ID attached to a metric sample; it is stored beside the sample, not as a label, so it creates no new series.

40.15 Interview questions

Basic

Q1. What are logs, metrics and traces, and when do you use each? Answer. Metrics are cheap aggregated numbers for dashboards and alerts (detect and scope). Traces show one request's path and timing across services (locate). Logs and wide events record details of individual events (explain). Link them with shared trace IDs and resource attributes.

Q2. Why are histograms preferred to summaries? Answer. Histogram buckets are counters and can be summed across instances to compute fleet percentiles; summary quantiles cannot be combined. Histograms cost more series and give estimated quantiles, bounded by bucket width.

Intermediate

Q3. Our Prometheus keeps running out of memory. What do you do? Answer. Check the head-series count and top metrics by series (TSDB status page). Look for unbounded labels (IDs, URLs with parameters, error messages). Drop or rewrite them with relabeling, set `sample_limit` per target, replace with recording rules or exemplars, and shard if genuine growth remains.

Q4. Design trace sampling for 20,000 requests/s where rare errors matter. Answer. Parent-based head sampling at a modest rate (or 100% if the network allows) into a collector tier; trace-ID load balancing to tail-sampling collectors keeping all errors, latency above the SLO threshold and a small baseline; span metrics computed before sampling. Size buffers with $R \cdot w \cdot S \cdot b$ at peak.

Advanced

Q5. Design observability for a 200-service platform on a budget. Answer. OpenTelemetry everywhere with semantic conventions; Collector agents and gateways; metrics in Prometheus with remote write to Mimir or Thanos; logs to a label-indexed store with 7-day hot and 90-day cold tiers; traces in object-storage-backed Tempo with tail sampling; exemplars linking metrics to traces; SLO burn-rate pages per journey; per-team volume and cardinality budgets on a cost dashboard.

Q6. Pages are ignored. How do you fix alerting? Answer. Measure precision and pages per shift; delete or demote non-actionable alerts; replace cause alerts with SLO burn-rate alerts; group and inhibit; require runbooks; review alert quality in postmortems and on-call handovers.

40.16 Practical exercises

1. Extend the histogram program of §40.5.2 with exponential buckets of growth factor 1.1 and compare errors and bucket counts.
2. Add a rate-limiting policy (at most N traces/s) to the tail sampler of §40.6.3 and measure what it drops during an error storm.
3. Run Prometheus, Grafana and an OTel-instrumented demo service locally; build a RED dashboard from recording rules.
4. Write a log redaction function for card numbers and emails, and test it against 20 tricky strings.

40.17 Design challenges

1. **Global payments observability.** 50,000 requests/s in three regions, 99.95% SLO. Choose sampling, retention and storage; estimate monthly volume per signal.
2. **Cardinality governance.** Design admission controls that stop a team from shipping a metric over 100,000 series, without blocking deploys.
3. **Incident-ready by design.** For a ride-hailing dispatch service, list the wide-event fields, span attributes and alerts that would explain a city-specific outage.

40.19 Open verification items

- OpenTelemetry signal status per language and the profiles signal’s maturity (alpha versus later) as of late 2026; reported CNCF graduation of OpenTelemetry in 2026.
- Native histograms declared stable in Prometheus v3.8 (December 2025), with scraping still opt-in.
- W3C Trace Context Level 2 status and the `ot=th:` tracestate encoding for consistent probability sampling.
- Honeycomb founders’ prior use of Scuba via Parse.
- SRE book ch. 11 guidance of at most two incidents per 12-hour shift.
- The 4 KB-per-series memory figure and ~1% continuous-profiling overhead are planning assumptions, not measurements.

Chapter 41 — Cloud Computing

> **Level:** 2 · **Track:** A (Traditional) · **Estimated reading time:** 3 h

In Chapter 1, PhotoShare launched on “a single rented virtual machine” and grew to ten million daily users with load balancers, replicated databases and “managed object storage”. Every box was rented from a cloud provider, and every rental was a decision: raw machine or finished service, one zone or three, hourly or committed, NAT gateway or private endpoint. This chapter is the map of that rental market. You will learn what the service models (IaaS, PaaS, SaaS, FaaS) actually transfer to the provider, how regions and availability zones turn into an availability budget, what the core services of AWS, Google Cloud and Azure are for, how a cloud network is wired, how Aurora rebuilt the relational database for the cloud, how IAM decides “allow” or “deny”, and how to estimate, and cut, a monthly bill. Networking fundamentals (Chapter 7), security fundamentals and KMS (Chapter 10) and the internals of block, file and object storage (Chapter 15) are assumed and cross-referenced rather than repeated.

41.1 Learning objectives

After this chapter you should be able to:

- Define cloud computing with NIST’s five essential characteristics, and draw the responsibility split for IaaS, PaaS, SaaS and FaaS.
- Explain regions, availability zones and edge locations, and compute the availability gain of a multi-zone deployment.
- State in one line what each core AWS, Google Cloud and Azure service is for, and translate a design between the three providers.
- Choose an instance family and purchase option, explain how Nitro-style offload and Firecracker microVMs work, and compute the expected cost of a spot workload with checkpointing.
- Draw a reference VPC with public and private subnets, NAT and endpoints, and find the data-transfer charges hidden in it.
- Explain Aurora’s “log is the database” design and its 4-of-6 quorum, and decide between managed and self-run databases.
- Trace an IAM authorization decision through identity, resource and guardrail policies, and name the most common cloud misconfigurations.
- Compute reserved-capacity break-even utilization and build a labeled monthly cost estimate for a three-tier web application.

41.2 Prerequisites

- IP addressing, CIDR and subnet arithmetic — §7.4 (every VPC is a CIDR block carved into subnets).
- NAT, firewalls, security groups and network ACLs — §7.13–§7.14 (cloud networking reuses them).
- Availability arithmetic for redundant components — §4.14 and Chapter 39 (zones are redundancy units).
- Least privilege, secrets management, KMS and envelope encryption — §10.8–§10.10 (cloud IAM and KMS implement them).
- Block, file and object storage and storage tiers — §15.3 and §15.9 (cloud storage services are instances of them).
- Serverless cost model and cold starts — §33.9 (FaaS economics are derived there).
- Units: **GB/TB** are powers of ten for billing (providers bill decimal GB unless stated); a **month** is 730 hours. All prices in this chapter are **illustrative list prices for a US region, as of 2026**; check the provider's pricing page before using them.

41.3 IaaS, PaaS, SaaS and FaaS

41.3.1 What "cloud" means

> DEFINITION
>
> **Definition — Cloud computing.** "A model for enabling ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction" [Mell and Grance 2011]. NIST lists five **essential characteristics**: on-demand self-service, broad network access, resource pooling, rapid elasticity and measured service; three **service models** (SaaS, PaaS, IaaS); and four **deployment models** (private, community, public, hybrid).

First-principles explanation

Think about getting dinner. You can buy a kitchen, groceries and cook (your own data center); rent a fully equipped kitchen by the hour and bring your own recipe (**infrastructure as a service**); order a meal kit where the ingredients arrive prepared and you only assemble (**platform as a service**); or eat at a restaurant (**software as a service**). **Function as a service** is a restaurant that bills you per bite and closes the kitchen when nobody is eating. In each step up, you give up control and receive convenience; the line between "what I manage" and "what the provider manages" moves upward.

The NIST characteristics separate the cloud from a leased rack: capacity arrives by API call (*self-service*), shares hosts with strangers (*pooling*), appears and disappears in minutes (*elasticity*) and is billed per second, request or gigabyte (*measured service*).

Why does this exist?

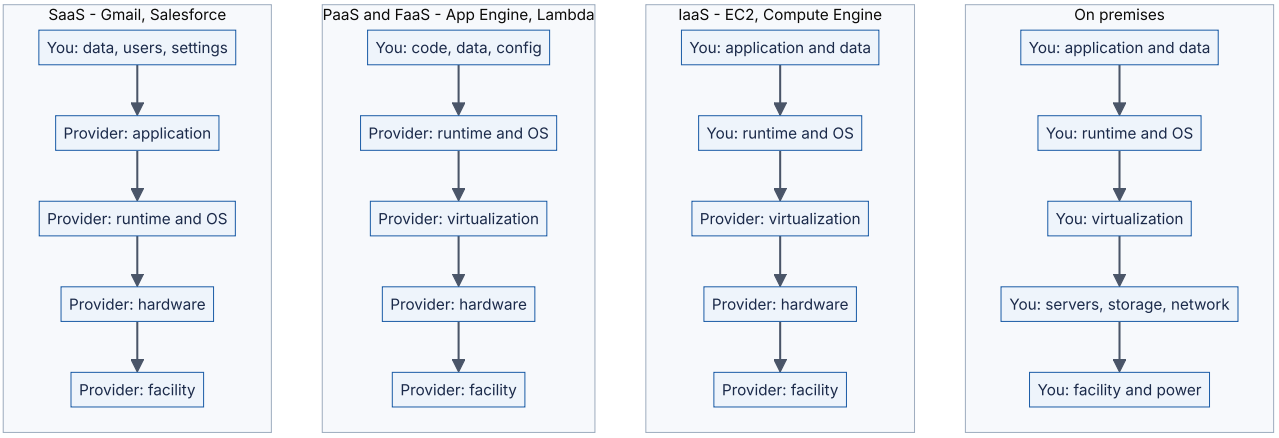
A warehouse-scale computer amortizes buildings, power, cooling, networks and operations teams across millions of servers Barroso et al. 2018. A single company running a few hundred servers pays the full fixed cost of a data center but uses it at low and uneven utilization. The cloud converts that fixed capital expense into a variable operating expense and lets one organization's idle capacity serve another's peak. The engineering consequence is that capacity becomes a software decision: an autoscaling policy (Chapter 18) can only exist if machines can be created by API.

41.3.2 The responsibility split

DEFINITION

Definition — Service models. IaaS (infrastructure as a service): the provider runs physical hardware, the network and the hypervisor; you rent virtual machines, disks and networks and manage the operating system upward (Amazon EC2, Google Compute Engine, Azure Virtual Machines). **PaaS** (platform as a service): the provider also runs the operating system and runtime; you deploy code or containers (Google App Engine, Azure App Service, AWS Elastic Beanstalk, Cloud Run). **SaaS** (software as a service): the provider runs the whole application; you configure it and own your data and users (Gmail, Salesforce, Microsoft 365). **FaaS** (function as a service): a PaaS whose unit of deployment is a function invoked per event, scaled to zero and billed per invocation and duration (AWS Lambda, Cloud Run functions, Azure Functions).

Figure 41.1 — Who manages each layer under each service model.



Reading the diagram. Each column is a stack of layers from the application (top) to the building (bottom); the label says who operates that layer. Arrows mean "runs on", not network traffic. Moving right, the You/Provider boundary rises, but *your data* and *who may access it* never move, so access misconfiguration is a risk under every model (§41.12). Failure points follow responsibility: an unpatched kernel is your incident on IaaS and the provider's on PaaS; a deleted table is yours on all four. Scaling too: on IaaS you configure autoscaling; on PaaS and FaaS the platform scales within quotas.

Table 41.1 — Service models compared.

Aspect	IaaS	PaaS (incl. managed containers)	FaaS	SaaS
Unit you deploy	VM image	Application or container	Function	Nothing (configuration)
You patch	OS, runtime, app	App and dependencies	Function code and dependencies	Nothing
Scaling	Your autoscaling rules	Platform, by instances	Platform, per request, to zero	Provider
Billing grain	Per second/hour of VM	Per instance or per request	Per request + GB-second	Per user or per usage
Control	Maximum (kernel, network, GPUs)	Medium	Low (time and memory limits)	Minimal
Lock-in	Low (VMs are portable)	Medium	High (event sources, IAM, triggers)	Highest (data formats, workflows)
Choose when	Special hardware, legacy software, full control	Standard web services and workers	Spiky, event-driven, glue code	Commodity capabilities (email, CRM)

Serverless containers (Fargate, Cloud Run, Azure Container Apps) sit between IaaS and PaaS: you supply an image, the platform the host. Managed Kubernetes is covered in Chapter 42.

COMMON MISTAKE

"Serverless means there are no servers to worry about." There are servers; you no longer patch or size them. You still own timeouts, concurrency limits, downstream connection storms, IAM permissions, cost per invocation and cold-start latency. The break-even analysis in §33.9.3 shows that at roughly 20–45 requests per second of *sustained* load, always-on instances become cheaper than functions in that example.

INTERVIEW TIP

Interview tip. When an interviewer asks “which service model?”, answer with what you want to stop owning. “We do not want to patch OSes or manage capacity, and the workload is a stateless HTTP API, so a container platform such as Cloud Run or Fargate; we keep VMs only for the GPU batch job that needs specific drivers.”

41.4 Regions, availability zones, edge locations and the shared responsibility model

41.4.1 The physical hierarchy

DEFINITION

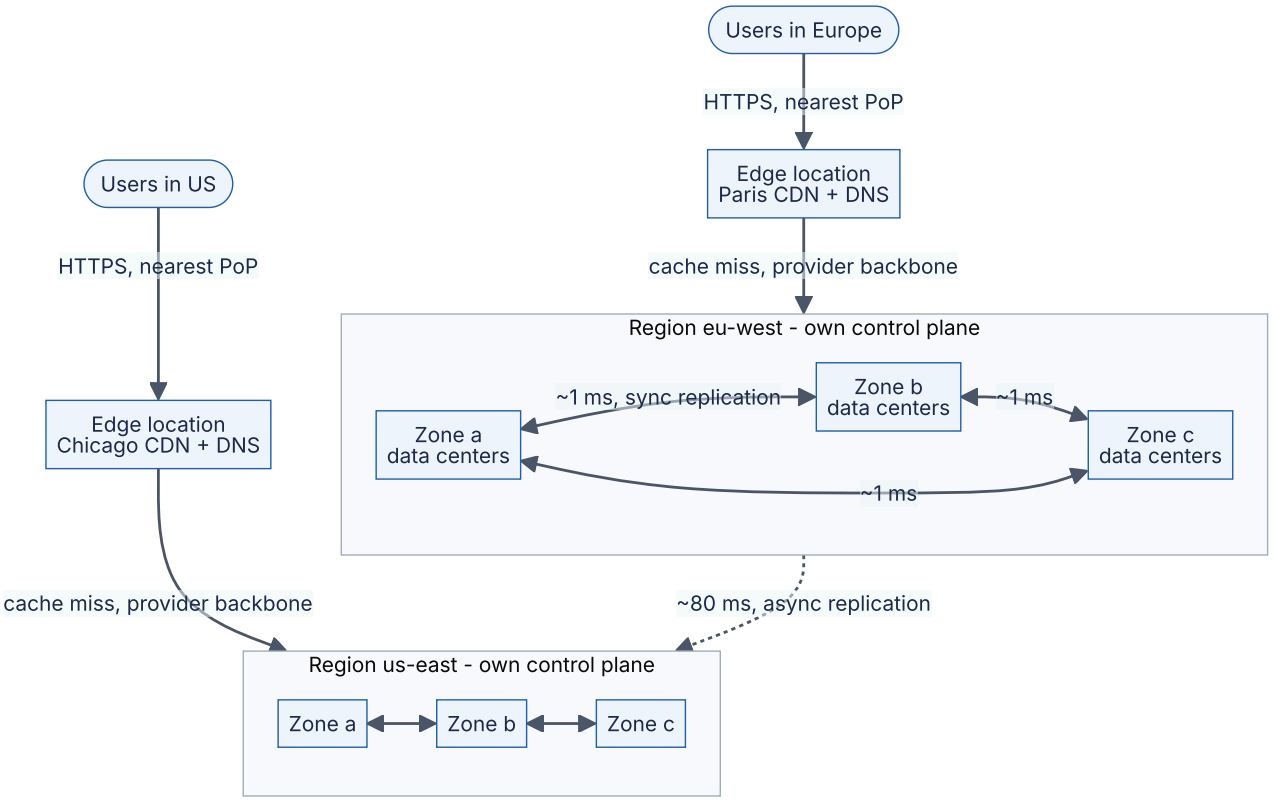
Definition — Region, availability zone, edge location. A **region** is a geographic area (for example `us-east-1`, `europe-west1`, `West Europe`) containing several isolated data-center groups, with its own control plane and, by default, its own copy of regional services. An **availability zone (AZ)** is one or more data centers within a region with independent power, cooling and networking, connected to the other zones of the region by redundant, low-latency links, so that a fire, flood or power failure in one zone should not take down another. An **edge location** (point of presence) is a smaller site in a metropolitan area that runs CDN caches, DNS and edge compute close to users, but not general-purpose VMs and databases.

First-principles explanation

Imagine a retail chain. A **region** is a city with its own distribution hub and local laws; inside it, stock sits in three **warehouses** on different power grids and flood plains (zones), so one fire stops none of the others; **edge locations** are corner kiosks holding best-sellers near customers.

The hierarchy exists because failures and latency both have *geography*. Light in fiber travels about 200 km per millisecond (§7.15), so zones a few tens of kilometers apart can replicate synchronously with round trips of about a millisecond, while regions on different continents are 70–150 ms apart and must replicate asynchronously. AWS documents its zones as separated by a meaningful distance yet within 100 km (60 miles) of each other, with single-digit-millisecond latency between them [AWS Docs: Regions and Zones]; Google Cloud and Azure zones follow the same idea, and Azure also pairs regions for staged updates and geo-redundant storage [Azure Docs: Availability zones].

Figure 41.2 — Regions, zones and edge locations.



Reading the diagram. Users reach the **nearest edge location** over HTTPS (DNS or anycast routing, §21.3.3). Cache hits are served there; misses travel over the provider's private backbone to the **origin region**. Inside a region, three **zones** are fully meshed with roughly 1 ms links, which is why synchronous replication (a database standby, a quorum write) across zones is affordable. Between regions the dotted arrow is **asynchronous** replication: at about 80 ms per round trip, waiting for the other region on every write would multiply write latency. Storage boundaries: block volumes are zonal; regional services span zones; nothing spans regions unless you configure it. Failure points: a zone, a regional control plane (rarer, larger blast radius), a PoP (users shift to the next one). Scaling: add zones for availability, regions for latency, data residency and disaster recovery (Chapter 44).

Between edge and region sit metro **Local Zones** and on-premises racks (**Outposts**, **Google Distributed Cloud**, **Azure Local**); treat each as a zone with fewer services.

Mathematical foundations

FORMULA

Availability and over-provisioning of an N-zone deployment

$$A_{\text{svc}} \approx A_{\text{reg}} \cdot (1 - (1 - A_z)^n) \qquad f_{\text{over}} = \frac{n}{n-1}$$

Symbol	Meaning	Units
A_{svc}	Availability of the service as seen by users	fraction
A_{reg}	Availability of shared regional dependencies (control plane, regional DNS, IAM)	fraction
A_z	Availability of one zone's copy of the service, assumed independent across zones	fraction
n	Number of zones serving traffic	count
f_{over}	Capacity each deployment must hold relative to the load, to survive losing one zone	ratio

WORKED EXAMPLE

Worked example — Two zones or three? PhotoShare's API runs identical stacks per zone; measured history suggests a single-zone stack is available $A_z = 99.9\%$, and regional dependencies $A_{\text{reg}} = 99.99\%$.

1. One zone: $A_{\text{svc}} = 0.9999 \times 0.999 = 0.9989$, about 9.6 hours of downtime a year.
2. Two zones: $1 - (0.001)^2 = 0.999999$; times 0.9999 gives 0.9999, about 53 minutes a year.
3. Three zones: $1 - (0.001)^3 \approx 1$; times 0.9999 is still 0.9999.
4. Over-provisioning to survive one zone loss: two zones need $2/1 = 2.0\times$ the peak load in total (each zone alone carries 100%); three zones need $3/2 = 1.5\times$ (each zone is sized for $1/(n-1) = 50\%$ of peak, so the two survivors together still carry 100%).

Interpretation. Going from one zone to two removes almost all zone-caused downtime; after that, the shared regional term dominates, and a third zone adds almost no availability. Its real benefit is cost: surviving one zone loss needs $1.5\times$ capacity with three zones versus $2\times$ with two, and zonal quorum systems (Aurora, etcd) need three locations to keep a majority. **Engineering implication.** Use three zones for stateful quorum systems and to cut spare capacity; to improve on A_{reg} you need a second region, not a fourth zone (§39.10, Chapter 44). Remember the independence assumption: a bad deploy pushed to all zones at once is a correlated failure that this formula ignores, which is why deployments roll out zone by zone (Chapter 43).

INDUSTRY EXAMPLE

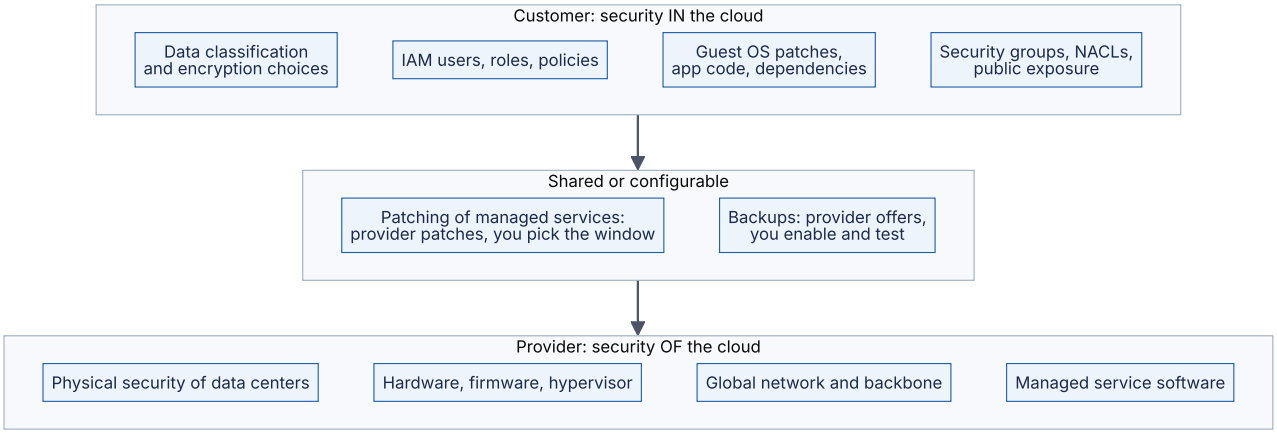
Static stability across zones. AWS's Builders' Library describes designing services to be **statically stable**: each zone is provisioned to keep working without making control-plane calls (such as launching new instances) when another zone fails, because control-plane actions are exactly what degrade during large events [AWS Builders' Library: Static stability using Availability Zones]. EC2 itself separates its *control plane* (launching instances) from its *data plane* (running instances), and the guidance is to pre-provision capacity across zones rather than plan to scale up during an outage. *Evidence: Primary* — [AWS Builders' Library: Static stability]

41.4.2 The shared responsibility model

DEFINITION

Definition — Shared responsibility model. The division of security and operational duties between the provider and the customer. In AWS's phrasing, the provider is responsible for security **of** the cloud (facilities, hardware, hypervisor, global network, the managed services' own software), and the customer for security **in** the cloud (data, identities and permissions, OS and application patching on IaaS, network rules, encryption choices) [AWS: Shared Responsibility Model]. The exact line moves with the service model (Figure 41.1).

Figure 41.3 — Shared responsibility for an IaaS workload.



Reading the diagram. Bands list duties from customer (top) to provider (bottom); arrows mean "builds on". The *customer* band never empties: data, identity and exposure are always yours. The *shared* band holds features the provider offers (backups, patch windows) that protect you only if enabled and tested. The *provider* band is audited through compliance reports (SOC 2, ISO 27001) and published designs such as Nitro (§41.8.3). Failure points concentrate at the top: a public bucket or over-broad role is a customer failure no provider control prevents.

COMMON MISTAKE

"The provider is responsible for my data's durability, so I do not need backups." The provider keeps the bytes you wrote durable; it faithfully keeps your mistakes too. A `DROP TABLE`, a ransomware encryption run with stolen credentials, or a lifecycle rule on the wrong prefix destroys data durably. Point-in-time recovery, versioning, and copies in a separate account with separate credentials are the customer's responsibility (§39.9).

41.5 AWS core services

41.5.1 One line each

Amazon Web Services offers more than two hundred services, but a typical web system is assembled from about a dozen. Learn these by the problem each solves; the rest of the catalog is mostly variations.

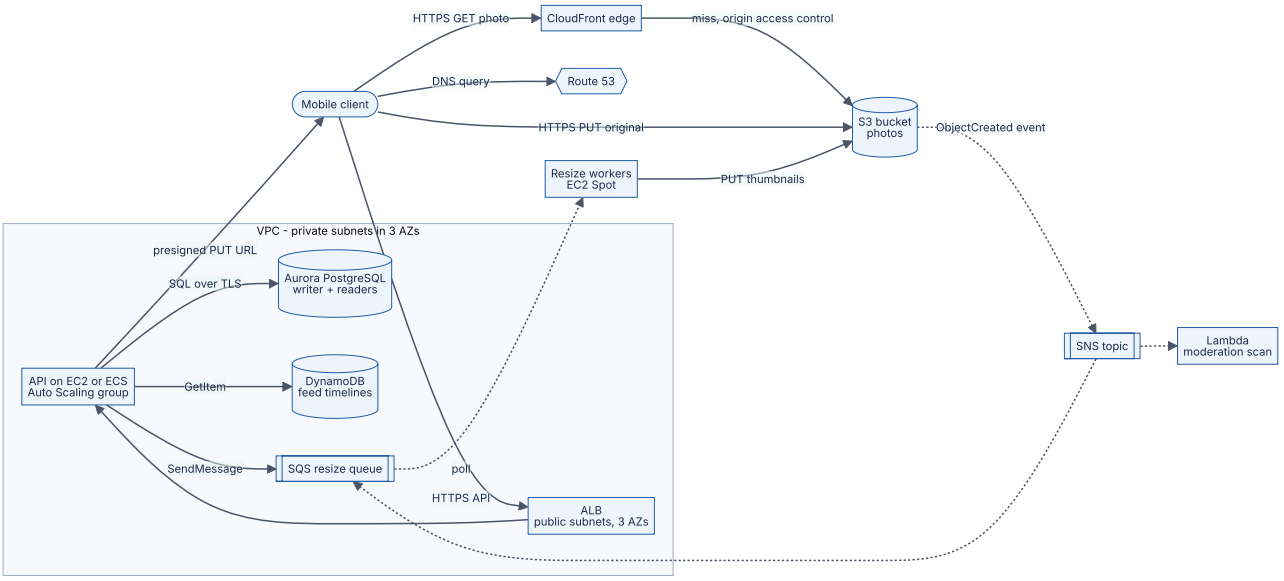
Table 41.2 — AWS core services: what each is for.

Service	Category	What it is for, in one line
EC2 (Elastic Compute Cloud)	Compute, IaaS	Rent virtual machines (instances) by the second in many shapes, including GPUs
S3 (Simple Storage Service)	Object storage	Store unlimited immutable objects in buckets over HTTPS, designed for eleven nines of durability (§15.4)
EBS (Elastic Block Store)	Block storage	Network-attached virtual disks for one instance, in one zone, with snapshots to S3
VPC (Virtual Private Cloud)	Networking	Your isolated, software-defined IP network: subnets, route tables, gateways, firewalls
IAM (Identity and Access Management)	Security	Who (principal) may do what (action) on which resource, under which conditions
RDS / **Aurora**	Relational DB	Managed MySQL, PostgreSQL, SQL Server, Oracle, MariaDB; Aurora adds a cloud-native storage layer (§41.11)
DynamoDB	NoSQL key-value	Serverless key-value and document store with single-digit-millisecond reads at any scale (§12.4)
SQS (Simple Queue Service)	Messaging	Managed queue between producers and consumers; standard (at-least-once) or FIFO
SNS (Simple Notification Service)	Messaging	Publish/subscribe fan-out of one message to many queues, functions, HTTP endpoints or phones
Lambda	FaaS	Run a function per event (HTTP, queue message, object upload) without managing servers
CloudFront	CDN	Cache and accelerate content at hundreds of edge locations, in front of S3 or any origin (Chapter 21)
ELB (Elastic Load Balancing)	Load balancing	ALB for HTTP/gRPC (layer 7), NLB for TCP/UDP (layer 4), GWLB for inline appliances (Chapter 19)
Supporting cast	—	Route 53 (DNS), KMS (keys), Secrets Manager, CloudWatch (metrics, logs), CloudTrail (API audit log), ECS/EKS/Fargate (containers), ElastiCache (Redis/Valkey/Memcached)

41.5.2 A deeper example: PhotoShare's upload and view paths on AWS

The services become meaningful only when wired together. Figure 41.4 shows PhotoShare's production design from Chapter 1 mapped onto AWS.

Figure 41.4 — PhotoShare on AWS core services.



Reading the diagram. *Upload path:* the client calls the API through the **ALB** (synchronous HTTPS); the API writes a pending row to **Aurora** and returns a **presigned S3 URL** (§15.8.2), so photo bytes go straight to **S3**. S3 emits an `ObjectCreated` event to **SNS** (dotted: asynchronous), which fans out to an **SQS** queue consumed by resize workers and to a **Lambda** function that runs a moderation scan. *View path:* the client resolves the domain with **Route 53** and fetches images from **CloudFront**, which serves hits from the edge and pulls misses from S3 using origin access control, so the bucket itself stays private. Feed timelines are read from **DynamoDB** with single-key lookups. Failure points: a zone loss removes one third of the API and worker capacity (Auto Scaling replaces it; static stability means pre-provisioning it); the Aurora writer fails over to a reader replica, typically in tens of seconds; SQS buffers resize jobs if workers fall behind. Scaling: the API scales by instance count, workers by queue depth, and the managed services within account quotas.

Three choices recur in every cloud design: **keep bulk bytes off your servers** (presigned URLs, CDN), **turn waiting into events** (S3 → SNS → SQS), and **keep state in managed regional services** so zone failures are the provider's replication problem.

INDUSTRY EXAMPLE

AWS Well-Architected Framework. AWS publishes a review framework of six pillars — operational excellence, security, reliability, performance efficiency, cost optimization and sustainability — with design principles and review questions for each, plus “lenses” for workloads such as serverless and SaaS [AWS Well-Architected Framework]. Google Cloud’s equivalent is the Google Cloud Well-Architected Framework (formerly the Google Cloud Architecture Framework) and Microsoft’s is the Azure Well-Architected Framework; all three organize guidance around nearly the same pillars. They are useful as checklists in design reviews and interviews, not as architectures. *Evidence: Primary* — [AWS Well-Architected Framework; Google Cloud Well-Architected Framework; Azure Well-Architected Framework]

41.6 Google Cloud core services

Google Cloud (GCP) grew out of Google’s internal infrastructure: Borg for cluster management (Chapter 46), Colossus for storage (§15.5.3), Jupiter and Andromeda for networking, Spanner and Bigtable for data. Its distinctive design choices follow from that history.

Table 41.3 — Google Cloud core services: what each is for.

Service	AWS analog	What it is for, in one line
Compute Engine	EC2	Virtual machines, with custom machine shapes and live migration during host maintenance
Cloud Storage (GCS)	S3	Object storage with Standard, Nearline, Coldline and Archive classes and strong global consistency
Persistent Disk / Hyperdisk	EBS	Network block storage, zonal or regional (synchronously replicated across two zones)
VPC network	VPC	A **global** private network: one VPC spans all regions, with regional subnets
Cloud IAM	IAM	Role bindings on a resource hierarchy (organization → folders → projects → resources)
Cloud SQL / AlloyDB	RDS / Aurora	Managed MySQL, PostgreSQL, SQL Server; AlloyDB is a PostgreSQL-compatible engine with disaggregated storage
Spanner	(Aurora DSQL, DynamoDB global tables)	Globally distributed, strongly consistent relational database (§41.11.3)
Bigtable / Firestore	DynamoDB	Wide-column store for large analytical/time-series data; document database for apps
Pub/Sub	SNS + SQS, Kinesis	Global publish/subscribe messaging with pull and push subscriptions
Cloud Run / Cloud Run functions	Fargate, App Runner / Lambda	Run containers or functions per request, scaling to zero
GKE	EKS	Managed Kubernetes; Autopilot mode also manages nodes (Chapter 42)
Cloud Load Balancing / Cloud CDN	ELB / CloudFront	Global anycast layer-7 and layer-4 load balancing, with integrated CDN
BigQuery	Redshift, Athena	Serverless columnar data warehouse billed per byte scanned or by slot capacity

Two differences matter in design reviews. **The VPC is global**: VMs in `us-central1` and `europe-west1` share one VPC and private IPs without peering, while AWS and Azure networks are regional. **The external HTTP(S) load balancer is global**: one anycast IP routes each user to the nearest healthy region (§19.8.2), which on AWS takes Global Accelerator or Route 53 latency routing plus per-region ALBs. Google's software-defined network stack, Andromeda, is described in [Dalton et al. 2018].

41.7 Azure core services

Microsoft Azure's strength is integration with enterprise identity and Microsoft software: Entra ID (formerly Azure Active Directory) is the identity provider for many organizations' employees already, and Windows Server, SQL Server and .NET workloads move there with licensing benefits.

Table 41.4 — Azure core services: what each is for.

Service	AWS analog	What it is for, in one line
Virtual Machines / VM Scale Sets	EC2 / Auto Scaling	VMs and autoscaled groups of identical VMs
Blob Storage	S3	Object storage in storage accounts with Hot, Cool, Cold and Archive tiers
Managed Disks	EBS	Block volumes (Standard HDD/SSD, Premium SSD, Premium SSD v2, Ultra Disk)
Azure Files / NetApp Files	EFS / FSx	Managed SMB and NFS file shares
Virtual Network (VNet)	VPC	Regional private network with subnets, NSGs, route tables
Entra ID + Azure RBAC	IAM (+ IAM Identity Center)	Identities (users, groups, managed identities) and role assignments at scopes
Azure SQL Database / Database for PostgreSQL and MySQL	RDS	Managed relational databases; Hyperscale tier separates compute from log and page servers
Cosmos DB	DynamoDB	Globally distributed multi-model database with five tunable consistency levels (§41.11.3)
Service Bus / Event Hubs / Event Grid	SQS+SNS / Kinesis / EventBridge	Enterprise queues and topics; high-throughput event streaming; event routing
Azure Functions / Container Apps	Lambda / Fargate	Functions per event; serverless containers
AKS	EKS	Managed Kubernetes
Load Balancer / Application Gateway / Front Door	NLB / ALB / CloudFront + Global Accelerator	Layer-4 regional balancing; layer-7 regional with WAF; global layer-7 entry with CDN
Key Vault	KMS + Secrets Manager	Keys, secrets and certificates in one service

Azure's resource model differs in a way that confuses newcomers: every resource lives in a **resource group** inside a **subscription**, inside **management groups** under one Entra

tenant. Subscriptions are the billing and quota boundary, roughly like AWS accounts, and management groups carry **Azure Policy** guardrails, roughly like AWS Organizations' organizational units and SCPs (§41.12.4).

COMMON MISTAKE

"Same name, same thing." Names that look alike hide different semantics. A GCP VPC is global, an Azure VNet regional; an AWS security group is stateful and allow-only while an Azure **network security group** has ordered allow *and* deny rules (but is stateful); Google "Cloud Functions" is now branded Cloud Run functions. Translate by *behavior* using §41.14, then check the provider's documentation for limits.

41.8 Compute

41.8.1 Instances and instance families

DEFINITION

Definition — Instance type and family. An **instance type** is a fixed shape of virtual hardware: vCPUs, memory, network bandwidth, local storage and accelerators. Types are grouped into **families** optimized for a ratio of resources. In AWS naming, `m7g.xlarge` means family `m` (general purpose), generation `7`, attribute `g` (AWS Graviton Arm processor), size `xlarge` (4 vCPUs). A **vCPU** is one hardware thread on most x86 instances (two vCPUs per physical core with simultaneous multithreading) and one physical core on Graviton.

Table 41.5 — Instance families (AWS letters; GCP and Azure analogs).

Family	AWS	GCP	Azure	Memory per vCPU	Use cases
General purpose	M, T (burstable)	N2, N4, E2, C4A (Arm)	D, B (burstable)	~4 GiB	Web/API servers, small databases
Compute optimized	C	C3, C4, H3	F, FX	~2 GiB	Batch, encoding, high-RPS stateless services
Memory optimized	R, X, U	M3, M4	E, M	8–32+ GiB	Databases, in-memory caches, analytics
Storage optimized	I, D	Z3	L	varies, local NVMe	Self-managed NoSQL, search, data warehouses
Accelerated	P, G, Trn, Inf	A3, A4, G2, TPU VMs	NC, ND, NV	varies	ML training and inference, graphics

Family letters as of 2026; generations change yearly. **Burstable** types (T, E2 shared-core, B) earn CPU credits while idle and spend them under load; they are cheap for spiky low-average workloads and a classic trap when a sustained load drains the credits and the instance is throttled to its baseline.

Choose a family from the **binding resource** (Chapter 23): measure CPU, memory, network and disk utilization under realistic load, pick the family whose ratio matches, then the smallest size that keeps the binding resource below a target utilization (often 60–70% for latency-sensitive services, §4.10.3).

41.8.2 Virtualization and hypervisors

DEFINITION

Definition — Hypervisor. Software (sometimes with hardware assistance) that runs multiple **guest** operating systems on one physical host, giving each the illusion of its own machine. A **type 1** hypervisor runs directly on hardware (Xen, KVM as part of Linux, Hyper-V); a **type 2** runs as an application on a host OS (VirtualBox). Modern CPUs provide hardware virtualization extensions (Intel VT-x, AMD-V, Arm virtualization extensions) so that guest instructions run natively and only privileged operations trap to the hypervisor.

On a classic virtualized host, the hypervisor and a privileged management domain (Xen's "dom0") also emulate or mediate **devices**: every network packet and disk block of every guest passes through software on the host's own CPUs. That costs two things a cloud

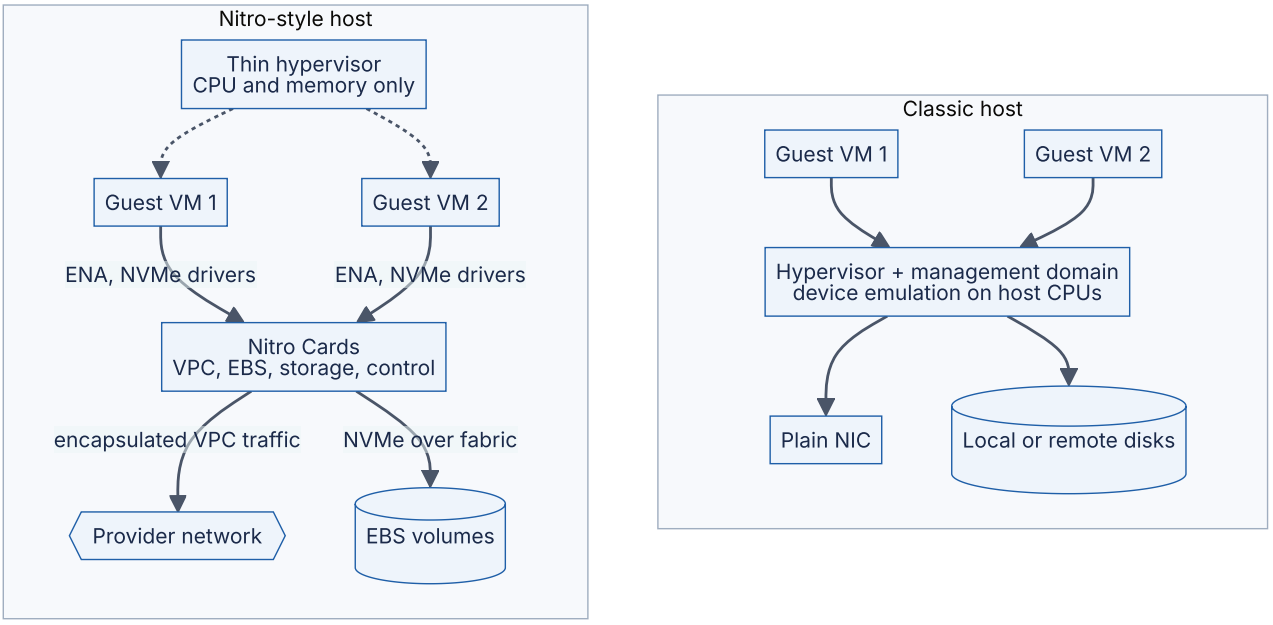
provider cares about: host CPU cycles that cannot be sold, and **jitter**, because a noisy guest's I/O competes with yours for the same management domain.

41.8.3 Nitro-style offload

AWS's published answer is the **Nitro System**: move device emulation, networking, storage and management off the host CPU onto dedicated cards, and shrink the hypervisor to almost nothing [AWS Nitro System docs; AWS Nitro security whitepaper 2022]. As published:

1. **Nitro Cards** implement the VPC data plane (encapsulation, security groups, routing), EBS access (presented to the guest as NVMe devices, encrypted on the card), local instance storage, and the system controller. The guest talks to them through standard NVMe and Elastic Network Adapter (ENA) drivers.
2. The **Nitro Security Chip** controls the host's firmware and hardware root of trust.
3. The **Nitro Hypervisor**, built on KVM, only partitions CPU and memory and assigns card functions to guests. It has no networking stack, no general-purpose shell and, per AWS, no mechanism for operators to log in to the host.

Figure 41.5 — Classic hypervisor versus Nitro-style offload.



Reading the diagram. On the *classic host*, both guests' I/O flows through the hypervisor and management domain, which run on the same CPUs that customers rent; every packet is a software hop, and a busy neighbor adds queueing delay to yours. On the *Nitro-style host*, each guest's drivers talk directly to functions exposed by the cards (solid arrows, synchronous I/O), and the cards perform VPC encapsulation, firewalling and encrypted EBS access in dedicated hardware. The thin hypervisor (dotted: it configures, it does not sit on the data path) only partitions CPU and memory. Storage boundary: EBS volumes

are remote, reached over the provider network as NVMe. Failure points: a card failure affects the whole host, so the provider migrates or restarts instances; a remote EBS path adds network latency compared with local NVMe. Effect: nearly all host cores become sellable, and **bare-metal** instances become possible.

Other providers publish similar directions: Google's Titanium offload system and Azure Boost both move networking and storage processing onto dedicated hardware (as of 2026, see provider docs). The general lesson for system designers is that **cloud I/O is network I/O**: an EBS or Persistent Disk "disk" is a remote service with its own throughput and IOPS limits per volume and per instance.

41.8.4 Containers, microVMs and serverless

Containers (Chapter 42) share one kernel among many isolated processes using namespaces and cgroups, which makes them start in well under a second and pack densely, but makes the kernel a shared attack surface: unsafe for running *untrusted* code from different customers side by side. Full VMs give strong isolation but start in tens of seconds and cost hundreds of megabytes each.

Firecracker is the microVM monitor AWS built to get VM isolation at container-like cost for Lambda and Fargate [Agache et al. 2020]. It is a KVM-based virtual machine monitor written in Rust with a deliberately minimal device model (virtio network and block, a serial console, a minimal keyboard controller used for reset, no PCI, no BIOS). The paper reports booting a microVM to user-space code in as little as 125 ms, a memory overhead below 5 MiB per microVM, and creation rates up to 150 microVMs per second per host. Each Lambda execution environment runs inside one microVM, and thousands run on one host. Chapter 47 compares isolation levels and Chapter 48 covers Lambda's internals.

In short: VMs give the most control and the slowest start; containers on managed nodes pack densely but share a kernel; serverless containers and functions run each task or environment in a microVM and bill per use, trading control and time limits (15 minutes per Lambda invocation) for the lowest operational load. §33.9 and §42.16 compare them in depth.

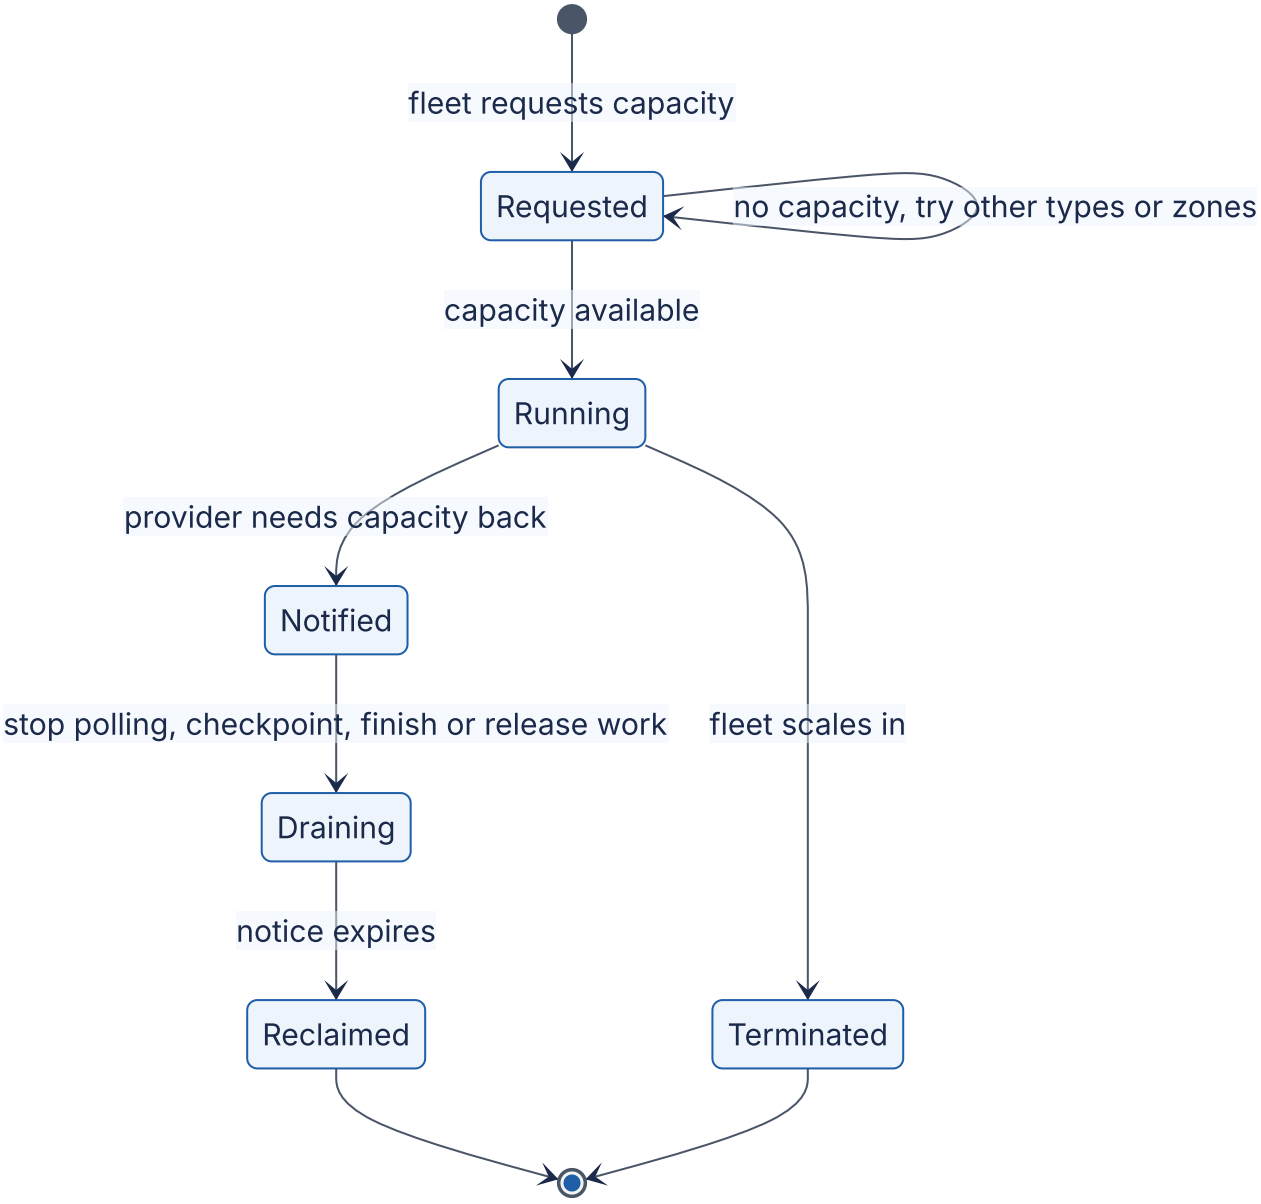
41.8.5 Spot and preemptible capacity

DEFINITION

Definition — Spot capacity. Spare provider capacity sold at a steep discount (often 60–90% off on-demand, varying by type, zone and time) that the provider can reclaim when it needs the capacity back. AWS **Spot Instances** receive a two-minute interruption notice; Google **Spot VMs** (successor to preemptible VMs, which were limited to 24 hours) and Azure **Spot VMs** receive about 30 seconds' notice [AWS EC2 docs: Spot; Google Cloud docs: Spot VMs; Azure docs: Spot VMs].

Spot is excellent for work that is **interruptible and restartable**: stateless web replicas behind a load balancer (with on-demand base capacity), queue workers, CI runners, batch analytics and checkpointed ML training. It is a poor fit for singletons, databases and anything that cannot finish its shutdown in the notice period.

Figure 41.6 — Lifecycle of a spot instance in a queue-worker fleet.



Reading the diagram. A fleet manager (an Auto Scaling group with mixed types, a GKE spot node pool) requests capacity and **diversifies** across instance types and zones when one pool is empty. The *Notified* transition is asynchronous: the instance learns of it from the metadata service or an event. In *Draining* the worker stops polling, checkpoints, and lets unfinished messages' visibility timeouts expire so another worker retries them (at-least-once processing, Chapter 30). Failure points: work since the last checkpoint is lost; a fleet concentrated on one type can lose most capacity at once. Replacement capacity is requested immediately from the most available pools.

Mathematical foundations

FORMULA

Expected cost of a checkpointed spot job (first-order model)

$$T_{\text{wall}} \approx T\left(1 + \frac{c}{\tau} + \lambda\left(\frac{\tau}{2} + R\right)\right), \qquad E[C_{\text{spot}}] = p_{\text{spot}}\, T_{\text{wall}}, \qquad \tau^{*} = \sqrt{\frac{2c}{\lambda}}$$

Without checkpoints (restart from scratch), the expected wall time is $T_{\text{wall}} = \left(\frac{1}{\lambda} + R\right)\left(e^{\lambda T} - 1\right)$.

Symbol	Meaning	Units
T	Useful compute the job needs	hours
T_{wall}	Expected billed instance time including overheads	hours
c	Time to write one checkpoint	hours
τ	Interval between checkpoints	hours
λ	Interruption rate (1/mean time between interruptions)	1/hour
R	Restart overhead per interruption: acquire capacity, boot, load checkpoint	hours
p_{spot}	Spot price	$/hour
τ^{*}	Checkpoint interval minimizing T_{wall} (Young's approximation)	hours

The three overhead terms are checkpoint cost (c/τ per unit of work), lost work (on average half an interval per interruption) and restart time. The model holds when $\lambda\tau \ll 1$.

WORKED EXAMPLE

Worked example — A 100-hour batch job on spot. Illustrative prices (as of 2026): on-demand p_{od} = \$2.00/h, spot p_{spot} = \$0.70/h. Interruptions average one per 20 hours ($\lambda = 0.05$/h); a checkpoint takes 3 minutes ($c = 0.05$ h); a restart takes 6 minutes ($R = 0.1$ h); $T = 100$ h.

1. Optimal interval: $\tau^* = \sqrt{2 \times 0.05/0.05} = \sqrt{2} = 1.41$ h.
2. Checkpoint overhead: $c/\tau = 0.05/1.41 = 0.035$.
3. Interruption overhead: $\lambda(\tau/2 + R) = 0.05 \times (0.71 + 0.1) = 0.040$.
4. $T_{wall} = 100 \times (1 + 0.035 + 0.040) = 107.6$ h; $E[C_{spot}] = 0.70 \times 107.6 = \$75.30$.
5. On-demand: $2.00 \times 100 = \$200$. Spot saves about 62%.
6. Sensitivity: checkpointing every 15 minutes gives $T_{wall} = 121.1$ h (\$84.79); every 6 hours gives 116.3 h (\$81.43). Both still beat on-demand, but the optimum is flat and in between.
7. No checkpoints: $T_{wall} = (20 + 0.1)(e^5 - 1) = 20.1 \times 147.4 \approx 2,963$ h, so $E[C] \approx \$2,074$, more than ten times the on-demand cost.

Interpretation. Spot's discount survives interruptions only if lost work per interruption is small relative to the mean time between interruptions; a job much longer than $1/\lambda$ without checkpoints almost never finishes. **Engineering implication.** Make long jobs checkpoint at roughly $\sqrt{2c/\lambda}$, keep tasks short (minutes) for queue workers, diversify instance types to lower λ, and keep an on-demand floor for latency-critical capacity.

41.9 Storage

Chapter 15 explains how block, file and object stores work inside. Here you need only the cloud names, the semantics that differ between providers, and the storage classes that drive cost.

Table 41.6 — Cloud storage services by interface.

Interface	AWS	Google Cloud	Azure	Scope and key property
Block (network)	EBS: gp3, io2 Block Express, st1, sc1	Persistent Disk, Hyperdisk	Managed Disks: Standard, Premium SSD v2, Ultra	Zonal (GCP and Azure also offer zone-redundant/regional disks); one attached VM, multi-attach limited
Block (local)	Instance store NVMe	Local SSD	Temp disk / local NVMe	Fastest; **lost when the instance stops or the host fails**
File	EFS (NFS), FSx for Lustre/Windows/ONTAP/OpenZFS	Filestore, Managed Lustre	Azure Files (SMB/NFS), NetApp Files	Shared POSIX; regional or zonal
Object	S3	Cloud Storage	Blob Storage	Regional (multi-zone) or multi-region; strong read-after-write on all three
Archive	S3 Glacier classes	Archive class	Archive tier	Cheapest; minimum durations and retrieval fees

Table 41.7 — Object storage classes and their minimum storage durations (as of 2026).

Access pattern	AWS S3	Google Cloud Storage	Azure Blob	Minimum duration
Hot	Standard	Standard	Hot	none
Infrequent (monthly)	Standard-IA, One Zone-IA	Nearline	Cool	30 days
Cold (quarterly)	Glacier Instant Retrieval	Coldline	Cold	90 days
Archive (yearly)	Glacier Flexible Retrieval, Deep Archive	Archive	Archive	90–180 days (S3), 365 (GCS), 180 (Azure)
Unknown pattern	Intelligent-Tiering	Autoclass	Lifecycle rules on last access	none (small monitoring fee on S3)
Lowest latency, single zone	Express One Zone	zonal options vary by release	Premium block blobs	none

Three cloud-specific facts change designs. **Zonal block volumes do not survive a zone outage**, so a database on EBS needs cross-zone replication or snapshots (what managed databases do, §41.11). **Local NVMe is ephemeral**: use it only for caches, scratch and

replicated stores. **Object storage bills requests and retrieval** as well as gigabytes: §15.9's tiering plan saves 79% for large objects and loses money for tiny ones.

RECOMMENDATION

Pick storage by failure domain first, then by price. Ask "what happens to this data if one zone disappears?" before "which class is cheapest?". Zonal volume plus snapshots gives minutes-to-hours recovery; regional object storage gives none to lose; a single-zone class such as One Zone-IA or Express One Zone is acceptable only for data you can regenerate.

41.10 Networking

41.10.1 The VPC and its parts

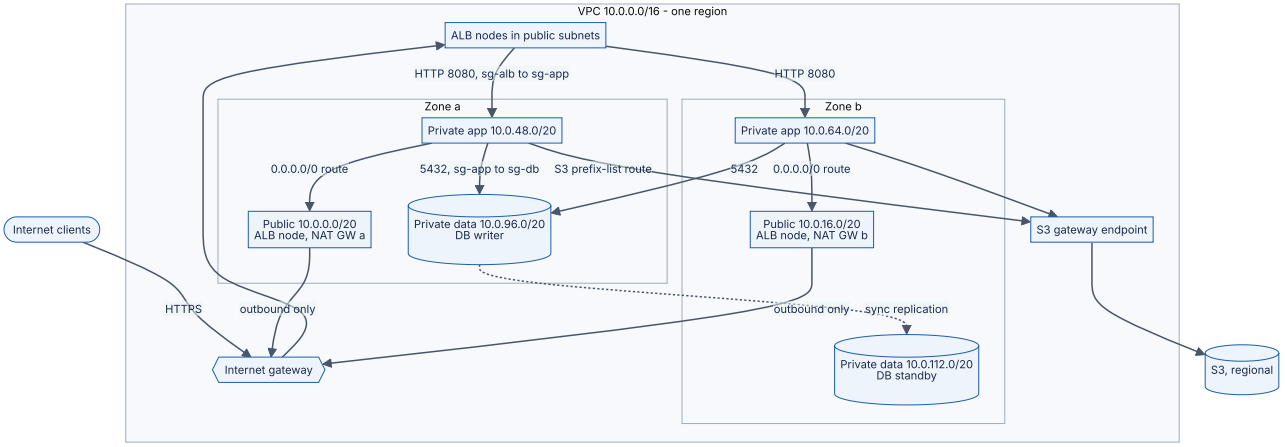
DEFINITION

Definition — Virtual private cloud (VPC). A logically isolated, software-defined network in a provider's cloud, defined by a private CIDR range (§7.4) and divided into **subnets**. Packets between instances are encapsulated by the provider's virtual network (on Nitro, by the cards) and delivered according to the VPC's **route tables** and firewall rules, regardless of which physical hosts the instances are on.

The parts, in the order a packet meets them:

1. **Subnet.** A slice of the VPC's CIDR in one zone (AWS, Azure) or region (GCP). It is **public** if its route table sends `0.0.0.0/0` to an **internet gateway**, otherwise **private**: a routing property, not a checkbox.
2. **Route table.** Longest-prefix-match rules (§7.5.1) per subnet: the VPC CIDR is local; `0.0.0.0/0` goes to an internet gateway or a NAT gateway; service prefixes can go to gateway endpoints.
3. **Internet gateway (IGW).** A redundant, horizontally scaled component doing one-to-one NAT between private and public IPs; no charge of its own.
4. **NAT gateway.** A managed, per-zone source NAT (§7.13) for outbound-only internet access from private subnets, billed per hour **and per gigabyte processed**.
5. **Security groups and network ACLs.** Stateful instance-level allow rules versus stateless subnet-level ordered rules (§7.14). Security groups that reference other groups are the primary control; NACLs are coarse guardrails.
6. **Endpoints. Gateway endpoints** (AWS, for S3 and DynamoDB) add a free route to the service's prefix list. **Interface endpoints** (PrivateLink) put a private IP for a service in your subnet, billed per zone-hour and per gigabyte.

Figure 41.7 — A reference VPC across three zones.

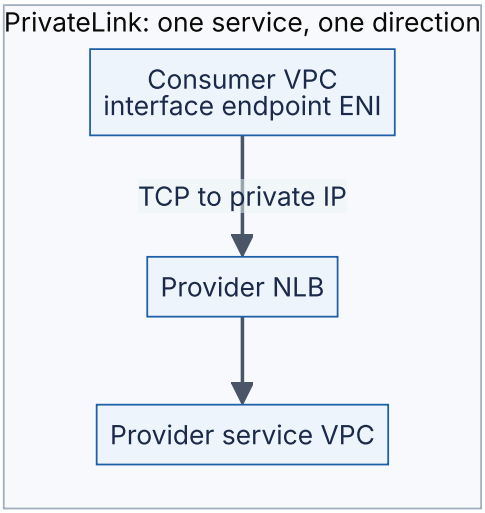


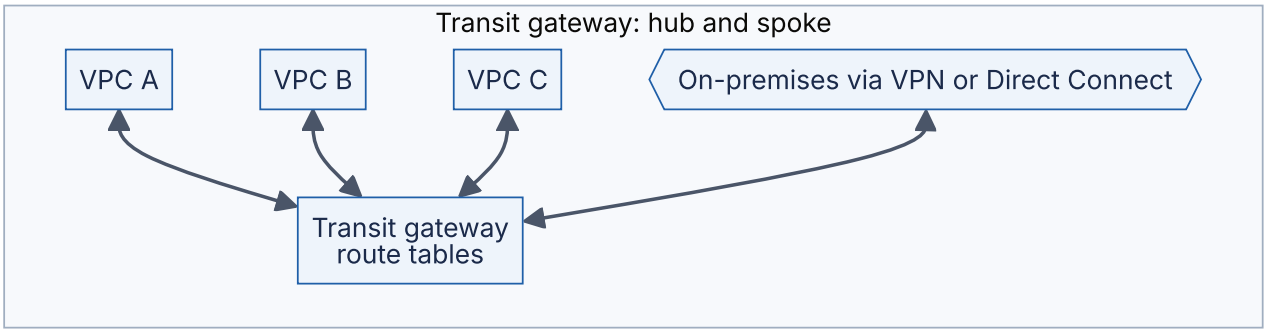
Reading the diagram. The VPC `10.0.0.0/16` is split into `/20` subnets, three tiers per zone (zone c, omitted for space, mirrors zones a and b; the `/20` carving extends the one worked in §7.4.2 with a third, data tier). *Inbound:* client HTTPS enters through the **internet gateway** to **ALB** nodes in the public subnets, which forward to app instances in private subnets; security groups allow only `sg-alb → sg-app` on 8080 and `sg-app → sg-db` on 5432. *Outbound:* app instances follow the private route table's default route to the **NAT gateway in their own zone**, and from there out of the IGW; nothing on the internet can initiate a connection to them. *Provider services:* traffic to S3 matches the more specific prefix-list route and takes the **gateway endpoint** instead of the NAT. All arrows are synchronous request paths except replication (dotted). S3 is outside the VPC but reached privately. Failure points: one NAT gateway per zone keeps a zone failure from cutting off the others' egress; a single shared NAT would be a cross-zone dependency and a cross-zone data charge. Scaling: size subnets for pods, not just instances (§7.4.2).

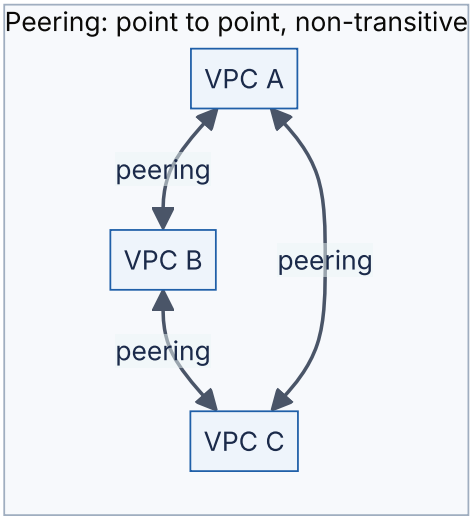
41.10.2 Connecting networks: peering, transit gateways and private service endpoints

As an organization grows from one VPC to hundreds (one per team, environment and account), it needs to connect them, and to on-premises networks, without exposing services to the internet.

Figure 41.8 — Peering mesh, transit hub and private service endpoint.







Reading the diagram. *Peering* connects two VPCs directly; it is **non-transitive**, so A cannot reach C through B, and n fully connected VPCs need $n(n-1)/2$ peerings, each with routes on both sides (45 peerings for 10 VPCs). Address ranges must not overlap (§7.4.2). *Transit gateway* replaces the mesh with a regional hub that has its own route tables, so n VPCs need n attachments and on-premises links attach once; segmentation is enforced by which attachments share a route table. It is billed per attachment-hour and per gigabyte processed, and it adds a hop. *PrivateLink* (and Google's **Private Service Connect**, Azure

Private Link) is different in kind: it exposes **one service**, not a network. The consumer gets a private IP in its own subnet; connections can only be initiated from consumer to provider; address ranges may overlap. Failure points: a bad route on the hub affects every spoke; endpoints are per-zone, so create one in each zone you use.

Table 41.8 — Network connectivity options.

Aspect	VPC peering	Transit gateway / hub	PrivateLink / Private Service Connect
What it connects	Two whole networks	Many networks and on-premises	A consumer to one service
Transitive	No	Yes, by hub route tables	N/A
Overlapping CIDRs	Not allowed	Not allowed between routed spokes	Allowed
Cost model (AWS, illustrative)	Data transfer only	~$0.05/attachment-hour + ~$0.02/GB	~$0.01/endpoint-zone-hour + ~$0.01/GB
Choose when	Few VPCs, high-volume pairs	Many VPCs, central inspection	SaaS or shared platform services, strict isolation

41.10.3 Data-transfer costs and the NAT gateway trap

Cloud networks charge for movement in ways that on-premises networks do not. As of 2026 on AWS (illustrative, us-east-1): inbound data from the internet is free; outbound to the internet costs about $0.09/GB for the first 10 TB a month and less in higher tiers; traffic between zones costs $0.01/GB **in each direction**; traffic between regions costs about $0.02/GB; a NAT gateway costs $0.045/hour and $0.045/GB processed; and every public IPv4 address costs $0.005/hour [AWS: EC2 and VPC pricing]. Google Cloud and Azure differ in detail but share the shape: internet egress is the largest unit price, and cross-zone and cross-region traffic is not free.

FORMULA

Monthly data-transfer and NAT cost

$$C_{\text{xfer}} = \sum_k V_k^{\text{int}}\, p_k^{\text{int}} \;+\; 2\,V_{\text{xaz}}\, p_{\text{az}} \;+\; V_{\text{xreg}}\, p_{\text{reg}} \qquad C_{\text{NAT}} = n_{\text{gw}}\, H\, p_{\text{hr}} \;+\; V_{\text{NAT}}\, p_{\text{proc}}$$

Symbol	Meaning	Units
V_k^{int}, p_k^{int}	Internet egress volume in pricing tier k, and its price	GB, $/GB
V_{xaz}, p_{az}	Cross-zone volume, and per-direction price (charged on both sides, hence the 2)	GB, $/GB
V_{xreg}, p_{reg}	Cross-region volume and price	GB, $/GB
n_{gw}	Number of NAT gateways	count
H	Hours in the month (730)	hours
p_{hr}, p_{proc}	NAT hourly price and per-GB processing price	$/hour, $/GB
V_{NAT}	Volume processed by NAT gateways, in either direction	GB

WORKED EXAMPLE

Worked example — Where PhotoShare's network bill comes from. Illustrative AWS prices (as of 2026): internet egress \$0.09/GB for the first 10 TB, \$0.085/GB for the next 40 TB, \$0.07/GB for the next 100 TB; p_{az} = \$0.01; p_{reg} = \$0.02; NAT \$0.045/h and \$0.045/GB. In one month PhotoShare serves 100 TB of API and image responses directly from its origin, its microservices exchange 200 TB across zones, it replicates 10 TB to a disaster-recovery region, and its resize workers download 40 TB of originals from S3 through three NAT gateways. Ignore free tiers.

1. Internet egress:
   $10,000 \times 0.09 + 40,000 \times 0.085 + 50,000 \times 0.07 = 900 + 3,400 + 3,500 = \$7,800.$
2. Cross-zone: $2 \times 200,000 \times 0.01 = \$4,000.$
3. Cross-region: $10,000 \times 0.02 = \$200.$
4. NAT hours: $3 \times 730 \times 0.045 = \$98.55.$
5. NAT processing of S3 downloads: $40,000 \times 0.045 = \$1,800.$
6. Total: $7,800 + 4,000 + 200 + 98.55 + 1,800 \approx \$13,900$ per month.

Fixes, one per line item: serve images through a CDN, which shields the origin and is usually cheaper per GB than origin egress (§21.5.4); keep chatty calls zone-local with topology-aware routing, which can remove most of the \$4,000; and add an **S3 gateway endpoint**, which costs nothing and removes the \$1,800 entirely, because S3 traffic no longer passes through the NAT.

Interpretation. Two of the five lines are "invisible" internal traffic, and the NAT line is pure waste: the bytes never needed to leave the provider's network. **Engineering implication.** Always create gateway endpoints for object storage and key-value services in every VPC; tag and measure data transfer by source and destination (cost and usage reports, VPC flow logs); and treat cross-zone traffic as a design parameter, not a rounding error.

WARNING / TRADE-OFF

The NAT gateway trap in one sentence. Anything in a private subnet that talks to a provider service by its public endpoint (object storage, container registry pulls, logging and metrics APIs) is billed twice, once for NAT processing and possibly again as cross-zone transfer if the NAT is in another zone, unless a private endpoint carries it.

41.11 Managed databases

41.11.1 What “managed” buys

DEFINITION

Definition — Managed database service. A database engine operated by the provider: provisioning, OS and engine patching, automated backups with point-in-time recovery, replication and failover across zones, monitoring and storage scaling are provider tasks exposed through an API. You keep schema design, queries, indexes, capacity choices, parameter tuning and access control. Examples: Amazon RDS and Aurora, Google Cloud SQL and AlloyDB, Azure SQL Database and Azure Database for PostgreSQL/MySQL.

A classic managed deployment such as **RDS Multi-AZ** is the primary–standby design of §27.4 packaged as a product: the primary’s block-level writes are replicated synchronously to a standby in another zone, and on failure a DNS name is moved to the standby, typically in a minute or two. It is the same database engine on the same kind of block storage, with operations automated. Aurora changed the architecture itself.

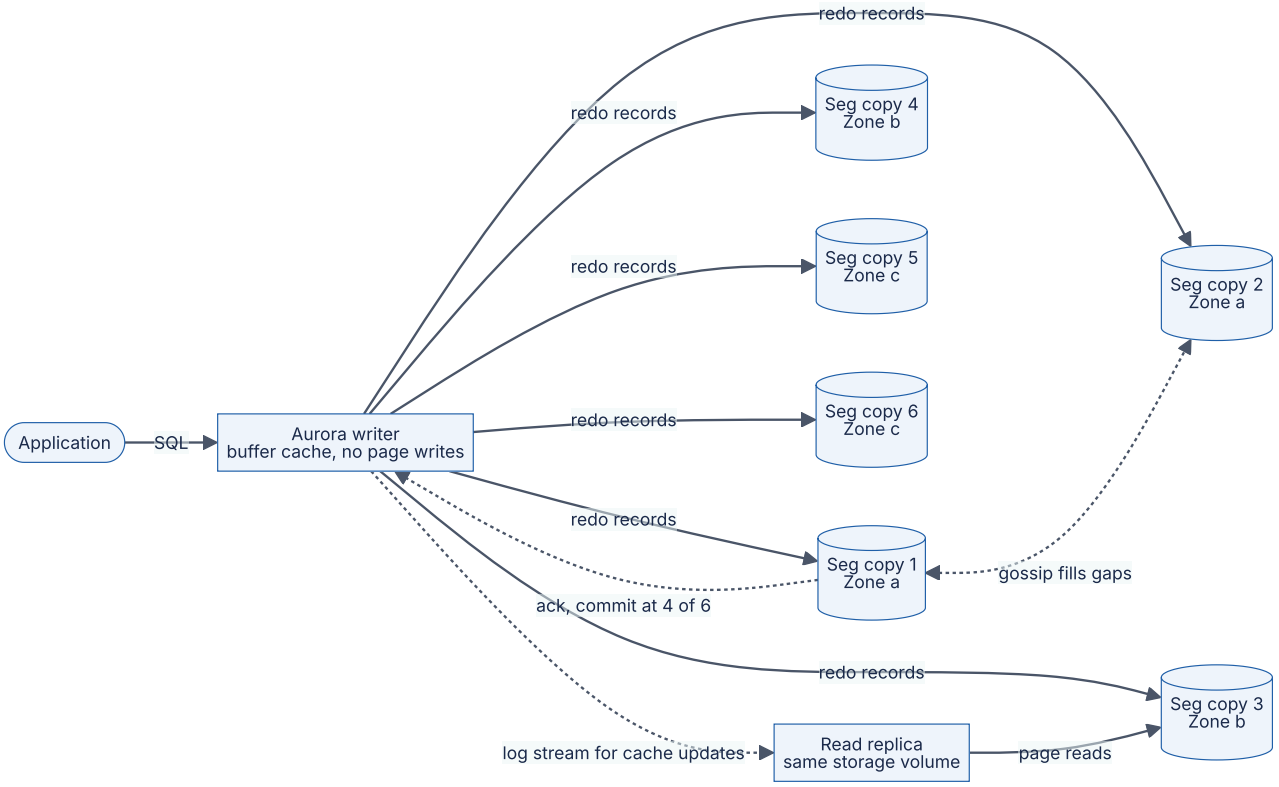
41.11.2 Aurora: the log is the database

Verbitski et al. observed that once storage is remote and replicated across zones, the bottleneck of a cloud relational database is no longer CPU or disk but the **network**: a traditional engine mirrored across zones writes redo log records, full data pages, double-write buffers and replication logs, many of them synchronously and in sequence [Verbitski et al. 2017]. Aurora’s answer, as published at SIGMOD 2017:

1. **Ship only the redo log.** The writer sends only redo log records to storage; never data pages, checkpoints or double-write buffers.
2. **Storage applies the log.** A multi-tenant storage service acknowledges durable log records and materializes pages in the background or on read: **the log is the database**.
3. **Small segments, six copies, three zones.** The volume is split into 10 GB **segments**; each segment is replicated six ways as a **protection group**, two copies in each of three zones.
4. **Quorums.** A write is durable when 4 of 6 copies acknowledge; a read quorum is 3 of 6 (used for repair and recovery; normal reads go to a copy known to be current, without a quorum).
5. **Fast repair.** Because a segment is only 10 GB, the paper reports it can be re-replicated in about 10 seconds on a 10 Gb/s link, which keeps the window for a second failure short.

6. **Replicas share storage.** Read replicas attach to the same volume and use the log stream only to refresh cached pages; adding one copies no data.
7. **Recovery without replay.** Storage applies the log continuously, so a restarted writer finds the durable point and resumes in seconds.

Figure 41.9 — Aurora's write path: redo records to a six-way quorum across three zones.



Reading the diagram. The writer sends each **redo record** in parallel to the six copies of the affected segment (solid arrows, synchronous network writes); it declares a transaction committed once four acknowledgments arrive (dotted acknowledgment). Storage nodes persist records, then asynchronously sort, **gossip** with peers to fill gaps, coalesce records into pages, and back up to S3. The **read replica** receives the same log stream asynchronously, only to update or invalidate pages in its own cache, and reads any missing page from storage; AWS documents replica lag as typically under 100 ms. Storage boundary: there is one shared, replicated volume per cluster; instances are stateless apart from caches. Failure points: losing a zone removes two copies and leaves four, still a write quorum; losing a zone plus one more node leaves three, enough to read and repair but not to write until repair completes. Scaling: one writer scales up; reads scale out with replicas; storage grows by adding segments.

Mathematical foundations

FORMULA

Quorum conditions for a replicated segment

$$V_r + V_w > V \qquad V_w > \frac{V}{2} \qquad P_{\text{unavail}}(k) = \sum_{i=V-k+1}^{V} \binom{V}{i} p^i (1-p)^{V-i}$$

Symbol	Meaning	Units
V	Copies of each segment	count
V_w, V_r	Write and read quorum sizes	count
p	Probability that one copy is unavailable at a given moment, assumed independent	fraction
k	Quorum size required (V_w or V_r)	count
$P_{\text{unavail}}(k)$	Probability that fewer than k copies are up	fraction

The first condition makes every read quorum overlap every write quorum, so a read (or a recovering writer) always sees the latest durable write; the second makes any two write quorums overlap, so two writers cannot both commit conflicting histories (§27.8).

WORKED EXAMPLE

Worked example — Why six copies and 4/3 quorums? $V = 6$, $V_w = 4$, $V_r = 3$.

1. Overlap: $3 + 4 = 7 > 6$ and $4 > 3$. Both conditions hold.
2. Lose one zone (two copies): 4 remain $\geq V_w$, so writes continue.
3. Lose a zone plus one node: 3 remain $\geq V_r$, so data is readable and can be re-replicated, though writes pause until repair restores a fourth copy.
4. Independent failures with $p = 0.01$: write quorum lost when 3 or more of 6 are down: $\binom{6}{3} p^3 (0.99)^3 + \ldots \approx 20 \times 10^{-6} \times 0.97 + \ldots \approx 1.96 \times 10^{-5}$.
5. Read quorum lost when 4 or more are down: $\approx 15 \times 10^{-8} \approx 1.5 \times 10^{-7}$.
6. Compare a 3-copy, majority-2 design (one copy per zone): unavailable when 2 or more of 3 are down: $3p^2(1-p) + p^3 \approx 2.98 \times 10^{-4}$, about 15 times worse than Aurora's write quorum; and losing one zone leaves it one failure from losing writes.

Interpretation. Two copies per zone make a whole zone just "two failures", so the system tolerates a zone loss plus background node failures, the realistic case at scale. **Engineering implication.** When you design your own replicated store, place copies so that the largest correlated failure you plan for (usually a zone) consumes less than the slack between V and V_w, and keep repair time short so that the independent-failure probability p stays small.

INDUSTRY EXAMPLE

Aurora's measured effect. In the paper's comparison of a MySQL configuration mirrored across zones with Aurora under a write-only SysBench workload, Aurora sustained 35 times more transactions while issuing 7.7 times fewer I/Os per transaction on the database node, which the authors attribute to shipping only redo records and to the removal of synchronous page and double-write traffic [Verbitski et al. 2017]. Google's AlloyDB and Azure SQL Hyperscale publish related disaggregated-storage designs (log service plus page servers), and Amazon's Aurora DSQL (2025) extends the idea to distributed, multi-region SQL. *Evidence: Primary* — [Verbitski et al. 2017; provider documentation]

41.11.3 Globally distributed managed databases

- **Google Spanner** is a globally distributed relational database that shards data into splits replicated with Paxos and uses TrueTime to provide **external consistency** for transactions across regions [Corbett et al. 2012]. Its mechanism is covered in §25.10.3 and §28.8. Choose it for SQL with horizontal write scaling and cross-region strong consistency, accepting cross-region commit latency.

- **Azure Cosmos DB** is a globally distributed, multi-model database that offers five consistency levels — strong, bounded staleness, session, consistent prefix and eventual — selectable per account and relaxable per request, with single-region or multi-region writes [Azure Docs: Cosmos DB consistency levels]. Session (the default) gives each client read-your-writes.
- **DynamoDB** (Chapter 12) offers global tables for multi-region active–active replication with last-writer-wins conflict resolution, and as of 2025 a multi-region strong-consistency option (verify availability per region).
- **Cloud SQL** is Google's RDS equivalent (MySQL, PostgreSQL, SQL Server) with a regional high-availability configuration that uses a standby in another zone over regional persistent disk.

41.11.4 Managed versus self-run

Table 41.9 — Managed database service versus self-run database on VMs.

Aspect	Managed (RDS, Cloud SQL, Aurora)	Self-run on VMs or Kubernetes
What you operate	Schema, queries, sizing, parameters	Everything: installs, patches, backups, replication, failover, monitoring
Failover	Built in, tested by the provider at scale	You build and rehearse it (Patroni, orchestrators)
Backups and PITR	Automatic, retention up to weeks	You script, store and test them
Control	Limited: no superuser, restricted extensions and versions	Full: any version, extension, kernel tuning
Cost	Premium on compute (roughly 1.3–2× equivalent VMs, illustrative)	Lower infrastructure, higher engineering time
Lock-in	Medium (standard engines) to high (Aurora, Spanner, Cosmos DB features)	Low
Choose when	Almost always, unless a hard requirement rules it out	Unsupported engine or extension, extreme scale with a dedicated DB team, strict cost at very large fleets

RECOMMENDATION

Default to managed. A senior engineer's time spent on backup scripts and failover drills is worth more than the managed-service premium for nearly every team below a very large scale. Revisit when the database bill is large enough to fund a dedicated team, or when a specific feature (an extension, a major version, a storage engine) is not available managed.

41.12 Cloud security

41.12.1 IAM: principals, policies and roles

DEFINITION

Definition — IAM building blocks. A **principal** is an entity that makes requests: a human user, a workload, or a federated identity. A **policy** is a document of statements, each with an **Effect** (Allow or Deny), **Actions** (for example `s3:GetObject`), **Resources** (identified by ARN or resource path) and optional **Conditions** (source network, tags, MFA, time). **Identity-based policies** attach to principals; **resource-based policies** (bucket policies, key policies, queue policies) attach to resources and name which principals may use them. A **role** is an identity with permissions but no long-term credentials: trusted principals **assume** it and receive temporary credentials (on AWS, from the Security Token Service, typically valid for an hour).

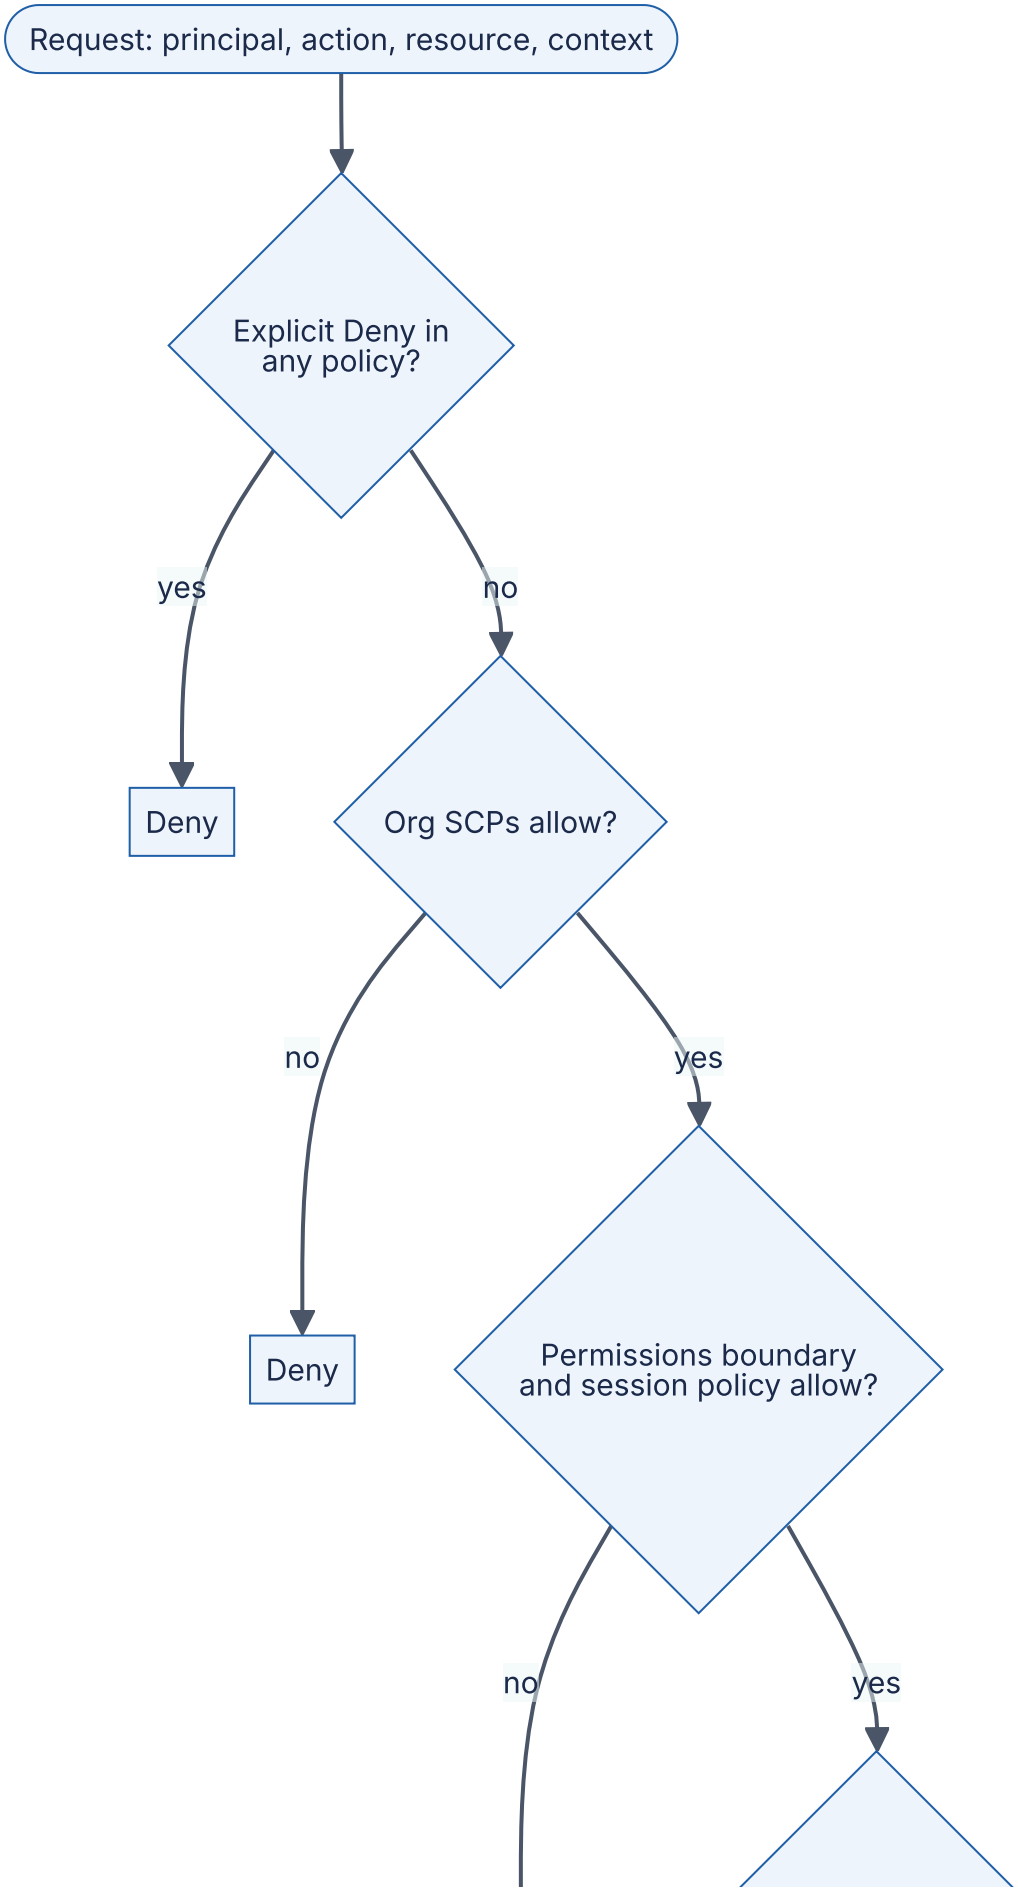
Google Cloud uses **role bindings** (principal, role, resource; inherited down the hierarchy) and **service accounts**; Azure uses **role assignments** of RBAC roles to Entra ID principals at a scope, and **managed identities**. In all three, workloads should get platform-issued, short-lived credentials, never long-lived keys in files or environment variables (§10.8).

Least privilege (§10.10.3) translates to: one role per service; actions listed explicitly rather than `*`; resources scoped to the service's own buckets, tables and keys; conditions where they help (for example, only from the organization's VPC endpoints); and periodic pruning using "last accessed" data.

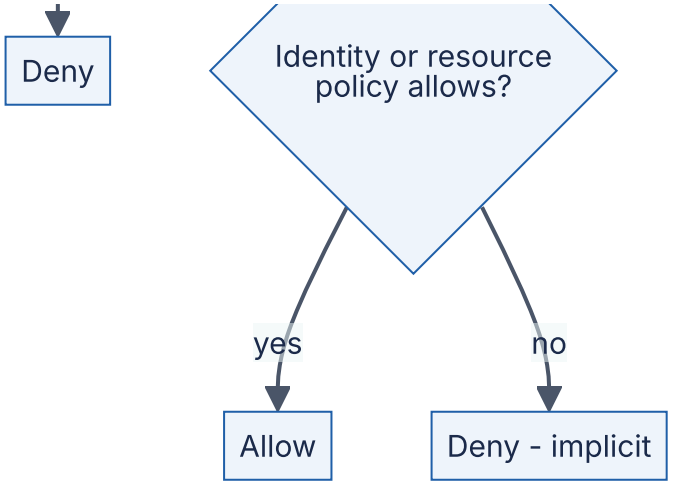
41.12.2 Policy evaluation logic

When a request arrives, the provider gathers every policy that applies and computes one decision. AWS documents the logic as follows (simplified for requests within one account) [AWS IAM User Guide: Policy evaluation logic]: everything starts as an **implicit deny**; an **explicit deny** in any applicable policy is final; organization guardrails (**service control policies**, and resource control policies) must allow the action; a **permissions boundary** or **session policy**, if present, must allow it; and then an allow in an identity-based *or* a resource-based policy grants access. Across accounts, both the caller's identity policy *and* the resource's policy must allow.

Figure 41.10 — Simplified AWS policy evaluation for a request.



Request: principal, action, resource, context
Explicit Deny in any policy?
yes
no
Deny
Org SCPs allow?
no
yes
Deny
Permissions boundary and session policy allow?
no
yes



Reading the diagram. Evaluation is a synchronous, in-line decision made by the service's authorization layer on every API call. The order encodes three rules: a *deny anywhere wins*; *guardrails* (SCPs, boundaries, session policies) can only **remove** permissions, never grant them; and *grants* come only from identity-based or resource-based policies. Missing a grant is a denial, which is why a new role can do nothing until you attach a policy. Failure points: an over-broad grant (`"Action": "s3:*", "Resource": "*"`) passes every box; an SCP that accidentally denies a needed action breaks every account under that organizational unit at once. Scaling: policies are cached and evaluated locally by each service, so authorization adds no extra network round trip, but policy size and count are limited.

Code example

```
        from fnmatch import fnmatchcase

        def matches(stmt, action, resource):
            """True if a statement's Action and Resource patterns cover the request."""
            acts = stmt["Action"] if isinstance(stmt["Action"], list) else
[stmt["Action"]]
            ress = stmt["Resource"] if isinstance(stmt["Resource"], list) else
[stmt["Resource"]]
            return (any(fnmatchcase(action, a) for a in acts)
                    and any(fnmatchcase(resource, r) for r in ress))

        def effect(policies, action, resource):
            """Return 'Deny', 'Allow' or None (no matching statement) for a set of poli-
cies."""
            found = None
            for policy in policies:
                for stmt in policy:
                    if matches(stmt, action, resource):
                        if stmt["Effect"] == "Deny":
                            return "Deny"
                        found = "Allow"
            return found

        def evaluate(action, resource, identity, resource_pol=(), scps=None,
boundary=None):
            """Simplified single-account AWS-style evaluation (no conditions, no ses-
sions)."""
            every = [identity, list(resource_pol), boundary or [], *(scps or [])]
            if any(effect([p], action, resource) == "Deny" for p in every):
                return "DENY (explicit)"
            if scps is not None and any(effect([s], action, resource) != "Allow" for s
in scps):
                return "DENY (not allowed by an SCP guardrail)"
            if boundary is not None and effect([boundary], action, resource) != "Allow":
                return "DENY (outside permissions boundary)"
            if effect([identity], action, resource) == "Allow":
                return "ALLOW (identity policy)"
            if effect([list(resource_pol)], action, resource) == "Allow":
                return "ALLOW (resource policy)"
            return "DENY (implicit: nothing allowed it)"

        worker = [{"Effect": "Allow", "Action": ["s3:GetObject", "s3:PutObject"],
                   "Resource": "arn:aws:s3:::photos/*"}]
        org_scp = [{"Effect": "Allow", "Action": "*", "Resource": "*"},
                   {"Effect": "Deny", "Action": "s3:PutBucketPublicAccessBlock",
"Resource": "*"}]
        bucket = [{"Effect": "Deny", "Action": "s3:DeleteObject", "Resource":
"arn:aws:s3:::photos/*"}]

        tests = [("s3:GetObject", "arn:aws:s3:::photos/u1/a.jpg"),
```

```
                ("s3:DeleteObject", "arn:aws:s3:::photos/u1/a.jpg"),
                ("s3:GetObject", "arn:aws:s3:::billing/report.csv"),
                ("s3:PutBucketPublicAccessBlock", "arn:aws:s3:::photos")]
        for act, res in tests:
            print(f"{act:<30} {res:<32} -> {evaluate(act, res, worker, bucket,
[org_scp])}")
```

Output:

```
s3:GetObject                   arn:aws:s3:::photos/u1/a.jpg     -> ALLOW (identity pol-
icy)
s3:DeleteObject                arn:aws:s3:::photos/u1/a.jpg     -> DENY (explicit)
s3:GetObject                   arn:aws:s3:::billing/report.csv  -> DENY (implicit: noth-
ing allowed it)
s3:PutBucketPublicAccessBlock  arn:aws:s3:::photos              -> DENY (explicit)
```

What to notice:

- `evaluate` checks explicit denies across *all* policy types first; the bucket's resource policy blocks deletes even though nothing else mentions them.
- The SCP begins with `Allow *` because an SCP must allow an action for it to be usable at all; its `Deny` makes "turn off public-access protection" impossible for every role in the account, including administrators.
- The billing object is denied *implicitly*: no statement allowed it. This is least privilege by construction.
- Real evaluation also handles conditions, cross-account requests, `NotAction`, session policies and service-specific rules; this sketch is for intuition only.

41.12.3 Keys, secrets and encryption

Cloud KMS services (AWS KMS, Google Cloud KMS, Azure Key Vault) implement §10.9.2's envelope encryption: every unwrap of a data key is authorized by IAM and the **key policy**, and logged. A **customer-managed key** adds a second, independent check (an attacker needs both `s3:GetObject` and `kms:Decrypt`) and an audit trail. Keys are regional and deletion is irreversible after a waiting period, so multi-region designs need multi-region or per-region keys. Secrets belong in a secrets manager with rotation (§10.8), fetched through the workload's role.

41.12.4 Guardrails across accounts

Large organizations use **many accounts** (projects, subscriptions) as blast-radius and billing boundaries: production, staging, security logging, shared networking, each team. **AWS Organizations** applies **SCPs** to organizational units; **Google Cloud Organization Policy** and **Azure Policy** play the same role. Typical guardrails deny disabling the audit trail, unused regions, and public buckets or internet gateways outside networking ac-

counts. Pair these preventive controls with detective ones (configuration rules, posture scanners).

Table 41.10 — Common cloud misconfigurations.

What goes wrong	Why	Detection	Recovery	Prevention
Public object bucket leaks data	Bucket policy or ACL grants `*`; "public for one file" became the whole bucket	Posture scanner, access analyzer findings, access logs	Block public access, rotate exposed data, notify	Account-level Block Public Access (default on new S3 buckets since April 2023); SCP deny
Leaked long-lived access key	Key committed to Git or baked into an image	Secret scanning, anomalous API calls in the audit log	Deactivate key, review audit trail	No user access keys; roles and federation only
Over-broad role exploited via SSRF	Instance role with `s3:*` on `*`; metadata reachable	Unusual data volume, audit log	Revoke sessions, narrow policy	IMDSv2 required, least-privilege roles (§10.7.3)
Database open to the internet	Security group allows `0.0.0.0/0` on 5432	Config rules, external scans	Restrict group, rotate credentials	Data subnets without internet routes; SCP and policy checks in IaC review
Audit logging disabled or deleted	Attacker or mistake turns off the trail	Alert on the configuration change	Re-enable; logs in a separate account	Org-level trail, SCP denying `StopLogging`, write-once log bucket

COMMON MISTAKE

"Encryption at rest protects a public bucket." Default server-side encryption is transparent to anyone authorized to read; if the bucket policy authorizes everyone, the provider decrypts for everyone. Encryption with a customer-managed key helps only because the key policy is a *second* access check that the public is not granted.

41.13 Cost optimization

41.13.1 Purchase options

Table 41.11 — Compute purchase options (AWS names; GCP and Azure equivalents).

Option	Commitment	Typical discount vs on-demand (as of 2026)	Risk	Use for
On-demand / pay-as-you-go	None	0%	None	Unpredictable or short-lived load
Savings Plans; GCP committed use discounts; Azure savings plan	$/hour of spend for 1 or 3 years	up to ~66–72%	Paying for unused commitment	The steady floor of compute
Reserved Instances; Azure Reservations	A specific type and region for 1 or 3 years	up to ~72%	Less flexible than spend commitments	Databases and fixed fleets
Sustained use discounts (GCP)	None, automatic	up to ~30% on some families	None	Long-running VMs without commitments
Spot / Spot VMs	None; capacity can be reclaimed	~60–90%	Interruption (§41.8.5)	Interruptible, restartable work

FORMULA

Break-even utilization for a commitment

$$C_{\text{od}} = u\,p_{\text{od}}\,H, \qquad C_{\text{commit}} = p_{\text{c}}\,H, \qquad u^{*} = \frac{p_{\text{c}}}{p_{\text{od}}} = 1 - d$$

Symbol	Meaning	Units
u	Fraction of the month the capacity is actually needed	fraction
p_{od}	On-demand hourly price	$/hour
p_{c}	Effective committed hourly price (upfront amortized), paid whether used or not	$/hour
H	Hours in the month (730)	hours
d	Commitment discount, $1 - p_{\text{c}}/p_{\text{od}}$	fraction
u^{*}	Utilization above which the commitment is cheaper	fraction

WORKED EXAMPLE

Worked example — Should PhotoShare commit? Illustrative: p_{od} = \$0.100/h; a one-year plan at p_c = \$0.065/h (d = 35%); a three-year plan at p_c = \$0.040/h (d = 60%).

1. One-year break-even: u^* = 0.065/0.100 = 65%, about 15.6 hours a day.
2. Three-year break-even: u^* = 0.040/0.100 = 40%, about 9.6 hours a day.
3. API fleet floor (never below 4 instances, 24/7, u = 100%): on-demand $4 \times 0.10 \times 730 = \$292$; one-year $4 \times 0.065 \times 730 = \$189.80$. Saves \$102.20 a month.
4. Daily batch server running 10 h/day ($u = 0.42$): on-demand $0.10 \times 0.42 \times 730 = \$30.66$; one-year commitment \$47.45. Committing *loses* \$16.79 a month; on the three-year plan (\$29.20) it barely wins and locks in for three years.

Interpretation. Commitments pay only for capacity used more than $1 - d$ of the time. **Engineering implication.** Commit to the **floor** of your load curve (the minimum you run every hour), serve the daily peak with on-demand or spot, and prefer spend-based plans that follow you across instance families and to containers and functions. Re-check coverage monthly; an unused commitment is a sunk cost.

41.13.2 Rightsizing, scheduling and architecture

The cheapest instance-hour is the one you do not run. In order of typical payoff:

1. **Turn off what is idle.** A test environment used 50 of 168 hours a week wastes about 70% of its cost.
2. **Rightsize.** Measure p95 CPU and memory for weeks; a fleet at 10% CPU can often drop a size (half the price) or move to cheaper Arm instances after benchmarking.
3. **Autoscale on the right signal** (Chapter 18): queue depth for workers, concurrency or latency for APIs.
4. **Fix data transfer** (§41.10.3): endpoints, zone-local routing, CDN offload, compression.
5. **Tier storage** (§15.9) and delete what nobody reads: old snapshots, unattached volumes, incomplete multipart uploads, idle public IPv4 addresses.
6. **Buy commitments last**, after rightsizing, or you commit to waste.

Cost-aware architecture at scale (unit economics, FinOps practice, carbon-aware scheduling) is the subject of Chapter 51.

41.13.3 Worked estimate: a three-tier web app

Consider a three-tier web app in one region across three zones: an ALB; six general-purpose 2-vCPU/8-GiB instances; a Multi-AZ PostgreSQL database with 4 vCPUs and 32 GiB; 500 GB of database storage; 2 TB in object storage; three NAT gateways; 5 TB of internet

egress and 3 TB of cross-zone traffic a month. The program below is the estimate; every price is an illustrative US-region list price as of 2026.

```
        H = 730  # hours per month

        # Illustrative US-region list prices, as of 2026 (verify before use).
        P = {
            "alb_hr": 0.0225, "alb_lcu_hr": 0.008,
            "app_hr": 0.0816,           # general-purpose 2 vCPU / 8 GiB Arm instance
            "db_hr_multi_az": 0.86,     # 4 vCPU / 32 GiB PostgreSQL, Multi-AZ (two in-
stances)
            "db_gb_multi_az": 0.23,     # gp3 database storage, Multi-AZ
            "ebs_gb": 0.08, "s3_gb": 0.023,
            "nat_hr": 0.045, "nat_gb": 0.045,
            "egress_gb": 0.09, "xaz_gb": 0.01, "ipv4_hr": 0.005,
        }

        def monthly(app_n=6, sp_discount=0.0, sp_share=0.0, db_discount=0.0,
nat_gb=2000, logs=80.0):
            """Return {line item: $/month} for a three-tier web app in one region, three
zones."""
            app = app_n * P["app_hr"] * H
            return {
                "Load balancer (ALB, 10 LCU avg)": H * (P["alb_hr"] + 10 *
P["alb_lcu_hr"]),
                "App instances": app * (1 - sp_discount * sp_share),
                "App root volumes (30 GB each)": app_n * 30 * P["ebs_gb"],
                "Database instances (Multi-AZ)": P["db_hr_multi_az"] * H * (1 -
db_discount),
                "Database storage (500 GB)": 500 * P["db_gb_multi_az"],
                "Object storage (2 TB)": 2000 * P["s3_gb"],
                "NAT gateways (3) + processing": 3 * H * P["nat_hr"] + nat_gb *
P["nat_gb"],
                "Internet egress (5 TB)": 5000 * P["egress_gb"],
                "Cross-zone traffic (3 TB)": 3000 * 2 * P["xaz_gb"],
                "Public IPv4 addresses (6)": 6 * H * P["ipv4_hr"],
                "Logs and metrics": logs,
            }

        def breakeven_utilization(p_commit, p_on_demand):
            """Commitment is cheaper whenever utilization exceeds this fraction."""
            return p_commit / p_on_demand

        base = monthly()
        opt = monthly(app_n=5, sp_discount=0.30, sp_share=0.8, db_discount=0.35,
nat_gb=100)
        for k in base:
            print(f"{k:<34} {base[k]:>9,.2f} {opt[k]:>9,.2f}")
        print(f"{'Total':<34} {sum(base.values()):>9,.2f} {sum(opt.values()):>9,.2f}")
        print(f"Break-even utilization, 35% discount: {breakeven_utilization(0.065,
0.10):.0%}")
```

What to notice:

- Every price is a named constant in one dictionary, so you can replace it with your region's current list price and re-run.
- Hourly resources multiply by $H = 730$; storage and transfer are per GB-month or per GB.
- The optimized scenario changes four inputs only: one fewer instance after rightsizing, 80% of app compute under a 30% savings plan, a 35% one-year database reservation, and an S3 gateway endpoint that removes 1.9 TB from NAT processing.

Table 41.12 — Monthly estimate for the three-tier app (illustrative prices, as of 2026).

Line item	Baseline $/month	Optimized $/month
Load balancer (ALB, 10 LCU average)	74.83	74.83
App instances	357.41	226.36
App root volumes (30 GB each)	14.40	12.00
Database instances (Multi-AZ)	627.80	408.07
Database storage (500 GB)	115.00	115.00
Object storage (2 TB)	46.00	46.00
NAT gateways (3) and processing	188.55	103.05
Internet egress (5 TB)	450.00	450.00
Cross-zone traffic (3 TB)	60.00	60.00
Public IPv4 addresses (6)	21.90	21.90
Logs and metrics	80.00	80.00
Total	**2,035.88**	**1,597.20**

The database is the largest line (about 31% of the baseline) and internet egress the second largest; together, network-related lines (NAT, egress, cross-zone, IPv4) are about 35% of the bill, more than the app servers. The optimized column saves about 22% without changing the architecture. The next steps would be architectural: put images behind a CDN, add read replicas only when measured load needs them, and consider whether a cache would let the database move down one size.

41.14 Cross-cloud service mapping

Table 41.13 — AWS, Google Cloud and Azure equivalents (as of 2026).

Capability	AWS	Google Cloud	Azure
Virtual machines	EC2	Compute Engine	Virtual Machines
Autoscaled VM group	Auto Scaling group	Managed instance group	VM Scale Sets
Serverless containers	Fargate, App Runner	Cloud Run	Container Apps
Functions	Lambda	Cloud Run functions	Azure Functions
Managed Kubernetes	EKS	GKE	AKS
Object storage	S3	Cloud Storage	Blob Storage
Block storage	EBS	Persistent Disk, Hyperdisk	Managed Disks
File storage	EFS, FSx	Filestore	Azure Files, NetApp Files
Private network	VPC (regional)	VPC (global)	Virtual Network (regional)
Private service access	PrivateLink	Private Service Connect	Private Link
Network hub	Transit Gateway	Network Connectivity Center	Virtual WAN, hub VNet
Layer-7 load balancer	ALB	Application Load Balancer (global or regional)	Application Gateway, Front Door
Layer-4 load balancer	NLB	Network Load Balancer	Load Balancer
CDN	CloudFront	Cloud CDN	Front Door
DNS	Route 53	Cloud DNS	Azure DNS
Managed relational	RDS, Aurora	Cloud SQL, AlloyDB	Azure SQL Database, Azure Database for PostgreSQL/MySQL
Global relational	Aurora DSQL	Spanner	No direct equivalent (Cosmos DB, SQL Hyperscale closest)
Key-value / document	DynamoDB	Firestore, Bigtable	Cosmos DB
In-memory cache	ElastiCache, MemoryDB	Memorystore	Azure Cache for Redis / Azure Managed Redis
Queue	SQS	Pub/Sub, Cloud Tasks	Service Bus queues, Storage queues
Pub/sub fan-out	SNS, EventBridge	Pub/Sub, Eventarc	Service Bus topics, Event Grid
Event streaming	Kinesis, MSK	Pub/Sub, Managed Service for Apache Kafka	Event Hubs
Data warehouse	Redshift, Athena	BigQuery	Synapse Analytics, Fabric
Identity and access	IAM, IAM Identity Center	Cloud IAM, Cloud Identity	Entra ID, Azure RBAC
Keys and secrets	KMS, Secrets Manager	Cloud KMS, Secret Manager	Key Vault

Capability	AWS	Google Cloud	Azure
Org guardrails	Organizations SCPs	Organization Policy	Azure Policy, management groups
Monitoring and logs	CloudWatch	Cloud Monitoring, Cloud Logging	Azure Monitor
API audit log	CloudTrail	Cloud Audit Logs	Activity Log

Use the table to translate a design, then check behavior: global versus regional scope, consistency, limits and pricing units differ even where names match (§41.7).

Multi-cloud versus single-cloud

Multi-cloud means running production workloads on more than one provider. It is often proposed for resilience and negotiating leverage, and often regretted for its cost.

Table 41.14 — Single-cloud versus multi-cloud.

Aspect	Single cloud (multi-region)	Multi-cloud
Resilience	Regions fail independently; provider-wide failures are rare but possible	Survives a provider-wide failure, if failover is actually built and rehearsed
Engineering cost	One IAM model, one network, one toolchain	Lowest common denominator or duplicated designs; two of everything
Managed services	Full use (Aurora, Spanner, DynamoDB)	Restricted to portable layers (Kubernetes, PostgreSQL, Kafka)
Data transfer	Intra-provider pricing	Internet or interconnect egress between providers
Leverage and lock-in	Higher lock-in	Negotiating leverage; exit option
Choose when	Almost always	Regulatory or customer mandate, acquired workloads, a specific best-of-breed service (for example, analytics on one provider)

The common healthy forms are **pragmatic multi-cloud** (different workloads on different providers, each single-cloud) and **portable foundations** (containers, Terraform, open-source data stores) that keep an exit possible without paying for active–active across providers. Multi-region on one provider (Chapter 44) buys most of the resilience for a fraction of the cost.

41.15 Summary and revision notes

SUMMARY

- **Cloud** (NIST SP 800-145): on-demand self-service, broad network access, resource pooling, rapid elasticity, measured service. **IaaS → PaaS → FaaS → SaaS** moves the responsibility line upward; data, identity and exposure always stay yours.
- **Regions** (latency, residency, disaster recovery) contain three or more **zones** (independent failure domains about 1 ms apart); **edge locations** serve CDN and DNS. $A_{\text{svc}} \approx A_{\text{reg}}(1-(1-A_z)^n)$; two zones remove most zone downtime, three cut spare capacity to $n/(n-1) = 1.5\times$ and allow quorums.
- **Shared responsibility**: provider secures *of* the cloud, customer *in* it.
- Learn core services by the problem they solve and translate with Table 41.13; GCP's VPC and HTTP load balancer are global, AWS and Azure networks regional.
- **Nitro-style offload** moves networking, storage and management to dedicated cards and leaves a thin hypervisor; **Firecracker** gives VM isolation with ~125 ms boot and < 5 MiB overhead for serverless.
- **Spot** saves 60–90% if lost work is small: $T_{\text{wall}} \approx T(1 + c/\tau + \lambda(\tau/2 + R))$, $\tau^* = \sqrt{2c/\lambda}$.
- **VPC**: public subnet = route to internet gateway; private subnets egress via per-zone NAT; security groups (stateful) first, NACLs (stateless) as guardrails; gateway endpoints for object storage. Peering is non-transitive; transit gateways are hubs; PrivateLink exposes one service.
- **Data transfer** is a first-class cost: internet egress, cross-zone (both directions) and NAT processing. The NAT trap: provider-service traffic through NAT instead of a free gateway endpoint.
- **Aurora**: only redo records cross the network; storage applies the log; 10 GB segments, six copies in three zones, $V_w = 4$, $V_r = 3$; survives a zone loss for writes and zone + 1 for data.
- **IAM**: implicit deny → explicit deny wins → guardrails (SCPs, boundaries, session policies) only restrict → grants from identity or resource policies. Roles with short-lived credentials; least privilege; customer-managed KMS keys add a second check.
- **Cost**: commit to the floor when utilization exceeds $u^* = 1 - d$; rightsize before committing; fix transfer paths; tier storage. In the worked three-tier estimate, network lines were about 35% of the bill.

41.16 Knowledge checkpoint

1. Name NIST's five essential characteristics of cloud computing.

2. On which service models is OS patching the customer's job?
3. Why does a third zone add little availability but still matter?
4. What makes a subnet "public"?
5. Why should each zone have its own NAT gateway?
6. What does a gateway endpoint for S3 change, and what does it cost?
7. Why is VPC peering unsuitable for connecting 50 VPCs?
8. How does PrivateLink differ from peering?
9. What does Aurora send from the writer to storage, and why?
10. Show that $V = 6$, $V_w = 4$, $V_r = 3$ satisfies both quorum conditions.
11. In AWS policy evaluation, can an SCP grant a permission?
12. A one-year commitment gives 30% off. Above what utilization does it pay?
13. Compute τ^* for $c = 0.1$ h and $\lambda = 0.02$/h.
14. Why is a T-family (burstable) instance risky for a steady CPU-heavy service?

Answers

1. On-demand self-service, broad network access, resource pooling, rapid elasticity, measured service.
2. IaaS (guest OS). On PaaS, FaaS and SaaS the provider patches the OS.
3. After two zones the regional term dominates availability; a third zone reduces survive-one-loss capacity from 2× to 1.5× and gives quorum systems a majority after a zone loss.
4. Its route table sends `0.0.0.0/0` to an internet gateway.
5. So that a zone failure does not cut egress for the other zones, and to avoid cross-zone transfer charges.
6. It adds a prefix-list route so S3 traffic bypasses the NAT gateway; it is free, removing NAT processing charges.
7. Peering is non-transitive and needs $n(n-1)/2 = 1,225$ connections and route entries; use a transit hub.
8. PrivateLink exposes one service via a private IP in the consumer's subnet, one direction only, allowing overlapping CIDRs; peering joins whole networks.
9. Only redo log records; storage materializes pages, removing page, double-write and replication traffic that limited mirrored databases.
10. $3 + 4 = 7 > 6$ and $4 > 3$.
11. No. SCPs only limit the maximum permissions; grants come from identity or resource policies.
12. $u^* = 1 - 0.30 = 70\%$.
13. $\sqrt{2 \times 0.1/0.02} = \sqrt{10} \approx 3.2$ h.
14. Sustained load spends its CPU credits, after which it is throttled to baseline (or billed for surplus credits in unlimited mode).

41.17 Interview questions

Basic

Q1. Explain regions and availability zones and how you would use them for a web service. Answer. A region is a geographic area with independent services; zones are isolated data-center groups in it about a millisecond apart. Run stateless tiers in at least two (preferably three) zones behind a regional load balancer, use a managed database with a synchronous standby in another zone, keep state in regional services such as object storage, and pre-provision enough capacity to lose one zone. Use a second region only for disaster recovery, latency or residency requirements.

Q2. Security groups versus network ACLs? Answer. Security groups are stateful allow-lists on instances or interfaces and can reference other groups; NACLs are stateless ordered allow/deny lists on subnets that need explicit return-traffic rules. Use security groups for tier-to-tier rules and NACLs for coarse subnet guardrails.

Intermediate

Q3. Your AWS bill shows $20,000 a month in NAT gateway charges. Diagnose and fix. Answer. Break down NAT processed bytes by source using VPC flow logs. Usual causes: S3 or DynamoDB traffic (add free gateway endpoints), container image pulls and AWS API calls (interface endpoints, or caching registries), and cross-zone NAT use (one NAT per zone and zone-local routes). Check for unexpected internet downloads such as repeated package fetches in CI.

Q4. When would you choose Aurora over RDS PostgreSQL, and when not? Answer. Aurora for write-heavy or availability-sensitive workloads: log-only writes to six-way, three-zone storage, fast failover, replicas that share storage, automatic storage growth. Not when cost per I/O dominates at low scale, a needed extension or version is unavailable, or portability to self-run PostgreSQL storage behavior matters. Measure with your workload.

Q5. Design IAM for a service that reads uploads from one bucket and writes thumbnails to another. Answer. One role, assumed by the compute platform (instance profile, task role, workload identity); an identity policy allowing `GetObject` on `uploads/*` and `PutObject` on `thumbs/*` only; bucket policies restricting access to that role and to the organization's VPC endpoints; customer-managed KMS key whose policy allows `Decrypt` for uploads and `GenerateDataKey` for thumbnails; an SCP denying public-access changes; IMDSv2 enforced.

Advanced

Q6. Should a fintech startup go multi-cloud from day one? Answer. Usually not. Multi-cloud doubles IAM, networking, tooling and on-call knowledge, forbids the best managed services, and adds cross-provider egress, while multi-zone plus a tested second region on one provider meets most availability targets. Keep exit options with containers, infrastructure as code and standard engines; revisit if a regulator or major customer mandates provider diversity, then start with pragmatic multi-cloud for a specific workload.

Q7. A batch platform spends $400,000 a month on on-demand compute. Plan a 40% reduction. Answer. Rightsize first. Move interruptible work to diversified spot fleets with checkpoints at $\tau^{*} = \sqrt{2c/\lambda}$ and an on-demand floor for deadlines. Commit to the steady floor where $u > 1 - d$. Remove idle resources, fix cross-zone and NAT data paths, and track savings per team with tagged cost reports.

41.18 Practical exercises

1. Draw the route tables for Figure 41.7, including zone c and a DynamoDB gateway endpoint; list every route and its target.
2. Re-run the cost program with your region’s current list prices; add a CDN that offloads 80% of egress and recompute the total.
3. Extend the IAM evaluator with `Condition` support for `aws:SourceVpce` and test a bucket policy that denies access from outside a VPC endpoint.
4. Using the spot formula, plot T_{wall}/T against τ for $\lambda = 0.01$, 0.05 and 0.2 per hour with $c = 3$ minutes.

41.19 Design challenges

1. **Landing zone.** Design the account, network and guardrail structure for a 40-team company: account layout, transit hub, shared egress with inspection, central logging, SCPs, and the cost of the network hub at 50 TB/month of inter-VPC traffic.
2. **PhotoShare cost halving.** Using Figure 41.4 and the worked egress example, reduce PhotoShare’s monthly cloud bill by half without lowering availability. State each change, its saving and its risk.

41.21 Open verification items

- All prices (NAT $0.045/h and /GB, inter-zone $0.01/GB per direction, egress tiers, Transit Gateway and PrivateLink rates, IPv4 $0.005/h, instance and RDS rates in §41.13): verify against current AWS pricing pages; AWS’s newer regional NAT gateway option may change multi-zone NAT arithmetic.
- Firecracker figures (125 ms, < 5 MiB, 150 microVMs/s/host) and Aurora figures (35× throughput, 7.7× fewer I/Os, 10 s segment repair): confirm against the papers’ text.
- Discount ranges for commitments and spot; GCP and Azure spot notice periods.
- Launch status and names: Aurora DSQL, DynamoDB multi-region strong consistency, Google Titanium, Azure Boost, Google Cloud Managed Lustre, Managed Service for Apache Kafka.
- S3 Block Public Access default for new buckets (April 2023).

Chapter 42 — Containers and Kubernetes

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

Chapter 41 described what the cloud rents you: virtual machines, disks and networks. This chapter is about the layer most teams now put on top of those machines. A **container** packages a service with everything it needs to run and starts it as an isolated Linux process in a fraction of a second. **Kubernetes** takes a fleet of machines and a declaration such as "run 12 copies of the ordering service, each with 1 CPU and 2 GiB, spread across zones" and keeps that declaration true while machines fail, deploys roll out and load changes.

The chapter has three parts: **the container** (§42.3–§42.5: namespaces, cgroups, images, registries), **the orchestrator** (§42.6–§42.11: control plane, reconciliation, pods, workloads, networking, configuration) and **operating it** (§42.12–§42.16: autoscaling, scheduling arithmetic, storage, operators, serverless). QuickBite, the food-delivery platform of Chapter 2, is the running example; with about 40 services, hand-placed processes on VMs no longer scale as an operating model.

42.1 Learning objectives

After this chapter you should be able to:

- Explain how Linux namespaces and cgroups v2 isolate a container, and compute CPU throttling from a CFS quota.
- Compare containers, virtual machines and sandboxed runtimes, and trace the runtime stack from kubelet to runc.
- Build small, cacheable images with multi-stage builds, explain the OCI image format, and estimate image pull time.
- Pull images by digest, sign and verify them, and place vulnerability scanning in the pipeline.
- Name every Kubernetes control-plane and node component, and trace `kubectl apply` to a running pod.
- Write a level-triggered reconciliation loop and explain why Kubernetes is built from them.
- Configure pods with init containers, native sidecars and the three probes, and roll out a Deployment while computing capacity during the rollout.
- Choose between Service types, kube-proxy modes, Ingress and Gateway API.

- Size nodes from requests and allocatable, explain QoS classes and scheduling constraints, and estimate cluster cost.
- Combine HPA, VPA, node autoscalers and KEDA without them fighting.
- Use persistent volumes, operators and CRDs, and decide between Kubernetes and serverless.

42.2 Prerequisites

- Processes, threads, CFS scheduling and the OOM killer — §6.3, §6.5.5, §6.6.4 (containers are processes with extra kernel bookkeeping).
- IP addressing, NAT and reverse proxies — §7.4, §7.12, §7.13 (pod networking and Services rewrite addresses).
- Load balancing and health checks — §19.3, §19.5, §19.10 (Services and probes are both).
- Autoscaling and target tracking — §18.8 (the HPA formula is derived there and only used here).
- Raft and etcd — §26.7, §26.9 (the control plane's database).
- Secrets management and envelope encryption — §10.8, §10.9.
- Service mesh — §34.10 (sidecars and ambient mode).
- IaaS and managed container services — Chapter 41.

42.3 Containers: namespaces, cgroups and runtimes

42.3.1 What a container is

DEFINITION

Definition — Container. A process (or group of processes) that the Linux kernel runs with a restricted *view* of the system, provided by **namespaces**, and a restricted *share* of its resources, enforced by **control groups (cgroups)**, starting from a root file system unpacked from an **image**. A container shares the host's kernel; it is not a virtual machine.

First-principles explanation

Think of an office building. A virtual machine is a separate building with its own foundations, plumbing and reception: strong separation, slow to build. A container is an office inside a shared building: its own door, its own nameplate and its own phone extension, but the same foundations and plumbing as everyone else. Namespaces are the walls and the private phone directory, deciding what you can *see*. Cgroups are the metered utilities,

deciding how much water and power you can *use*. The image is the furniture delivered pre-assembled in a crate, so every office with the same crate looks identical.

Why does this exist?

Before containers, services shared servers: two needing different library versions collided ("works on my machine"), and a runaway process starved its neighbors. Virtual machines solved both at the cost of a full guest operating system per service. Google added cgroups to Linux in 2008 (kernel 2.6.24, originally called "process containers") to share machines between batch and serving work in Borg [Verma et al. 2015]; Docker made namespaces, cgroups and a layered image format easy to use in 2013. The result is VM-like packaging with process-like cost.

How it works internally

A container runtime starts a container in roughly these steps:

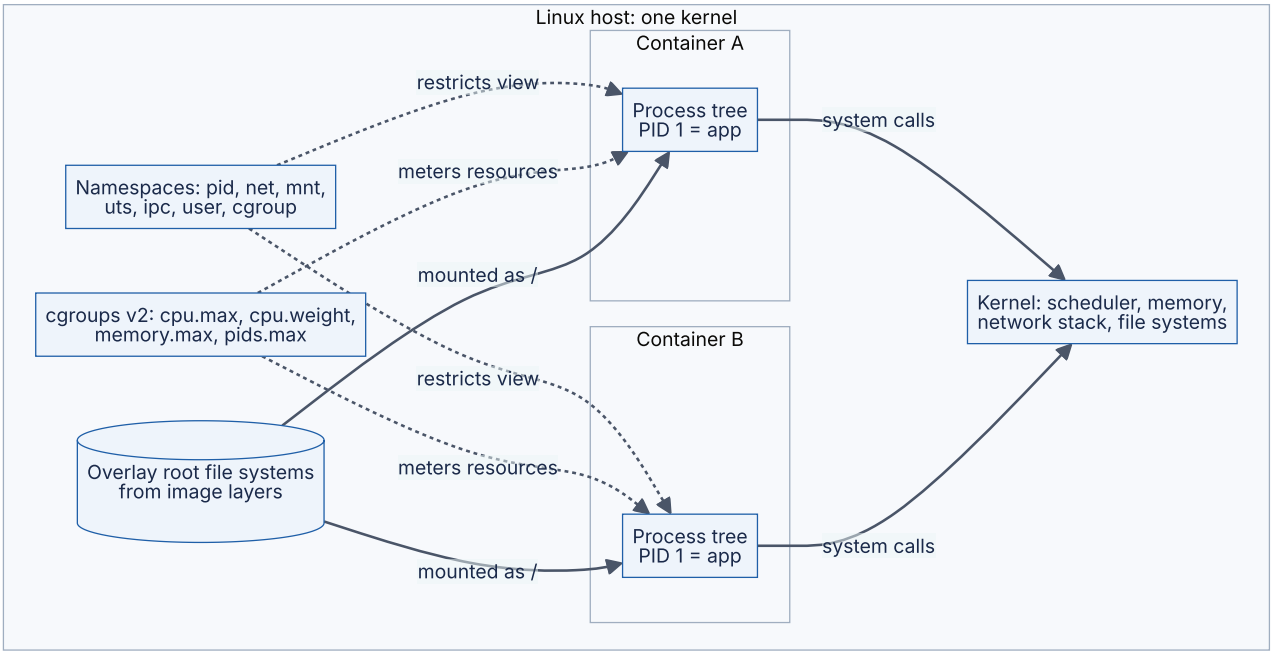
1. **Unpack the image** into a root file system, usually as an overlay of read-only layers plus one writable layer (§42.4).
2. **Create namespaces** with the `clone()` or `unshare()` system calls, giving the process its own process IDs, network stack, mount table, host name and so on (Table 42.1).
3. **Create a cgroup** under `/sys/fs/cgroup/...`, write limits into its interface files, and move the process into it.
4. **Switch root** to the unpacked file system (`pivot_root`), drop Linux **capabilities** (fine-grained slices of root privilege), and apply a **seccomp** filter that blocks dangerous system calls.
5. **Exec** the entry point. From here on, the container *is* that process; when it exits, the container stops.

Table 42.1 — Linux namespaces used by containers.

Namespace	Isolates	What the container sees
PID	Process IDs	Its entry point is PID 1; host processes are invisible
Network (net)	Interfaces, IPs, routes, ports, firewall rules	Its own `eth0`, `lo` and port space
Mount (mnt)	Mount table	Its own root file system and mounts
UTS	Host name and domain name	Its own host name (the pod name in Kubernetes)
IPC	System V IPC, POSIX message queues	Only its own shared-memory segments
User	User and group IDs	Root inside maps to an unprivileged ID outside
Cgroup	View of the cgroup tree	Its own cgroup appears as the root

The **user namespace** matters most for security: without it, root inside the container is root on the host, held back only by dropped capabilities and seccomp. Kubernetes supports user namespaces for pods (`hostUsers: false`), a feature still maturing as of 2026.

Figure 42.1 — A container is a host process with namespaces, a cgroup and an image root file system.



Reading the diagram. Both containers are ordinary process trees making synchronous system calls into one shared kernel. Namespaces (dotted, configuration applied at start) decide what each process can see; cgroups decide how much CPU, memory and how many processes it can use; the overlay file systems built from image layers are the storage boundary mounted as each container's root. The single kernel is the shared failure

point: a kernel bug or panic affects every container, which is why the isolation is weaker than a VM's (§42.3.4). Scaling is cheap: another container is another process, with no guest operating system to boot.

42.3.2 Cgroups v2: CPU and memory control

DEFINITION

Definition — Control group (cgroup). A kernel mechanism that groups processes into a hierarchy and applies resource accounting and limits to each group through **controllers** (cpu, memory, io, pids). **cgroup v2** is the unified hierarchy, stable since Linux 4.5 (2016), in which every controller uses one tree and one set of interface files [Linux Docs: cgroup v2].

The interface is a directory of files. Writing to them configures the kernel; reading them reports usage.

Table 42.2 — The cgroup v2 controls that matter for containers, and what Kubernetes writes into them.

File	Meaning	Kubernetes source
`cpu.weight`	Relative CPU share under contention (1–10,000, default 100)	CPU **request**, converted proportionally
`cpu.max`	Quota and period: `200000 100000` = 200 ms of CPU per 100 ms	CPU **limit** × 100 ms period
`memory.max`	Hard memory limit; exceeding it triggers the OOM killer in the group	Memory **limit**
`memory.high`	Soft limit: the kernel throttles and reclaims above it	Optional memory QoS feature
`pids.max`	Maximum number of processes	Pod PID limit (kubelet setting)
`cpu.stat`	`nr_periods`, `nr_throttled`, `throttled_usec`	Read by monitoring
`memory.events`	Counts of `high`, `max`, `oom`, `oom_kill` events	Read by monitoring

Two CPU mechanisms behave very differently. **Weight** is work-conserving: a container with weight 200 gets twice the CPU of one with weight 100 *only when they compete*; on an idle machine either may use every core. **Quota** (CFS bandwidth control, §6.5.5) is a hard ceiling enforced per period, even when cores sit idle. Memory has no weight-like soft option by default: past `memory.max` the kernel reclaims what it can (page cache first) and then kills a process in the cgroup with `SIGKILL`. Kubernetes reports this as `OOMKilled` with exit code 137 (128 + signal 9).

Mathematical foundations: CPU throttling from a CFS quota

Chapter 6 introduced throttling; here is the arithmetic you need to size limits.

FORMULA

CPU throttling under a CFS quota

$$Q = L \times P \qquad t_{\text{run}} = \frac{Q}{k} \qquad t_{\text{throttle}} = \max\left(0,\ P - \frac{Q}{k}\right)$$

Symbol	Meaning	Units
L	CPU limit	CPUs (cores)
P	Enforcement period (Kubernetes default 100 ms)	ms
Q	CPU time the cgroup may use per period, summed over all its threads	CPU-ms per period
k	Number of threads simultaneously runnable on separate cores during a burst	threads
t_{run}	Wall-clock time until the quota is exhausted	ms
t_{throttle}	Wall-clock time the whole cgroup is frozen for the rest of the period	ms

WORKED EXAMPLE

Worked example — A Go service with a 2-CPU limit on a 16-core node. QuickBite's pricing service has `limits.cpu: 2`. Its runtime, unaware of the limit, starts 16 worker threads, and during a garbage-collection cycle plus a request burst, $k = 8$ threads are runnable at once.

1. Quota: $Q = 2 \times 100 = 200$ CPU-ms per period.
2. Time to burn it with 8 threads: $t_{\text{run}} = 200/8 = 25$ ms.
3. Throttled time: $t_{\text{throttle}} = 100 - 25 = 75$ ms.
4. A request needing 10 ms of CPU that arrives just as the quota runs out waits up to 75 ms before it can run, so its latency becomes roughly $75 + 10 = 85$ ms instead of 10 ms.
5. Over a whole minute the service may still average only 0.8 CPUs (40% of its limit), because the bursts are short.

Now set the runtime to 2 threads ($k = 2$): $t_{\text{run}} = 200/2 = 100$ ms, so $t_{\text{throttle}} = 0$.

Interpretation. Throttling is caused by *parallelism inside a burst*, not by average usage; dashboards showing 40% CPU hide 75 ms stalls. **Engineering implication.** Size thread pools and runtime parallelism to the limit, not to the host's cores; alert on `nr_throttled / nr_periods` from `cpu.stat`; and for latency-critical services consider setting a CPU request with no CPU limit, relying on weights (§42.13.3).

INDUSTRY EXAMPLE

Runtimes became container-aware. The JVM reads cgroup limits to size its heap and thread pools (since JDK 10, backported to 8u191). Go 1.25 (August 2025) made the default `GOMAXPROCS` respect the cgroup CPU limit; earlier Go versions needed the `automaxprocs` library to avoid exactly the throttling above. Trade-off: the runtime now sizes itself to the limit, so an overly tight limit also caps parallelism. *Evidence: Primary* — [Go Release Notes 1.25]; [Linux Docs: cgroup v2]

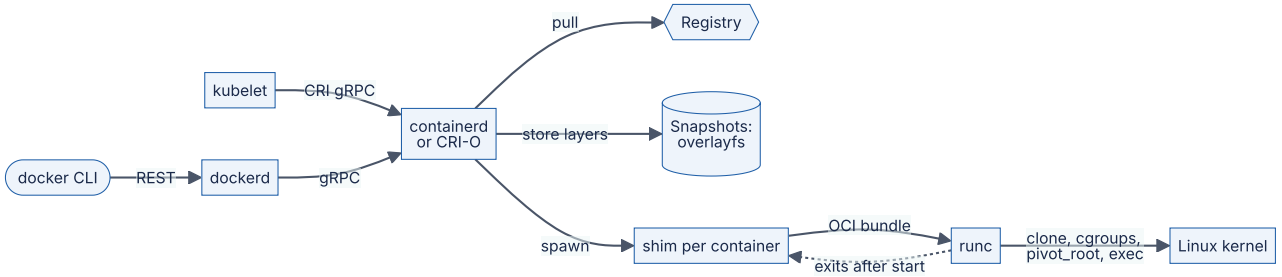
42.3.3 Runtimes: runc, containerd and the CRI

A container runtime is really a stack of three layers.

- **Low-level (OCI) runtime. runc** is the reference implementation of the **OCI Runtime Specification**: given a `config.json` and a root file system (a **bundle**), it creates namespaces and cgroups, starts the process, and exits [OCI Runtime Spec]. Alternatives implement the same contract: `crun` (written in C, faster start), gVisor's `runsc`, and Kata Containers (a lightweight VM per pod).

- **High-level runtime. containerd** and **CRI-O** pull and store images, unpack snapshots, manage container lifecycles and call the low-level runtime. A small **shim** process per container stays as its parent, so containerd can restart without killing containers.
- **The Container Runtime Interface (CRI).** A gRPC API between the kubelet and the high-level runtime, with an image service and a runtime service (“run pod sandbox”, “create container”, “start container”). Kubernetes removed its built-in Docker adapter (**dockershim**) in version 1.24 (2022); Docker-built images still run unchanged, because they are OCI images.

Figure 42.2 — The runtime stack from kubelet to kernel.



Reading the diagram. On a Kubernetes node the kubelet calls containerd (or CRI-O) synchronously over the CRI gRPC API; on a developer laptop the Docker CLI reaches the same containerd through `dockerd`. containerd pulls layers from a registry (an external system), stores them as overlayfs snapshots (the node’s storage boundary) and spawns a shim per container. The shim invokes runc with an OCI bundle; runc makes the system calls that create the container and then exits (dotted), leaving the shim as the container’s parent to collect its exit status. Failure points: a registry outage blocks new pods but not running ones; a full snapshot disk triggers image garbage collection and evictions.

42.3.4 Containers versus virtual machines

Table 42.3 — Isolation options compared.

Aspect	Container (runc)	Sandboxed container (gVisor)	MicroVM (Firecracker, Kata)	Virtual machine
What it is	Host process with namespaces and cgroups	Process whose system calls a user-space kernel handles	Minimal VM per workload	Full guest OS on a hypervisor
Kernel	Shared host kernel	User-space kernel in front of host	Own guest kernel	Own guest kernel
Start time	~0.1–1 s	Slightly slower	~125 ms boot for Firecracker	Tens of seconds
Overhead	Near zero	System-call overhead	< 5 MiB memory per microVM (Firecracker)	Hundreds of MB+
Isolation	Weakest: kernel is attack surface	Stronger	Strong (hardware virtualization)	Strong
Choose when	Trusted code, one tenant	Untrusted code, dense packing	Multi-tenant serverless, untrusted code	Different OS, strict tenancy

Firecracker figures are from its paper [Agache et al. 2020]; Chapter 47 compares isolation levels in depth. Kubernetes selects among these per pod through a **RuntimeClass**.

COMMON MISTAKE

Common misconception — "Containers are lightweight VMs." A container is a process. It shares the kernel, so a kernel vulnerability can become a container escape, and a container that runs as root without a user namespace is root on the host if it escapes. Treat containers as a packaging and resource-control boundary; add a sandbox or VM boundary when tenants do not trust each other.

Failure scenarios — containers.

What goes wrong	Why	Detection	Recovery	Prevention
Container killed, exit 137	Exceeded `memory.max`	`OOMKilled` status; `memory.events` `oom_kill`	Restart; raise limit	Limit above peak RSS; bound caches
Latency spikes at low average CPU	CFS quota exhausted by parallel bursts	`nr_throttled` rising	Raise or remove CPU limit	Size threads to limit
Fork bomb starves node	No process limit	Node PID exhaustion	Kill container	`pids.max` per pod
Zombie processes accumulate	App as PID 1 does not reap children	Process count grows	Restart	Tiny init (`tini`) or reaping entry point
Container escape	Kernel bug plus root inside	Runtime security alerts	Isolate node, rotate credentials	Non-root, user namespaces, seccomp, sandboxed runtime

42.4 Docker, images and layers

42.4.1 Images as stacks of layers

DEFINITION

Definition — Container image. An immutable, content-addressed package containing a root file system, stored as an ordered list of **layers** (each a compressed tar archive of file-system changes), plus a **configuration** (entry point, environment, user, working directory) and a **manifest** that lists them by cryptographic digest. The **OCI Image Specification** standardizes the format [OCI Image Spec].

First-principles explanation

Picture transparent overhead-projector sheets stacked on top of each other. The bottom sheet draws a Debian file system; the next adds Python; the next adds your libraries; the top adds your code. Looking down through the stack you see one picture. If two images share the bottom three sheets, a machine stores and downloads those sheets once. When a running container “changes” a file, it draws on a fresh clear sheet on top; the sheets underneath are never touched.

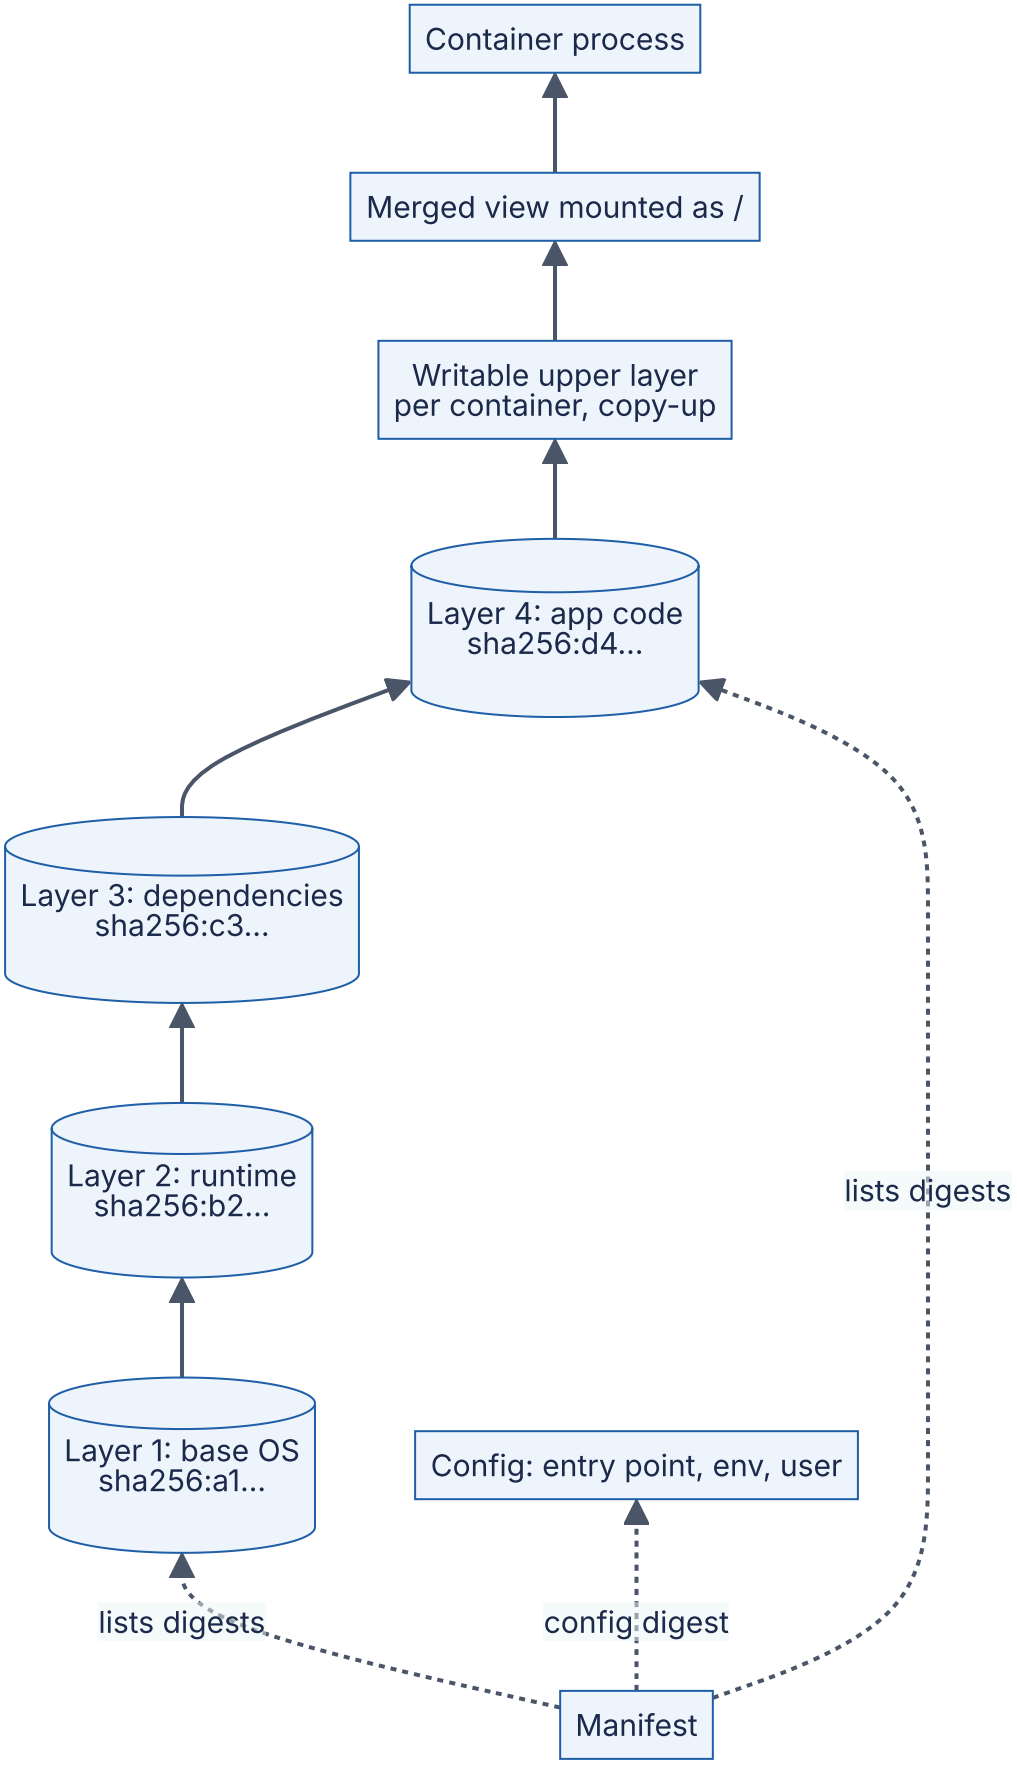
How it works internally

1. Each filesystem-changing Dockerfile instruction (`RUN` , `COPY` , `ADD`) produces one layer: the difference between the file system before and after it.
2. Each layer is archived, compressed (gzip or zstd) and named by the SHA-256 **digest** of its bytes, so identical content always has the same name and any corruption is

detectable.

3. The **config** JSON records the uncompressed layer digests (`diff_ids`), entry point, environment and history. The **manifest** lists the config and layer descriptors (media type, digest, size). An **image index** lists one manifest per platform (`linux/amd64`, `linux/arm64`), which is how one tag serves several CPU architectures.
4. On the node, **overlayfs** mounts the read-only layers as `lowerdir`s and a per-container writable `upperdir`, presenting a merged view as the container’s root. The first write to a lower-layer file **copies it up** whole into the upper directory; a deletion creates a **whiteout** entry that hides the lower file.

Figure 42.3 — Image layers merged by overlayfs, with a writable container layer.



Container process
Merged view mounted as /
Writable upper layer per container, copy-up
Layer 4: app code sha256:d4...
Layer 3: dependencies sha256:c3...
Layer 2: runtime sha256:b2...
Layer 1: base OS sha256:a1...
Config: entry point, env, user
lists digests
lists digests
config digest
Manifest

Reading the diagram. Read bottom to top. Four read-only layers, each named by its digest, are shared by every container on the node that uses them; only the writable upper layer is per container. Overlayfs presents the merged view as the process's root file system; writes go to the upper layer through copy-up, and are lost when the container is removed, so durable data belongs on volumes (§42.14). The manifest (dotted) references the config and layers by digest, which is what makes the image verifiable. Failure points: copy-up of a large file (a database file in a lower layer) is slow and doubles its disk use; a full node disk blocks unpacking. Scaling: shared base layers mean the hundredth image on a node often downloads only its top layer.

42.4.2 Writing good Dockerfiles

Layer caching is the key mechanism: a builder reuses a cached layer if the instruction and its inputs are unchanged, and **every layer after the first changed one is rebuilt**. Order instructions from least to most frequently changing.

```
        # syntax=docker/dockerfile:1
        # ---- build stage: full toolchain, never shipped ----
        FROM golang:1.23 AS build
        WORKDIR /src
        COPY go.mod go.sum ./
        RUN go mod download                      # cached until dependencies change
        COPY . .
        RUN CGO_ENABLED=0 go build -trimpath -ldflags="-s -w" -o /out/pricing
./cmd/pricing

        # ---- runtime stage: only the static binary ----
        FROM gcr.io/distroless/static-debian12:nonroot
        COPY --from=build /out/pricing /pricing
        USER nonroot:nonroot
        ENTRYPOINT ["/pricing"]
```

What to notice:

- **Multi-stage build.** The compiler, source and module cache live only in the `build` stage; the final image starts from a minimal base and copies one file from the earlier stage.
- **Dependency layer first.** Copying `go.mod` and `go.sum` before the source means a code-only change reuses the cached `go mod download` layer.
- **Distroless, non-root.** No shell or package manager in the final image shrinks the attack surface; `USER nonroot` means a compromised process is not root.
- **Exec-form `ENTRYPOINT`.** The JSON-array form makes the binary PID 1 so it receives `SIGTERM` directly; the shell form wraps it in `/bin/sh -c`, which may not forward signals and breaks graceful shutdown (§42.7.4).

Also: keep a `.dockerignore`; never `COPY` secrets (they persist in a layer; use BuildKit secret mounts); clean package caches in the same `RUN`; pin the base image by digest.

Mathematical foundations: why image size matters

FORMULA

Image pull time on a cold node

$$T_{\text{pull}} \approx \frac{S_c}{B} + \frac{S_u}{R}$$

Symbol	Meaning	Units
S_c	Compressed size of the layers not already on the node	MB
B	Effective download throughput from registry to node	MB/s
S_u	Uncompressed size of those layers	MB
R	Decompress-and-write (unpack) throughput on the node	MB/s
T_{pull}	Time from pull start to a runnable root file system	s

The two terms overlap partly in practice (layers download and unpack in parallel), so the sum is an upper estimate.

WORKED EXAMPLE

Worked example — Single-stage versus multi-stage for the pricing service. Sizes are approximate and vary by version. A single-stage image built on the Go toolchain image is about $S_u = 850$ MB uncompressed, $S_c = 300$ MB compressed. The multi-stage image is a ~2 MB distroless base plus a 20 MB binary: $S_u = 22$ MB, $S_c = 9$ MB. Assume $B = 50$ MB/s and $R = 150$ MB/s.

1. Single-stage: $300/50 + 850/150 = 6.0 + 5.7 = 11.7$ s.
2. Multi-stage: $9/50 + 22/150 = 0.18 + 0.15 = 0.33$ s.
3. A scale-out that adds 30 fresh nodes downloads $30 \times 300 = 9,000$ MB $= 9$ GB versus $30 \times 9 = 270$ MB from the registry.

Interpretation. The fat image adds about 11 s to every cold start on a new node, on top of node provisioning, and concentrates 9 GB of registry egress into the minute when you most need capacity. **Engineering implication.** Small images shorten the reaction time T_{react} that autoscaling headroom must cover (§18.8.4). Pre-pull large shared base images in the node image, use a pull-through registry mirror inside the region, and consider lazy-pulling formats (which fetch file contents on demand) when images must be large, such as ML images with GPU libraries.

COMMON MISTAKE

Common misconception — "Deleting files in a later layer makes the image smaller." The earlier layer still contains the bytes; the later layer only adds a whiteout. Remove temporary files in the *same* `RUN` that created them, or build them in a discarded stage [Docker Docs: Multi-stage Builds].

42.5 Registries

42.5.1 The pull flow, tags and digests

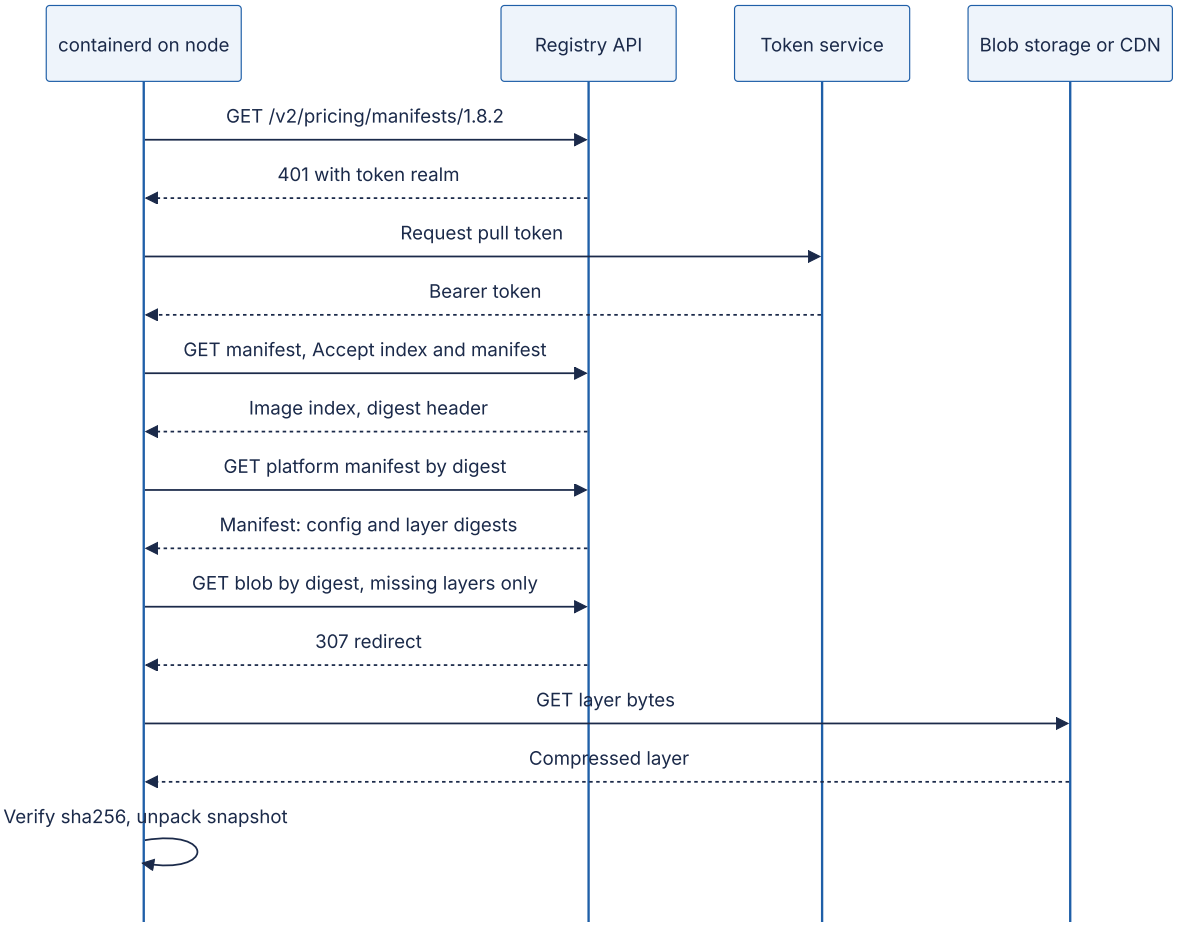
DEFINITION

Definition — Container registry. A content-addressed store for images and related artifacts, organized into repositories, that serves manifests by **tag** or **digest** and layers (blobs) by digest over the HTTP API standardized by the **OCI Distribution Specification** [OCI Distribution Spec].

A **tag** (`pricing:1.8.2`, `pricing:latest`) is a mutable pointer that anyone with push rights can move. A **digest** (`pricing@sha256:9f2c...`) names exact bytes and can never change. Production manifests should reference images by digest, or tags should be made im-

mutable in the registry; otherwise two nodes pulling “the same” tag a minute apart can run different code, and a rollback to a tag may not restore the old bytes.

Figure 42.4 — Pulling and verifying an image by digest.



Reading the diagram. The runtime asks for the tag’s manifest; the registry challenges for authentication and a token service issues a short-lived bearer token. The image index returns per-platform manifests and the digest the tag currently points to; from then on everything is fetched by digest. Only layers missing from the node are downloaded, often redirected to object storage or a CDN (a separate storage boundary). Every blob’s SHA-256 is checked against the manifest before unpacking, so a tampered or corrupted layer is rejected. All steps are synchronous HTTPS. Failure points: the token service and registry are on the critical path of every new pod on a fresh node, so a registry outage blocks scale-out and rescheduling; a regional mirror removes that dependency. Scaling: blob downloads parallelize across layers and are cacheable because digests never change.

42.5.2 Signing, provenance and scanning

A digest proves the bytes are the ones the registry stored; it does not prove *who built them*. **Signing** closes that gap. Sigstore’s **cosign** supports **keyless signing**: the CI job proves its identity with an OpenID Connect token, the **Fulcio** certificate authority issues

a certificate valid for minutes, the job signs the image digest, and the signature is recorded in the **Rekor** transparency log; the signature is stored in the registry next to the image [Sigstore Docs]. OCI Image Spec 1.1 (2024) added a `subject` field so signatures, software bills of materials (SBOMs) and build provenance attestations can be attached to an image and discovered through the registry's referrers API. An **admission policy** in the cluster then rejects pods whose image digest lacks a valid signature from the expected CI identity.

Vulnerability scanning compares the packages in each layer against vulnerability databases (CVE feeds). Scan at three points: in CI (fail the build on fixable critical issues), in the registry (re-scan stored images daily, because new vulnerabilities are published for old images) and at runtime (report what is actually deployed). Distroless and multi-stage images help most here: fewer packages, fewer findings to triage.

RECOMMENDATION

Recommendation — A minimal supply-chain baseline. Build in CI only; push by digest; sign with keyless cosign and attach an SBOM; make release tags immutable; enforce signature and registry allow-lists at admission; scan continuously; mirror images into a regional registry so production never depends on a public registry's availability or rate limits.

42.6 Kubernetes architecture

42.6.1 From containers to an orchestrator

Containers solve packaging on one machine. With 400 containers on 50 machines, something must place each container, restart it, move it when its machine fails, give it a stable address, roll out versions and add machines. Kubernetes replaces doing that by hand.

DEFINITION

Definition — Kubernetes. An open-source container orchestrator that runs workloads across a cluster of nodes from **declarative** specifications. Users write the *desired state* of API objects to a central API server; independent **controllers** continuously compare it with the *observed state* and act to close the gap [Kubernetes Docs: Components].

INDUSTRY EXAMPLE

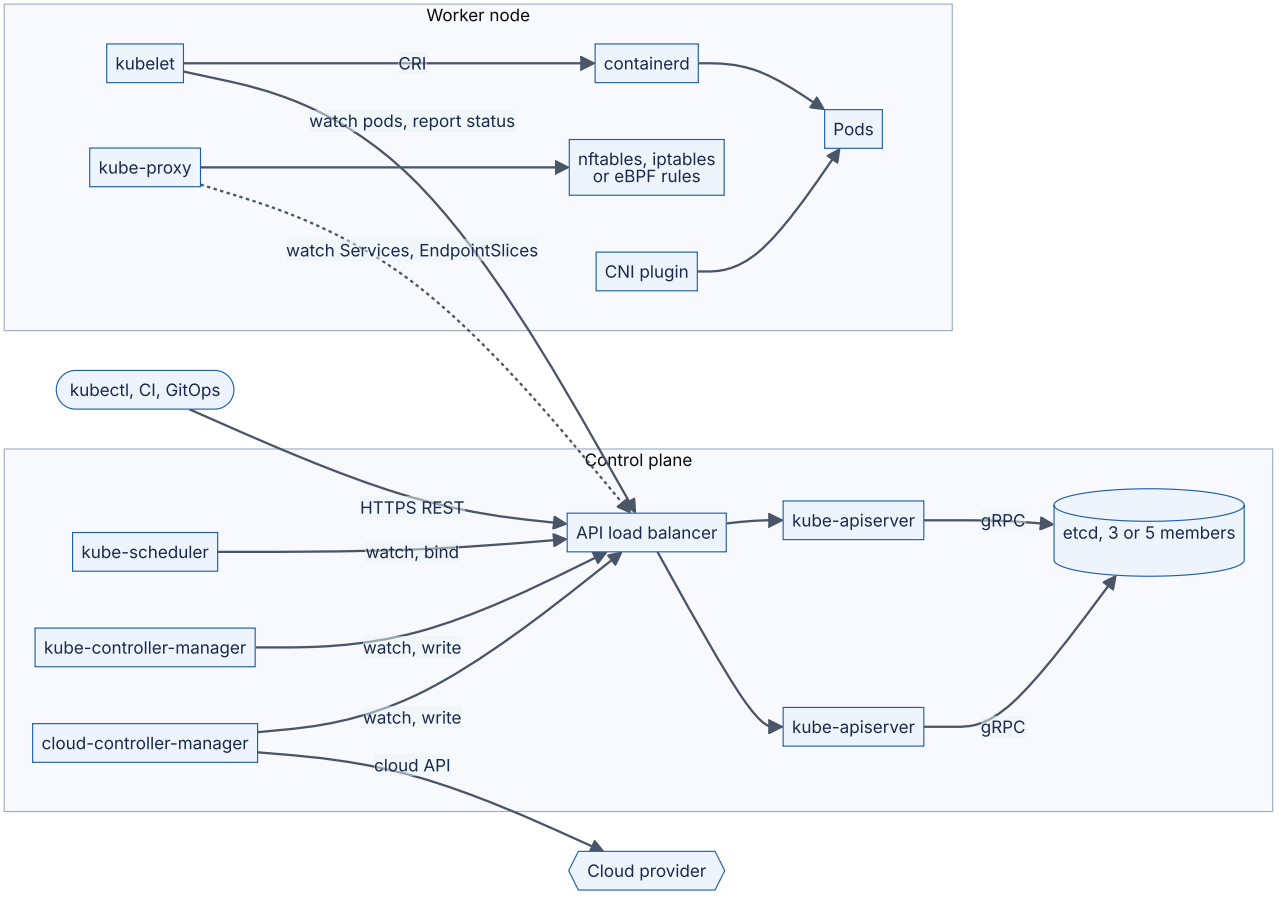
From Borg to Kubernetes. Google's Borg ran "hundreds of thousands of jobs" across cells of about 10,000 machines, with a Paxos-replicated controller, the Borgmaster (five replicas per cell) and a scheduler that checks feasibility and then scores machines [Verma et al. 2015]. Omega explored shared-state, optimistically concurrent schedulers [Schwarzkopf et al. 2013]. Kubernetes (open-sourced in 2014, 1.0 in 2015) carried over the lessons Burns et al. list: group co-scheduled containers into **pods**; give every pod its own IP address instead of sharing the host's ports; identify groups with **labels** rather than fixed job membership; make all components talk through one API rather than to the store directly; and build the system from **reconciliation loops** [Burns et al. 2016]. *Evidence: Primary* — [Verma et al. 2015]; [Burns et al. 2016]

42.6.2 Control plane and nodes

The **control plane** decides; the **nodes** do.

- **kube-apiserver.** The only component that talks to etcd. It authenticates and authorizes every request (RBAC), runs **admission** plugins and webhooks that may mutate or reject objects, validates schemas, persists objects and serves **watches** that stream changes. It is stateless and runs as several replicas behind a load balancer.
- **etcd.** The Raft-replicated key–value store holding every object (§26.9). Three or five members; its latency bounds every write in the cluster.
- **kube-scheduler.** Watches pods with no node assigned and binds each to a node (§42.13).
- **kube-controller-manager.** One process running dozens of controllers (Deployment, ReplicaSet, StatefulSet, Job, node lifecycle, EndpointSlice, namespace, garbage collector). One replica is active at a time through leader election (§26.9.2).
- **cloud-controller-manager.** Controllers that call the cloud provider: create load balancers for `LoadBalancer` Services, attach node metadata, delete nodes whose VM is gone.
- **kubelet** (every node). Watches the pods bound to its node, asks the runtime through the CRI to start them, runs probes, mounts volumes and reports status. It is a controller too, with the node as its world.
- **kube-proxy** (every node, optional with some network plugins). Programs packet-forwarding rules that implement Services (§42.9).
- **Container runtime and CNI plugin** (every node). containerd or CRI-O runs containers (§42.3.3); the **Container Network Interface (CNI)** plugin gives each pod its network (§42.9.1).

Figure 42.5 — Kubernetes architecture.



Reading the diagram. Every component, inside or outside the control plane, talks only to the API server over HTTPS; only the API servers talk to etcd, the storage boundary. Controllers and the scheduler watch for changes and write back decisions; the kubelet watches pods assigned to its node and reports status; kube-proxy watches Services and EndpointSlices asynchronously (dotted) to program forwarding rules. Failure points and their effect: if the whole control plane is down, running pods keep running and Services keep forwarding, but nothing new is scheduled, failed pods on dead nodes are not replaced and deploys stall. If etcd loses quorum, the API becomes read-only or unavailable. Scaling: API servers scale horizontally; etcd scales vertically and limits cluster size; Kubernetes documents tested limits of 5,000 nodes, 150,000 pods and 110 pods per node [Kubernetes Docs: Large Clusters].

42.6.3 The reconciliation loop

Kubernetes has no central workflow engine that says “step 1, create the ReplicaSet; step 2, create pods”. Instead, each controller runs the same loop on its own kind of object.

DEFINITION

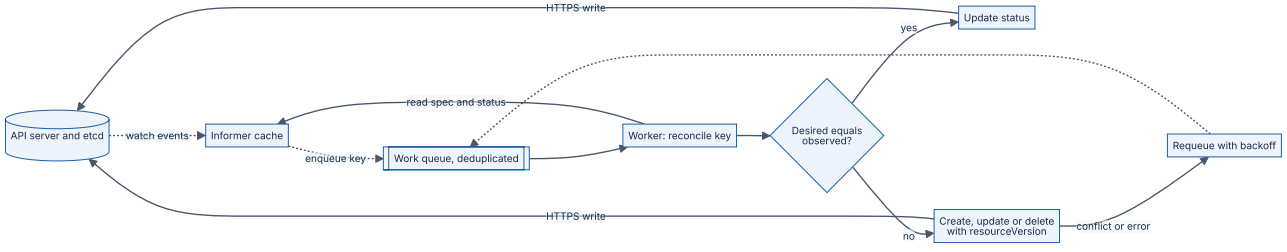
Definition — Reconciliation loop (control loop). A loop that repeatedly reads an object's desired state (`spec`), observes actual state, computes the difference and takes actions to reduce it, then records what it observed (`status`). It is **level-triggered**: it acts on the current state of the world, not on the sequence of events that produced it.

A thermostat is again the right analogy (§18.8.2). It does not count how many times the door opened; it measures the temperature now and heats if it is too low. If it misses an event, the next measurement still tells it the truth. An **edge-triggered** design ("on pod-deleted event, create a pod") breaks when an event is lost, duplicated or arrives during a controller restart; a level-triggered one simply converges on the next pass.

How it works internally.

1. An **informer** lists all objects of a kind once, then watches the API server for changes, keeping a local cache. A watch resumes from the last seen `resourceVersion` (an etcd revision), so restarts do not lose changes.
2. Each change enqueues only the object's *key* into a **work queue**, which deduplicates keys: ten rapid changes to one Deployment cause one reconciliation.
3. A worker pops a key, reads the *current* object from the cache and reconciles: compare, then create, update or delete through the API server.
4. Writes use **optimistic concurrency**: each update carries the `resourceVersion` it read; if someone else wrote first, the API server returns a conflict and the controller re-reads and retries.
5. On error, the key is requeued with exponential backoff. A periodic **resync** re-reconciles everything as a safety net.

Figure 42.6 — The reconciliation loop of a controller.



Reading the diagram. Watch events flow asynchronously (dotted) from the API server into the informer's cache and then, as keys, into a deduplicated work queue. A worker reads the latest cached state, decides whether desired and observed state match, and either writes status or performs actions through the API server, synchronously. Its own writes generate new watch events, so the loop naturally runs again until nothing changes. Failure points: a conflict (someone wrote in between) or an API error requeues the key

with backoff; a controller crash loses nothing because state lives in etcd and the loop restarts from a fresh list. Scaling: workers process different keys in parallel, and many independent controllers share the API server instead of calling each other.

Code example: a toy cluster built from reconcilers

The program below models the API server’s store and four controllers: the ReplicaSet controller, the scheduler, the kubelet and the node lifecycle controller. None of them calls another; each reads the shared store and fixes one kind of difference.

```
        """A toy Kubernetes: level-triggered controllers converging on desired state."""

            print("all checks passed")
```

Output:

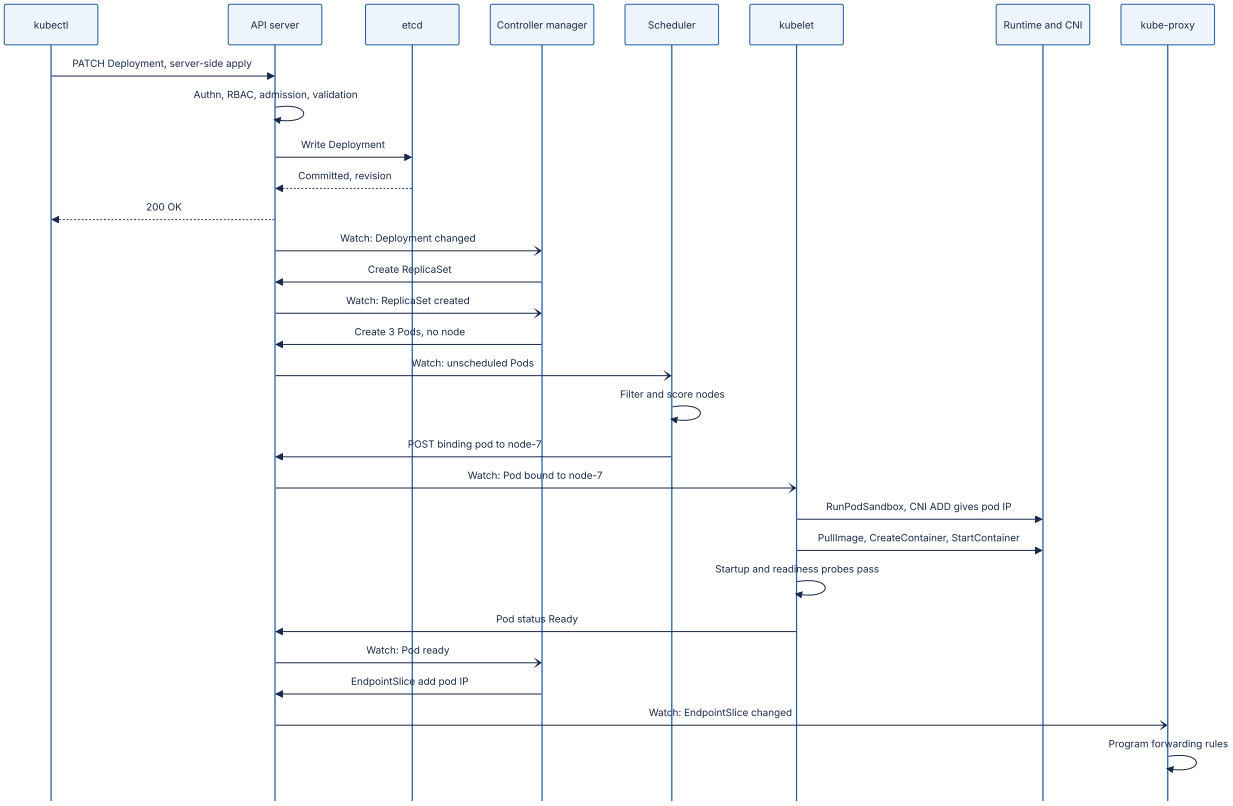
```
after apply:      {'node-1': 2, 'node-2': 2, 'node-3': 2} running = 6 rounds = 2
after node loss:  {'node-1': 3, 'node-2': 3, 'node-3': 0} running = 6
after scale-up:   {'node-1': 4, 'node-2': 4, 'node-3': 0} running = 8 pending = 2
after recovery:   {'node-1': 4, 'node-2': 4, 'node-3': 2} running = 10
LeastAllocated  {'node-1': 2, 'node-2': 2, 'node-3': 2} empty nodes = 0
MostAllocated   {'node-1': 0, 'node-2': 2, 'node-3': 4} empty nodes = 1
all checks passed
```

What to notice:

- **No controller knows why the world changed.** When node-3 dies, the node lifecycle controller deletes its pods; the ReplicaSet controller merely sees “4 pods, want 6” and creates two; the scheduler merely sees two unbound pods. Recovery emerges from independent loops.
- **Pending is a normal state.** Pods that fit nowhere stay unbound, and are placed automatically once node-3 returns. In a real cluster that pending state is the signal a node autoscaler acts on (§42.12).
- **Scale-down deletes the cheapest pods first**: unscheduled, then newest, as the real ReplicaSet controller prefers.
- **The scheduler’s score function decides spreading versus packing**; §42.13.4 uses the last two lines of output.
- **Convergence is checked, not assumed**: `reconcile_until_stable` stops when a full pass changes nothing.

42.6.4 From `kubectl apply` to a running pod

Figure 42.7 — Sequence from `kubectl apply` of a Deployment to a ready pod receiving traffic.



Reading the diagram. Solid arrows are synchronous requests; open arrowheads are asynchronous watch notifications. The only synchronous part the user waits for is the API write: authentication, RBAC authorization, admission webhooks, validation and the etcd commit; `kubectl` returns as soon as the Deployment is *stored*, long before anything runs. Everything after is a chain of independent controllers reacting to watch events: the Deployment controller creates a ReplicaSet, the ReplicaSet controller creates pods, the scheduler binds them, the kubelet asks the runtime to create the pod sandbox (whose network namespace receives an IP from the CNI plugin), pull images and start containers, then reports readiness. The EndpointSlice controller adds the ready pod's IP and kube-proxy on every node updates its rules. Failure points: a slow admission webhook delays every write; no feasible node leaves pods Pending; an image pull failure shows as `ImagePullBackOff`; a failing readiness probe keeps the pod out of the EndpointSlice. End to end this takes a few seconds on a warm node, dominated by image pull and application start-up.

Table 42.4 — What breaks when a control-plane component fails.

Component down	Running workloads	What stops working	Typical mitigation
One API server	Unaffected	Nothing, if others remain	3 replicas behind a load balancer
All API servers	Keep running	All changes, scheduling, scaling, status	Managed control plane, multi-zone
etcd quorum	Keep running	API writes (and reads)	3 or 5 members across zones; backups
Scheduler	Keep running	New pods stay Pending	Leader-elected standby
Controller manager	Keep running	Replacements, rollouts, endpoints updates	Leader-elected standby
kubelet on a node	Containers keep running, unmanaged	Probes, restarts, status; node marked NotReady	Node auto-repair

42.7 Pods

42.7.1 What a pod is

DEFINITION

Definition — Pod. The smallest deployable unit in Kubernetes: one or more containers that are always scheduled together on one node and share a network namespace (one IP address and port space), IPC namespace and volumes. Pods are disposable: a replaced pod is a new pod with a new name and IP.

A pod is an apartment shared by roommates: one street address (IP), a shared kitchen (volumes), separate bedrooms (each container's own file system, cgroup and image). The runtime first creates a **pod sandbox**, a tiny "pause" process that holds the shared namespaces; the application containers then join them. Containers in a pod reach each other on `localhost`, so two of them cannot both listen on port 8080.

Put containers in one pod only if they must share a lifecycle and a node: a log shipper reading the app's log volume, a proxy that intercepts its traffic, a process that refreshes credentials into a shared file. Independent services belong in separate pods so they scale and fail independently.

42.7.2 Init containers and native sidecars

Init containers run to completion, one after another, before the app containers start: run a schema check, wait for a dependency, render configuration into a shared volume. If one fails, the kubelet retries it and the app never starts.

A **sidecar** is a helper container that runs *alongside* the app for the pod's whole life: a service-mesh proxy (§34.10), a log forwarder, a secrets agent. Before native support, sidecars were ordinary containers, which caused two classic bugs: the app started before its proxy was ready (failed first requests), and a Job's pod never completed because the sidecar never exited. Kubernetes' **native sidecar containers** fix both: an init container with `restartPolicy: Always` starts before the app containers, keeps running, is restarted if it dies, does not block Job completion, and is stopped *after* the app containers on shutdown. The feature has been stable since Kubernetes 1.33 (2025) [Kubernetes Docs: Sidecar Containers].

42.7.3 Probes

Table 42.5 — The three probes.

Probe	Question	On failure	Typical check
Startup	Has the app finished starting?	Keep waiting; after `failureThreshold × periodSeconds`, restart	Same endpoint as liveness, generous threshold
Liveness	Is the process stuck beyond recovery?	Restart the container	Cheap in-process check; no dependencies
Readiness	Should this pod receive traffic now?	Remove from Service endpoints; no restart	Can serve: warmed up, not overloaded

Liveness and readiness probes do not run until the startup probe succeeds. Defaults are a 10 s period, 1 s timeout and 3 failures. The most damaging mistake is a liveness probe that checks a shared dependency: when the database slows, every pod fails liveness and restarts at once, turning a slowdown into an outage (§19.5.2).

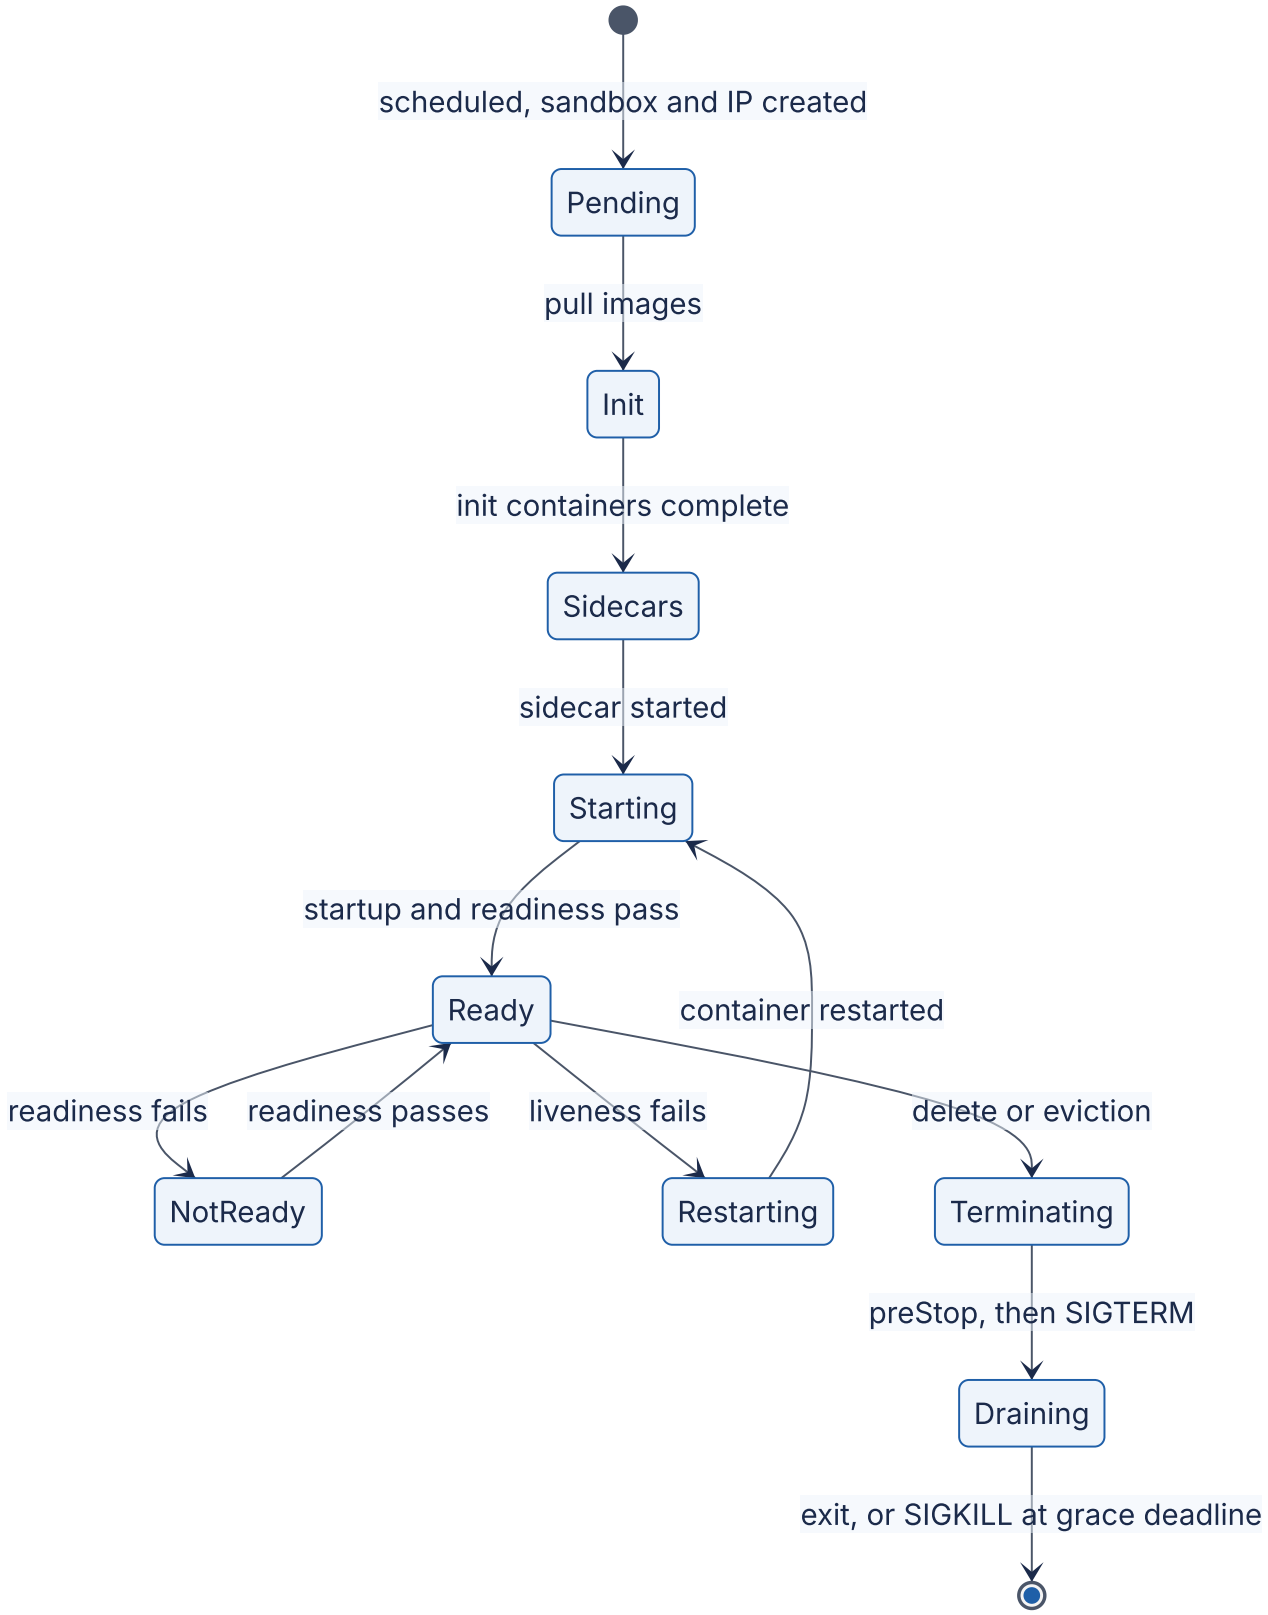
```yaml
apiVersion: v1
kind: Pod
metadata:
  name: ordering
spec:
  terminationGracePeriodSeconds: 45
  initContainers:
  - name: migrate-check                    # runs to completion first
    image: registry.example.com/ordering-migrate@sha256:1c4e...
  - name: mesh-proxy                       # native sidecar
    image: registry.example.com/proxy@sha256:7ab0...
    restartPolicy: Always
  containers:
  - name: app
    image: registry.example.com/ordering@sha256:9f2c...
    resources:
      requests: {cpu: "500m", memory: "1Gi"}
      limits:   {memory: "1Gi"}            # memory limit; no CPU limit
    startupProbe:
      httpGet: {path: /healthz, port: 8080}
      periodSeconds: 5
      failureThreshold: 24                 # allow up to 120 s to start
    livenessProbe:
      httpGet: {path: /healthz, port: 8080}
    readinessProbe:
      httpGet: {path: /ready, port: 8080}
      periodSeconds: 5
    lifecycle:
      preStop:
        sleep: {seconds: 10}               # let endpoint removal propagate
```

What to notice: the sidecar is an init container with `restartPolicy: Always`; the startup probe gives a slow-starting app 120 s without weakening liveness afterwards; memory request equals memory limit while CPU has only a request (§42.13.3); images are pinned by digest (§42.5.1).

42.7.4 Graceful termination

When a pod is deleted, two things happen *in parallel*: the kubelet starts shutdown, and the EndpointSlice controller removes the pod from Services, after which every node's kube-proxy and every ingress proxy must update. The kubelet runs the `preStop` hook, sends `SIGTERM`, waits up to `terminationGracePeriodSeconds` (default 30 s) counted from the start of termination, then sends `SIGKILL`. Because endpoint removal is asynchronous, a pod that exits immediately on `SIGTERM` still receives requests for a second or two and those clients see connection errors. The standard fix is a short `preStop` sleep, then draining in-flight requests, then exiting; long-lived connections such as WebSockets need a longer grace period (§9.9.7 computes the drain budget).

Figure 42.8 — Pod lifecycle: ordered start-up and graceful shutdown.



Reading the diagram. A scheduled pod first gets its sandbox and IP, pulls images, runs init containers in order, starts native sidecars, then starts the app. Only when startup and readiness probes pass does the pod join Service endpoints. Readiness failures toggle traffic without restarts; liveness failures restart the container in place (same pod, same IP).

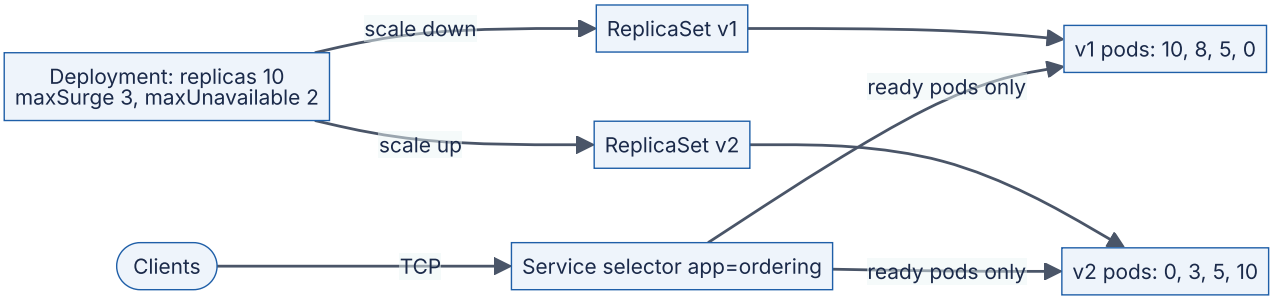
Deletion leads to `preStop`, `SIGTERM`, draining and finally exit or `SIGKILL`, while endpoint removal proceeds asynchronously elsewhere in the cluster. Failure points: a slow image pull or init container shows as a pod stuck in `Init`; a repeatedly failing container enters `CrashLoopBackOff` with exponentially growing restart delays (capped at 5 minutes); an app that ignores `SIGTERM` is killed at the deadline mid-request.

42.8 Workload controllers

42.8.1 Deployments and ReplicaSets

A **ReplicaSet** keeps *N* identical pods matching a label selector running, exactly the loop of §42.6.3. A **Deployment** manages ReplicaSets to roll out changes: when the pod template changes (a new image digest), it creates a new ReplicaSet and shifts replicas from old to new under two limits. **maxSurge** is how many pods above the desired count may exist; **maxUnavailable** is how many below the desired count may be unavailable. Both default to 25%; surge rounds up and unavailability rounds down. Old ReplicaSets are kept (scaled to zero, 10 by default) so `kubectl rollout undo` is just scaling the old one back up. Canary and blue–green strategies build on this and belong to §43.5–§43.6.

Figure 42.9 — A rolling update shifting replicas between ReplicaSets.



Reading the diagram. The Deployment controller scales the new ReplicaSet up and the old one down in steps, never exceeding 13 pods in total or dropping below 8 available. The Service selects pods by label only, so during the rollout it sends traffic to ready pods of *both* versions: clients must tolerate mixed versions, which is why API and schema changes must be backward compatible (§34.8.4). Readiness gates each step: an unready new pod does not count as available, so a broken image stops the rollout after a few pods instead of replacing everything. If no progress is made for `progressDeadlineSeconds` (default 600 s), the Deployment is marked failed; it does not roll back automatically unless your pipeline does. Scaling: surge pods need spare cluster capacity, or they wait as Pending for a node autoscaler.

Mathematical foundations: capacity during a rollout

FORMULA

Rolling update bounds and duration

$$s = \lceil \sigma R \rceil \qquad u = \lfloor uR \rfloor \qquad A_{\min} = R - u \qquad N_{\max} = R + s \qquad T_{\text{roll}} \approx \lceil \frac{R}{s+u} \rceil \times t_{\text{wave}}$$

Symbol	Meaning	Units
R	Desired replicas	pods
σ, u	maxSurge and maxUnavailable as fractions (or use absolute numbers directly)	dimensionless
s, u	Surge and unavailability in pods	pods
$A_{\min}$	Minimum available pods during the rollout	pods
$N_{\max}$	Maximum pods existing at once (sets the spare capacity needed)	pods
t_{wave}	Time for one batch: schedule, pull, start, readiness, `minReadySeconds`	s
T_{roll}	Approximate rollout duration (the controller overlaps waves, so this is an estimate)	s

WORKED EXAMPLE

Worked example — Rolling QuickBite's ordering service at peak. $R = 10$ pods; a load test showed each pod serves 550 RPS within its latency objective; the evening peak is 4,800 RPS; one wave takes $t_{\text{wave}} = 45$ s.

Defaults (25%, 25%).

1. $s = \lceil 0.25 \times 10 \rceil = \lceil 2.5 \rceil = 3$; $u = \lfloor 2.5 \rfloor = 2$.
2. $A_{\min} = 10 - 2 = 8$ pods, able to serve $8 \times 550 = 4,400$ RPS.
3. Peak needs $4,800/550 = 8.7$, so 9 pods. **4,400 < 4,800: a rollout at peak overloads the service.**
4. $T_{\text{roll}} \approx \lceil 10/5 \rceil \times 45 = 90$ s.

maxSurge 3, maxUnavailable 0.

1. $A_{\min} = 10$, capacity $5,500$ RPS; $N_{\max} = 13$.
2. $T_{\text{roll}} \approx \lceil 10/3 \rceil \times 45 = 4 \times 45 = 180$ s.
3. Spare capacity needed: 3 surge pods × 500 m CPU and 1 GiB = 1.5 CPU and 3 GiB.

Interpretation. Default settings quietly remove 20% of capacity during every deploy. Setting `maxUnavailable: 0` keeps full capacity for twice the rollout time and a little spare room. **Engineering implication.** For services running near their capacity, use `maxUnavailable: 0` with a surge, and make sure the HPA's target leaves headroom for $A_{\min}$, not just R; a PodDisruptionBudget protects the same floor against voluntary disruptions such as node drains.

42.8.2 StatefulSets, DaemonSets, Jobs and CronJobs

Table 42.6 — Workload controllers.

Controller	Guarantees	Pod identity	Typical use
Deployment (ReplicaSet)	*N* interchangeable replicas; rolling updates	Random names, new IP each time	Stateless services
StatefulSet	Stable ordinal names (`db-0`, `db-1`), stable DNS through a headless Service, one PersistentVolumeClaim per ordinal; ordered start and update by default	Stable name and storage	Databases, Kafka, ZooKeeper, etcd
DaemonSet	One pod per (matching) node, including new nodes	Per node	Log agents, CNI, node exporters, kube-proxy
Job	Run pods until *C* complete successfully; `parallelism`, `backoffLimit` (default 6), indexed completions	Per task	Batch, migrations, ML training steps
CronJob	Creates Jobs on a cron schedule; `concurrencyPolicy` Allow, Forbid or Replace	Per run	Reports, cleanups, backups

A StatefulSet gives identity, not replication: `db-1` reattaches to the same volume after rescheduling, but electing a primary, copying data and failing over remain the database's job (or an operator's, §42.15). Its rolling update replaces pods one at a time from the highest ordinal down, and a `partition` setting enables staged rollouts. Two cautions for CronJobs: a missed schedule (controller down) may run late or be skipped depending on `startingDeadlineSeconds`, and with `Allow` a slow job can overlap its next run, so jobs must be idempotent (§22.15).

42.9 Networking: CNI and Services

42.9.1 The pod network

Kubernetes imposes one rule and leaves the implementation to a **CNI plugin**: every pod gets its own IP address, and every pod can reach every other pod's IP directly, across nodes, **without NAT** [Kubernetes Docs: Cluster Networking]. Applications therefore see the same addresses senders used, and no two pods compete for host ports, the Borg lesson of §42.6.1.

When the runtime creates a pod sandbox, it calls the CNI plugin with `ADD`. The plugin creates a virtual Ethernet pair (one end in the pod's network namespace as `eth0`, the other on the host), assigns an IP from the node's pod range (for example a /24 per node), and programs routes. Across nodes, plugins use one of two approaches:

- **Overlay**: encapsulate pod packets in VXLAN or Geneve between nodes. Works on any network, costs about 50 bytes of header per packet and some CPU.
- **Native routing**: pod IPs are routable in the underlying network, through BGP (Calico) or cloud VPC addresses attached to the node (the AWS VPC CNI). Faster and visible to cloud firewalls, but consumes real subnet addresses (§7.4.2).

Calico, Cilium and Flannel are common plugins; Cilium and Calico also enforce **NetworkPolicy**, the pod-level firewall (by default every pod can reach every other pod).

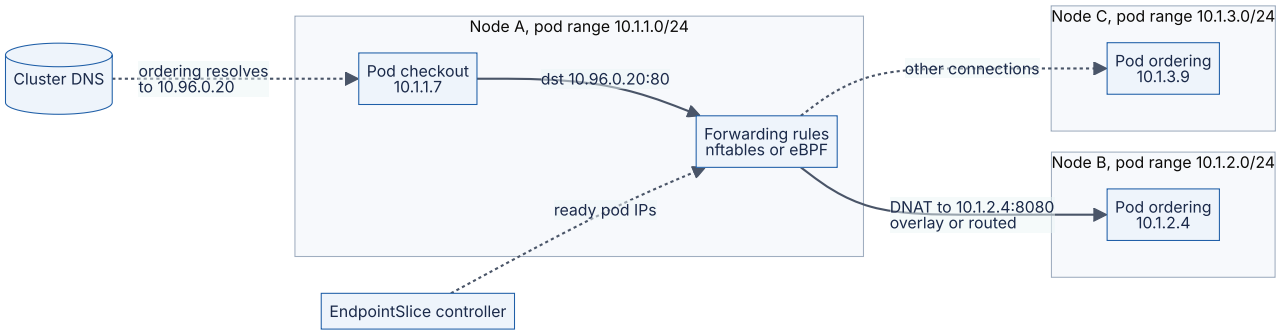
42.9.2 Services

Pods come and go with new IPs, so clients need a stable name. A **Service** selects pods by label and gives them one virtual IP and a DNS name such as `ordering.prod.svc.cluster.local`. The EndpointSlice controller keeps the list of *ready* pod IPs behind it (in slices of up to 100 endpoints each, so a change rewrites one small object, not one huge list).

Table 42.7 — Service types.

Type	What clients get	Reachable from	Use
ClusterIP (default)	Virtual IP and DNS name	Inside the cluster	Service-to-service calls
NodePort	A port (30000–32767) on every node	Anything that reaches nodes	Building block for external balancers
LoadBalancer	A cloud load balancer, provisioned by the cloud controller	Internet or VPC	Exposing a single L4 service
Headless (`clusterIP: None`)	DNS returns pod IPs directly; no virtual IP	Inside the cluster	StatefulSets, client-side balancing
ExternalName	DNS CNAME to an outside name	Inside the cluster	Aliasing an external dependency

Figure 42.10 — Pod-to-Service traffic across a flat pod network.



Reading the diagram. The checkout pod resolves `ordering` through cluster DNS to the Service's virtual IP 10.96.0.20, which belongs to no machine. Forwarding rules on the

client's own node (programmed by kube-proxy or an eBPF data plane from EndpointSlices, asynchronously) rewrite the destination to one ready pod IP at connection set-up (DNAT), and the packet crosses the flat pod network by overlay or native routing. Each new TCP connection may pick a different pod (dotted alternative). Failure points: stale rules after a pod dies send connections to a dead IP until endpoints update; the per-node conntrack table can fill under very many short connections; DNS is a shared dependency for every call. Scaling: there is no central balancer to saturate, because every node balances its own outgoing traffic.

42.9.3 kube-proxy modes

Table 42.8 — Service data-plane implementations (as of 2026).

Mode	How it works	Lookup cost	Status
iptables	Chains of rules; random-probability jump to an endpoint	Linear in rules; full-table rewrites	Long-time default; slow at tens of thousands of endpoints
IPVS	Kernel L4 load balancer with hash tables; several algorithms	Constant	Deprecated in Kubernetes 1.35
nftables	Successor to iptables with maps and sets	Near constant; incremental updates	Stable since 1.33; recommended for new clusters
eBPF (Cilium)	Programs at socket and network hooks; translates the address at `connect()`	Constant hash-map lookups	Replaces kube-proxy entirely [Cilium Docs]

All four balance **connections**, not requests. A gRPC client holds one HTTP/2 connection and sends every request to one pod, however many pods exist. Use a headless Service with client-side balancing, or an L7 proxy or mesh (§19.10, §34.10).

42.10 Ingress and Gateway API

A `LoadBalancer` Service per service means one cloud load balancer, one IP and one bill each, and only L4. HTTP routing by host and path, TLS termination and traffic splitting need an L7 entry point (§19.3).

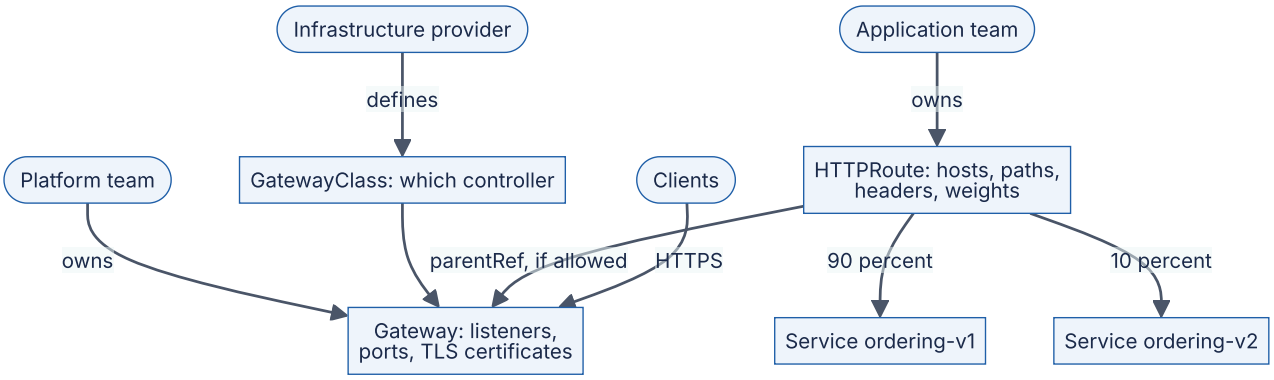
Ingress was the first answer: host and path rules implemented by an **ingress controller** (NGINX, Envoy or a cloud load balancer watching Ingress objects). Anything beyond host, path and TLS went into controller-specific annotations, so manifests were not portable, and one object mixed platform concerns (listeners, certificates) with application concerns (routes). The Ingress API is frozen: still supported, no new features.

INDUSTRY EXAMPLE

Ingress NGINX retirement. In November 2025 the Kubernetes project announced that the community `ingress-nginx` controller, one of the most widely deployed, would receive only best-effort maintenance until March 2026 and no releases or security fixes afterwards, citing a lack of maintainers; the project recommended migrating to Gateway API or another controller. Trade-off: existing installations keep working, which makes unpatched exposure easy to overlook. *Evidence: Primary* — [Kubernetes Blog 2025]

Gateway API is the successor, generally available since v1.0 (October 2023), with HTTP, gRPC and TLS routes, header matching, weighted backends, and backend TLS (v1.4, 2025) in its standard channel [Gateway API Docs]. Its central idea is **role separation** across resources.

Figure 42.11 — Gateway API resources and the roles that own them.



Reading the diagram. The infrastructure provider supplies a GatewayClass naming the controller (a cloud load balancer, Envoy Gateway, Cilium, and others). The platform team creates a Gateway with listeners and certificates, and states which namespaces may attach routes. Application teams create HTTPRoutes in their own namespaces that attach to the Gateway and split traffic by weight between Services, here a 10% canary. Clients connect over HTTPS to the Gateway's data plane, which forwards synchronously to pod endpoints. Failure points: the data plane is a shared entry point to replicate across zones; a route that the Gateway does not permit is simply not attached, visible in the route's status conditions. Scaling: the data plane scales horizontally, and routing changes no longer require platform-team edits.

```yaml
apiVersion: gateway.networking.k8s.io/v1
kind: HTTPRoute
metadata:
  name: ordering
  namespace: ordering
spec:
  parentRefs:
  - name: public-gateway
    namespace: platform
  hostnames: ["api.quickbite.example"]
  rules:
  - matches:
    - path: {type: PathPrefix, value: /orders}
    backendRefs:
    - {name: ordering-v1, port: 8080, weight: 90}
    - {name: ordering-v2, port: 8080, weight: 10}
```

The same API also describes east–west mesh routing (the GAMMA initiative), so one vocabulary covers both edge and service-to-service traffic.

42.11 ConfigMaps and Secrets

Images are identical across environments; what differs (endpoints, flags, credentials) is injected at run time. A **ConfigMap** holds non-secret key–value data or files (up to 1 MiB); a **Secret** has the same shape but is meant for credentials and is handled more carefully: kept off node disks (memory-backed volumes), with separate RBAC.

Both reach a pod as environment variables or mounted files, and the difference matters operationally. **Environment variables are read once at container start**; changing the ConfigMap changes nothing until pods restart. **Mounted files are updated in place** by the kubelet after a delay (its sync period plus cache, typically up to a minute or two), except when mounted with `subPath`, which never updates. A common, deliberate pattern is to treat configuration as immutable: put a hash of the configuration in the pod template (or create a new, `immutable: true` ConfigMap per version) so that a configuration change triggers an ordinary rolling update with readiness gates and rollback.

Security needs three layers, because a Secret is only base64-encoded, not encrypted (§10.8):

1. **Encryption at rest.** Configure the API server's encryption provider so Secrets are encrypted before reaching etcd, ideally with the **KMS v2** provider, which uses envelope encryption with a key held in a cloud KMS or HSM (§10.9.2) [Kubernetes Docs: Encrypting Secret Data at Rest].
2. **Access control.** RBAC `get`/`list` on Secrets in a namespace is equivalent to holding every credential in it; anyone who can create a pod in a namespace can mount its Secrets.

3. **External secret stores.** Keep the source of truth in a vault (HashiCorp Vault, AWS Secrets Manager, Google Secret Manager) and sync it in with the External Secrets Operator, or mount it directly with the Secrets Store CSI driver. Better still, avoid static secrets: give pods a workload identity that cloud IAM trusts, so they obtain short-lived credentials (§10.8).

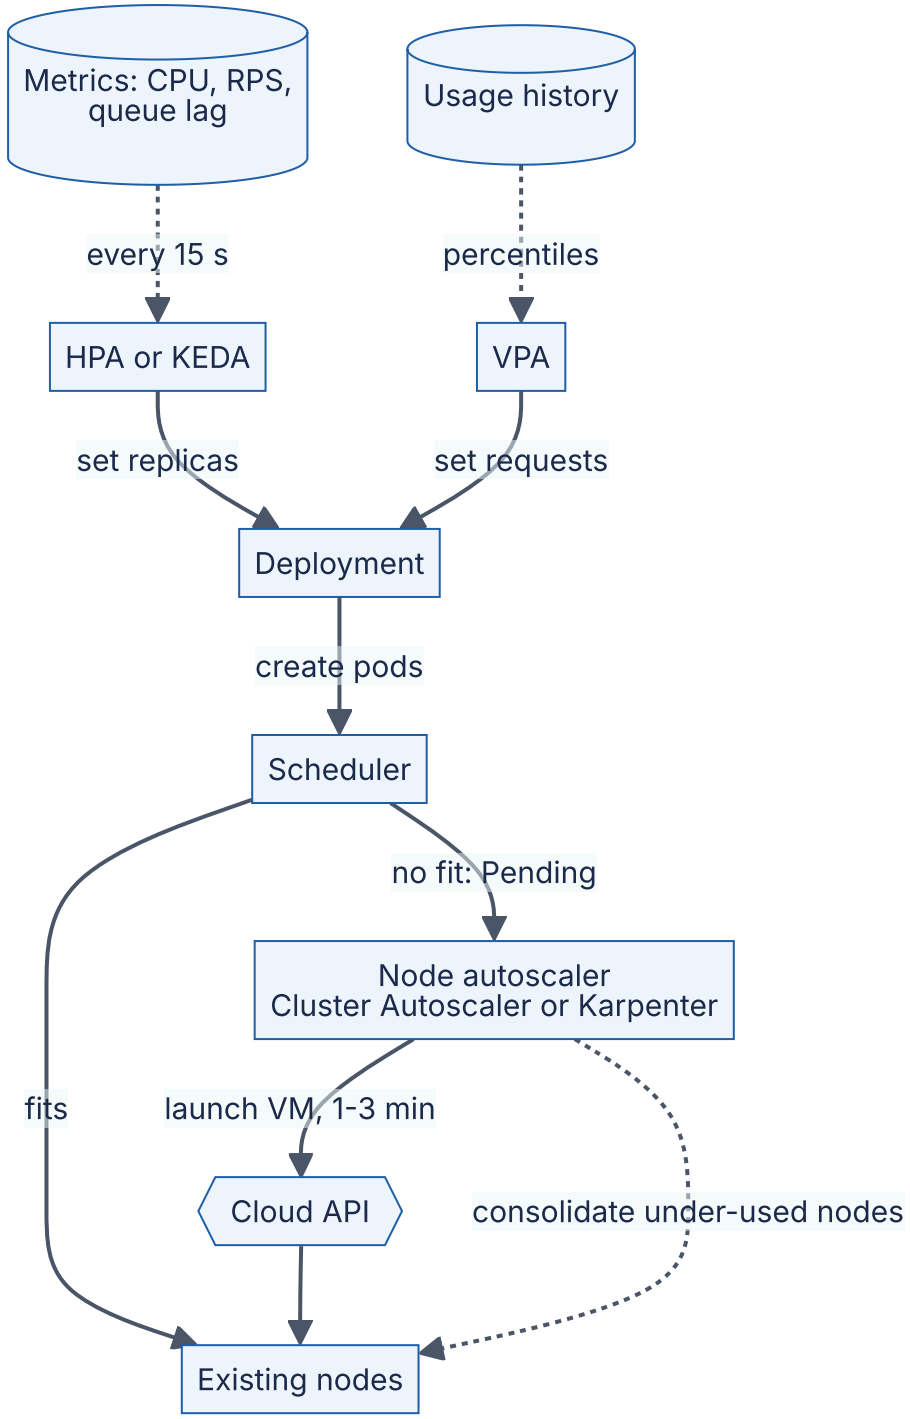
> WARNING / TRADE-OFF
>
> **Warning — Secrets leak through the edges.** Environment variables appear in crash dumps, debug endpoints and `kubectl describe` output of some tools; image layers keep anything ever copied into them; and etcd backups contain every Secret unless encryption at rest is enabled. Prefer mounted files, short-lived credentials and encrypted backups.

42.12 Autoscaling

Kubernetes autoscaling has three layers, owned by different controllers: *how many pods* (horizontal), *how big each pod* (vertical) and *how many nodes* (cluster). They interact through one shared quantity: **resource requests**.

- **Horizontal Pod Autoscaler (HPA).** Sets a Deployment's replica count by target tracking, $n_{desired} = \lceil n_{current} \times m_{current} / m_{target} \rceil$, derived with its tolerance, stabilization window and reaction time in §18.8.3–§18.8.4. Note the denominator for CPU: **utilization is measured as a percentage of the pod's CPU request**, not of the node or the limit. A pod requesting 250 m that uses 500 m is at 200%.
- **Vertical Pod Autoscaler (VPA).** Watches historical usage and recommends, or applies, requests (and proportionally limits). Modes range from `Off` (recommendations only) to modes that apply them at pod creation or by evicting pods; with in-place pod resize, stable since Kubernetes 1.35, resources can change without restarting the pod.
- **Node autoscalers.** The **Cluster Autoscaler** watches for pods that are Pending because nothing fits, simulates scheduling against each configured node group, and grows the cheapest group that fits; it removes a node when the *requests* on it stay below a threshold (default 50%) for a period (default 10 minutes) and its pods can be placed elsewhere [Kubernetes Autoscaler Docs]. **Karpenter** has no node groups: it reads the pending pods' requirements, picks instance types directly from the cloud catalog (including spot capacity), launches right-sized nodes, and continuously **consolidates** by replacing under-used nodes with fewer or cheaper ones [Karpenter Docs].
- **KEDA** (Kubernetes Event-Driven Autoscaling) scales on external event sources such as queue depth, Kafka consumer lag or a Prometheus query, and can scale a workload to and from **zero**; above zero it drives an HPA it creates for you [KEDA Docs].

Figure 42.12 — The autoscaling layers and the signals between them.



Reading the diagram. Metrics flow asynchronously into the HPA (or KEDA) and usage history into the VPA; both write to the Deployment, one setting the replica count, the other the per-pod requests. New pods go to the scheduler; those that fit nowhere stay Pending, which is the *only* signal the node autoscaler acts on: it calls the cloud API and a new node joins one to three minutes later. Scale-down runs the other way: the node autoscaler drains and removes nodes whose requested capacity is low. Failure points: a stale metrics pipeline freezes the HPA; cloud quota or capacity shortages leave pods

Pending indefinitely; aggressive consolidation evicts pods repeatedly. Scaling: the total reaction time is the sum of the stages, which is what headroom must cover (§18.8.4).

Table 42.9 — Autoscaler interaction pitfalls.

Pitfall	What happens	Fix
HPA and VPA both on CPU	VPA raises requests, so HPA's utilization falls and it removes pods; per-pod usage rises; VPA raises requests again	HPA on RPS or lag; VPA for memory or recommendations only
Requests far below real usage	Nodes run hot, but by requests they look empty: no scale-up, and scale-down removes busy nodes	Set requests from measured p95 usage (VPA recommendations)
HPA `maxReplicas` beyond node-autoscaler limits	HPA asks for pods that stay Pending at peak	Size node pool limits and quotas for `maxReplicas` × requests
No PodDisruptionBudget	Scale-down or consolidation evicts several replicas at once	PDB with `maxUnavailable: 1` on every service
Scale to zero on a latency path	First request waits for pod start, and maybe a node	Keep `minReplicas ≥ 1` where cold starts break the objective
KEDA plus a hand-written HPA on one Deployment	Two controllers fight over replicas	Let KEDA own the HPA

RECOMMENDATION

Recommendation — A default autoscaling stack. HPA (or KEDA for queue workers) on a metric proportional to load; VPA in recommendation mode feeding request reviews; a node autoscaler with some always-on headroom (low-priority placeholder pods that real pods preempt, §42.13.2) so scale-out does not wait for a VM; PodDisruptionBudgets everywhere.

42.13 Scheduling

Placing pods on nodes is a multi-dimensional bin-packing problem solved online, one pod at a time, under constraints. Chapter 46 treats cluster scheduling theory (Borg, Omega, gang scheduling, fairness); this section covers what you configure in Kubernetes and the arithmetic that sizes a cluster.

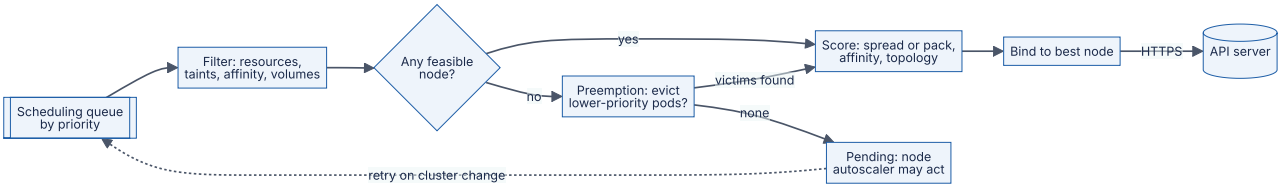
42.13.1 Filtering and scoring

The scheduler takes one pod at a time from a priority queue and runs it through a pipeline of **plugins** [Kubernetes Docs: Scheduling Framework]:

1. **Filter.** Remove nodes that cannot run the pod: not enough *unrequested* CPU or memory (`NodeResourcesFit`), a taint the pod does not tolerate, unmet node affinity, a topology-spread violation, a volume in another zone.
2. **PostFilter.** If no node passes, try **preemption** (§42.13.2); otherwise the pod stays Pending and the node autoscaler takes over.
3. **Score.** Each scoring plugin rates every feasible node from 0 to 100; weighted scores are summed.
4. **Bind.** Write the decision to the API server; the kubelet does the rest.

For large clusters the scheduler stops filtering once it has found enough feasible nodes; by default the fraction searched falls from 50% of nodes at 100 nodes to a floor of 5% in very large clusters, trading placement quality for throughput.

Figure 42.13 — The scheduling pipeline for one pod.



Reading the diagram. Pods leave a priority queue one at a time. Filtering removes infeasible nodes; if none remain, the scheduler checks whether evicting lower-priority pods would make room (their graceful termination then proceeds asynchronously), and otherwise leaves the pod Pending and requeues it when the cluster changes, such as a new node joining. Scoring ranks the survivors and the binding is a synchronous write to the API server, the storage boundary. Failure points: unsatisfiable constraints (a required anti-affinity with more replicas than nodes) leave pods Pending forever; a slow scheduler delays every rollout. Scaling: one active scheduler handles typically hundreds of pods per second; constraints such as inter-pod affinity are the expensive ones.

42.13.2 Placement constraints

- **Taints and tolerations** repel. A taint on a node (`gpu=true:NoSchedule`) keeps off every pod without a matching toleration; `NoExecute` also evicts running ones. Use them to reserve special nodes (GPUs, a dedicated tenant). Pods tolerate `not-ready` and `unreachable` node taints for 300 s by default, which is how long a pod on a dead node waits before eviction.
- **Node affinity** attracts: “only on `arm64` nodes”, “prefer spot nodes”. `required...` rules filter; `preferred...` rules score.
- **Pod affinity and anti-affinity** place pods relative to other pods: a cache near its service (affinity), two replicas never on the same node (anti-affinity).
- **Topology spread constraints** bound the imbalance: with `maxSkew: 1` and `topologyKey: topology.kubernetes.io/zone`, replica counts across zones differ by at most

one, so losing a zone loses about a third of replicas in a three-zone cluster.

- **Priority and preemption.** A `PriorityClass` ranks pods. When a high-priority pod cannot fit, the scheduler evicts lower-priority pods to make room, honoring PodDisruptionBudgets where possible. A cheap trick for fast scale-out is a Deployment of negative-priority **placeholder pods** that reserve headroom: real pods preempt them instantly, and the evicted placeholders go Pending, prompting the node autoscaler to add a node in the background.

42.13.3 Requests, limits and QoS classes

The scheduler packs by **requests** only; the kernel enforces **limits** (§42.3.2). Actual usage plays no part in placement. From requests and limits, Kubernetes derives a **quality-of-service class** that decides who dies first under memory pressure.

Table 42.10 — QoS classes.

Class	Rule	Eviction order under node pressure	OOM score adjustment
Guaranteed	Every container has CPU and memory requests equal to limits	Last	−997
Burstable	At least one request or limit, not Guaranteed	Middle, by usage above request	2–999
BestEffort	No requests or limits at all	First	1,000

Practical rules: always set memory request equal to memory limit for services (memory is not compressible, and a pod using more than it requested is the first evicted); set a CPU request from measured usage; set CPU limits only where you must cap a noisy or untrusted workload, because limits cause throttling even on idle nodes (§42.3.2). Use Guaranteed for latency-critical pods, optionally with the kubelet’s static CPU manager, which gives integer-CPU Guaranteed pods dedicated cores.

42.13.4 Bin-packing, pods per node and cluster cost

FORMULA

Pods per node

$$N_{\text{pods}} = \min\left(\min_{r \in \{\text{cpu, mem}\}} \left\lfloor \frac{A_r - D_r}{q_r} \right\rfloor,\ N_{\max},\ N_{\text{IP}}\right) \qquad A_r = C_r - K_r$$

Symbol	Meaning	Units
C_r	Node capacity of resource r	CPU or GiB
K_r	Reserved for kubelet, system daemons and the eviction threshold	CPU or GiB
A_r	Allocatable: what pods may request	CPU or GiB
D_r	Requests of DaemonSet pods on every node (CNI, logging, monitoring)	CPU or GiB
q_r	Request of one application pod	CPU or GiB
$N_{\max}$	Kubelet `max-pods` (default 110)	pods
N_{IP}	Pod IP limit of the network plugin (for example, per-node interface limits with VPC-native CNIs)	pods

WORKED EXAMPLE

Worked example — Packing the ordering service onto 8 vCPU / 32 GiB nodes. Assume the provider reserves $K = 0.09$ CPU and 4.4 GiB (managed providers publish formulas reserving a shrinking fraction of larger nodes), DaemonSets request $D = 0.4$ CPU and 0.75 GiB, and each ordering pod requests 0.5 CPU and 1 GiB.

1. Allocatable: $8 - 0.09 = 7.91$ CPU; $32 - 4.4 = 27.6$ GiB.
2. After DaemonSets: 7.51 CPU; 26.85 GiB.
3. CPU bound: $\lfloor 7.51/0.5 \rfloor = 15$ pods. Memory bound: $\lfloor 26.85/1 \rfloor = 26$ pods. $N_{\max} = 110$.
4. $N_{\text{pods}} = 15$, CPU-bound. Memory left unrequested: $26.85 - 15 = 11.85$ GiB, 44% of what pods could use.

Interpretation. Nearly half the memory you pay for is stranded because the pod's shape (1 GiB per CPU) does not match the node's (4 GiB per CPU). **Engineering implication.** Match node shape to the dominant pod shape (a compute-optimized family here), or co-locate memory-heavy pods so both resources fill; with VPC-native networking check N_{IP} too, which on small instances can be lower than either resource bound.

The scheduler's default scoring spreads load; you can switch the `NodeResourcesFit` strategy to pack instead.

FORMULA

Resource scoring strategies (per resource, then averaged with weights)

$$\text{LeastAllocated} = 100 \times \frac{A_r - U_r}{A_r} \qquad \text{MostAllocated} = 100 \times \frac{U_r}{A_r}$$

Symbol	Meaning	Units
A_r	Allocatable amount of resource r on the node	CPU or GiB
U_r	Requests on the node including the pod being placed	CPU or GiB
Score	Node preference, higher is better	0–100

WORKED EXAMPLE

Worked example — Spreading versus packing six 1-CPU pods on three 4-CPU nodes (the last lines of the §42.6.3 program).

1. Placing a pod when node-1 is empty and node-3 already holds 2 CPU: LeastAllocated scores node-1 at $100 \times 3/4 = 75$ and node-3 at $100 \times 1/4 = 25$, so it picks node-1. MostAllocated scores them 25 and 75 and picks node-3.
2. Result: LeastAllocated places 2/2/2; MostAllocated places 4/2/0.
3. Now a pod requesting 3 CPU arrives. Spread: every node has $4 - 2 = 2$ CPU free, so it is **unschedulable** although 6 CPU are free in total. Packed: the empty node fits it, or, if no such pod comes, the node autoscaler removes the empty node and saves a third of the cost.

Interpretation. Spreading leaves balanced headroom and limits the blast radius of a node failure (2 of 6 pods lost instead of 4); packing reduces fragmentation and cost. **Engineering implication.** Use packing in cost-sensitive or batch clusters, and keep availability with topology spread constraints and PodDisruptionBudgets rather than relying on the default spread.

FORMULA

Cluster size and monthly cost from requests

$$N_{\text{nodes}} = \max_{r} \left\lceil \frac{\sum q_r}{(A_r - D_r)\,\eta} \right\rceil \qquad C_{\text{month}} = N_{\text{nodes}} \times p \times 730 + C_{\text{cp}}$$

Symbol	Meaning	Units
$\sum q_r$	Total requests of resource r across all pods at peak replica counts	CPU or GiB
$A_r - D_r$	Requestable capacity per node after DaemonSets	CPU or GiB
η	Achievable packing efficiency (fragmentation, surge and headroom)	fraction
p	Node price	$/hour
730	Hours per month	h
C_{cp}	Managed control-plane fee	$/month

WORKED EXAMPLE

Worked example — QuickBite's production cluster. Its 40 services request 120 vCPU and 360 GiB at peak. Nodes are 16 vCPU / 64 GiB with 15.4 CPU and 56 GiB requestable after reservations and DaemonSets, at an illustrative $0.77 per hour on demand; $\eta = 0.8$; the managed control plane costs an illustrative $0.10 per hour (similar to published EKS and GKE fees as of 2026).

1. CPU: $120/(15.4 \times 0.8) = 120/12.32 = 9.7 \Rightarrow 10$ nodes.
2. Memory: $360/(56 \times 0.8) = 360/44.8 = 8.04 \Rightarrow 9$ nodes.
3. $N_{\text{nodes}} = 10$ (CPU-bound).
4. Cost: $10 \times 0.77 \times 730 = \$5,621$; control plane $0.10 \times 730 = \$73$; total about $5,694 per month.
5. Monitoring shows pods use on average 40% of their CPU requests, so real CPU utilization is $120 \times 0.4/(10 \times 16) = 48/160 = 30\%$. Rightsizing CPU requests to 85 vCPU (p95 usage plus margin) gives $85/12.32 = 6.9 \Rightarrow 7$ nodes for CPU, but memory still needs 9: $9 \times 0.77 \times 730 + 73 = \$5,132$, saving about 10%.

Interpretation. Requests, not usage, decide the bill, and once CPU is rightsized memory becomes the binding resource, so further savings need memory rightsizing or a node shape with more memory per CPU. **Engineering implication.** Review requests against usage regularly (VPA recommendations), choose node shapes for the binding resource, run interruption-tolerant stateless pods on discounted spot capacity, and remember that surviving the loss of one of three zones requires about 50% more nodes than this steady-state figure (§18.11.2 derives zone-level sizing; Chapter 44 extends it to regions).

42.14 Persistent volumes

A container's writable layer dies with it, and a pod can be rescheduled to another node, so durable state needs storage whose lifetime is independent of pods. Kubernetes separates *what an application needs* from *what the infrastructure provides*:

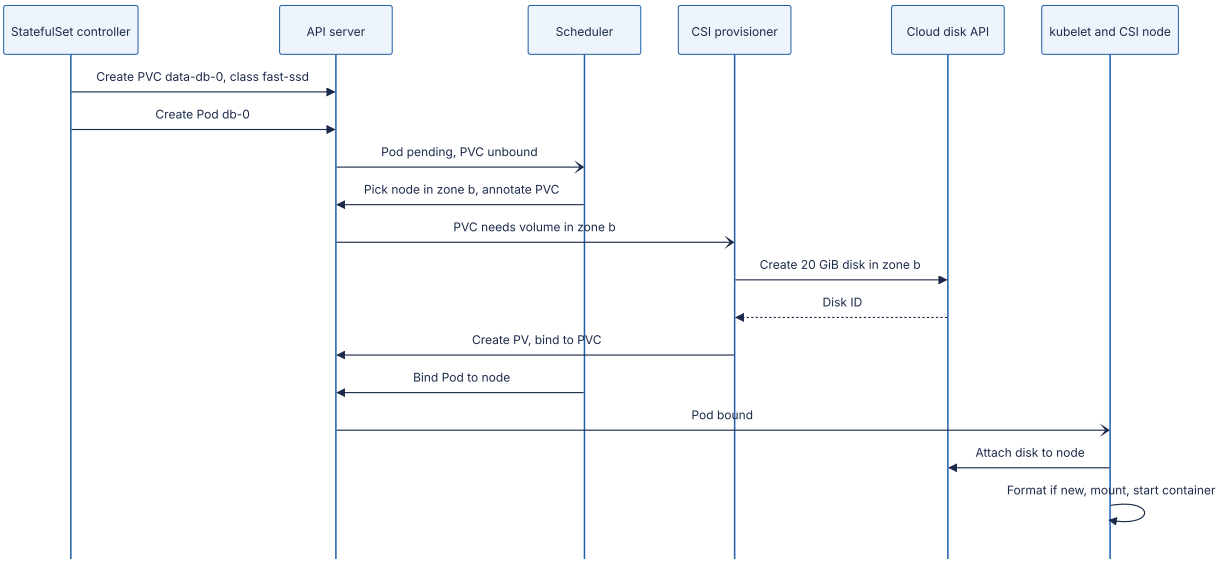
- A **PersistentVolumeClaim (PVC)** is the application's request: "20 GiB, ReadWriteOnce, class `fast-ssd`".
- A **PersistentVolume (PV)** is a piece of real storage (a cloud block disk, an NFS export) bound to one claim.
- A **StorageClass** describes how to create PVs on demand: the provisioner, disk type, and the **reclaim policy** (`Delete` destroys the disk with the claim; `Retain` keeps it for manual recovery).
- The **Container Storage Interface (CSI)** is the plugin API through which storage vendors implement provisioning, attaching and mounting, outside the Kubernetes

code base.

Table 42.11 — Access modes.

Mode	Meaning	Typical backing
ReadWriteOnce (RWO)	Read-write by pods on one node	Cloud block disks
ReadWriteOncePod (RWOP)	Read-write by exactly one pod	Block disks, strict single writer
ReadOnlyMany (ROX)	Read-only from many nodes	Snapshots, shared datasets
ReadWriteMany (RWX)	Read-write from many nodes	NFS and cloud file services

Figure 42.14 — Dynamic provisioning with topology-aware binding.



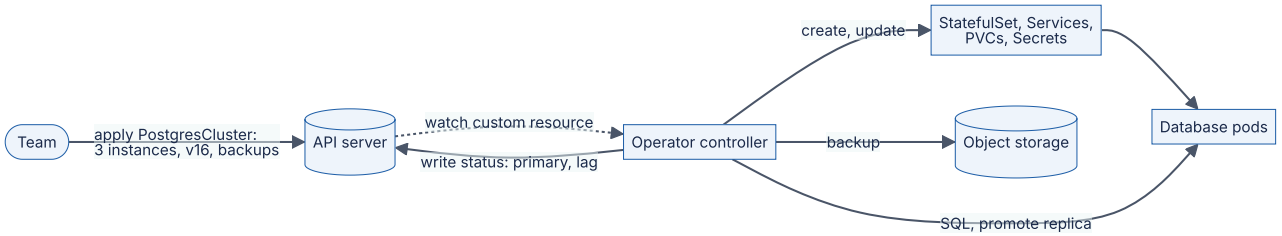
Reading the diagram. With `volumeBindingMode: WaitForFirstConsumer`, the disk is not created until the scheduler has chosen a node, so the disk lands in the same zone as the pod; creating it first (`Immediate`) can strand a pod whose disk sits in a zone with no capacity. The provisioner creates the disk through the cloud API and records it as a PV bound to the claim; the kubelet attaches and mounts it. Arrows with open heads are watch notifications. Failure points: zonal block disks cannot follow a pod to another zone, so a zone outage strands RWO volumes; attach and detach take tens of seconds and can hang when a node dies uncleanly; deleting a claim under a `Delete` policy destroys the data. Scaling: one disk per StatefulSet ordinal, so capacity grows with replicas; replication across zones is the application's job (Chapter 27).

42.15 Operators and custom resources

A **CustomResourceDefinition (CRD)** adds a new object type to the API server, such as `PostgresCluster`, with a schema, validation and versioning, stored in etcd and served with the same RBAC, watches and `kubectl` support as built-in types. A CRD alone is just data.

An **operator** is a custom controller that reconciles those objects, encoding a human operator's knowledge (how to bootstrap a replica, fail over a primary, take a backup, upgrade one minor version at a time) in a reconciliation loop. CoreOS introduced the pattern in 2016 [Philips 2016].

Figure 42.15 — The operator pattern for a database.



Reading the diagram. The team declares a whole database cluster as one custom resource. The operator watches it asynchronously and reconciles it into built-in objects (StatefulSet, Services, claims, Secrets), and it also acts *inside* the application, synchronously: checking replication lag, promoting a replica when the primary fails, triggering backups to object storage. Status flows back to the custom resource. Failure points: the operator is privileged automation, so a bug can fail over or delete many databases at once; if the operator is down, the database runs but does not self-heal. Scaling: one operator manages many instances, which is the point.

Operators are built with Kubebuilder, controller-runtime or the Operator SDK. Adopting one means trusting its failover logic with your data: test its failure handling (Chapter 27) as you would your own.

> COMMON MISTAKE
>
> **Common misconception — "With an operator, running databases on Kubernetes is the same as a managed database."** The operator automates procedures; you still own disks, backups, restore drills, upgrades, capacity and the operator itself. For teams without database operations experience, a managed cloud database is usually cheaper in total.

42.16 Kubernetes versus serverless

Kubernetes gives control and portability at the price of operating a platform; serverless gives the platform away at the price of control (§33.9 introduced the trade-off and its break-even arithmetic, Chapter 48 goes deeper).

Table 42.12 — Managed Kubernetes, serverless containers and functions (as of 2026).

Row	Managed Kubernetes (EKS, GKE, AKS)	Serverless containers (Cloud Run, Fargate)	Functions as a service (Lambda)
What it is	You run workloads on node pools; provider runs the control plane	You supply an image; provider runs hosts and scaling	You supply a function; provider runs everything
How it works	Pods scheduled onto your nodes by controllers	Instances per image, scaled by requests or tasks	Sandbox per concurrent invocation, scale to zero
Advantages	Full control, any workload, rich ecosystem, portable	Little operations, containers unchanged, scale to zero (Cloud Run)	No servers, per-request billing, event integration
Disadvantages	Platform team needed; upgrades every few months	Fewer knobs; limits on resources and networking	Cold starts, duration and package limits, lock-in
Performance	Warm pods; predictable latency	Cold starts when scaling from zero	Cold starts; one request per environment on Lambda
Operational complexity	High	Low to medium	Low
Cost	Pay for nodes, used or not; cheapest at steady high load	Per vCPU-second while serving or running	Per request and GB-second; cheapest when spiky or low
Use cases	Large service fleets, stateful systems, GPUs, custom networking	Web APIs, workers, teams without a platform team	Event glue, bursty APIs, scheduled tasks
Choose when	Many services, steady load, a platform team, special hardware	Containers wanted without cluster operations	Traffic is low or spiky and functions are small

The choice is rarely all-or-nothing: a common pattern is Kubernetes for the steady core (QuickBite's ordering, dispatch and pricing) and functions for event glue (thumbnails, webhooks, nightly exports). Kubernetes-native options such as Knative and KEDA bring scale-to-zero into a cluster, but you still pay for the nodes beneath it.

42.17 Summary and revision notes

SUMMARY

- A container is a host process with namespaces (what it sees), cgroups (what it uses) and an image root file system; it shares the kernel, so isolation is weaker than a VM's. Sandboxed runtimes and microVMs close the gap.
- cgroup v2 weights share CPU only under contention; `cpu.max` quotas throttle even on idle nodes: $t_{\text{throttle}} = P - LP/k$ when k threads burst. Memory past `memory.max` means an OOM kill (exit 137).
- kubelet → CRI → containerd → shim → runc → kernel. OCI specifications standardize runtime, image and distribution.
- Images are content-addressed layers; order Dockerfiles for caching, use multi-stage builds and minimal bases; pull time $\approx S_c/B + S_u/R$ adds directly to scale-out reaction time.
- Deploy by digest, sign with cosign, scan continuously, mirror registries.
- Every component talks only to the API server; etcd stores everything; controllers are level-triggered reconciliation loops, so the system converges after any failure.
- Pods share a network namespace; init containers run first; native sidecars (stable since 1.33) start before and stop after the app; startup, liveness and readiness probes answer different questions; drain with `preStop` and a grace period.
- Rolling updates keep at least $R - \lfloor uR \rfloor$ pods available; use `maxUnavailable: 0` near capacity. StatefulSets give identity and storage, not replication.
- Every pod has a routable IP; Services balance connections, not requests; nftables and eBPF replace iptables and IPVS; Gateway API replaces Ingress.
- Encrypt Secrets at rest with KMS v2, restrict RBAC and prefer external stores or workload identity.
- HPA, VPA, node autoscalers and KEDA interact through requests; never let HPA and VPA act on the same metric.
- The scheduler filters and scores on requests; QoS classes order evictions; pods per node and cluster cost follow from requests, allocatable and packing efficiency.
- PVC, PV, StorageClass and CSI decouple storage; operators encode operations in controllers; choose serverless when load is spiky and there is no platform team.

42.18 Knowledge checkpoint

1. Which namespace gives a container its own port space, and which makes root inside unprivileged outside?

2. A pod has a 1-CPU limit and 4 runnable threads. How long is it throttled per 100 ms period?
3. Why does deleting a file in a later Dockerfile layer not shrink an image?
4. Why pin images by digest rather than tag?
5. What happens to running pods if the whole control plane goes down?
6. Why is a level-triggered controller more robust than an edge-triggered one?
7. What problem do native sidecar containers solve for Jobs?
8. Why should a liveness probe not check the database?
9. $R = 20$, defaults 25%/25%. Compute minimum available and maximum pods.
10. Why does one gRPC client often send all its requests to a single pod behind a ClusterIP Service?
11. A pod requests 250 m CPU and uses 400 m. What CPU utilization does the HPA see?
12. A node has 7.5 CPU and 28 GiB requestable after DaemonSets; pods request 1 CPU and 3 GiB. How many fit, and which resource binds?
13. Why use `WaitForFirstConsumer` for zonal disks?
14. Which QoS class is evicted first under memory pressure?

Answers

1. The network namespace; the user namespace.
2. $Q = 100$ ms; $t_{run} = 100/4 = 25$ ms; throttled 75 ms.
3. The earlier layer still holds the bytes; the later layer only adds a whiteout.
4. A tag is mutable; a digest names exact bytes, so every node runs identical code and rollbacks are exact.
5. They keep running and Services keep forwarding; nothing new is scheduled, replaced or rolled out.
6. It acts on current state, so missed, duplicated or reordered events and restarts do not cause wrong results.
7. A sidecar running as an ordinary container never exits, so the Job never completes; native sidecars are stopped after the main containers finish.
8. When the shared database slows, every pod fails liveness and restarts together, turning a slowdown into an outage.
9. $u = \lfloor 5 \rfloor = 5$, so 15 available; $s = \lceil 5 \rceil = 5$, so 25 pods at most.
10. Services balance connections at set-up, and gRPC multiplexes all requests over one long-lived HTTP/2 connection.
11. $400/250 = 160\%$.
12. CPU allows 7, memory $\lfloor 28/3 \rfloor = 9$; 7 pods, CPU-bound.
13. The disk is created in the zone of the node the scheduler chose, so the pod and its disk cannot end up in different zones.
14. BestEffort.

42.19 Interview questions

Basic

Q1. What is the difference between a container and a virtual machine? Answer. A container is a process isolated by namespaces and limited by cgroups on a shared kernel; it starts in under a second with almost no overhead. A VM runs its own kernel on a hypervisor, giving stronger isolation at the cost of boot time and memory. For untrusted tenants use a sandboxed runtime or microVM.

Q2. Walk through what happens after `kubectl apply` of a Deployment. Answer. The API server authenticates, authorizes, runs admission and validation, and stores the object in etcd. The Deployment controller creates a ReplicaSet, which creates pods; the scheduler binds each to a node; the kubelet has the runtime create the sandbox (CNI assigns an IP), pull images and start containers; once readiness passes, the pod is added to EndpointSlices and kube-proxy programs rules.

Intermediate

Q3. Latency spikes but CPU is at 40% of the limit. Diagnose. Answer. Suspect CFS throttling: parallel bursts exhaust the per-period quota and freeze the cgroup. Check `nr_throttled` and `throttled_usec`. Fix by sizing runtime parallelism to the limit, raising the limit, or removing CPU limits for latency-critical services while keeping accurate requests.

Q4. How do you deploy without dropping requests? Answer. Readiness probes gate traffic; `maxUnavailable: 0` with a surge keeps capacity; a `preStop` delay lets endpoint removal propagate before `SIGTERM`; the app drains in-flight requests within `terminationGracePeriodSeconds`; a PodDisruptionBudget protects against concurrent node drains; compatible API and schema changes handle mixed versions.

Advanced

Q5. Design autoscaling for a service with a daily peak and a Kafka-based worker tier. Answer. HPA on per-pod RPS for the service with a target derived from load tests and reaction time (§18.8.4); KEDA on consumer lag for workers, possibly to zero off-peak; VPA in recommendation mode for requests; Karpenter or Cluster Autoscaler with placeholder pods for headroom; scheduled pre-scaling before the peak; PDBs; check that `maxReplicas` fits node limits and that downstream databases tolerate the extra connections.

Q6. Your 300-node cluster costs too much. What do you do? Answer. Compare requests with usage per service and rightsize (VPA data); find the binding resource and

stranded capacity per node shape; switch scoring to MostAllocated or use Karpenter consolidation; move interruption-tolerant pods to spot; remove idle namespaces and oversized DaemonSets; check that availability constraints (topology spread, PDBs) still hold after packing.

42.20 Practical exercises

1. Run a container with `docker run --cpus=1` and a 4-thread busy loop; read `cpu.stat` and compare `nr_throttled` with the formula of §42.3.2.
2. Rewrite a single-stage Dockerfile for a service you know as a multi-stage, non-root, distroless build; record size and pull time before and after.
3. Extend the §42.6.3 program with a Deployment controller that performs a rolling update with maxSurge and maxUnavailable, and assert the bounds of §42.8.1 at every round.
4. In a test cluster, delete a pod while sending steady traffic, with and without a `preStop` sleep; count failed requests.
5. Compute pods per node and cluster cost for your own services with the formulas of §42.13.4 and compare with your real bill.

42.21 Design challenges

1. **Multi-tenant SaaS platform.** 200 customers each run the same three services; some demand isolation. Choose namespaces, node pools, RuntimeClasses, NetworkPolicies and quotas, and estimate the cost of dedicated nodes for 10% of tenants.
2. **Stateful on Kubernetes.** QuickBite wants PostgreSQL on Kubernetes across three zones. Choose an operator, storage class, backup and failover design, and state what happens on a zone loss.
3. **Platform choice.** A 12-engineer startup with 8 services and spiky traffic: Kubernetes, serverless containers or functions? Decide with cost arithmetic (§33.9.3, §42.13.4) and an operations budget.

42.23 Open verification items

- Kubernetes feature status (as of 2026): native sidecars stable in 1.33; nftables kube-proxy stable in 1.33; in-place pod resize stable and IPVS mode deprecated in 1.35; maturity of pod user namespaces and the `preStop` sleep action.
- Go 1.25 cgroup-aware default `GOMAXPROCS`; JVM container support since JDK 10 / 8u191.
- Firecracker figures (≈125 ms boot, < 5 MiB overhead) against the NSDI 2020 paper.
- Scheduler default for nodes searched (50% at 100 nodes, 5% floor).

- Image sizes, node reservations and cloud prices in worked examples are illustrative.
- Borg quotations (“hundreds of thousands of jobs”, ~10,000-machine cells, five-replica Borgmaster) against Verma et al. 2015.

Chapter 43 — Deployment and Infrastructure

> **Level:** 3 · **Track:** A (Traditional) · **Estimated reading time:** 5.5 h

Most outages do not come from hardware failing at random. They come from people changing a running system: a new build, a configuration edit, a schema migration, a firewall rule. Google's SRE book reports that roughly 70% of outages are caused by changes to a live system [Beyer et al. 2016]. You cannot stop changing software, because every feature and every fix is a change. What you can control is *how* change reaches production: how small each change is, how many users see it first, how quickly you notice a problem, and how quickly you undo it.

This chapter covers the pipeline from commit to artifact (§43.3), four ways to expose a new version (§43.4–§43.7) with the statistics that judge a canary, infrastructure as reviewed code (§43.8–§43.10), pipeline credentials and supply chain (§43.11), change-aware monitoring (§43.12) and database migrations (§43.13). The running example is QuickBite, the hypothetical food-delivery platform of Chapter 2; every QuickBite number is a teaching assumption.

43.1 Learning objectives

After this chapter you should be able to:

- Describe a continuous-delivery pipeline, trunk-based development and the four DORA metrics.
- Compare rolling, blue–green and canary deployments and feature flags on risk, cost and complexity, and choose one for a given service.
- Compute the blast radius of a bad deploy under all-at-once and canary rollouts, and the cost of blue–green.
- Judge a canary with a two-proportion z-test, size the canary sample, and explain how Kayenta-style judges score many metrics.
- Use feature flags for release, kill switches and progressive rollout while controlling flag debt.
- Explain declarative IaC, idempotence and drift; write a small Terraform configuration with locked remote state; explain GitOps reconciliation.
- Replace long-lived pipeline keys with OIDC workload identity, and describe SLSA levels, SBOMs and artifact signing.

- Correlate incidents with deployments, and plan an expand–contract database migration that is safe under rolling deploys.

43.2 Prerequisites

- SLOs and error budgets — §39.6, §39.7 (deployment risk is measured against them).
- Kubernetes Deployments and rolling updates — §42.8 (summarized, not repeated, in §43.4).
- Secrets management, workload identity and mTLS — §10.8, §10.10.2 (the pipeline applies them).
- Load balancing and health checks — Chapter 19 (traffic switching relies on them).
- Binomial distribution, normal distribution and standard error — §4.6.4, §4.7.2, §4.18.4 (the canary statistics).
- Relational schemas and table locks — §11.15 (why `ALTER TABLE` can stall traffic).
- Independent deployability of microservices — §34.12.

43.3 CI/CD

43.3.1 Continuous integration, delivery and deployment

DEFINITION

Definition — Continuous integration (CI). The practice of merging every developer's work into a shared mainline at least daily, with each merge verified by an automated build and test run.

Definition — Continuous delivery (CD). The practice of keeping the mainline always releasable, so that any commit that passes the automated pipeline *could* be deployed to production by pushing a button [Humble and Farley 2010].

Definition — Continuous deployment. Continuous delivery with the button removed: every commit that passes the pipeline is deployed to production automatically.

First-principles explanation

Picture a kitchen where every cook works alone for a week and the dishes are combined on Friday night: the sauces clash and nobody knows whose change broke the menu. Now picture every cook bringing a spoonful to the head chef every hour, so problems are found while small. CI is the hourly tasting. CD is keeping every plate ready to serve at any moment.

Why does this exist?

Before CI, integration was a project measured in weeks (“integration hell”): conflicts grew with time since the last merge, a failure could hide in any of hundreds of changes, and releases became rare, risky events. Humble and Farley’s *Continuous Delivery* (2010) argued that the remedy is counter-intuitive: if releasing hurts, do it *more often*, so each release is small and the process is automated and rehearsed thousands of times.

How it works internally: the deployment pipeline

A **deployment pipeline** is the automated path from a commit to production. Each stage gives more confidence and costs more time, so the cheap, fast checks run first and fail fast.

1. **Build.** Compile, resolve dependencies from pinned versions, and produce a build once. A rule from Humble and Farley: *build binaries once*, then promote the same artifact through every later stage, so the thing you tested is the thing you ship.
2. **Unit test.** Thousands of fast tests with no network or disk, typically finishing in under 5–10 minutes.
3. **Static analysis.** Linters, type checkers, security scanners (static application security testing), dependency vulnerability scans and secret scanning (§10.8).
4. **Artifact.** Package an immutable, versioned artifact (a container image identified by its content digest, §42.4), generate its SBOM and provenance and sign it (§43.11), and push it to a registry (§42.5).
5. **Integration and acceptance test.** Deploy the artifact to a production-like environment and run API, contract (§34.8.5) and end-to-end tests against real dependencies or high-fidelity fakes.
6. **Deploy.** Promote the same artifact to staging and then production with a progressive strategy (§43.4–§43.7), watched by automated analysis (§43.6.4).

Figure 43.1 — A deployment pipeline from commit to production.

Reading the diagram. A push to the Git mainline triggers the CI system by webhook. The pipeline builds once, tests and scans that build, and stops on any failure (only the final gate’s failure path is drawn). Packaging pushes an immutable, signed artifact to the registry, the storage boundary between “built” and “deployed”: every later stage pulls the same digest. Production deploys progressively while monitoring receives metrics and deployment markers asynchronously (dotted arrows) and can trigger rollback. Failure points: flaky tests, a slow integration stage that encourages batching, and a registry outage that halts all deploys. Scaling: parallel stages, dependency caches and sharded test suites keep the commit stage short.

RECOMMENDATION

Recommendation — Keep the commit stage under ten minutes. If build, unit tests and static analysis take 40 minutes, people batch commits and skip the pipeline before merging. Move slow suites later and parallelize the rest.

43.3.2 Trunk-based development

DEFINITION

Definition — Trunk-based development. A source-control practice in which all developers commit to a single shared branch (the trunk or mainline), either directly or through short-lived branches that live for hours to a day or two, and the trunk is kept releasable at all times [Hammant n.d.].

The alternative, long-lived feature branches, accumulates weeks of divergence that must be merged at once. The DORA research found that teams with fewer than three active branches, branch lifetimes under a day and no code freezes had higher delivery performance [Forsgren et al. 2018].

How do you commit half-finished work to an always-releasable trunk? Unfinished features hide behind **feature flags** (§43.7); large refactorings use **branch by abstraction** (§34.13.2); and incompatible changes are split into compatible steps with **expand and contract** (§43.13). Deployment and release are separated: code can be in production for weeks before any user sees it.

43.3.3 The DORA four key metrics

How do you know whether your delivery process is good? The DevOps Research and Assessment (DORA) program, presented in *Accelerate* [Forsgren et al. 2018] and the annual State of DevOps reports, identified four measures that predict organizational performance. Two measure **throughput** and two measure **stability**.

DEFINITION

Definition — The four key metrics.

- **Deployment frequency** — how often the organization deploys code to production.
- **Change lead time** — the time from a commit being made to that commit running successfully in production.
- **Change failure rate** — the percentage of deployments to production that cause a failure needing remediation (a rollback, hotfix, patch or incident).
- **Failed deployment recovery time** — how long it takes to restore service after a deployment causes a failure. Earlier reports called this *time to restore service* or mean time to restore (MTTR); the 2023 report narrowed it to deployment-caused failures [DORA 2023].

The central finding of *Accelerate* is that the two pairs are **not a trade-off**: across thousands of survey responses, teams that deployed more often also had lower change failure rates and faster recovery [Forsgren et al. 2018]. Small batches are the mechanism: a deployment of two changes is easy to diagnose and revert. In recent reports, the top performance cluster deploys on demand (several times a day), has a change lead time under a day and recovers from failed deployments in under an hour (as of 2024; cluster boundaries are recomputed each year) [DORA 2024].

Mathematical foundations

FORMULA

Expected degraded time from deployments

$$D = f \times \mathrm{CFR} \times T_{\text{restore}}$$

Symbol	Meaning	Units
D	Expected time per period during which a bad deployment is degrading service	minutes/week
f	Deployment frequency	deployments/week
CFR	Change failure rate	fraction (0–1)
T_{restore}	Mean failed deployment recovery time	minutes

WORKED EXAMPLE

Worked example — Is deploying more often riskier? Two QuickBite teams each merge 80 changes per week.

- *Team A* deploys twice a week, so each deploy carries $80/2 = 40$ changes. CFR is 20%; recovery takes 240 min, because finding the bad change among 40 is slow.
- *Team B* deploys 40 times a week, 2 changes per deploy, CFR 5%, recovery 30 min (automated rollback).

Failed deployments per week: Team A $2 \times 0.20 = 0.4$; Team B $40 \times 0.05 = 2.0$. Team B has *five times as many* failed deployments.

Degraded time per week: Team A $D = 0.4 \times 240 = 96$ min; Team B $D = 2.0 \times 30 = 60$ min.

Now relate this to an error budget (§39.7). Over a 30-day month ($30/7 = 4.29$ weeks), Team A is degraded for $96 \times 4.29 = 411$ min and Team B for $60 \times 4.29 = 257$ min. If a typical bad deploy fails 10% of requests, the full-outage equivalents are 41.1 min and 25.7 min. A 99.9% monthly SLO allows 43.2 min. Team A spends 95% of its budget on deployments alone; Team B spends 60%.

Interpretation: counting failed deployments makes Team B look worse; weighting by recovery time reverses the conclusion, because small changes are cheap to diagnose and undo. *Engineering implication:* read all four metrics together, and pair higher frequency with automated rollback.

COMMON MISTAKE

Mistake — Using DORA metrics as targets for individuals or teams. Targets invite gaming: artificially split deploys, reclassified incidents (Goodhart's law). Use the metrics to find bottlenecks, not to rank people.

43.4 Rolling deployments

DEFINITION

Definition — Rolling deployment. A deployment that replaces the instances of the old version with instances of the new version a few at a time, so that the service keeps serving throughout and, for the duration of the rollout, both versions serve traffic side by side.

A rolling deployment repaints a bridge one lane at a time, without closing it. It is the default in Kubernetes, where a Deployment's `RollingUpdate` strategy creates new pods up to `maxSurge` above the desired count and removes old pods while keeping at most `maxUnavailable` below it; a new pod receives traffic only once its readiness probe passes.

Chapter 42 covers the mechanism and derives the capacity floor and approximate duration of a rollout from `maxSurge` and `maxUnavailable` (§42.8.1). For QuickBite's 10-pod ordering service with `maxSurge: 3` and `maxUnavailable: 0`, a rollout takes about four 45-second waves, roughly three minutes. Read that number as a release-risk figure: a bug that readiness probes miss reaches *every* user within three minutes, and after the first wave 30% of traffic already sees it. A plain rolling update is a coarse canary with no judgment, so add a pause with analysis after the first wave (§43.6), or use a progressive-delivery controller such as Argo Rollouts or Flagger.

Rolling deployments are cheap (only the surge is extra capacity) and simple. Their weaknesses are that rollback is itself another rolling update (minutes, not seconds), that mixed versions serve simultaneously, and that exposure grows on a fixed schedule rather than on evidence.

43.5 Blue–green deployments

43.5.1 How blue–green works

> DEFINITION
>
> **Definition — Blue-green deployment.** A deployment that runs two complete production environments, one live (say blue) and one idle (green). The new version is deployed to and tested on the idle environment, and then all traffic is switched to it at once at the routing layer; the old environment is kept, unchanged, for instant rollback [Fowler 2010].

First-principles explanation

A theater with two stages can set up the next scene on the dark stage while the audience watches the lit one, then swap the lights. If the new set collapses, the lights go back.

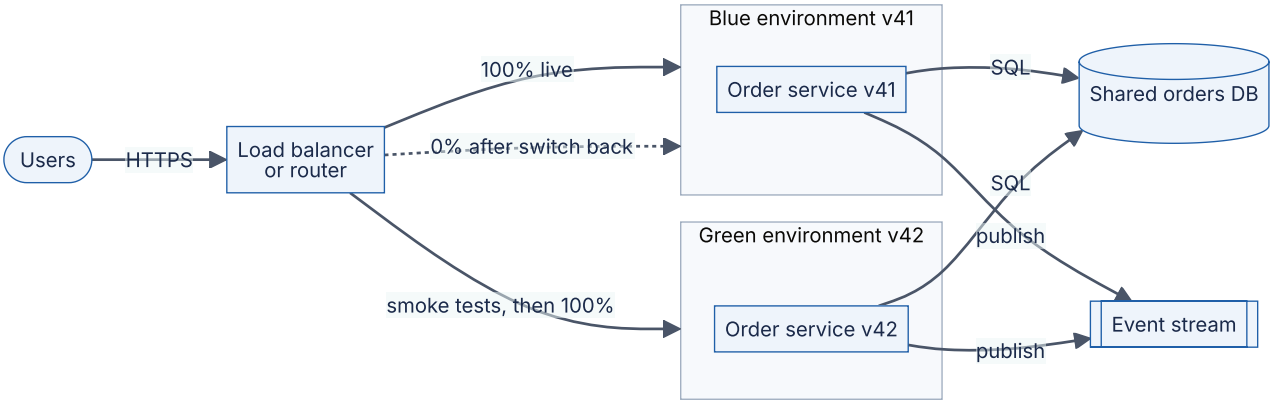
Why does this exist?

Rolling deployments mix versions and roll back slowly. Some systems need an atomic cutover (old and new versions disagree on a protocol), verification in production before exposure, or rollback in seconds. Blue–green provides all three.

How it works internally

1. **Blue is live.** The router (DNS, a load balancer listener, a Kubernetes Service selector or a service-mesh route) points at blue.
2. **Deploy to green.** Provision or update the green environment with the new artifact. It shares the same databases and queues as blue.
3. **Verify green.** Run smoke tests and synthetic transactions against green's private endpoint; warm caches and connection pools.
4. **Switch.** Change the router to send all new requests to green. Let blue drain in-flight requests.
5. **Watch.** Keep blue running and untouched for a bake period (minutes to hours).
6. **Roll back or retire.** If green misbehaves, switch the router back. Otherwise blue becomes the idle environment for the next release, or is torn down.

Figure 43.2 — Blue-green traffic switch at the load balancer.



Reading the diagram. Users reach one routing point over HTTPS. Before the switch it sends all traffic to blue (v41) while green (v42) receives only smoke tests; afterwards the roles reverse, and blue stands by at 0% (dotted arrow) for rollback. The subgraphs are separate deployment boundaries, but both use the *same* database and event stream, so the schema must suit both versions (§43.5.3). Failure points: DNS-based switches leave clients on blue for the TTL (§7.6), long-lived connections do not follow the switch, and blue's background workers keep consuming. Scaling: green must be sized for full load before the switch, which is the source of the cost.

43.5.2 Switching mechanisms

Table 43.1 — Ways to switch traffic between blue and green.

Mechanism	Switch time	Notes
DNS record change	Minutes to hours	Clients and resolvers cache for the TTL; avoid for fast rollback
Load balancer target group or listener rule	Seconds	Common on clouds; connection draining handles in-flight requests
Kubernetes Service selector (`version: green`)	Seconds	Endpoints update as kube-proxy or the dataplane reprograms
Service-mesh or gateway route weight	Seconds	Also enables gradual shifts, which turns blue–green into a canary

43.5.3 Database compatibility

The shared database is the hard part. Fowler's original description already points out that switching application code is easy while the database must serve both versions [Fowler 2010]. Three rules follow.

1. **Schema changes must be backward compatible.** Green's schema must still work for blue, or rollback is impossible. Apply schema changes as a separate, earlier step (expand), and remove old structures only after blue is gone (contract); see §43.13.
2. **Data written by green must be readable by blue.** If green writes a new enum value or a new event version, blue must tolerate it after a switch back. Use tolerant readers and avoid new required fields.
3. **Background work must be switched too.** Queue consumers, cron jobs and schedulers in blue keep running after the HTTP switch unless they are scaled down or disabled; otherwise both versions process messages.

43.5.4 Cost

FORMULA

Extra cost of blue-green

$$\Delta C = C_{\text{env}} \times k \times \frac{n_{\text{dep}} \times T_{\text{overlap}}}{T_{\text{month}}}$$

Symbol	Meaning	Units
ΔC	Extra infrastructure cost per month	$/month
C_{env}	Monthly cost of one full production environment	$/month
k	Fraction of the environment duplicated (1 for blue–green; the canary weight for a canary)	fraction
n_{dep}	Deployments per month	deployments/month
T_{overlap}	Time both versions run per deployment	hours
T_{month}	Hours in a month (≈ 730)	hours

WORKED EXAMPLE

Worked example — Blue-green cost for QuickBite. The order platform's compute costs $C_{\text{env}} = \$30,000$ per month. QuickBite deploys it $n_{\text{dep}} = 40$ times a month.

1. *Permanent blue–green* (two full environments always running): the overlap is the whole month, so $\Delta C = \$30,000$, a 100% overhead.
2. *Ephemeral green* (provisioned one hour before the switch and blue kept for one hour after, $T_{\text{overlap}} = 2$ h): $\Delta C = 30,000 \times 1 \times (40 \times 2)/730 = 30,000 \times 0.1096 = \$3,288$ per month, an 11% overhead.
3. *Canary* at 5% for one hour ($k = 0.05$, $T_{\text{overlap}} = 1$ h): $\Delta C = 30,000 \times 0.05 \times 40/730 = \$82$ per month.

Interpretation: blue–green's cost is driven by how long the duplicate runs, not by the switch itself. *Engineering implication:* on elastic infrastructure, create green on demand and retire blue after the bake period, scaling green to full capacity *before* the switch; keep permanent duplicates only where provisioning is slow or seconds-level rollback justifies a doubled bill.

INDUSTRY EXAMPLE

Cloud-managed blue-green. Several managed services implement blue–green directly: AWS CodeDeploy supports blue–green deployments for EC2, ECS and Lambda, shifting traffic between target groups or function aliases, and Amazon RDS offers blue/green deployments for database version upgrades, in which a staging copy is kept in sync by replication and switched over with a short write pause (as of 2026) [AWS Docs: CodeDeploy; AWS Docs: RDS Blue/Green]. The database case shows the general rule: a blue–green switch of a *stateful* system needs replication and a brief write freeze, not just a routing change. *Evidence: Primary* — [AWS Docs: CodeDeploy; AWS Docs: RDS Blue/Green]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Rollback breaks after a schema change	Green migrated the schema destructively	Blue errors on switch back	Restore schema or roll forward with a fix	Expand–contract; contract only after blue retired
Green overloaded at switch	Green scaled down or caches cold	Latency spike right after switch	Switch back; pre-scale	Size green to production peak; warm caches
Duplicate message processing	Blue's consumers still running	Duplicate side effects, consumer lag in both	Stop blue consumers	Include workers in the switch; idempotent consumers (§22.15)

43.6 Canary releases

43.6.1 What a canary release is

DEFINITION

Definition — Canary release. A deployment that sends a small, controlled fraction of production traffic to the new version, compares its behavior with the current version, and increases the fraction in steps only while the comparison stays healthy; otherwise traffic is returned to the old version [Sato 2014a].

First-principles explanation

Coal miners once carried a canary into the mine; the bird reacted to toxic gas before people did, giving the miners time to leave. A canary release sends the new version into production first with a small group of users. If it is going to fail, it fails for 1% of requests rather than 100%, and the failure is the warning that stops the rollout.

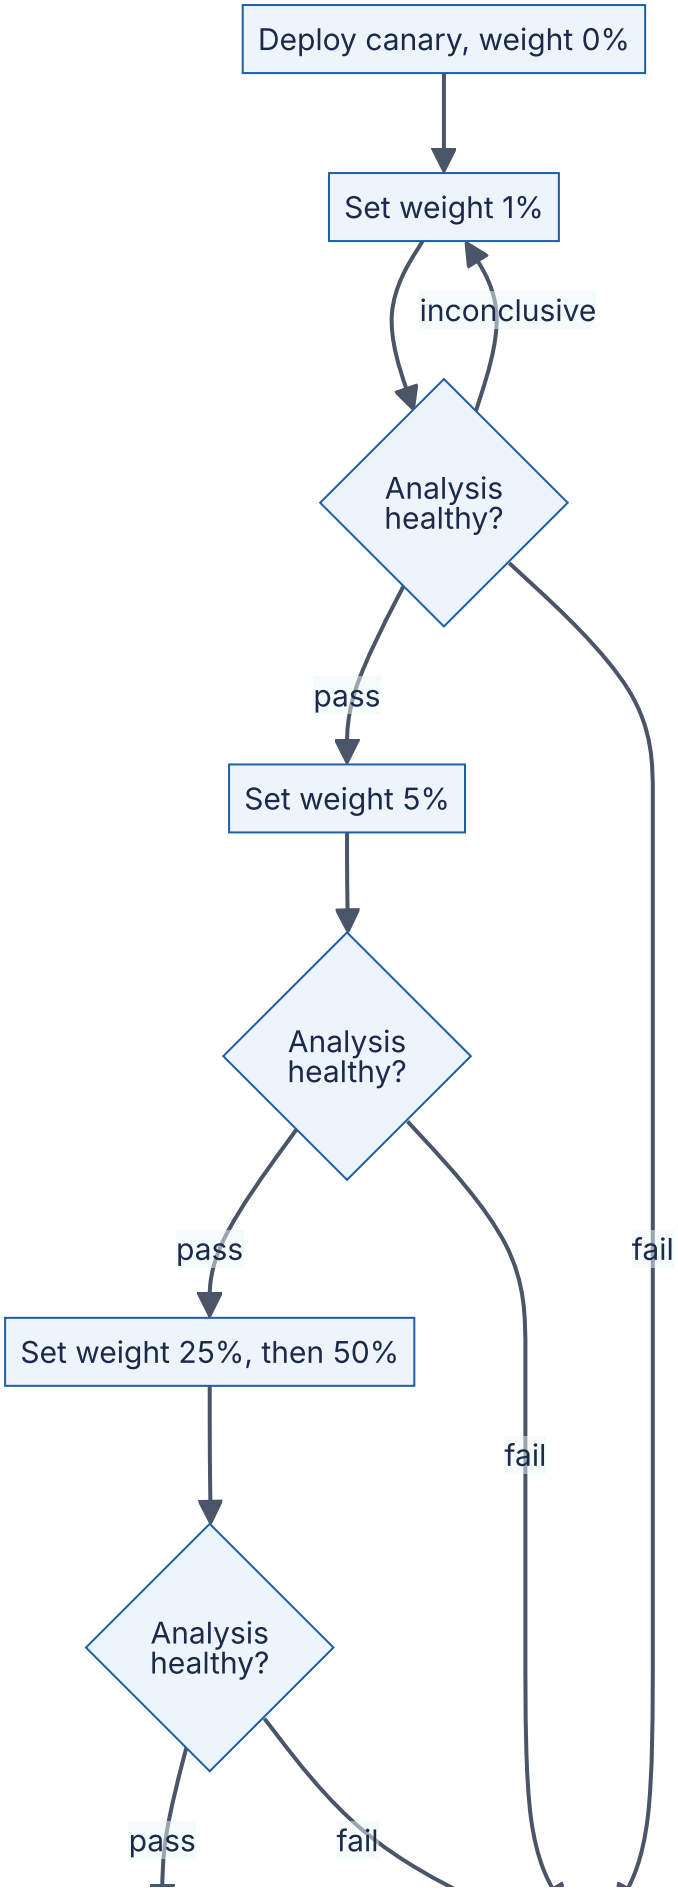
Why does this exist?

No staging environment reproduces production's traffic mix, data and scale; some bugs appear only under real load (a slow query on a hot partition) or real data (a name with an emoji). Blue–green verifies before exposure but then exposes everyone at once. A canary accepts production as the only full test and limits how many users it can hurt.

How it works internally

1. **Deploy** the new version alongside the old one with a small number of instances, but route it no traffic yet.
2. **Shift a small weight** of traffic (often 1–5%) to the canary.
3. **Observe** for an analysis interval: error rate, latency percentiles, saturation and business metrics (orders per minute), compared against a **baseline** running the old version.
4. **Judge.** If the canary is significantly worse, shift its weight to 0 and roll back automatically. If not, increase the weight (for example 1% → 5% → 25% → 50% → 100%), observing at each step.
5. **Promote** the new version to 100% and retire the old instances.

Figure 43.3 — Canary progression with automated analysis at each step.



Deploy canary, weight 0%
Set weight 1%
inconclusive
Analysis healthy?
pass
fail
Set weight 5%
Analysis healthy?
pass
fail
Set weight 25%, then 50%
fail
Analysis healthy?
pass
fail

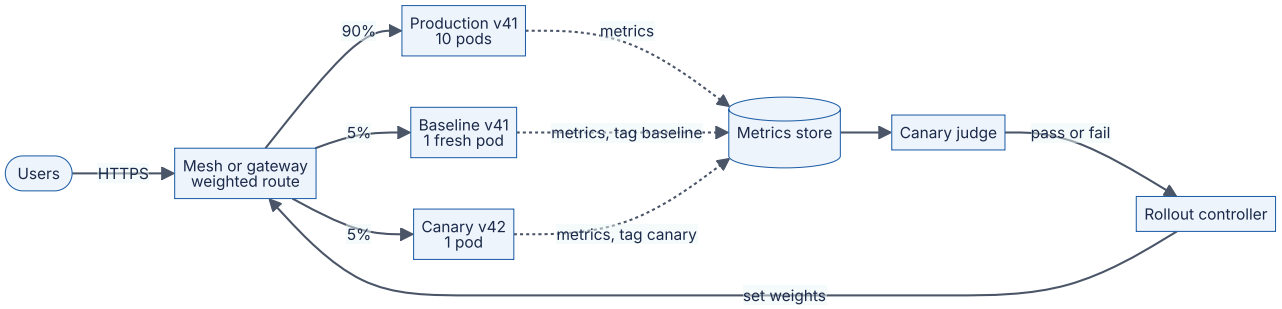
Reading the diagram. Rectangles set the traffic weight; diamonds are analysis intervals comparing canary with baseline. A pass advances, a fail at any step goes straight to roll-back, and an inconclusive result (too little data) repeats the interval (drawn only for the first step). A controller, not a person, makes every transition, so rollback takes seconds. Failure points: metrics that miss the failure, weights too small for the traffic, and an un-analyzed final jump to 100%. Scaling: high-traffic services pass the steps in minutes; low-traffic ones need longer steps.

43.6.2 Traffic splitting

The canary weight can be enforced at several layers:

- **By instance count.** Run 1 canary pod next to 19 old pods behind the same Service; a round-robin balancer sends about 5% of requests to the canary. Weights are limited to multiples of $1/N$.
- **By weighted routing.** A service mesh (§34.10), gateway or load balancer sends an exact percentage to each version, independent of instance counts. Argo Rollouts and Flagger work this way.
- **By request attribute.** Route by header, user cohort, region or tenant (employees first, then one city), giving a sticky population so users do not alternate between versions.

Figure 43.4 — Canary and baseline traffic split by a weighted router.



Reading the diagram. The router splits requests by weight: 90% to production, 5% to a small baseline and 5% to the canary. The baseline runs the *old* version but was started at the same moment and size as the canary, the comparison Netflix recommends, because comparing new processes with long-running ones confuses new code with cold caches and warm-up [Graff and Sanden 2018]. All groups emit tagged metrics asynchronously to a metrics store; the judge compares the baseline and canary series and the controller sets new weights. Failure points: missing or wrong tags, and routers that cannot split by exact weight. Scaling: the binding constraint is requests per interval in each group.

43.6.3 Blast radius

The **blast radius** of a bad deploy is the damage it does before it is reversed. A canary shrinks it in two ways: fewer users are exposed, and automated analysis shortens detection.

FORMULA

Blast radius of a bad deploy

$$B = \lambda \times w \times \Delta p \times (T_{\text{detect}} + T_{\text{rollback}})$$

Symbol	Meaning	Units
B	Extra failed requests caused by the bad version	requests
λ	Total request rate of the service	requests/s
w	Fraction of traffic sent to the new version	fraction (0–1)
Δp	Increase in error rate caused by the new version	fraction
T_{detect}	Time from exposure to the decision to roll back	s
T_{rollback}	Time to remove the new version from traffic	s

WORKED EXAMPLE

Worked example — All-at-once versus canary for a broken endpoint. QuickBite's order service (all endpoints, including order-status polling) handles $\lambda = 2,000$ requests/s at midday with a 0.5% baseline error rate. Version 42 breaks one endpoint and raises the error rate to 20%, so $\Delta p = 0.195$.

1. *All at once (or a fast rolling update):* $w = 1$. Humans notice through a symptom alert after $T_{\text{detect}} = 10$ min (600 s) and a redeploy of version 41 takes $T_{\text{rollback}} = 5$ min (300 s). $B = 2,000 \times 1 \times 0.195 \times 900 = 351,000$ failed requests.
2. *Canary at 5%:* $w = 0.05$. An error-rate jump this large is significant within the first 60 s analysis interval, and setting the weight to 0 takes 30 s. $B = 2,000 \times 0.05 \times 0.195 \times 90 = 1,755$ failed requests.

The canary's blast radius is $351,000/1,755 = 200$ times smaller: 20 times from exposure and 10 times from faster detection and rollback.

Against the error budget: a 99.95% monthly SLO (the order-placement target of §39.6) on $2,000 \times 2,592,000 = 5.18 \times 10^9$ requests (taking the midday rate as the monthly average, which understates both shares below) allows 2.59×10^6 failures. The all-at-once deploy burns $351,000/2.59 \times 10^6 = 13.5\%$ of the month's budget in 15 minutes; the canary burns 0.068%.

Engineering implication: the canary's value comes from *both* factors. A 5% canary watched by a human who notices after 10 minutes still loses $2,000 \times 0.05 \times 0.195 \times 900 = 17,550$ requests; automation contributes as much as the small weight.

43.6.4 Automated canary analysis: comparing proportions

A judge must answer: *is the canary's error rate higher than the baseline's by more than chance?* Errors are counts out of requests, so each group's error rate is a sample proportion. Even two identical versions will show slightly different rates in any interval, just as two fair coins tossed 1,000 times rarely show exactly the same number of heads. The **two-proportion z-test** measures the observed difference in units of its standard error (§4.18.4).

FORMULA

Two-proportion z-test (one-sided, canary worse)

$$\hat{p}_b = \frac{x_b}{n_b}, \quad \hat{p}_c = \frac{x_c}{n_c}, \quad \hat{p} = \frac{x_b + x_c}{n_b + n_c}$$

$$z = \frac{\hat{p}_c - \hat{p}_b}{\sqrt{\hat{p}(1-\hat{p})\left(\frac{1}{n_b} + \frac{1}{n_c}\right)}}, \qquad \text{p-value} = 1 - \Phi(z)$$

Symbol	Meaning	Units
x_b, x_c	Failed requests in baseline and canary	requests
n_b, n_c	Total requests in baseline and canary	requests
$\hat{p}_b, \hat{p}_c$	Observed error rates	fraction
$\hat{p}$	Pooled error rate, assuming no difference	fraction
z	Difference in standard errors	dimensionless
Φ	Standard normal cumulative distribution function	—
p-value	Probability of a z at least this large if the versions were equally good	probability

The test is valid when each group has at least about 10 expected errors and 10 expected successes, so that the normal approximation to the binomial (§4.6.4) holds. You choose a significance level α in advance, for example $\alpha = 0.01$; if the p-value is below α, the canary fails.

WORKED EXAMPLE

Worked example — Detecting an error-rate increase. In one analysis window the baseline served $n_b = 20,000$ requests with $x_b = 100$ errors, and the canary $n_c = 20,000$ requests with $x_c = 140$ errors.

1. Observed rates: $\hat{p}_b = 100/20,000 = 0.0050$; $\hat{p}_c = 140/20,000 = 0.0070$.
2. Pooled rate: $\hat{p} = 240/40,000 = 0.0060$.
3. Standard error: $\sqrt{0.006 \times 0.994 \times (1/20,000 + 1/20,000)} = \sqrt{0.005964 \times 0.0001} = \sqrt{5.964 \times 10^{-7}} = 7.723 \times 10^{-4}$.
4. $z = (0.0070 - 0.0050)/7.723 \times 10^{-4} = 0.0020/0.0007723 = 2.59$.
5. p-value $= 1 - \Phi(2.59) = 0.0048$.

Because $0.0048 < 0.01$, the judge fails the canary. If the canary had shown 104 errors instead of 140, $z = 0.28$ and the p-value would be 0.39: a difference of four errors is entirely consistent with chance, and the canary passes.

Interpretation: a 40% relative increase (0.5% → 0.7%) is detectable at this volume; with only 2,000 requests per group the same rates would give $z \approx 0.82$ and the judge could not tell. *Engineering implication:* a canary decision is only as good as its sample. Size the sample before choosing the canary weight and interval.

How many requests are enough? A test can make two errors: failing a healthy canary (a **false positive**, probability α) and passing a bad one (a **false negative**, probability β). The **power** $1 - \beta$ is the probability of catching a real regression of a given size.

FORMULA

Sample size per group to detect an increase from p_b to p_c

$$n = \frac{\left(z_{1-\alpha}\sqrt{2\bar{p}(1-\bar{p})} + z_{1-\beta}\sqrt{p_b(1-p_b)+p_c(1-p_c)}\right)^2}{(p_c - p_b)^2}, \qquad \bar{p} = \frac{p_b + p_c}{2}$$

$$T_{\text{decide}} = \frac{n}{\lambda \times w}$$

Symbol	Meaning	Units
n	Requests needed in each of baseline and canary	requests
p_b	Baseline error rate	fraction
p_c	Smallest canary error rate you want to catch	fraction
$z_{1-\alpha}$	Standard normal quantile for the false-positive rate (one-sided)	dimensionless
$z_{1-\beta}$	Standard normal quantile for the power	dimensionless
T_{decide}	Time for each group to collect n requests	s
λ, w	Service request rate; weight sent to each group	requests/s; fraction

WORKED EXAMPLE

Worked example — Sizing QuickBite's canary. Baseline error rate $p_b = 0.5\%$. You want to catch a 50% relative increase ($p_c = 0.75\%$) with $\alpha = 0.01$ ($z_{0.99} = 2.326$) and power 0.8 ($z_{0.80} = 0.842$).

1. $\bar{p} = (0.005 + 0.0075)/2 = 0.00625$.
2. First term: $2.326 \times \sqrt{2 \times 0.00625 \times 0.99375} = 2.326 \times \sqrt{0.012422} = 2.326 \times 0.11145 = 0.25928$.
3. Second term: $0.842 \times \sqrt{0.004975 + 0.0074438} = 0.842 \times \sqrt{0.012419} = 0.842 \times 0.11144 = 0.09379$.
4. Numerator: $(0.25928 + 0.09379)^2 = 0.35307^2 = 0.12466$.
5. Denominator: $(0.0075 - 0.005)^2 = 6.25 \times 10^{-6}$.
6. $n = 0.12466/6.25 \times 10^{-6} = 19,945.3$, so **19,946 requests per group**.

Time to decide at $\lambda = 2,000$ requests/s:

- $w = 5\%$ per group: 100 requests/s, $T_{\text{decide}} = 19,946/100 = 199$ s, about 3.3 minutes.
- $w = 1\%$ per group: 20 requests/s, $T_{\text{decide}} = 997$ s, about 17 minutes.
- At night, $\lambda = 200$ requests/s and $w = 1\%$: 2 requests/s, $T_{\text{decide}} = 9,973$ s, about 2.8 hours.

The required n falls quickly as the effect grows: about 6,000 requests per group to catch a doubling (0.5% → 1%), and 48 to catch the 0.5% → 20% break of §43.6.3. It rises quickly as the effect shrinks: about 110,000 for a 20% relative increase.

Interpretation: small regressions in rare events need a lot of traffic. *Engineering implication:* choose the smallest regression worth catching and set weight and interval so each step collects n requests; low-traffic services should also judge latency (every request reports it), lengthen steps, or accept catching only large breaks. Note that $B \approx \lambda w \Delta p \times n/(\lambda w) = n\,\Delta p$ when detection is sample-limited: about $19,946 \times 0.0025 \approx 50$ extra failures here, whatever the weight. A smaller weight hurts fewer users per second but for longer.

WARNING / TRADE-OFF

Warning — Peeking inflates false positives. If the judge re-runs the test every minute and fails the canary the first time $p < \alpha$, the chance of a false failure over many looks is much larger than α. Either test once at the planned sample size, divide α across the planned looks (a Bonferroni correction: 10 looks at $\alpha = 0.001$ each keeps the total at or below 0.01), or use a sequential test designed for repeated looks. The same issue appears in A/B testing (Chapter 57).

Code example: a canary judge

The following module implements the test, the sample-size formula and a three-way decision. It uses only the Python standard library.

```
        """Automated canary analysis for error rates: two-proportion z-test and sample
size."""
        from dataclasses import dataclass
        from math import ceil, sqrt
        from statistics import NormalDist

        STD_NORMAL = NormalDist()  # mean 0, standard deviation 1

        @dataclass(frozen=True)
        class Verdict:
            baseline_rate: float
            canary_rate: float
            z: float
            p_value: float          # one-sided: probability of a z this large if rates
are equal
            decision: str           # "PASS", "FAIL" or "INCONCLUSIVE"

        def two_proportion_z(x_base: int, n_base: int, x_can: int, n_can: int) ->
tuple[float, float]:
            """Return (z, one-sided p-value) for H1: canary error rate > baseline error
rate."""
            if min(n_base, n_can) <= 0:
                raise ValueError("both groups need at least one request")
            p_base, p_can = x_base / n_base, x_can / n_can
            pooled = (x_base + x_can) / (n_base + n_can)
            se = sqrt(pooled * (1 - pooled) * (1 / n_base + 1 / n_can))
            if se == 0:                       # no errors (or only errors) in both
groups
                return 0.0, 1.0
            z = (p_can - p_base) / se
            return z, 1 - STD_NORMAL.cdf(z)

        def required_n(p_base: float, rel_increase: float, alpha: float = 0.01, power:
float = 0.8) -> int:
            """Requests needed in EACH group to detect p_base -> p_base*
(1+rel_increase)."""
            p_can = p_base * (1 + rel_increase)
            z_a = STD_NORMAL.inv_cdf(1 - alpha)   # one-sided test
            z_b = STD_NORMAL.inv_cdf(power)
            p_bar = (p_base + p_can) / 2
            num = (z_a * sqrt(2 * p_bar * (1 - p_bar))
                   + z_b * sqrt(p_base * (1 - p_base) + p_can * (1 - p_can))) ** 2
            return ceil(num / (p_can - p_base) ** 2)

        def judge(x_base: int, n_base: int, x_can: int, n_can: int,
                  min_n: int, alpha: float = 0.01) -> Verdict:
            z, p = two_proportion_z(x_base, n_base, x_can, n_can)
            if p < alpha:
                decision = "FAIL"             # significant increase: roll back
            elif min(n_base, n_can) < min_n:
                decision = "INCONCLUSIVE"     # not enough traffic yet: keep waiting
            else:
```

```
                decision = "PASS"              # enough evidence that no large increase
exists
            return Verdict(x_base / n_base, x_can / n_can, z, p, decision)

        if __name__ == "__main__":
            n_needed = required_n(p_base=0.005, rel_increase=0.5)
            print(f"requests needed per group: {n_needed:,}")
            for label, x_can in [("healthy", 104), ("regressed", 140)]:
                v = judge(x_base=100, n_base=20_000, x_can=x_can, n_can=20_000,
min_n=n_needed)
                print(f"{label:9s} base={v.baseline_rate:.3%} canary=
{v.canary_rate:.3%} "
                      f"z={v.z:.2f} p={v.p_value:.4f} -> {v.decision}")
```

Running it prints:

```
requests needed per group: 19,946
healthy   base=0.500% canary=0.520% z=0.28 p=0.3894 -> PASS
regressed base=0.500% canary=0.700% z=2.59 p=0.0048 -> FAIL
```

The tests below check the worked examples and then simulate 400 canaries of each kind to confirm that the false-positive rate stays near α and the power near 0.8 (`random.binomialvariate` needs Python 3.12 or later). Save the module as `canary.py` next to the tests.

```
        import random
        from canary import two_proportion_z, required_n, judge

        z, p = two_proportion_z(100, 20_000, 140, 20_000)
        assert abs(z - 2.5898) < 1e-3 and abs(p - 0.0048) < 1e-4
        assert required_n(0.005, 0.5) == 19_946
        assert judge(100, 20_000, 104, 20_000, min_n=19_000).decision == "PASS"
        assert judge(100, 20_000, 140, 20_000, min_n=19_000).decision == "FAIL"
        assert judge(5, 1_000, 6, 1_000, min_n=19_000).decision == "INCONCLUSIVE"
        assert two_proportion_z(0, 100, 0, 100) == (0.0, 1.0)

        rng, n = random.Random(7), 19_946
        def fail_rate(p_canary: float, trials: int = 400) -> float:
            fails = 0
            for _ in range(trials):
                xb, xc = rng.binomialvariate(n, 0.005), rng.binomialvariate(n, p_canary)
                fails += judge(xb, n, xc, n, min_n=n).decision == "FAIL"
            return fails / trials

        false_positive, power = fail_rate(0.005), fail_rate(0.0075)
        print(f"false-positive rate {false_positive:.3f}, power {power:.3f}")
        assert false_positive < 0.03 and 0.72 < power < 0.88
        print("all tests passed")
```

What to notice:

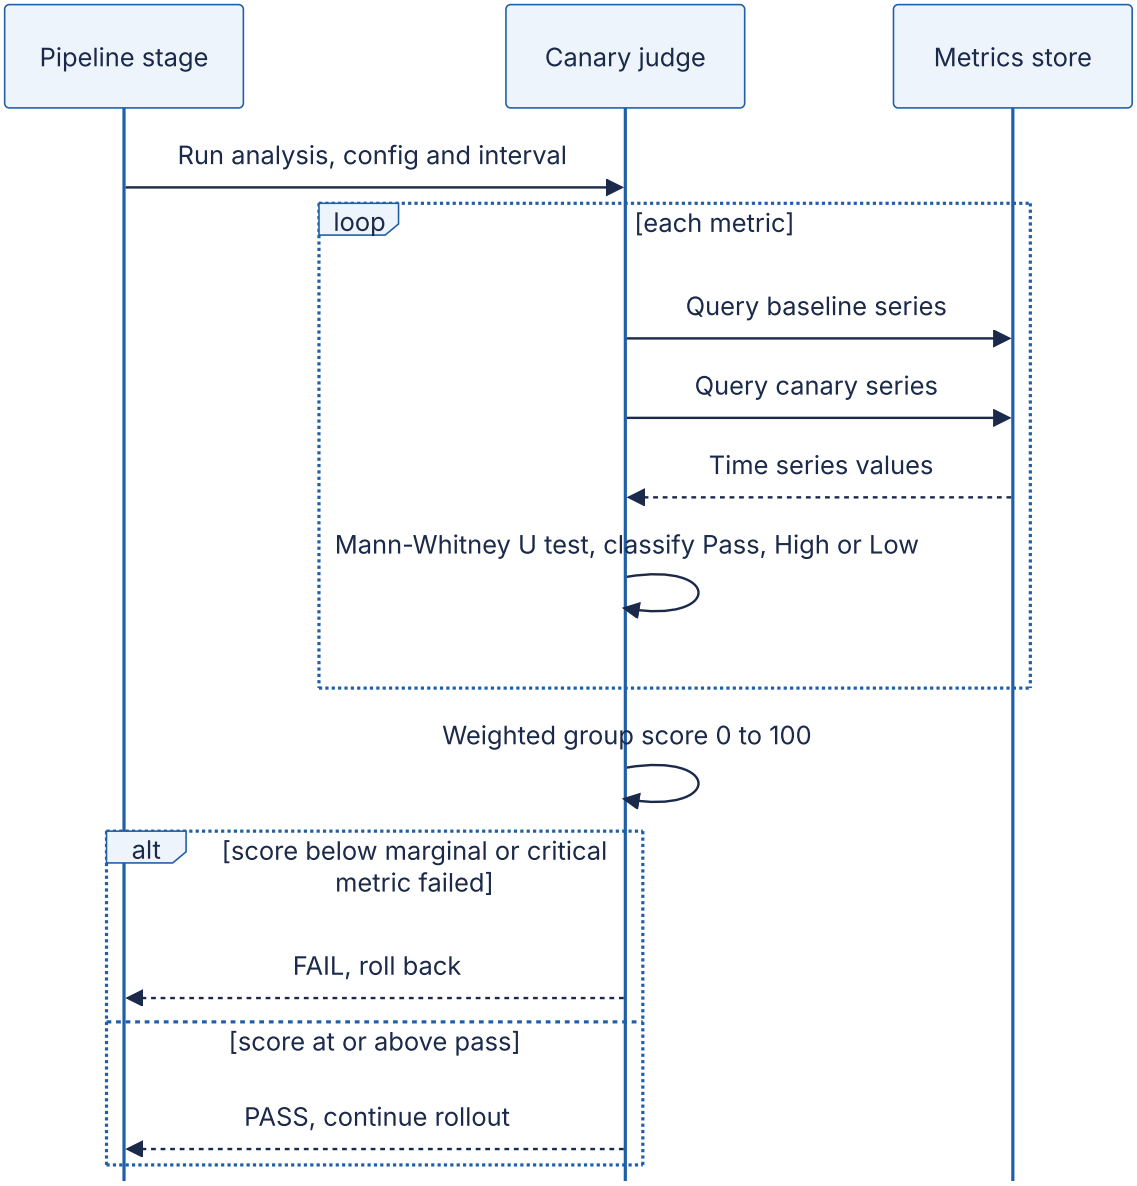
- The test is **one-sided** (only *worse* matters) and uses the pooled rate, because the null hypothesis says both groups share one error rate.
- The decision is three-way. A non-significant result on too little data is `INCONCLUSIVE`, not `PASS`; "no evidence of harm" is not "evidence of no harm".
- The simulation checks the error rates the design promises, not just the arithmetic.

43.6.5 Kayenta-style judging

Real canaries are judged on many metrics at once, not only on error rate: latency percentiles, CPU, memory, garbage-collection time, and business signals. In 2018 Netflix and Google released **Kayenta**, an open-source automated canary analysis service integrated with the Spinnaker continuous-delivery platform [Graff and Sanden 2018; Google Cloud 2018; Spinnaker Docs: Canary]. Its published design works as follows:

1. **Metric retrieval.** For each metric in a canary configuration, Kayenta queries the metrics store (Prometheus, Datadog, Stackdriver and others) for the baseline and canary time series over the analysis interval.
2. **Per-metric classification.** The default Netflix judge compares the two series with a nonparametric test, the **Mann–Whitney U test**, which does not assume normally distributed values (important for latency). Each metric is classified as *Pass*, *High* or *Low*; a configured direction says whether only increases, only decreases, or either count as failures.
3. **Scoring.** Metrics are grouped (for example "errors", "latency", "system"), and each group has a weight. The canary score is the weighted percentage of metrics that passed, from 0 to 100.
4. **Thresholds.** The configuration sets a *pass* threshold and a *marginal* threshold. A score below marginal fails the canary immediately; a score at or above pass lets it continue. Metrics can also be marked *critical*, so that their failure fails the whole canary regardless of score.

Figure 43.5 — A Kayenta-style judgment over one analysis interval.



Reading the diagram. The pipeline stage calls the judge with a configuration and interval. For each metric the judge fetches both series from the metrics store, classifies the metric with a statistical test, then combines the results into a weighted score and returns pass or fail. A canary stage runs several intervals and judges each one. Failure points: missing data (configurable as a failure), a metrics store outage (the rollout should pause, not pass), and noisy system metrics dominating the score. Scaling: queries grow with metrics × intervals, so configurations keep tens of metrics.

INDUSTRY EXAMPLE

Netflix and Google: Kayenta. Netflix ran automated canary analysis internally for years before open-sourcing Kayenta with Google in 2018. Its announcement describes a fresh, equal-size baseline cluster, per-metric Mann–Whitney classification and a weighted score that gates the Spinnaker pipeline [Graff and Sanden 2018]. Google's own guidance on canarying, in *The Site Reliability Workbook*, makes the same points about comparing against a control population and choosing metrics that reflect user-visible health [Beyer et al. 2018]. *Evidence: Primary* — [Graff and Sanden 2018; Google Cloud 2018; Beyer et al. 2018]

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Bad canary passes	Metrics miss the failure (for example correct HTTP 200 with wrong content)	Business metric drops after promotion	Roll back	Include business and correctness metrics; synthetic checks
Healthy canary fails repeatedly	Comparing against long-running production; noisy metrics	Many failed canaries with no real bug	Re-run with fresh baseline	Fresh equal-size baseline; drop noisy metrics
Canary contaminates shared state	New version writes bad data read by everyone	Data validation errors in old version	Roll back and repair data	Expand–contract; validate writes; limit canary to read paths first

COMMON MISTAKE

Mistake — "The canary passed, so the release is safe." A short canary on a sample cannot catch problems that appear only at 100% load (a saturated shared database), after hours (a memory leak) or for rare requests. Keep observing after promotion.

43.7 Feature flags

43.7.1 Separating release from deploy

DEFINITION

Definition — Feature flag (feature toggle). A runtime switch in the code that selects between code paths without a new deployment; its value is read from configuration or a flag service and can depend on the request context (user, tenant, region) [Hodgson 2017].

Definition — Deploy versus release. To **deploy** is to install a version of the code in production. To **release** is to let users experience a change. Feature flags make them separate events.

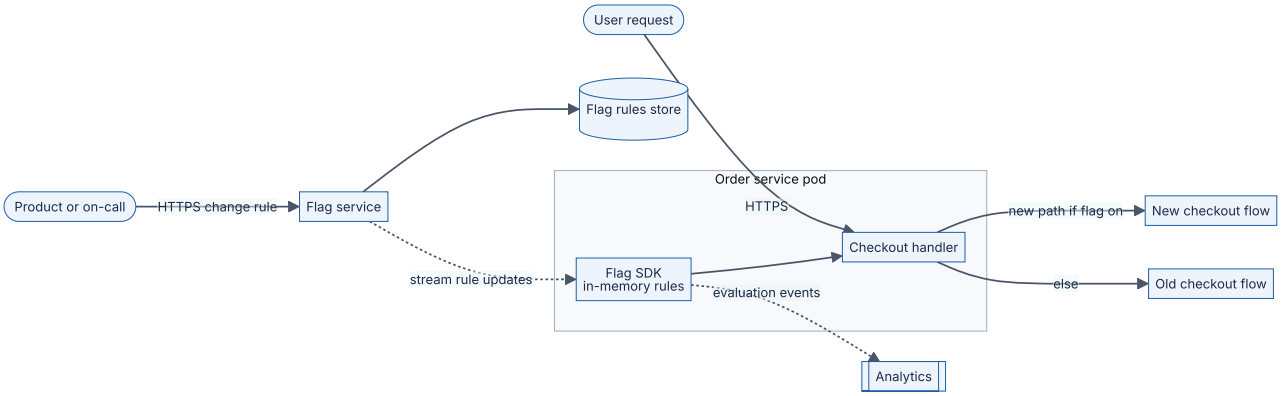
Deployment is the electrician installing wiring; the flag is the light switch, which a product manager can flip for 1% of users on Tuesday and everyone on Friday, and an on-call engineer can flip off at 3 a.m. without a rollback.

Without flags every deploy is also a product launch, and undoing the launch means undoing the deploy and every other change in it. With trunk-based development (§43.3.2), unfinished features must be merged daily, which is only possible if they can be turned off.

Hodgson classifies flags by how long they live and how dynamic they are [Hodgson 2017]:

- **Release toggles** hide unfinished or not-yet-launched features. They should live days to weeks.
- **Experiment toggles** split users between variants for A/B tests (Chapter 57). They live for the experiment.
- **Ops toggles** control operational behavior, including **kill switches** that disable an expensive or failing feature under load. Some live for years by design.
- **Permissioning toggles** enable features for specific users or plans (beta testers, premium tier). They are long-lived and are really product configuration.

Figure 43.6 — Feature flag evaluation in a service.



Reading the diagram. An administrator changes a rule in the flag service, which stores it and streams it asynchronously to an SDK in every pod. Evaluation is a local, in-memory call taking microseconds, with no network hop on the request path. Evaluation events flow asynchronously to analytics. Failure points: if the flag service is unreachable, SDKs keep last-known rules and need safe defaults at startup; a bad rule takes effect everywhere within seconds, so flag changes need review and audit like code. Scaling: streaming small rule sets to thousands of pods is cheap; never call the flag service per request.

43.7.2 Progressive rollout and kill switches

A **percentage rollout** must be *deterministic*: a user who sees the new checkout at 5% must still see it at 25%, and must not flip between versions on each request. The standard technique hashes the flag key together with the user ID into a bucket from 0 to 100 and compares the bucket with the rollout percentage.

```
        import hashlib

        def in_rollout(flag_key: str, user_id: str, percent: float) -> bool:
            """Deterministically place a user in [0, 100) and compare with the rollout
percent."""
            digest = hashlib.sha256(f"{flag_key}:{user_id}".encode()).digest()
            bucket = int.from_bytes(digest[:8], "big") % 10_000 / 100   # 0.00 .. 99.99
            return bucket < percent

        users = [f"user-{i}" for i in range(100_000)]
        at_5 = {u for u in users if in_rollout("new-checkout", u, 5)}
        at_25 = {u for u in users if in_rollout("new-checkout", u, 25)}
        print(len(at_5), len(at_25), at_5 <= at_25)   # prints: 5034 25212 True
```

What to notice:

- Including the flag key in the hash gives each flag an independent population; otherwise the same 5% of users would receive every experiment.
- Raising the percentage only adds users (`at_5 <= at_25`), so nobody loses a feature during a ramp.

- Python's built-in `hash()` is randomized per process for strings, so it would put a user in different buckets on different pods; a cryptographic or stable hash avoids that.

A **kill switch** is an ops toggle whose "off" position is a safe, degraded behavior: turn off restaurant recommendations and show a static list; turn off a new fraud model and fall back to rules. It is the fastest rollback you have (seconds, no deployment), but only for code paths someone thought to wrap in advance. Practice using kill switches, as you would practice restoring backups.

43.7.3 Flag debt

Every flag doubles the number of code paths it touches. A function influenced by k independent boolean flags has up to 2^k behaviors.

FORMULA

Configuration space of independent flags

$$S = 2^k$$

Symbol	Meaning	Units
S	Number of possible flag combinations	combinations
k	Number of independent boolean flags affecting the same code	flags

WORKED EXAMPLE

Worked example — Twelve flags in the checkout service. QuickBite's checkout service has accumulated $k = 12$ live flags. $S = 2^{12} = 4,096$ combinations. If an end-to-end test of one combination takes 2 minutes, testing all of them takes $4,096 \times 2 = 8,192$ min, about 5.7 days per release. Removing the eight release toggles that are already at 100% leaves $2^4 = 16$ combinations, 32 minutes. *Interpretation:* teams test only the combinations that production uses, so stale flags hide untested paths. *Engineering implication:* give every release toggle an owner and an expiry date at creation, fail the build when an expired flag is still referenced, and delete the flag and the dead branch in the same week the rollout reaches 100%.

INDUSTRY EXAMPLE

Knight Capital, 2012: a repurposed flag. According to the U.S. Securities and Exchange Commission's order, Knight Capital deployed new trading code to only seven of its eight servers. The new code reused a flag that had previously activated a long-unused function called "Power Peg". On the eighth server the old code was still present, so turning the flag on activated Power Peg, which sent millions of unintended orders in about 45 minutes; Knight lost more than $460 million [SEC 2013]. The failure combined three themes of this chapter: a manual, unverified deployment, dead code left behind an old flag, and the reuse of a flag with a different meaning. *Evidence: Primary* — [SEC 2013]

43.7.4 Comparing deployment strategies

Table 43.2 — Deployment strategies compared.

	Rolling	Blue–green	Canary	Feature flag (dark launch)
What it is	Replace instances in waves	Two full environments, atomic switch	Small, growing traffic share with analysis	Code deployed off; enabled at runtime
How it works	Orchestrator surges new, drains old	Router flips from blue to green	Weighted routing plus statistical judge	SDK evaluates rules per request
Advantages	Cheap; built into Kubernetes	Instant rollback; test before exposure	Smallest blast radius with evidence	Release without deploy; per-user targeting; kill switch
Disadvantages	Mixed versions; slow rollback; no judgment	Double capacity during overlap; all users at once	Needs traffic, metrics and tooling	Code complexity; flag debt; untested combinations
Performance	Surge capacity only	Cold caches risk at switch	Sample size limits speed (§43.6.4)	Microsecond local evaluation
Operational complexity	Low	Medium (two environments, shared data)	High (judge, mesh, baselines)	Medium (flag service, hygiene)
Cost	~ surge fraction during rollout	Up to 100% extra (§43.5.4)	~ canary weight during rollout	Flag service license or hosting
Use cases	Most stateless services	Stateful protocols; strict rollback needs	High-traffic, user-facing services	Product launches, experiments, ops toggles
Choose when	Changes are low risk and compatible	Rollback in seconds justifies cost	Bugs must be caught on a small sample	Release timing differs from deploy timing

The strategies combine rather than compete. A typical mature pipeline deploys each version with a canary (catching crashes and regressions in the code as a whole), while new features ship dark behind release toggles and are ramped separately (catching product and behavior problems per feature). Blue–green is common for components where mixed versions are dangerous and for infrastructure such as databases and load balancers.

COMMON MISTAKE

Mistake — Treating a flag as a substitute for compatibility. A flag switches *code paths*, not *data*. If the new path writes data the old path cannot read, turning the flag off does not restore correctness. Flagged features still need backward-compatible schemas and events (§43.13).

43.8 Infrastructure as code

43.8.1 Declarative versus imperative

DEFINITION

Definition — Infrastructure as code (IaC). Managing infrastructure (networks, machines, load balancers, databases, DNS, permissions) through machine-readable definition files kept in version control and applied by tools, instead of through manual console clicks or ad hoc scripts [Morris 2020].

Hand-configured servers become unique “snowflakes” nobody can reproduce, and a disaster-recovery region built by clicking is never quite like the primary. IaC makes every infrastructure change a reviewed commit, builds environments from the same code, and records who changed what and why.

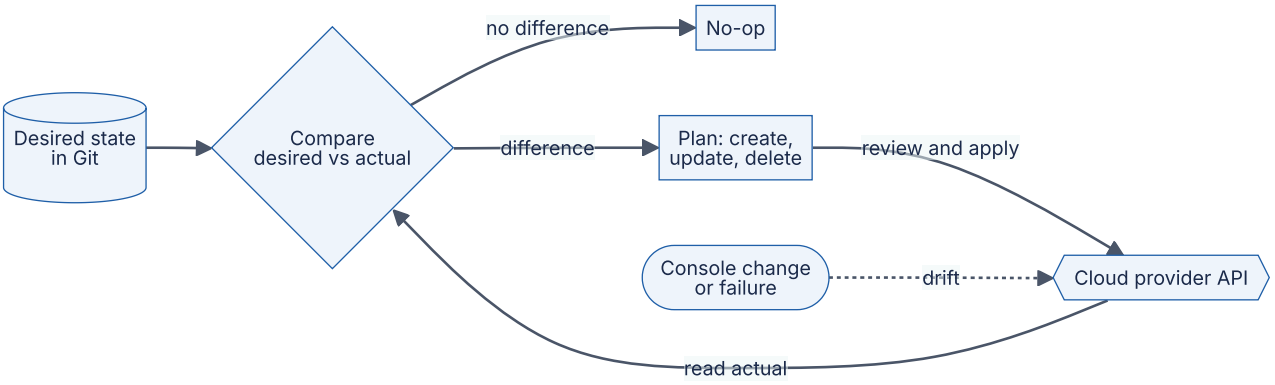
There are two styles. An **imperative** definition lists *steps*: “create a VM; then attach a disk; then open port 443”. A **declarative** definition states the *desired end state*: “there exist three VMs of this size, each with a disk, behind a load balancer that listens on 443”. A thermostat is declarative (you set 21 °C and it works out whether to heat), while “run the heater for ten minutes” is imperative. Terraform, OpenTofu, AWS CloudFormation and Kubernetes manifests are declarative; shell scripts and cloud SDK calls are imperative; Pulumi and the AWS CDK let you write general-purpose code that *produces* a declarative model.

DEFINITION

Definition — Idempotence. An operation is **idempotent** if applying it once or many times leaves the system in the same state. **Drift** is any difference between the state the code declares and the state that actually exists.

Declarative tools are idempotent by construction: they compare the desired state with the actual state and act only on the difference. Running “create a VM” twice gives two VMs; applying “there exist three VMs” twice gives three. Idempotence makes re-running an apply after a partial failure safe.

Figure 43.7 — The declarative reconciliation loop and drift.



Reading the diagram. The desired state lives in Git, a versioned storage boundary. The tool reads actual state from the provider API and computes the difference: none means a no-op (idempotence); otherwise it produces a plan of creates, updates and deletes that is reviewed and applied. The dotted arrow is drift: console edits, autoscalers or failures move the actual state asynchronously, and the next comparison shows a change that would revert it. Failure points: a plan that replaces a stateful resource, and blindly reverting an emergency fix. Scaling: large estates are split into many small configurations (§43.9.5).

Detecting drift. Run the comparison on a schedule. With Terraform, `terraform plan -detailed-exitcode` exits with code 0 when there are no changes and 2 when there are, which a scheduled job can turn into an alert [HashiCorp Docs: plan]. GitOps controllers (§43.10) detect and optionally revert drift continuously. When you find drift, decide deliberately: either revert it, or bring the code up to date so the change becomes reviewed history.

COMMON MISTAKE

Mistake — "We use IaC, so the console is fine for quick fixes." Every console change is drift that the next apply silently reverts or trips over. Make production consoles read-only, with a logged break-glass role followed by a code change.

43.9 Terraform

43.9.1 Providers, resources and the dependency graph

DEFINITION

Definition — Terraform. A declarative infrastructure-as-code tool from HashiCorp. Configurations are written in the HashiCorp Configuration Language (HCL); **providers** are plugins that translate resources into calls to a platform's API; a **resource** block declares one infrastructure object; **state** records which real object each resource corresponds to [HashiCorp Docs: Terraform].

A Terraform configuration is a set of `.tf` files in one directory (the **root module**). Its main building blocks are:

- `terraform` **block** — required Terraform version, required providers with version constraints, and the **backend** that stores state.
- **Providers** — `hashicorp/aws`, `hashicorp/google`, `hashicorp/kubernetes` and thousands more, downloaded from a registry by `terraform init` and pinned in a lock file (`.terraform.lock.hcl`).
- **Resources** — `resource "<type>" "<name>" { ... }` declares an object such as a bucket or a VM.
- **Data sources** — `data` blocks read existing objects without managing them.
- **Variables and outputs** — inputs to and results from a module.

Terraform builds a **dependency graph** from references between blocks. When a resource refers to `aws_s3_bucket.receipts.id`, Terraform knows the bucket must exist first. Independent resources are created in parallel (10 at a time by default).

43.9.2 A small, complete configuration

The configuration below creates a versioned bucket for QuickBite order receipts, stores state remotely in an S3 bucket with encryption and locking, and pins the provider version.

```
terraform {
  required_version = ">= 1.11"

  required_providers {
    aws = {
      source  = "hashicorp/aws"
      version = "~> 6.0"
    }
  }

  backend "s3" {
    bucket       = "quickbite-terraform-state"
    key          = "orders/receipts/terraform.tfstate"
    region       = "eu-west-1"
    encrypt      = true
    use_lockfile = true # S3-native state locking
  }
}

variable "environment" {
  type        = string
  description = "Deployment environment, for example staging or prod"

  validation {
    condition     = contains(["staging", "prod"], var.environment)
    error_message = "environment must be staging or prod."
  }
}

provider "aws" {
  region = "eu-west-1"

  default_tags {
    tags = {
      Service     = "orders"
      Environment = var.environment
      ManagedBy   = "terraform"
    }
  }
}

resource "aws_s3_bucket" "receipts" {
  bucket = "quickbite-receipts-${var.environment}"
}

resource "aws_s3_bucket_versioning" "receipts" {
  bucket = aws_s3_bucket.receipts.id

  versioning_configuration {
    status = "Enabled"
  }
}

resource "aws_s3_bucket_public_access_block" "receipts" {
  bucket                  = aws_s3_bucket.receipts.id
  block_public_acls       = true
```

```
  block_public_policy     = true
  ignore_public_acls      = true
  restrict_public_buckets = true
}

output "receipts_bucket_arn" {
  value = aws_s3_bucket.receipts.arn
}
```

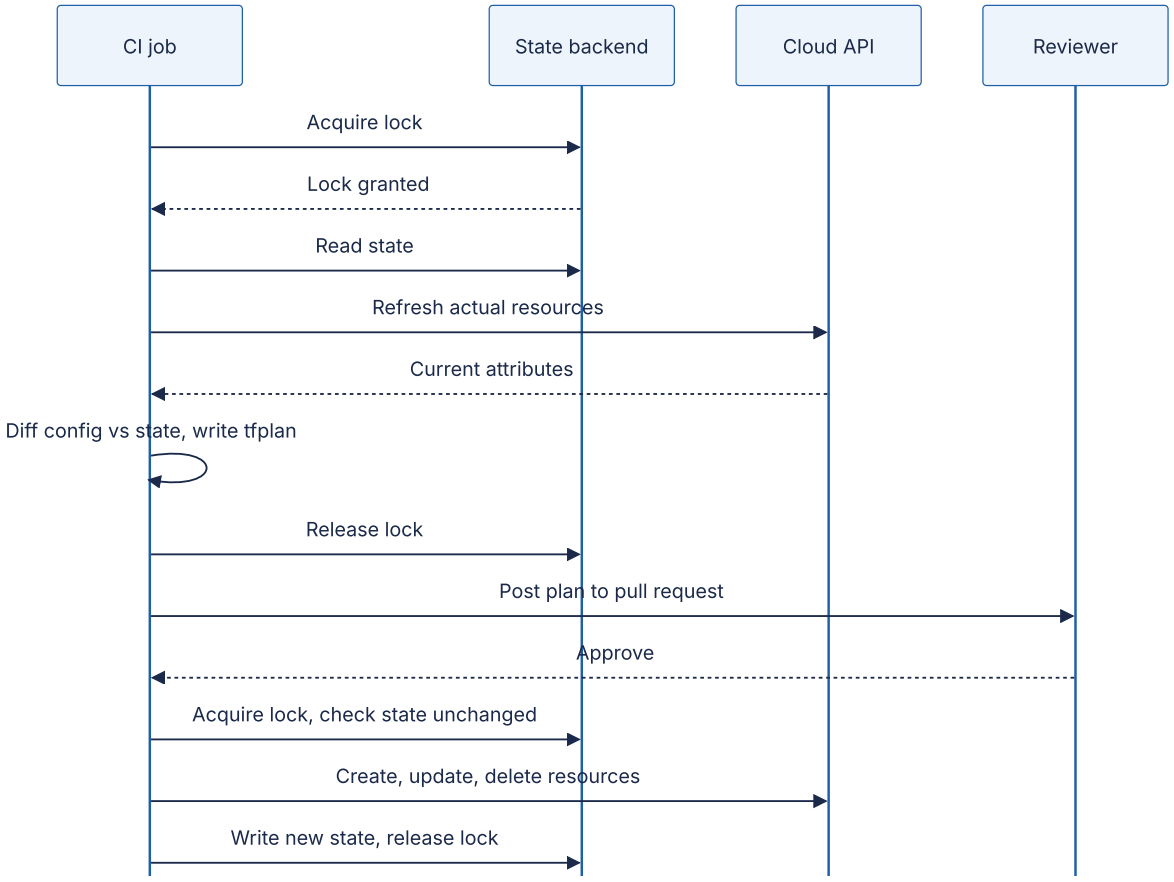
What to notice:

- `required_version` and the provider constraint `~> 6.0` (any 6.x) make runs reproducible; the lock file records the exact provider build.
- The backend block cannot use variables, because it is read before variables are evaluated; teams pass per-environment backend settings with `terraform init -backend-config=...`.
- `use_lockfile = true` enables S3-native locking (a lock object written next to the state). Before Terraform 1.10 the S3 backend locked through a DynamoDB table (`dynamodb_table`), which is now deprecated (as of 2026) [HashiCorp Docs: S3 backend].
- References to the bucket's `id` create the dependency order.
- The `validation` block rejects a typo such as `prd` at plan time rather than creating a stray bucket.

43.9.3 Plan and apply

Terraform's core workflow is **init → plan → apply**. `terraform init` downloads providers and configures the backend. `terraform plan` reads state, refreshes it against the real infrastructure, compares it with the configuration and prints the proposed actions: `+` create, `~` update in place, `-/+` replace, `-` destroy. `terraform apply` executes a plan. In a pipeline, save the plan with `terraform plan -out=tfplan`, have a person or policy check review it, and then run `terraform apply tfplan`, which applies exactly the reviewed actions or refuses if the state changed in between.

Figure 43.8 — A pipeline running plan and apply with remote state and locking.



Reading the diagram. The job locks the state so no concurrent run can use it, reads state, refreshes it against the cloud API and writes a plan, then releases the lock while the plan is reviewed on the pull request. After approval it re-locks; Terraform refuses to apply a saved plan if state changed in between. It applies through the API and writes new state. Failure points: a killed job leaves a stale lock (`terraform force-unlock` after checking no run is active) and a partial apply, which the next plan reveals. Scaling: one state per component keeps locks short and plans fast.

43.9.4 State and state locking

State is Terraform's memory. It maps each resource address (`aws_s3_bucket.receipts`) to a real object ID and caches its attributes. Without it Terraform could not know that a bucket it sees in the account is the one the code declares, or that a resource deleted from the code should be destroyed. Three properties follow:

1. **State must be shared and durable.** A state file on a laptop means the next person creates duplicates. Store it in a remote backend (an object store, HCP Terraform, or a database) with versioning so you can recover an earlier copy.
2. **State must be locked.** Two simultaneous applies against the same state can both read version 7, both make changes, and both write version 8, losing one set of changes and orphaning resources. Locking makes runs mutually exclusive, the same idea as a database lock (§11.15).

3. **State is sensitive.** It can contain plaintext secrets, such as a generated database password. Encrypt the backend, restrict who can read it, and prefer resources that pull secrets from a vault at runtime (§43.11).

43.9.5 Modules and workspaces

A **module** is a directory of Terraform files with inputs and outputs, called from another configuration. Modules package a reviewed pattern, such as "a service's queue, dead-letter queue, alarms and IAM policy", so that 40 teams do not write it 40 ways.

```
module "order_events_queue" {
  source = "./modules/queue"

  name              = "order-events-${var.environment}"
  retention_seconds = 345600 # 4 days
  max_receive_count = 5      # then move to the dead-letter queue
}
```

Version shared modules (a Git tag or registry version) so that a change to the module does not change every consumer at once; each consumer upgrades deliberately, like a library.

A **workspace** is a named instance of state for the same configuration: `terraform workspace new staging` creates a second state, and `terraform.workspace` can be interpolated into names. HashiCorp's documentation cautions that CLI workspaces are not suitable for isolating environments that need separate credentials and access controls [HashiCorp Docs: Workspaces]. For production versus staging, most teams use separate root configurations (or separate backends and accounts) per environment, calling the same versioned modules.

> RECOMMENDATION
>
> **Recommendation — Split state by blast radius.** One state for the whole company means every plan touches everything, every lock blocks everyone, and one mistaken `destroy` can remove production. Split by environment and by component (network, data stores, each service), with long-lived, rarely changed foundations separate from frequently changed service resources. Add `prevent_destroy` lifecycle rules on databases and state buckets.

43.9.6 OpenTofu

In August 2023 HashiCorp changed Terraform's license from the open-source Mozilla Public License 2.0 to the Business Source License 1.1, which restricts competing commercial use. In response, a group of companies and users forked the last MPL-licensed

version as **OpenTofu**, now a Linux Foundation project, with its first stable release (1.6) in January 2024 [OpenTofu 2024]. As of 2026, OpenTofu's `tofu` command accepts the same HCL and provider protocol, so most configurations run unchanged, but the two have diverged in newer features; for example, OpenTofu added client-side state encryption in version 1.7. IBM completed its acquisition of HashiCorp in 2025. When you choose between them, check license constraints, the features you need, and the support model, and pin your tool version as carefully as your providers.

Failure scenarios

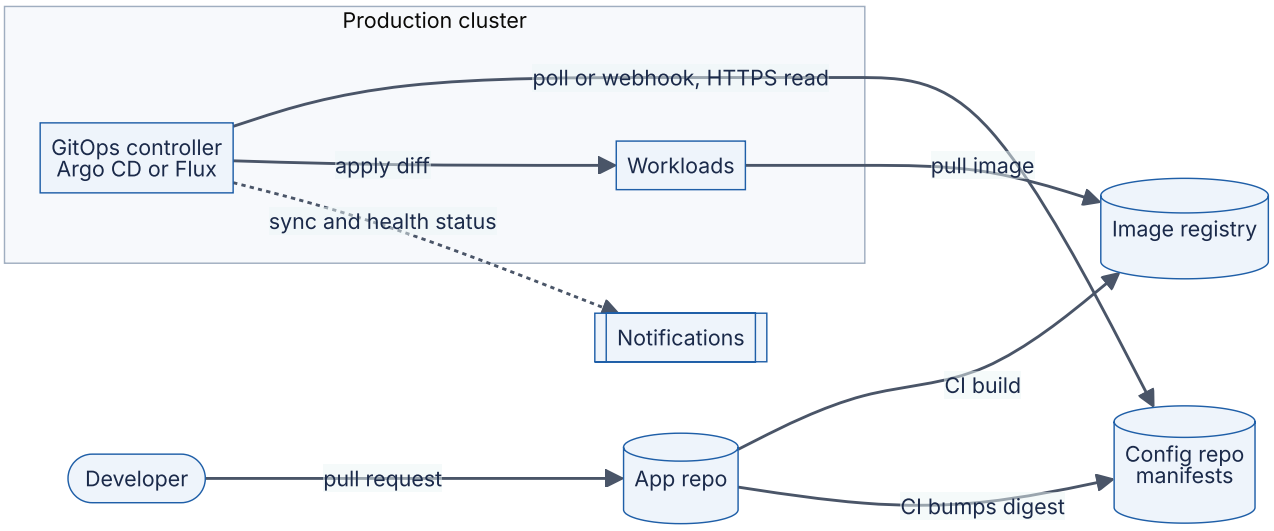
What goes wrong	Why	Detection	Recovery	Prevention
Database replaced by a harmless-looking change	Changing an immutable attribute forces `-/+`	Plan shows "must be replaced"	Abort; restore from backup if applied	Review plans; `prevent_destroy`; policy checks
Concurrent applies corrupt state	No locking or forced unlock	Orphaned or duplicated resources	Restore previous state version; import	Remote backend with locking
Secrets leaked from state	State readable by too many people	Access logs	Rotate secrets	Encrypted backend; least privilege; vault references
Provider upgrade changes behavior	Unpinned versions	Unexpected diff in plan	Pin back	Version constraints and lock file

43.10 GitOps

> DEFINITION
>
> **Definition — GitOps.** An operating model in which the desired state of a system is declared in Git, and software agents running inside the target environment continuously pull that state and reconcile the live system to it. The OpenGitOps principles state that the desired state is **declarative**, **versioned and immutable**, **pulled automatically** and **continuously reconciled** [OpenGitOps 2021].

In a **push** pipeline, the CI system holds production cluster credentials and runs `kubectl apply` at the end of a job: CI becomes a high-value target, and manual edits after deploy go unnoticed. GitOps inverts the direction. An agent runs *inside* the cluster, reads Git, and applies what it finds; CI's job ends when it updates the Git repository (for example, bumping an image digest). The cluster needs read access to Git, and nothing outside needs write access to the cluster.

Figure 43.9 — Pull-based GitOps with an in-cluster controller.



Reading the diagram. CI builds the application repository, pushes an image and commits its digest to a configuration repository of manifests; both repositories and the registry are storage boundaries. Inside the cluster, the controller reads the configuration repository over HTTPS on a polling interval or webhook, applies the difference, and reports status asynchronously. No external system holds cluster credentials. Failure points: if Git is unreachable the cluster keeps its last state but cannot change; a bad commit applies everywhere the controller watches. Scaling: one controller per cluster isolates failures; one controller can also manage many clusters.

Argo CD models each deployed unit as an `Application` resource that names a Git source and a destination cluster and namespace:

```
apiVersion: argoproj.io/v1alpha1
kind: Application
metadata:
  name: orders-prod
  namespace: argocd
spec:
  project: default
  source:
    repoURL: https://github.com/quickbite/deploy-config.git
    targetRevision: main
    path: apps/orders/overlays/prod
  destination:
    server: https://kubernetes.default.svc
    namespace: orders
  syncPolicy:
    automated:
      prune: true     # delete objects removed from Git
      selfHeal: true  # revert manual changes to live objects (drift)
```

Argo CD compares the rendered manifests with live objects, shows each Application as *Synced* or *OutOfSync* and *Healthy* or *Degraded*, and polls repositories every three minutes by default, or reacts to webhooks [Argo CD Docs]. **Flux** splits the same job into con-

trollers: a source controller fetches `GitRepository` (or OCI and Helm) sources on an interval, and a Kustomize or Helm controller applies them; an image-automation controller can commit new image tags back to Git [Flux Docs]. Both are CNCF graduated projects. Progressive delivery plugs in alongside them: Argo Rollouts and Flagger replace the plain Deployment rollout with canary or blue–green steps judged by metric analysis (§43.6).

Rollback in GitOps is `git revert`: the controller applies the previous state, and the history records who rolled back and why. Secrets need care, because Git is not a vault: store references, not values, using the External Secrets Operator (which syncs from a cloud secrets manager), or store encrypted values with Sealed Secrets or SOPS (§43.11).

WARNING / TRADE-OFF

Warning — Self-heal fights the emergency fix. With `selfHeal` on, an on-call engineer's `kubectl scale` during an incident is reverted within seconds or minutes. Agree in advance how to make emergency changes: commit to Git (fast path with post-review), or pause automated sync for the Application and record that you did.

43.11 Secrets management in pipelines

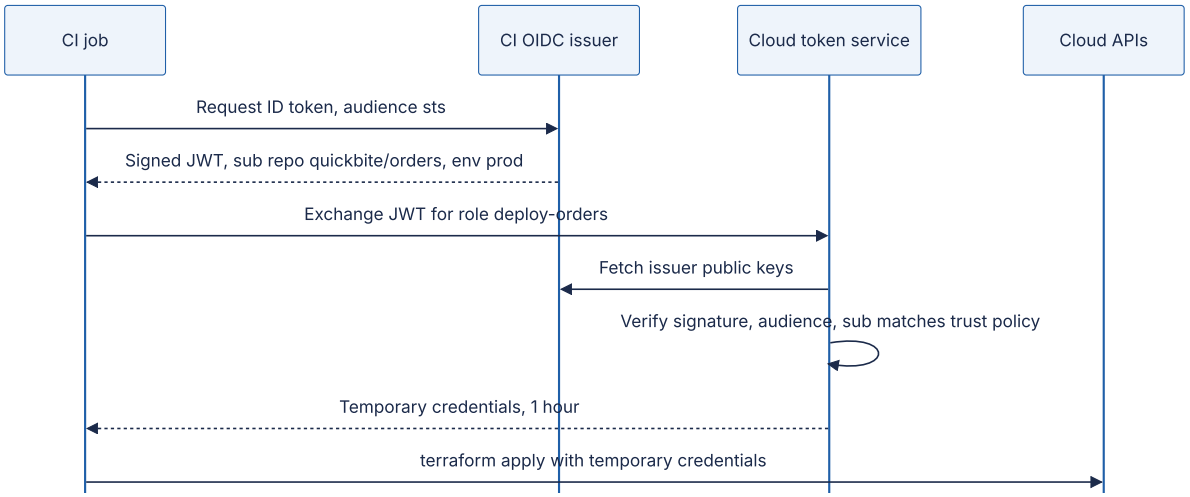
A deployment pipeline holds the keys to production: it pushes images, applies Terraform and changes clusters. Chapter 10 explains secrets management in general (§10.8); this section applies it to CI/CD, where the classic mistake is a long-lived cloud access key pasted into the CI system's secret settings. That key works from anywhere, never expires, is copied into every fork's logs if a step echoes it, and is rarely rotated.

43.11.1 OIDC workload identity instead of long-lived keys

DEFINITION

Definition — OIDC workload identity federation. A mechanism in which the CI platform issues each job a short-lived, signed OpenID Connect (OIDC) token describing the job (repository, branch, environment), and the cloud provider exchanges that token for temporary credentials according to a trust policy, so that no long-lived cloud key is stored in the pipeline.

Figure 43.10 — A CI job obtaining cloud credentials through OIDC federation.



Reading the diagram. The job obtains a signed JSON Web Token from the CI platform's issuer, with claims naming its repository and environment. The cloud token service verifies the signature with the issuer's public keys, checks the claims against the role's trust policy (for example only `repo:quickbite/orders:environment:prod`) and returns credentials that expire in about an hour. Nothing long-lived is stored. Failure points: trust policies that match any repository or branch, and issuer availability. GitHub Actions jobs request the `id-token: write` permission; AWS, Google Cloud and Azure support this federation (as of 2026) [GitHub Docs: OIDC].

Applying the misuse-window formula of §10.8: a leaked static key is usable until someone notices and rotates it, often months; a leaked federated credential is usable for at most its one-hour lifetime. Where the pipeline needs non-cloud secrets (a third-party API key, a signing key), it should fetch them at run time from a vault using the same OIDC identity (Vault's JWT auth method accepts CI tokens), scoped to the job and environment, rather than storing them as CI variables.

43.11.2 Supply-chain security: SLSA, SBOMs and signing

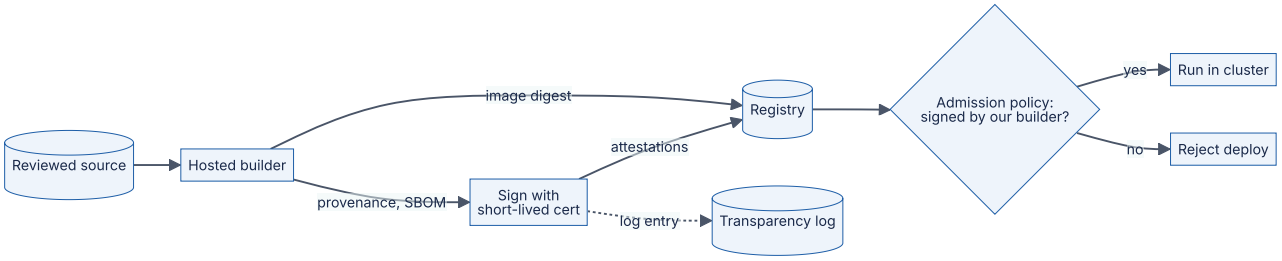
The pipeline is also the factory for every artifact you run, so attackers target it: a compromised build server can insert code into a correctly reviewed source tree. The SolarWinds compromise disclosed in 2020 did exactly this: malware on the build system inserted a backdoor into signed Orion software updates [CrowdStrike 2021]. Three controls answer the question "is this artifact what we think it is?" Chapter 50 treats supply-chain security in depth; here is the pipeline view.

- **Provenance and SLSA.** Supply-chain Levels for Software Artifacts (SLSA) defines a build track with increasing guarantees [SLSA 2023]. *Build L1*: the build produces provenance, a document stating what source, builder and parameters produced the artifact. *Build L2*: the build runs on a hosted build platform that generates and signs the provenance. *Build L3*: the build platform is hardened so that builds are isolated

from one another and user-defined build steps cannot access the signing key or forge provenance.

- **SBOM.** A software bill of materials lists every component and version in an artifact, in a standard format such as SPDX or CycloneDX. When a vulnerability is announced in a library, an SBOM answers "which of our images contain it?" in minutes.
- **Signing.** Sign the image digest and attach the provenance and SBOM as attestations. Sigstore's `cosign` supports *keyless* signing: the signer authenticates with OIDC, receives a short-lived certificate from the Fulcio certificate authority, and the signature is recorded in the Rekor transparency log [Sigstore Docs].

Figure 43.11 — From source to admission: signing and verification.



Reading the diagram. A hosted builder pushes the image by digest and produces provenance and an SBOM, which are signed and stored beside the image; the signing event is appended asynchronously to a transparency log. At deploy time an admission controller (such as Sigstore's policy controller or Kyverno) admits only images signed by the expected builder identity with provenance naming the expected repository. Failure points: verification left in audit-only mode, and overly broad signing identities. Scaling: verification is a few signature checks per pod, cached by digest.

43.12 Infrastructure monitoring

Chapter 40 covers metrics, logs, traces and alerting. Deployment adds one specific need: when something breaks, you must be able to ask "what changed?" and get an answer in seconds.

Deployment markers are events recorded by the pipeline at every deployment, flag change and infrastructure apply, with the service, version, commit, author and time. Dashboards overlay them on graphs (Grafana calls these annotations), so a latency step that lines up with a marker is visible at a glance. **Change correlation** goes further: an incident tool lists every change to the affected services and their dependencies in the hour before the alert.

FORMULA

Chance that an unrelated deploy precedes an incident

$$P_{\text{chance}} = 1 - e^{-fw}$$

Symbol	Meaning	Units
P_{chance}	Probability at least one deploy falls in the window by coincidence	probability
f	Rate of deploys among the changes you are looking at	deploys/min
w	Look-back window before the incident	min

WORKED EXAMPLE

Worked example — Is the last deploy the cause? QuickBite's teams deploy 120 times per day across all services, $f = 120/1,440 = 0.0833$ per min. Looking back $w = 30$ min, $fw = 2.5$ and $P_{\text{chance}} = 1 - e^{-2.5} = 0.92$. Some deploy almost always precedes any incident, so "there was a deploy just before" means nothing at the organization level. Restricted to the affected service, which deploys 3 times per day ($f = 0.00208$ per min), $fw = 0.0625$ and $P_{\text{chance}} = 0.061$. A deploy of *that* service in the window is strong evidence. *Engineering implication:* change correlation must be scoped by service and dependency graph; and the faster an organization deploys, the more it needs per-service canaries (§43.6), whose comparison against a baseline separates cause from coincidence directly.

Two further habits complete the picture. Alert on symptoms with error-budget burn rates (§40.10) so that a bad deploy pages within minutes; and track the DORA metrics (§43.3.3) from the same change events, so that delivery performance is measured from data, not surveys.

43.13 Database migrations

43.13.1 Why migrations are the hard part

Code is easy to roll back because old code has no memory. A database remembers. If version 42 renames a column, version 41 cannot read the table any more, so rollback is impossible; and during a rolling or canary deploy, versions 41 and 42 run *at the same time* against one schema (§43.4). A schema change is therefore safe only if every application

version that may run during the change can work with every schema state that may exist during it.

DEFINITION

Definition — Backward and forward compatibility. A schema change is **backward compatible** if the old application version still works after it is applied. An application change is **forward compatible** (with respect to rollback) if the data it writes can still be read correctly by the previous application version.

43.13.2 Expand and contract

DEFINITION

Definition — Expand–contract (parallel change). A pattern for making a backward-incompatible change as a sequence of compatible steps: **expand** the schema or interface to support both old and new forms, **migrate** readers, writers and existing data to the new form, then **contract** by removing the old form once nothing uses it [Sato 2014b].

Suppose QuickBite wants to replace the free-text `customer_phone` column in `orders` with a normalized `phone_e164` column. Renaming in one step breaks every running instance. The expand–contract sequence is:

1. **Expand the schema.** Add `phone_e164` as a nullable column. Old code ignores it.
2. **Dual-write.** Deploy application version A that writes both columns and still reads `customer_phone`. Rollback to the previous version is safe; it ignores the new column.
3. **Backfill.** Fill `phone_e164` for existing rows in small batches.
4. **Switch reads.** Deploy version B that reads `phone_e164` (falling back to the old column if null) and still writes both. Rollback to A is safe because both columns stay current.
5. **Stop writing the old column.** Deploy version C that writes only `phone_e164`. From here, rolling back to B or A would read a stale column, so wait until C has baked.
6. **Contract the schema.** Drop `customer_phone` (and add `NOT NULL` to `phone_e164` if required).

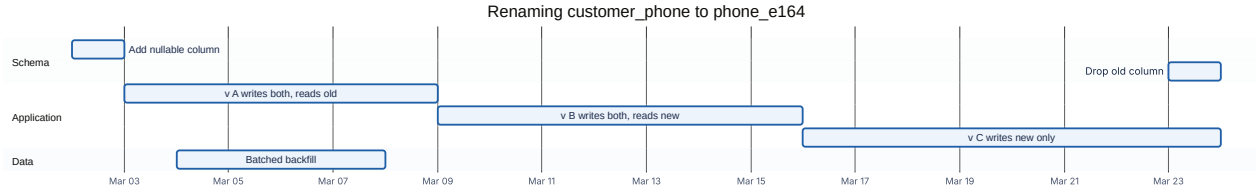
```
        -- Step 1: expand (PostgreSQL; adding a nullable column is a quick catalog
change)
        SET lock_timeout = '2s';
        ALTER TABLE orders ADD COLUMN phone_e164 text;

        -- Step 3: backfill one batch; the job repeats until no rows are updated
        UPDATE orders
        SET phone_e164 = normalize_phone(customer_phone)
        WHERE id IN (
          SELECT id FROM orders
          WHERE phone_e164 IS NULL AND customer_phone IS NOT NULL
          ORDER BY id
          LIMIT 2000
        );

        -- Step 6: contract, weeks later
        SET lock_timeout = '2s';
        ALTER TABLE orders DROP COLUMN customer_phone;
```

What to notice: `lock_timeout` makes the `ALTER` give up rather than queue all traffic behind it (the hazard of §11.15); the backfill touches 2,000 rows per transaction to keep locks and replication lag small; `normalize_phone` stands for an application-defined function; and steps 1 and 6 are separate releases, weeks apart.

Figure 43.12 — Expand-contract releases over time.



Reading the diagram. Time runs left to right over three weeks. Only two schema changes occur: expand at the start and contract at the end. The three application releases each deploy with the usual strategy, and at every boundary the two coexisting versions are compatible with the schema of that moment. The backfill runs asynchronously after version A writes both columns, so no row is missed. Failure points: contracting while any reader (batch jobs, reporting replicas) still uses the old column, and a backfill that overloads the database.

FORMULA

Backfill duration

$$T_{\text{backfill}} = \frac{R}{b \times r}$$

Symbol	Meaning	Units
T_{backfill}	Time to update all rows	s
R	Rows to update	rows
b	Rows per batch	rows/batch
r	Batches per second, including throttling pauses	batches/s

WORKED EXAMPLE

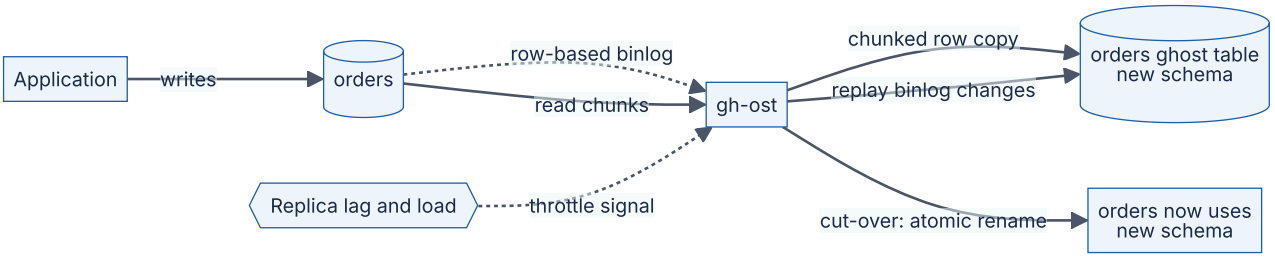
Worked example — Backfilling 300 million orders. $R = 3 \times 10^8$ rows, $b = 2,000$ rows per batch, each batch takes 50 ms and the job then sleeps 50 ms to leave headroom, so $r = 10$ batches/s. $T = 3 \times 10^8 / (2,000 \times 10) = 15,000$ s ≈ 4.2 h. Doubling the batch size would halve the time but double each transaction's lock footprint and the bursts of replication lag. *Engineering implication:* throttle backfills on replica lag and primary load, make them resumable (they run for hours), and schedule them as a release step with its own monitoring.

43.13.3 Online schema change tools

Some changes cannot be made as quick catalog edits: changing a column type, or adding an index on MySQL versions and table shapes that need a table copy. On a 500 GB table a blocking `ALTER` could lock writes for hours. **Online schema change** tools build a new copy of the table with the new schema while the original keeps serving, then swap them.

- **pt-online-schema-change** (Percona Toolkit) creates the new table, adds triggers on the original so that every insert, update and delete is mirrored to the copy, copies existing rows in chunks, and finally swaps the tables with an atomic `RENAME TABLE` [Percona Docs: pt-online-schema-change].
- **gh-ost** (GitHub's online schema migration tool for MySQL) is *triggerless*. It copies rows in chunks and applies ongoing changes by reading the MySQL binary log, so the migration adds no trigger work to the production write path. It can throttle itself on replica lag or load, be paused and resumed, and postpone the final cut-over until an operator removes a flag file [GitHub gh-ost]. It requires row-based binary logging and has limited support for foreign keys.

Figure 43.13 — gh-ost's triggerless migration.



Reading the diagram. The application keeps writing to the original table. gh-ost copies existing rows in chunks into a ghost table with the new schema while tailing the binary log asynchronously and replaying each change, throttling on replica lag and load. When caught up, the cut-over briefly locks the original and atomically renames the tables. Failure points: a cut-over stuck behind long transactions, disk space for a second copy, and foreign keys. Scaling: copy speed is deliberately throttled; a multi-terabyte table can take days without affecting production.

PostgreSQL makes many changes cheap without such tools: adding a nullable column, or (since version 11) a column with a constant default, avoids a table rewrite, and `CREATE INDEX CONCURRENTLY` builds an index without blocking writes [PostgreSQL Docs: ALTER TABLE]. MySQL 8 offers `ALGORITHM=INSTANT` for some column additions. Check your engine's documentation for which operations rewrite the table before choosing a tool.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Old pods crash after migration	Column renamed or dropped while old version still runs	Errors from old version during rollout	Re-add column; roll forward	Expand–contract; contract only after all readers gone
All queries stall	`ALTER` waits for a lock and blocks everything behind it	Sudden latency spike on one table	Cancel the `ALTER`	`lock_timeout`; online schema change
Replicas fall hours behind	Backfill or copy too aggressive	Replica lag alerts	Pause job	Throttle on lag; small batches
Rollback impossible	New version wrote data old version cannot read	Old version errors after rollback	Roll forward with a fix	Forward-compatible writes; dual-write phase

COMMON MISTAKE

Mistake — Running migrations automatically at application startup. If every pod runs pending migrations when it starts, a rolling deploy of 40 pods races 40 migrators, and a destructive migration runs before any canary analysis. Run migrations as a separate, single, observable pipeline step, ahead of the code that needs them.

43.14 Summary and revision notes

SUMMARY

- Most outages follow changes. Control how change reaches production: small batches, limited exposure, fast detection, fast undo.
- A deployment pipeline builds once and promotes one immutable artifact through unit tests, static analysis, packaging, integration tests and a progressive deploy. Trunk-based development keeps integration continuous.
- DORA's four metrics: deployment frequency, change lead time, change failure rate, failed deployment recovery time. Throughput and stability improve together; read them together ($D = f \times \mathrm{CFR} \times T_{\mathrm{restore}}$).
- Rolling updates are cheap and default, but mix versions and expose everyone on a fixed schedule. Blue–green gives an atomic switch and instant rollback at up to double capacity; shared databases must suit both versions.
- Canaries limit blast radius $B = \lambda w \Delta p (T_{\mathrm{detect}} + T_{\mathrm{rollback}})$. Judge them statistically: a one-sided two-proportion z-test with a sample sized in advance; beware peeking. Kayenta-style judges score many metrics with Mann–Whitney tests against a fresh baseline.
- Feature flags separate release from deploy, enable kill switches and deterministic percentage rollouts, and create flag debt (2^k paths); expire release toggles.
- Declarative IaC is idempotent and detects drift. Terraform uses providers, resources, remote locked state, plan/apply, modules and per-environment state; OpenTofu is the MPL-licensed fork.
- GitOps agents pull desired state from Git and reconcile continuously; rollback is `git revert`.
- Pipelines should use OIDC federation, not stored keys; SLSA provenance, SBOMs and signatures verified at admission protect the supply chain.
- Deployment markers and service-scoped change correlation answer "what changed?"
- Database changes use expand–contract so every coexisting version works with every schema state; online schema change tools (gh-ost, pt-osc) avoid blocking `ALTER`s.

43.15 Knowledge checkpoint

1. Name the six pipeline stages and explain "build once".
2. Define the four DORA metrics.
3. Team X deploys 10 times a week with CFR 10% and 60 min recovery. Compute weekly degraded time.
4. Why must a rolling update be backward compatible?

5. Why does blue–green rollback fail after a destructive schema change?
6. Green costs $20,000/month to run fully; 30 deploys/month with 3 h overlap. Compute the extra cost.
7. Compute the blast radius at 1,000 requests/s, 10% canary, $\Delta p = 0.1$, 60 s detection and 30 s rollback.
8. Baseline 50 errors in 10,000 requests; canary 80 in 10,000. Compute z and decide at $\alpha = 0.01$.
9. Why compare a canary with a fresh baseline rather than with production?
10. Why must percentage rollouts hash the user ID with the flag key?
11. What does idempotence give an IaC tool?
12. Why does Terraform need state locking?
13. What makes GitOps “pull-based”, and why is that more secure?
14. What does an OIDC trust policy check?
15. List the six expand–contract steps for a column rename.

Answers

1. Build, unit test, static analysis, artifact, integration test, deploy. The same artifact (by digest) is promoted, so what was tested is what ships.
2. Deployment frequency; change lead time (commit to production); change failure rate (share of deploys needing remediation); failed deployment recovery time.
3. $10 \times 0.10 \times 60 = 60$ min per week.
4. Old and new versions serve simultaneously and share data and clients.
5. Blue’s code no longer matches the schema, so switching back produces errors.
6. $20,000 \times 30 \times 3/730 = \$2,466$ per month.
7. $1,000 \times 0.1 \times 0.1 \times 90 = 900$ failed requests.
8. Pooled $= 130/20,000 = 0.0065$; SE $= \sqrt{0.0065 \times 0.9935 \times 0.0002} = 0.001137$; $z = 0.003/0.001137 = 2.64$; p $= 0.004 < 0.01$: fail.
9. New processes differ from long-running ones (cold caches, warm-up), which would be mistaken for code effects.
10. Determinism (same user, same answer on every pod) and independence (different flags select different users).
11. Re-running is safe; only differences are applied, so partial failures can be retried and drift detected.
12. Concurrent applies would read the same state and overwrite each other’s results, orphaning resources.
13. An in-cluster agent reads Git; no external system needs write credentials to the cluster, and drift is reconciled continuously.
14. The token’s signature and issuer, audience, and claims such as repository, branch or environment.
15. Add nullable column; dual-write; backfill; read new; stop writing old; drop old column.

43.16 Interview questions

Basic

Q1. What is the difference between blue–green and canary deployments? Answer. Blue–green prepares a full second environment and switches all traffic at once, with instant rollback by switching back; cost is up to double capacity during the overlap. A canary sends a small, increasing share of traffic to the new version and judges it against a baseline, limiting blast radius at the cost of more tooling and enough traffic for statistics.

Q2. What are feature flags for, and what is their main risk? Answer. They separate release from deploy: dark launches, percentage rollouts, experiments and kill switches. The main risk is flag debt: stale flags multiply untested code paths and can be misused, as in Knight Capital's repurposed flag.

Intermediate

Q3. How would you automate canary analysis for a service with 500 requests/s and a 0.2% error rate? Answer. Decide the smallest regression worth catching (say a doubling), then size the sample: about 15,000 requests per group at $\alpha = 0.01$ and 80% power. At 5% weight per group (25 requests/s) that is about 10 minutes per step. Judge error rate with a one-sided two-proportion test and latency with a nonparametric test against a fresh baseline; correct for repeated looks; add business metrics; auto-rollback on fail, hold on inconclusive.

Q4. How do you rename a column in a 2 TB table with zero downtime under rolling deploys? Answer. Expand–contract: add the new column, deploy dual-write, backfill in throttled batches, switch reads, stop old writes, drop the old column weeks later. Each step is a separate release compatible with its neighbors. Use `lock_timeout`, and gh-ost or pt-osc for operations that copy the table.

Advanced

Q5. Design the deployment platform for 300 microservices and 50 teams. Answer. Per-service pipelines that build once, sign and attach SBOM and provenance; OIDC to cloud; GitOps config repositories reconciled by Argo CD or Flux per cluster; Argo Rollouts or Flagger canaries with Kayenta-style judgment; a flag service with expiry; Terraform modules with per-service state; admission policy that verifies signatures; change events feeding deploy markers and DORA metrics; migrations as separate pipeline steps. Discuss rollout across regions or cells one at a time (Chapter 44).

Q6. A bad config change took down every region at once. What do you change? Answer. Treat config as code: review, version, validate in the pipeline. Roll out progres-

sively by region or cell with automated health checks between waves, so one wave fails, not all. Add a fast, tested rollback (previous version kept), deployment markers, and service-scoped change correlation. Measure the reduction in blast radius with $B = \lambda w \Delta p T$.

43.17 Practical exercises

1. Run the canary module of §43.6.4 with baseline rates of 0.1%, 1% and 5% and plot required n against relative increase.
2. Extend the judge with a Bonferroni-corrected repeated-look mode and verify by simulation that the false-positive rate stays below 1%.
3. Write a Terraform module for a queue plus dead-letter queue, call it for two environments with separate state, and run `plan -detailed-exitcode` after a manual console change.
4. Install Argo CD in a local cluster, deploy an app from Git, edit a Deployment by hand and watch self-heal revert it.
5. Perform the expand–contract column rename of §43.13.2 on a local PostgreSQL table of 10 million rows while a load generator runs.

43.18 Design challenges

1. **Payments canary.** A payment service handles 50 requests/s with a 0.05% error rate. Design a release process that catches a doubling of errors within one hour; decide what else besides error rate to judge on.
2. **Regulated GitOps.** A bank requires two-person approval and an audit trail for every production change and forbids CI credentials to production. Design the pipeline, GitOps layout and emergency-change path.
3. **Sharded schema change.** Add a non-null column to a table spread over 64 MySQL shards under continuous deployment, with a plan for partial failure on some shards.

Part IX — Advanced and Expert Topics

Chapter 44 — Multi-Region and Global Systems

> **Level:** 4 · **Track:** A (Traditional) · **Estimated reading time:** 6 h

Every chapter so far has assumed, at least implicitly, that your system lives in one region: a few availability zones milliseconds apart (§41.4), where synchronous replication is cheap and consensus commits in a couple of milliseconds. This chapter is about what changes when you stretch a system across regions hundreds or thousands of kilometers apart. Three facts drive everything. Light in fiber needs about 5 µs per kilometer, so cross-region round trips cost tens to hundreds of milliseconds and no product can remove that (§4.17, §7.15). Regions fail as units, rarely but for hours. And laws increasingly say *where* personal data may live.

The running example is QuickBite, the hypothetical food-delivery platform of Chapter 2. It has outgrown one country and now serves three markets: the United States, the European Union and Asia-Pacific. Every QuickBite number is a teaching assumption, not a measurement of any real company. Chapter 39 gave QuickBite its disaster-recovery (DR) tiers and introduced active–passive and active–active regions (§39.8, §39.10). Here we cover the physics, traffic steering, topologies, geo-replication, conflicts, residency, regional isolation and evacuation that a real multi-region design needs.

44.1 Learning objectives

After this chapter you should be able to:

- State the four reasons to go multi-region and estimate their cost in money, latency and complexity.
- Compute the fiber round-trip floor between regions and the client-perceived latency of a quorum write for a given replica placement.
- Design global traffic management with geo-DNS, latency-based routing, anycast and client-side selection, and compute realistic DNS failover times.
- Compare active–passive, read-local/write-global, multi-writer and home-region topologies, and compute their availability given failover time.
- Choose between asynchronous and synchronous geo-replication, compute the data-loss window (RPO) from replication lag, and describe what DynamoDB global tables, Spanner, CockroachDB and Aurora Global Database offer (as of 2026).

- Estimate cross-region conflict rates and pick a conflict strategy: ownership, CRDTs, application merge or last-writer-wins.
- Design regional data stores for residency requirements, splitting metadata from content.
- Remove global dependencies using regional independence and static stability.
- Size regional capacity to absorb the loss of one region, and plan detection, decision, traffic shift, failback and game days.
- Explain read-your-writes across regions and the role of the home region in user-visible consistency.

44.2 Prerequisites

- Speed of light in fiber, the four components of latency — §4.17, §7.15 (the RTT floor used throughout).
- BGP and anycast; DNS resolution, TTL and DNS load balancing — §7.5.3, §7.6.4, §7.6.5.
- Global server load balancing and health checks — §19.5, §19.9 (summarized, not re-taught).
- Session guarantees, PACELC and the CAP theorem — §25.6, §25.8, §25.9.
- Quorums and quorum commit latency; Raft; split brain and fencing — §26.4, §26.7, §26.12, §26.13.
- Multi-leader replication, failover, conflict resolution with LWW, version vectors and CRDTs — §27.6, §27.11, §27.14.
- Spanner and TrueTime; CockroachDB transactions — §28.8, §28.10.1.
- Cells and shuffle sharding — §33.12.
- Headroom and zone-level static stability — §18.11.2.
- DR tiers, RTO and RPO; availability composition — §39.8, §4.14.

44.3 Why go multi-region

44.3.1 Four reasons, and the bill that comes with them

DEFINITION

Definition — Region; multi-region system. A **region** is a cloud provider's geographic area containing several isolated availability zones, typically within roughly 100 km of each other, connected by low-latency links (§41.4). A **multi-region system** runs serving capacity, data, or both in two or more regions and has a defined policy for which region handles each request and each piece of data. A **global system** is a multi-region system whose users are spread across continents.

First-principles explanation

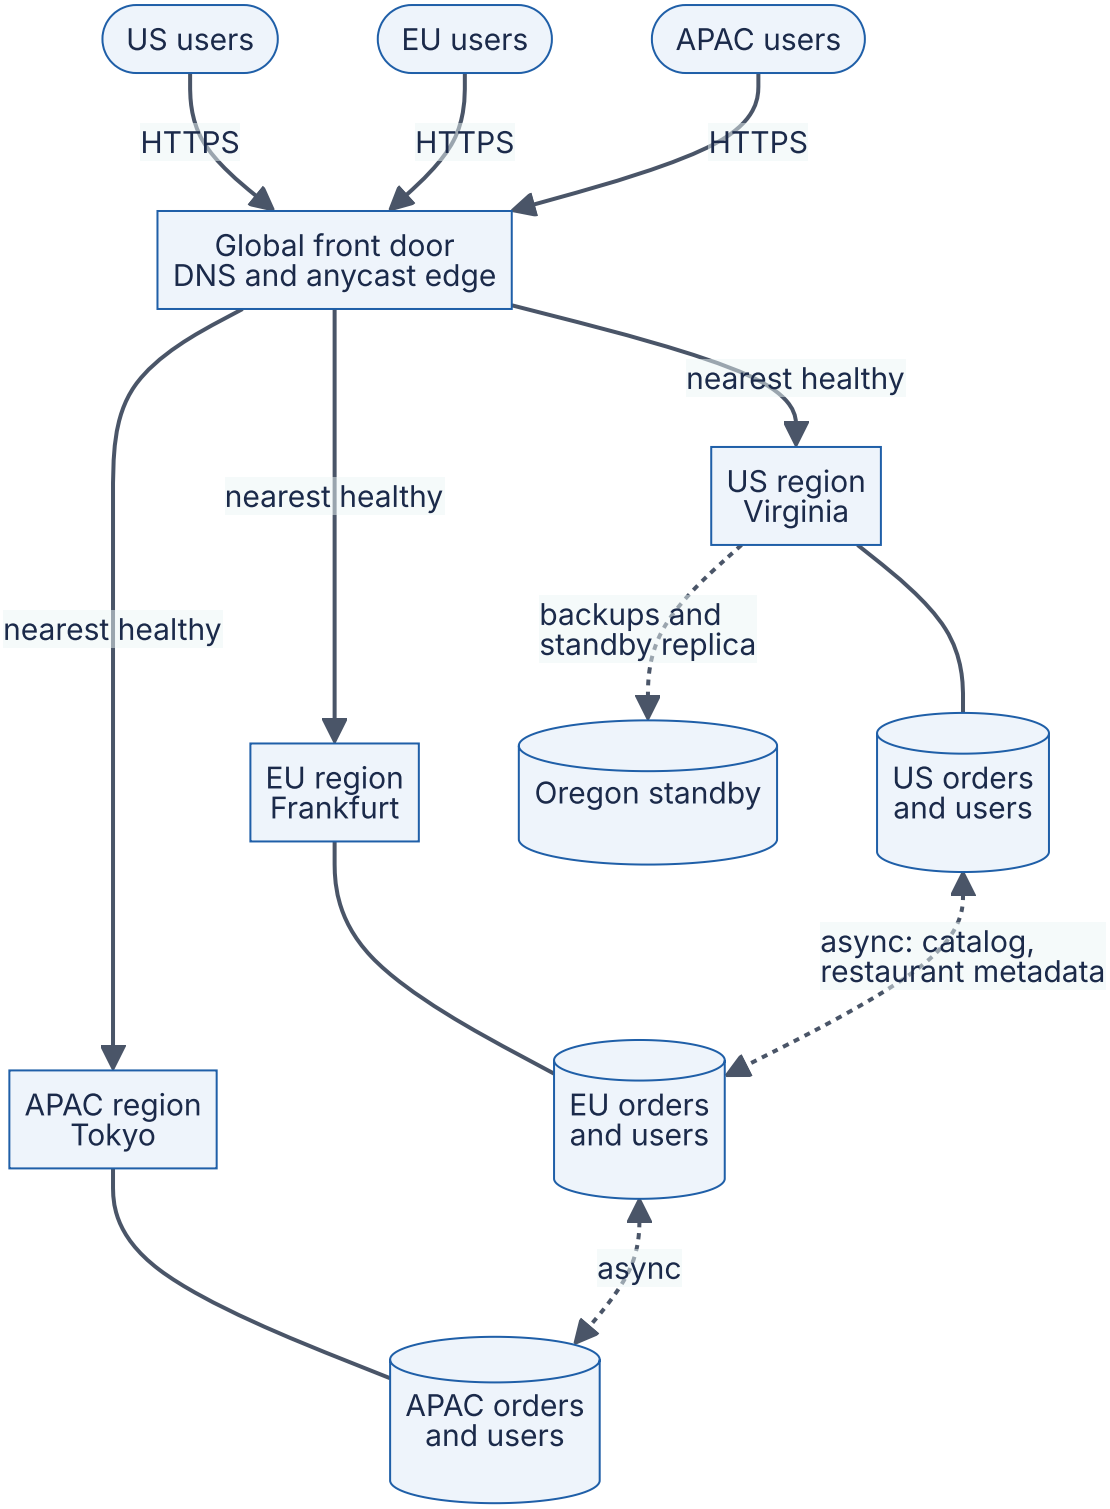
Imagine a restaurant chain with one central kitchen. Every order, from every city, is cooked there and driven out. It is simple: one menu, one stock count, one set of books. But customers far away wait an hour, a fire in the kitchen stops every city at once, and some cities forbid their customers' records leaving town. Opening local kitchens fixes all three, at the cost of keeping menus, stock and books in agreement across kitchens that cannot talk instantly. A multi-region system makes the same trade.

Why does this exist?

There are four distinct motives, and they lead to different designs. Be explicit about which ones apply.

1. **Latency.** A user in Frankfurt calling a service in Virginia pays at least a 66 ms fiber round trip, about 90 ms in practice, on *every* sequential round trip (§44.4). Serving from a nearby region removes most of it.
2. **Availability.** Zones protect against a datacenter fault; they do not protect against a region-wide event: a bad regional deployment, a regional control-plane outage, a cut that isolates a metro area, a natural disaster. Multiple regions turn a regional outage from total downtime into a traffic shift (§44.11).
3. **Data residency.** Laws, contracts and customer requirements may restrict where personal or regulated data is stored or processed (§44.9). This is a reason to *partition* data by geography, not to replicate it everywhere.
4. **Blast radius.** Regions are natural cells (§33.12). If each region is independent, a defect rolled out to one region or a poison request in one region affects only that region's users (§44.10).

Figure 44.1 — QuickBite's global footprint.



Reading the diagram. Users in three markets reach a global front door over HTTPS (§44.5), which sends each request synchronously to the nearest healthy region. Each region is a complete stack whose database (a storage boundary) holds its own market's orders and accounts. Only shared reference data, such as multi-market restaurant chains, replicates between regions, asynchronously (dotted). The US region also ships backups and a standby replica to Oregon for regional DR. Failure points: the global front door is shared by everyone and must itself be multi-region; a lost region takes its market's data

with it unless that data is replicated elsewhere. Scaling: add regions or cells within regions.

The bill

Multi-region costs are often understated. Table 44.1 states them plainly.

Table 44.1 — What multi-region costs.

Cost	Why it arises	Typical magnitude
Compute and storage	Each region needs headroom to absorb another's traffic (§44.11)	1.25× to 2× a single region, plus standby copies
Data transfer	Cross-region replication and request forwarding are billed per GB	Often a top-five cloud line item for chatty designs
Write latency	Strong consistency needs cross-region round trips (§44.4)	+10 ms to +250 ms per write
Engineering complexity	Conflicts, failover logic, region-aware routing, residency	Months of design; permanent operational load
Testing	Failover paths are rarely exercised and rot	Game days and continuous evacuation drills (§44.11)
Correlated risk	Global components (DNS, config, identity) are now shared fate (§44.10)	Can dominate total downtime (§44.6.5)

The cost multiples are planning ranges for illustration; derive your own from §44.11's headroom formula and your provider's price list.

Common misconceptions

COMMON MISTAKE

Mistake — "Multi-region automatically makes us more available." A second region adds components, a failover path and new global dependencies. If failover is manual, untested, or depends on the failed region's control plane, the second region adds cost and no availability. Worse, a global configuration system or global database can make *all* regions fail together. Multi-region improves availability only when regions are independent and failover is automatic and rehearsed (§44.10, §44.11).

RECOMMENDATION

Recommendation — Write down which of the four reasons you are solving for. Latency alone may need only read replicas and a CDN (Chapter 21); availability alone, a warm standby (§39.8); residency, geographic partitioning; blast radius, independence.

44.4 Latency physics across regions

44.4.1 The fiber floor

DEFINITION

Definition — Round-trip time floor. The **RTT floor** between two points is the minimum time for a signal to travel there and back along the great-circle path in optical fiber, about $2d/v$ with $v \approx 200,000$ km/s. **Route inflation** is the ratio of a measured RTT to that floor; it reflects cable paths that are longer than the great circle, plus equipment, queuing and routing policy.

Light in glass travels at about two-thirds of its vacuum speed, roughly 5 µs per kilometer (§7.15.1). Submarine and terrestrial cables follow coastlines, rights of way and landing stations, so real paths are longer than the great circle. Specialized links (microwave towers for trading, hollow-core fiber) narrow the gap on a few routes, but no cloud region pair beats the fiber floor by more than about a third, which is the vacuum limit.

FORMULA

Fiber RTT floor and observed RTT

$$\mathrm{RTT}_{\min} = \frac{2d}{v}, \qquad \mathrm{RTT}_{\mathrm{obs}} \approx k \cdot \mathrm{RTT}_{\min} + t_{\mathrm{equip}}$$

Symbol	Meaning	Units
d	Great-circle distance between the two sites	km
v	Signal speed in fiber, about 2×10^5	km/s
$\mathrm{RTT}_{\min}$	Physical lower bound on round-trip time	s (report in ms)
k	Route inflation factor, typically 1.3–2 for long-haul cloud paths	dimensionless
t_{equip}	Fixed processing and queuing in routers and hosts	ms
$\mathrm{RTT}_{\mathrm{obs}}$	Round-trip time you can expect to measure	ms

Table 44.2 — Approximate RTTs between region locations (as of 2026; measure your own).

Region pair (metro areas)	Great-circle distance	Fiber floor $2d/v$	Typical observed RTT	Inflation k
N. Virginia – Ohio	~480 km	~5 ms	~10–13 ms	~2.5 (short paths are dominated by routing)
N. Virginia – Oregon	~3,500 km	~35 ms	~60–70 ms	~1.8
N. Virginia – London	~5,900 km	~59 ms	~75–80 ms	~1.3
N. Virginia – Frankfurt	~6,500 km	~66 ms	~85–95 ms	~1.4
N. Virginia – São Paulo	~7,700 km	~77 ms	~115–125 ms	~1.5
N. Virginia – Tokyo	~10,900 km	~109 ms	~145–160 ms	~1.4
N. Virginia – Singapore	~15,500 km	~155 ms	~210–235 ms	~1.4
Frankfurt – London	~640 km	~6 ms	~13–18 ms	~2.4
Frankfurt – Mumbai	~6,600 km	~66 ms	~110–125 ms	~1.8
Tokyo – Singapore	~5,300 km	~53 ms	~65–75 ms	~1.3
Tokyo – Sydney	~7,800 km	~78 ms	~100–115 ms	~1.4

Distances are great-circle distances computed for this book; the observed column is an approximate range consistent with public inter-region measurements, not a provider guarantee.

WORKED EXAMPLE

Worked example — How far is Singapore from Virginia, in milliseconds?

1. Distance: about 15,500 km.
2. Floor: $2 \times 15,500 / 200,000 = 0.155$ s $= 155$ ms.
3. With $k = 1.4$ and $t_{equip} \approx 2$ ms: $1.4 \times 155 + 2 = 219$ ms, inside the observed range in Table 44.2.
4. Compare the vacuum limit: $2 \times 15,500 / 299,792 = 103$ ms. Even an impossible straight vacuum path would cost over 100 ms.

Interpretation. Roughly 70% of the observed RTT is unavoidable propagation; the rest is geography of cables and equipment. **Engineering implication.** Design budgets assume about 220 ms for Virginia–Singapore. No database, protocol or vendor can make a synchronous Virginia–Singapore commit fast; only a design that avoids the round trip can.

44.4.2 Round trips per user action

A user action rarely costs one round trip. A cold HTTPS request needs DNS, TCP and TLS before the first byte (§7.10), and an application that calls a remote database several times *sequentially* multiplies the RTT.

FORMULA

Latency of a user action with sequential cross-region round trips

$$T_{\text{action}} = n_{\text{setup}} \cdot \text{RTT}_u + n_{\text{app}} \cdot \text{RTT}_u + n_{\text{back}} \cdot \text{RTT}_b + T_{\text{compute}}$$

Symbol	Meaning	Units
n_{setup}	Round trips for connection setup (TCP + TLS 1.3 = 2; 0 when reused)	count
n_{app}	Sequential application round trips from the client to the serving region	count
RTT_u	RTT from the user to the serving region	ms
n_{back}	Sequential round trips from the serving region to a remote region (for example a remote database)	count
RTT_b	RTT between the serving region and the remote region	ms
T_{compute}	Server processing time	ms
T_{action}	Time the user waits	ms

WORKED EXAMPLE

Worked example — QuickBite checkout from Berlin. Checkout needs one new connection (TCP + TLS 1.3: 2 round trips), one API call, and on the server four sequential database calls (read cart, read prices, insert order, update inventory). Compute is 40 ms. User–Frankfurt RTT is 15 ms; Frankfurt–Virginia RTT is 90 ms; user–Virginia RTT is 100 ms.

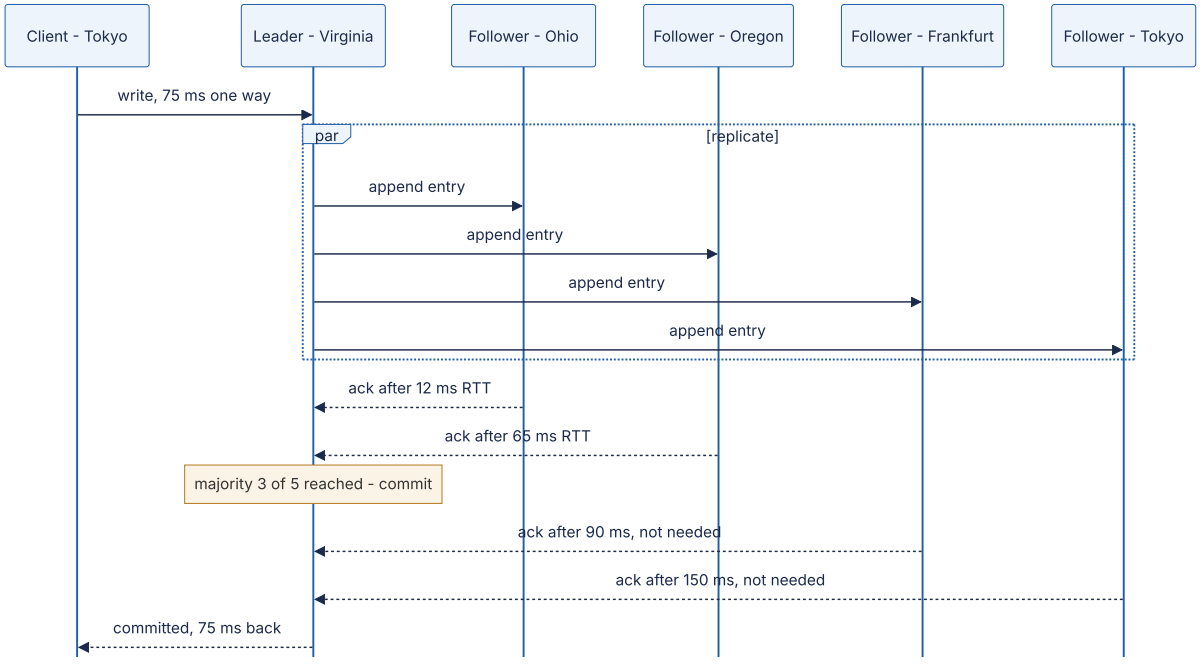
1. *Single region in Virginia:* $2 \times 100 + 1 \times 100 + 0 + 40 = 340$ ms.
2. *Frankfurt front end, database still in Virginia:* $2 \times 15 + 1 \times 15 + 4 \times 90 + 40 = 445$ ms. Moving only the stateless tier made it *slower*.
3. *Frankfurt front end and EU-homed data in Frankfurt:* $2 \times 15 + 15 + 4 \times 1 + 40 = 89$ ms.

Interpretation. The stateless tier is not where latency lives; the data is.
Engineering implication. Move data with compute, or batch backend calls into one round trip. Splitting the tiers across regions is a common anti-pattern; edge termination of TLS (Chapter 21) helps setup cost but not database round trips.

44.4.3 Consensus commit latency across regions

Chapter 26 showed that a leader commits once the fastest $q - 1$ followers acknowledge (§26.4.2). Across regions two further terms matter: the client's distance from the leader, and how many *regions* can fail without losing a quorum.

Figure 44.2 — A quorum write from Tokyo with a Virginia leader and five voters.



Reading the diagram. The Tokyo client sends its write synchronously to the leader in Virginia (half of a 150 ms RTT). The leader appends locally and sends the entry to all four followers in parallel. With five voters the quorum is three, the leader plus two followers, so the commit happens at the second-fastest acknowledgment, Oregon at 65 ms. Frankfurt and Tokyo receive the entry too, but the leader does not wait for them. The client then waits another 75 ms for the reply: about $150 + 65 = 215$ ms in total, even though a voter sits in Tokyo. Every replica is a storage boundary. Failure points: if Ohio fails, the commit waits for Frankfurt (90 ms); if Virginia fails, a new leader must be elected and clients re-routed (§26.7.2). Scaling: more voters raise the order statistic; moving the leader closer to writers cuts the first term.

FORMULA

Client-perceived quorum write latency and region-loss tolerance

$$L_{\text{write}}(c) \approx \text{RTT}(c, \ell) + t_{\text{fsync}} + \text{RTT}_{(q-1)}(\ell), \qquad \text{survives loss of region } r \Leftrightarrow N - n_r \geq q$$

Symbol	Meaning	Units
c	Region of the client (or of the service calling the database)	—
ℓ	Region of the leader (leaseholder)	—
$\text{RTT}(c, \ell)$	Round trip from client to leader; about 1 ms if in the same region	ms
t_{fsync}	Durable flush time	ms
$\text{RTT}_{(q-1)}(\ell)$	The $(q-1)$-th smallest RTT from the leader to the other voters	ms
N	Number of voting replicas	replicas
q	Quorum size, $\lfloor N/2 \rfloor + 1$	replicas
n_r	Voting replicas placed in region r	replicas

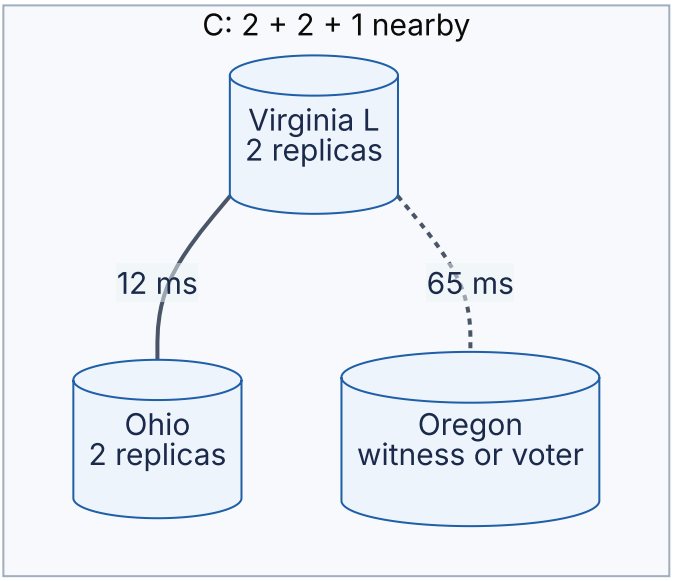
WORKED EXAMPLE

Worked example — Placing QuickBite's global account database: three versus five regions. QuickBite wants one strongly consistent store for global accounts (email uniqueness, payment-method tokens). Writers are 50% Virginia, 30% Frankfurt, 20% Tokyo. Use Table 44.2 midpoints: Virginia–Ohio 12, Virginia–Oregon 65, Virginia–Frankfurt 90, Virginia–Tokyo 150 ms; $t_{\text{fsync}} = 1$ ms; leader in Virginia.

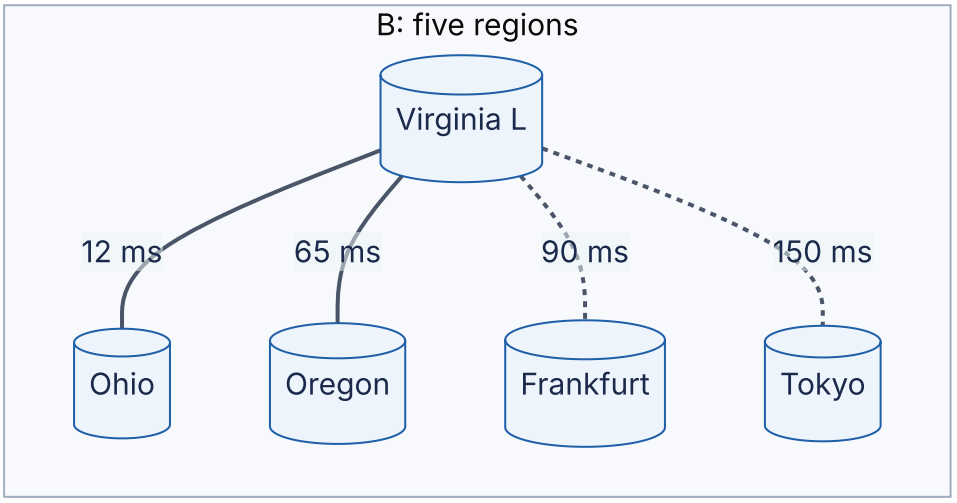
1. *Placement A — three regions, one per market (Virginia, Frankfurt, Tokyo):* $q = 2$, so one follower: $\min(90, 150) = 90$ ms. Write latency from Virginia $1 + 1 + 90 = 92$ ms; Frankfurt $90 + 1 + 90 = 181$ ms; Tokyo $150 + 1 + 90 = 241$ ms. Weighted mean: $0.5 \times 92 + 0.3 \times 181 + 0.2 \times 241 = 148.5$ ms. Survives the loss of any one region.
2. *Placement B — five regions (Virginia, Ohio, Oregon, Frankfurt, Tokyo):* $q = 3$; follower RTTs sorted 12, 65, 90, 150; second-smallest 65 ms. Virginia $1 + 1 + 65 = 67$; Frankfurt $90 + 66 = 156$; Tokyo $150 + 66 = 216$ ms. Weighted mean $0.5 \times 67 + 0.3 \times 156 + 0.2 \times 216 = 123.5$ ms. Survives the loss of any *two* regions.
3. *Placement C — five replicas in three nearby regions, 2 + 2 + 1 (Virginia ×2 in different zones, Ohio ×2, Oregon ×1):* $q = 3$; follower RTTs 1, 12, 12, 65; second-smallest 12 ms. Virginia $1 + 1 + 12 = 14$; Frankfurt $90 + 13 = 103$; Tokyo $150 + 13 = 163$ ms. Weighted mean $0.5 \times 14 + 0.3 \times 103 + 0.2 \times 163 = 70.5$ ms. Loss of Virginia leaves $5 - 2 = 3 \geq q$; loss of Ohio leaves 3; loss of Oregon leaves 4. Survives any one region.
4. *Sensitivity in B:* if Ohio is down, the second-smallest becomes 90 ms, and Virginia writes rise from 67 to 92 ms.

Interpretation. Spreading voters across continents (A) buys geographic diversity at roughly double the mean latency of a clustered placement (C). Adding regions (B) adds failure tolerance and, here, *reduces* latency compared with A, because more nearby voters exist. **Engineering implication.** Put the voters that form the usual quorum close to the leader, put the leader close to most writers, and serve distant readers from non-voting replicas or follower reads (§44.12). This is the shape of Spanner's multi-region configurations, which place two read-write regions with two replicas each and a nearby witness region [Google Cloud Docs: Spanner instance configurations].

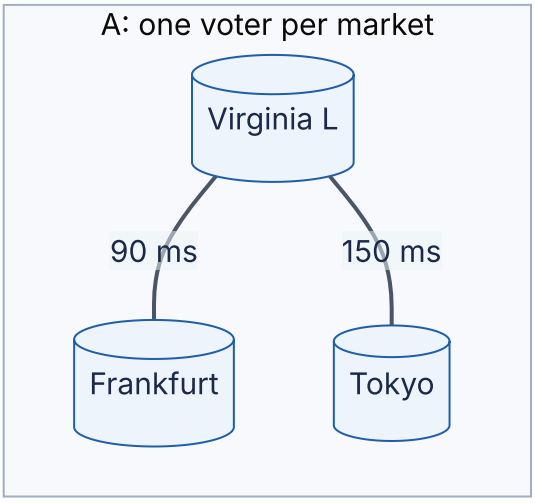
Figure 44.3 — Three voter placements and their usual quorum.



C: 2 + 2 + 1 nearby
Virginia L
2 replicas
12 ms
65 ms
Ohio
2 replicas
Oregon
witness or voter



B: five regions
Virginia L
12 ms
65 ms
90 ms
150 ms
Ohio
Oregon
Frankfurt
Tokyo



A: one voter per market
Virginia L
90 ms
150 ms
Frankfurt
Tokyo

Reading the diagram. Each box is one placement of the same replicated database; cylinders are voting replicas and "L" marks the leader. Solid links are the round trips that form the leader's usual quorum; dotted links reach voters that receive every write but are not normally waited for. Placement A must wait for an ocean crossing on every write. Placement B's quorum stays in North America while still holding copies in Europe and Asia. Placement C keeps the quorum within 12 ms and uses Oregon only as a tie-breaker when Virginia or Ohio is lost. Failure points: in C, a continent-wide event (a major North American routing failure) takes out all voters; in A, every write pays the ocean. Scaling: reads scale with non-voting replicas in each market without slowing writes.

Failure scenarios

Table 44.3 — Latency-related failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Write p99 doubles after a region blip	A nearby voter failed; quorum now needs a distant one	Commit-latency histogram per range; voter health	Restore voter; move leader	Place *q* voters close; alert on order-statistic shift
Service slower after "moving closer"	Stateless tier moved, data did not (§44.4.2)	Trace shows many cross-region DB spans	Co-locate data or batch calls	Count backend round trips in design review
Leader drifts to a far region	Election after failure picks a distant voter	Leader-location metric	Transfer leadership	Leader preferences and lease affinity
Latency regression after cable cut	Routing moves to a longer path	Inter-region RTT probes	Shift traffic or leaders	Budget for *k* up to 2; diverse paths

44.5 Global traffic management

44.5.1 Steering a request to a region

DEFINITION

Definition — Global traffic management. Global traffic management (GTM) is the set of mechanisms that choose, for each client or request, which region (or edge site) serves it, using proximity, measured latency, health, capacity and policy. It is global server load balancing (§19.9) extended with residency rules, home-region affinity and evacuation controls.

First-principles explanation

A national taxi company has one phone number. A dispatcher looks at where you are calling from, which depots are open, and which have cars, and sends you to one. The dispatcher must decide *before* the ride starts, cannot see traffic perfectly, and sometimes

has stale information about which depots are open. Every GTM mechanism is a dispatcher with a different view and a different delay.

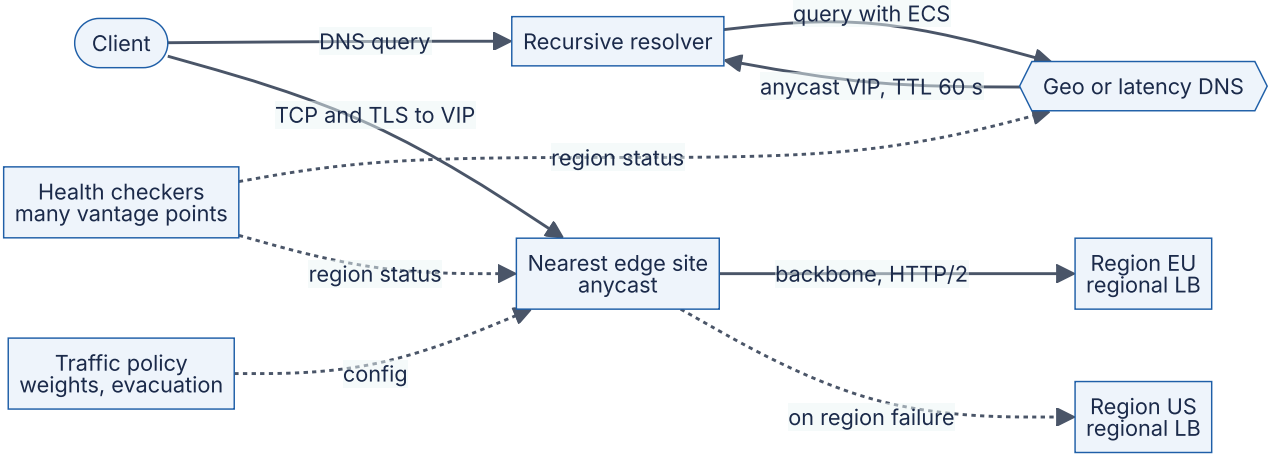
How it works internally

There are four steering mechanisms, often layered:

1. **Geo-DNS.** The authoritative DNS server answers with the address of a region chosen from the location of the querying resolver, or of the client subnet if the resolver sends EDNS Client Subnet (§7.6.5).
2. **Latency-based DNS.** The DNS service answers with the region that has the lowest *measured* latency from the resolver's network, using latency tables built from probes; AWS Route 53's latency-based routing is an example [AWS Docs: Route 53 routing policies].
3. **Anycast front door.** One IP address is announced by BGP from many edge sites (§7.5.3). Each client reaches the nearest edge by network path; the edge terminates TCP and TLS and forwards over the provider's backbone to a healthy region. Google's global load balancing works this way [Beyer et al. 2018, ch. 11], as do AWS Global Accelerator and Azure Front Door (as of 2026).
4. **Client-side selection.** The client itself holds a list of regional endpoints, measures them or is told its home region, and chooses (§44.5.4).

Health checks feed all four. A GSLB health system probes each region from many vantage points, aggregates the results so that one bad vantage point does not evacuate a region, and marks regions in or out of rotation (§19.5).

Figure 44.4 — Layers of global traffic management.



Reading the diagram. The client first resolves the service name through its recursive resolver; the GSLB-style authoritative server answers with an anycast virtual IP (VIP) and a TTL. The client then connects synchronously to that VIP, and BGP delivers the connection to the nearest edge site, which terminates TCP and TLS and forwards requests over

the provider's private backbone to a regional load balancer. Health checkers report region status asynchronously (dotted) to both the DNS layer and the edges, and a traffic-policy service pushes weights and evacuation settings. Because the address is stable, a region failure is handled by the edge choosing another backend within seconds, not by waiting out DNS caches. Failure points: the health system (a false "unhealthy" evacuates a good region), the policy service (a bad push can misroute everyone) and the edge fleet itself. Scaling: add edge sites; regional capacity is the real limit.

44.5.2 DNS TTL limits on failover

DNS-only failover is bounded by caches you do not control (§7.6.4). The total time from failure to clients reaching a healthy region has four parts.

FORMULA

DNS-based failover time

$$T_{\text{fo}} = T_{\text{detect}} + T_{\text{decide}} + T_{\text{TTL}} + T_{\text{reconnect}}, \qquad \bar{T}_{\text{fo}} \approx T_{\text{detect}} + T_{\text{decide}} + \tfrac{1}{2}T_{\text{TTL}} + T_{\text{reconnect}}$$

Symbol	Meaning	Units
T_{detect}	Time for health checks to declare the region unhealthy (probe interval × failures required)	s
T_{decide}	Time for automation or a human to approve the shift (0 if fully automatic)	s
T_{TTL}	Record TTL: worst-case time a resolver keeps serving the old answer	s
$T_{\text{reconnect}}$	Time for clients with open connections to notice failure and reconnect (timeouts, retries)	s
$T_{\text{fo}}, \bar{T}_{\text{fo}}$	Worst-case and mean failover time for well-behaved resolvers	s

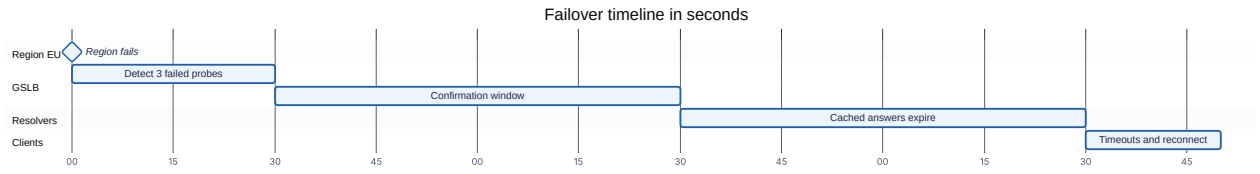
WORKED EXAMPLE

Worked example — QuickBite's DNS failover budget. Health checks probe every 10 s and require 3 consecutive failures from a majority of vantage points: $T_{\text{detect}} = 30$ s. Policy: automatic shift, but only after a 60 s confirmation window to avoid flapping: $T_{\text{decide}} = 60$ s. TTL is 60 s. Mobile clients use a 10 s request timeout and one retry: $T_{\text{reconnect}} \approx 20$ s.

1. Worst case: $30 + 60 + 60 + 20 = 170$ s.
2. Mean: $30 + 60 + 30 + 20 = 140$ s.
3. With a TTL of 300 s instead: worst case $30 + 60 + 300 + 20 = 410$ s, almost 7 minutes.
4. With an anycast front door, the TTL term disappears for region failures because the VIP does not change; the edge re-routes within its own health-check interval: about $30 + 60 + 0 + 20 = 110$ s, and less if the confirmation window is shortened.

Interpretation. With modest TTLs, detection and decision dominate; with long TTLs, caching dominates. Resolvers or runtimes that ignore TTLs add an unbounded tail. **Engineering implication.** Use short TTLs (30–60 s) on records that steer between regions, put a stable anycast address in front where you need fast failover, and measure the real tail from client telemetry rather than trusting the TTL.

Figure 44.5 — Timeline of a DNS-based regional failover (worst case, from the example).



Reading the diagram. Time runs left to right from the regional failure at 0 s. Detection takes 30 s, the deliberate confirmation window 60 s, and the TTL up to 60 s more while resolvers keep handing out the old address; clients that already had connections then need about 20 s of timeouts and retries. The phases are sequential, so they add: 170 s. Nothing is stored here; the failure point is the longest phase, which is where to invest. Shortening detection risks false evacuations; shortening the TTL raises DNS query volume; an anycast VIP removes the TTL phase entirely.

44.5.3 Anycast front doors and provider backbones

An anycast front door terminates TCP and TLS at an edge near the user, so the setup round trips of §44.4.2 cost a few milliseconds, and the long haul runs over warm, pooled

backbone connections. Google's SRE book describes the layering: DNS chooses among sites, and virtual IPs at each site are balanced to the application frontends [Beyer et al. 2016, ch. 19].

> INDUSTRY EXAMPLE
>
> **Google Cloud Load Balancing and Pokémon GO.** The SRE Workbook's "Managing Load" chapter describes how Google's global load balancing uses anycast VIPs, Google Front Ends at the edge and Maglev network load balancers, and recounts the launch of Pokémon GO on Google Cloud, where traffic far above forecast had to be absorbed and shaped at the global load-balancing layer while the backends were scaled. Lesson: the front door is the place to shed, spill and protect overloaded regions. *Evidence: Primary* — [Beyer et al. 2018, ch. 11]

44.5.4 Client-side region selection

Mobile and desktop clients can choose a region themselves. Three patterns are common:

1. **Home-region hint.** At login the service returns the user's home region (§44.6.4), often in the session token; the client calls that region's endpoint directly (`eu.api.example.com`) and falls back to a global name.
2. **Measured selection.** The client periodically measures a small probe to each candidate region and picks the fastest healthy one. This sees the client's own network, which DNS cannot.
3. **Server-directed steering.** Responses carry a header telling the client to use another region from now on (for example during evacuation), which converges faster than any DNS change for active clients.

Client-side logic moves failover speed, and risk, into your code: a region-selection bug ships to millions of devices and cannot be rolled back instantly. Keep a server-controlled kill switch and randomize cross-region retries.

Table 44.4 — Global traffic management mechanisms compared.

Mechanism	Unit of decision	Failover speed	Sees load?	Main limitation
Geo-DNS	Resolver (or client subnet)	TTL-bound: minutes	No	Resolver may be far from user
Latency-based DNS	Resolver network	TTL-bound	No (latency only)	Coarse; tables lag reality
Anycast front door	Network path per connection	Seconds (edge re-routes)	Yes, at edge	BGP path ≠ lowest latency; one shared fleet
Client-side selection	Each client	Seconds, under app control	Can be told	Client bugs are slow to fix; needs fleet control

Failure scenarios

Table 44.5 — Global traffic management failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Healthy region evacuated	Health checker or one vantage point misreports	Traffic drop with healthy server metrics	Override via traffic policy	Quorum of vantage points; cap automatic shift size
Failover does not happen	Clients pinned to dead IPs; long TTLs	Client error telemetry by region	Server-directed steering; retries	Short TTLs; anycast VIP; client fallback list
Thundering herd on survivor	Whole region's traffic arrives at once	Survivor saturation	Load shedding (§22.9); stepwise weights	Headroom (§44.11); ramped shifts
Global misroute	Bad traffic-policy push	All regions see wrong traffic mix	Roll back config	Progressive config rollout by edge or region

44.6 Deployment topologies

A multi-region topology answers two questions: *which regions serve traffic,* and *which regions may accept a write to a given record*. Four answers cover almost every design.

44.6.1 Active–passive: warm and hot standby

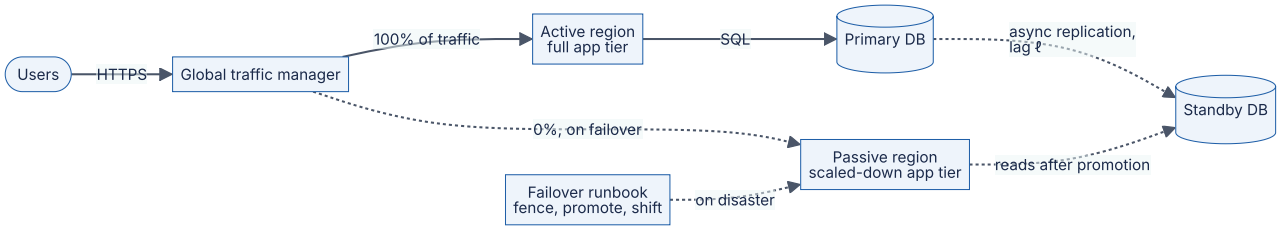
DEFINITION

Definition — Active-passive (warm or hot standby). One **active** region serves all traffic and owns all writes; one or more **passive** regions receive replicated data and take over only on failover. In **warm standby** the passive region runs a scaled-down application tier that must scale up during failover; in **hot standby** it runs at full capacity, ready to take all traffic at once (§39.8).

How it works internally

1. The active region commits writes locally and replicates asynchronously to the standby (synchronous replication across regions would add a full cross-region RTT to every write, §44.7).
2. The standby applies the stream and lags by the replication delay ℓ.
3. On failover: confirm the active region is really lost, **fence** it so it cannot accept writes (revoke credentials, stop its writers, bump an epoch, §26.13), promote the standby database, scale the standby application tier (warm) or not (hot), and shift traffic (§44.5).
4. Writes acknowledged in the active region but not yet replicated are lost or must be reconciled later. The loss window is the lag at failure time (§44.7.2).

Figure 44.6 — Active–passive with a warm standby.



Reading the diagram. All user traffic goes synchronously to the active region, whose application tier reads and writes the primary database. The primary replicates asynchronously to the standby (dotted), which lags by ℓ. The passive region's small application tier receives no traffic until a failover, which a runbook or automation drives in three steps: fence the old primary, promote the standby, shift traffic. Storage boundaries: one primary, one standby. Failure points: the failover path is rarely used, so it decays; the standby may be under-sized when it is needed; writes inside the lag window are lost. Scaling: the active region carries all load, so the design does not reduce latency for distant users.

> WARNING / TRADE-OFF
>
> **Warning — Split brain across regions.** A network partition can make the active region *look* dead to the failover controller while it still serves some users. If you promote the standby without fencing the old primary, both regions accept writes and diverge (§26.12). Fence first, by a mechanism that works even if the old region is unreachable (for example, revoking its database credentials from a third region, or a lease it must renew).

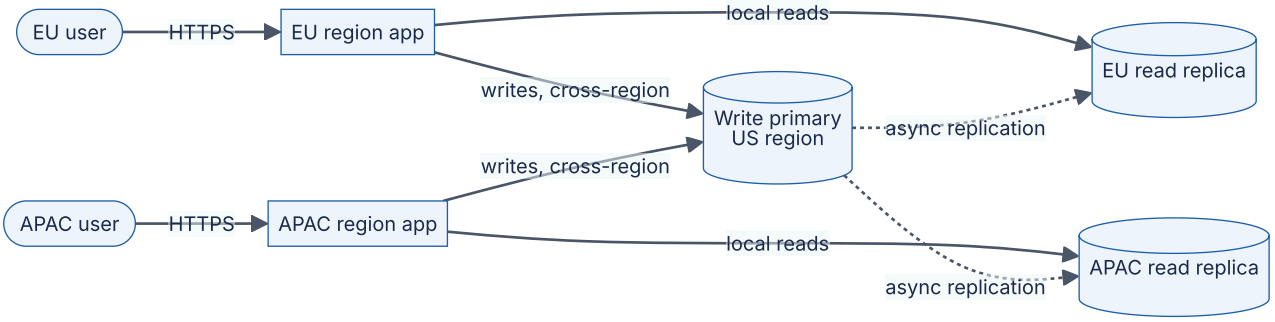
44.6.2 Active–active, read-local, write-global

DEFINITION

Definition — Read-local/write-global. Every region serves traffic and reads from a local replica, but writes for any record go to a single write location: one global primary region, or the leader of each record's consensus group.

Most user traffic is reads, so most requests stay local and fast. Writes pay RTT(c, ℓ) plus the commit. The price is **staleness**: a local replica may not yet show a write that just committed elsewhere, including the user's own write (§44.12).

Figure 44.7 — Active-active, read-local and write-global.



Reading the diagram. Each region's application serves its users and reads synchronously from a local replica: a few milliseconds. Writes travel synchronously across regions to the single write primary in the US, so an EU write pays about 90 ms and an APAC write about 150 ms. The primary replicates asynchronously (dotted) back to every read replica, so a read issued right after a write may not see it. Storage boundaries: one primary and one replica per region. Failure points: the write primary is a global single point for writes; if the US region fails, writes stop everywhere until failover, while reads continue from replicas. Scaling: reads scale per region; writes are limited by one primary, unless partitioned so each partition has its own leader.

44.6.3 Active–active, multi-writer

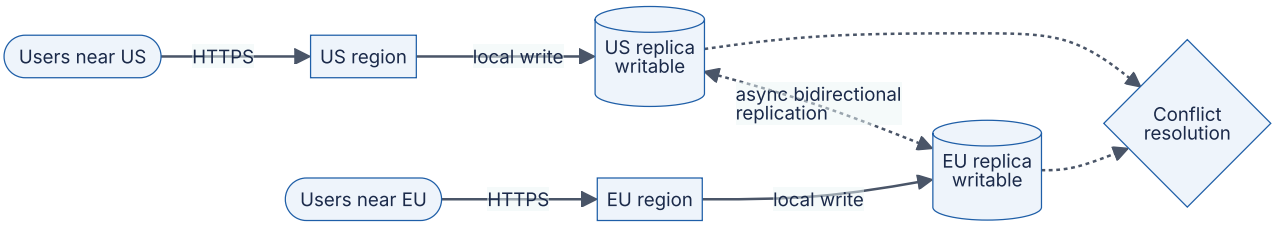
DEFINITION

Definition — Multi-writer active-active. Every region accepts writes to any record locally and replicates them asynchronously to the other regions; concurrent writes to the same record in different regions are **conflicts** that must be detected and resolved (§44.8). This is multi-leader replication (§27.6) at regional scale.

Writes are as fast as local writes, and every region stays writable during a partition: PA/EL in PACELC terms (§25.9) [Abadi 2012]. The bill is conflict handling, and the knowl-

edge that a write acknowledged in one region can still be overwritten by a concurrent write elsewhere.

Figure 44.8 — Multi-writer active-active.



Reading the diagram. Each region writes synchronously to its own writable replica and acknowledges the user at local latency. Replicas exchange changes asynchronously in both directions (dotted). When both regions changed the same record within the replication lag, the conflict-resolution step decides the outcome: last-writer-wins, a merge function or a CRDT (§44.8). Storage boundaries: one writable replica per region. Failure points: silent loss of one side of a conflict, replication loops, and divergence if a region is cut off for hours and then reconnects with a large backlog. Scaling: writes scale with regions, but global uniqueness constraints (usernames, seat inventory) cannot be enforced locally.

44.6.4 Home region per user: data partitioned by geography

DEFINITION

Definition — Home region; geo-partitioning. Geo-partitioning splits data by a geographic key so that each record has exactly one **home region** that owns its writes. Requests for a record are served by, or forwarded to, its home region. **Follow-the-sun** placement moves ownership or leadership over time to where activity is (for example, moving a partition's leader to the region in daytime working hours), and is a variant of the same idea.

First-principles explanation

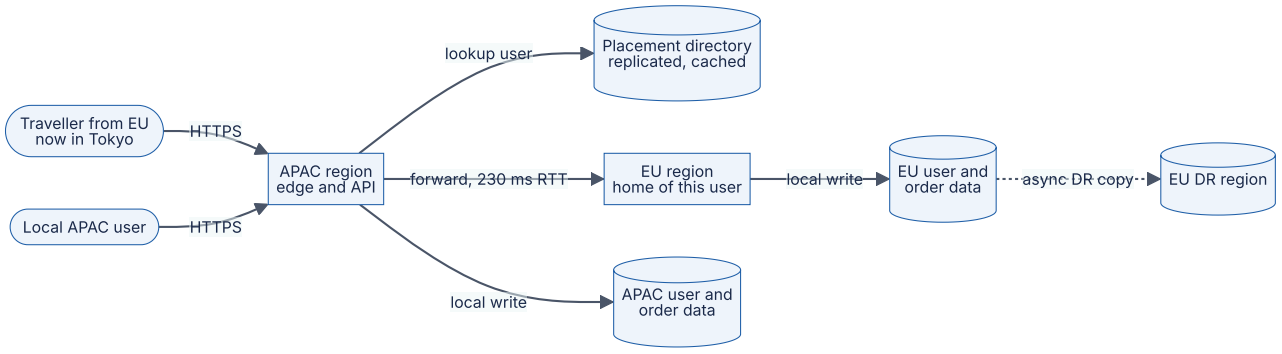
A bank account belongs to a branch. You can walk into any branch and ask about it, and the clerk will phone your home branch, but only your home branch changes the balance. Because only one place writes, there are no conflicts; because most customers bank near home, most visits need no phone call.

How it works internally

1. A **placement directory** maps each user (or tenant, restaurant, order) to a home region. QuickBite homes customers by sign-up market and orders by the restaurant's city.

2. The edge or the first region looks up the home region (cached; the directory is small and changes rarely) and routes or forwards the request.
3. The home region writes locally with in-region synchronous replication (RPO 0 within the region) and optionally ships an asynchronous copy to a DR region.
4. Moving a user between regions is a controlled migration: freeze writes for that user, copy, flip the directory entry, unfreeze.

Figure 44.9 — Home-region routing with a placement directory.



Reading the diagram. A local APAC user's requests are handled entirely in the APAC region against APAC-homed data. An EU user traveling in Tokyo arrives at the APAC region too, but the directory lookup (served from a local cached replica) says the user's home is the EU, so the request is forwarded synchronously over the long-haul link; that user pays the 230 ms round trip but sees consistent data. Each home region replicates asynchronously to its own DR region (dotted). Storage boundaries: one per market plus DR copies, which helps residency (§44.9). Failure points: the directory must be highly available and cacheable; losing the EU region makes EU-homed users' writes unavailable until DR failover; users whose activity spans regions (a group order across markets) need a cross-region protocol. Scaling: add regions or cells and assign new users to them.

44.6.5 Comparing topologies

Table 44.6 — Multi-region topologies compared.

Row	Active–passive	Read-local / write-global	Multi-writer	Home region (geo-partitioned)
What it is	One region serves; standby waits	All serve reads; one place writes	All regions write anything	Each record written only in its home
How it works	Async replication, promote on failover	Local replicas, remote leader	Async bidirectional replication	Directory routes to owner
Advantages	Simple; no conflicts	Fast reads; one source of truth	Fast local writes; writable in partitions	Local reads and writes for most; no conflicts
Disadvantages	No latency gain; failover rots; RPO > 0	Slow writes for distant users; stale reads	Conflicts, lost updates, no global constraints	Cross-home access is slow; migrations
Performance	Distant users pay full RTT	Reads local; writes $+\mathrm{RTT}(c,\ell)$	Reads and writes local	Local for home users; RTT for travellers
Operational complexity	Low day to day, high at failover	Medium	High	Medium–high (directory, migration)
Cost	Standby 30–100% of active	Replicas in every region	Full capacity everywhere	Regions sized for own market plus headroom
Use cases	Internal tools, DR for one-region apps	Catalogs, content, profiles	Carts, presence, collaborative state	Accounts, orders, tenants, residency
Choose when	Latency is fine, RTO minutes is OK	Reads dominate; writes tolerate RTT	Conflicts are mergeable	Data has a natural geographic owner

Mathematical foundations: availability with failover time

The availability benefit of a topology depends on how long a regional incident hurts users, not just on how many regions exist.

FORMULA

Annual user-weighted downtime by topology

$$D_{\text{AP}} = f\,[\,p_s T_{\text{fo}} + (1 - p_s) T_{\text{out}}\,] + f_g T_g \qquad D_{\text{AA}} = Nf \cdot \tfrac{1}{N} \cdot T_{\text{shift}} + f_g T_g = f T_{\text{shift}} + f_g T_g$$

$$A = 1 - \frac{D}{525,600 \text{ min}}$$

Symbol	Meaning	Units
f	Region-level incidents per region per year	incidents/year
T_{out}	Duration of a regional incident if you simply wait	min
T_{fo}	Active–passive failover time: detect + decide + promote + shift	min
p_s	Probability the failover works when attempted	probability
N	Number of active regions, each carrying $1/N$ of users	regions
T_{shift}	Time for an active–active system to move the affected region's users	min
f_g, T_g	Frequency and duration of *global* incidents that no topology contains (bad global config, shared dependency)	incidents/year, min
$D_{\text{AP}}, D_{\text{AA}}$	Expected user-weighted downtime per year	min/year
A	Resulting availability	fraction

The active–active formula counts incidents in all N regions, but each affects only $1/N$ of users, so the N cancels. Double failures (two regions down together) are ignored; they are rare compared with the terms kept, unless failures are correlated.

WORKED EXAMPLE

Worked example — How much does each topology buy QuickBite? Assume $f = 2$ regional incidents per region-year lasting $T_{out} = 180$ min; active–passive failover $T_{fo} = 45$ min (human decision, promotion, warm-up); active–active shift $T_{shift} = 3$ min (automatic); one global incident per year of 30 min.

1. *Single region:* $D = 2 \times 180 + 30 = 390$ min; $A = 1 - 390/525,600 = 99.926\%$.
2. *Active–passive, failover always works ($p_s = 1$):* $2 \times 45 + 30 = 120$ min; $A = 99.977\%$.
3. *Active–passive, failover works 80% of the time:*
   $2 \times (0.8 \times 45 + 0.2 \times 180) + 30 = 2 \times 72 + 30 = 174$ min; $A = 99.967\%$.
4. *Active–active, $N = 3$:* $2 \times 3 + 30 = 36$ min; $A = 99.993\%$.
5. *Active–active with the global incident removed:* 6 min; $A = 99.9989\%$.

Interpretation. Active–active turns 360 minutes of regional pain into 6, but the single 30-minute global incident then accounts for 83% of the remaining downtime. An unreliable failover path quietly gives back a fifth of the active–passive benefit (54 of 270 minutes). **Engineering implication.** Once you are multi-region, the highest-value work is eliminating global dependencies (§44.10) and rehearsing failover (§44.11), not adding a fourth region.

INDUSTRY EXAMPLE

Netflix: active–active across AWS regions. After a 2012 outage in a single AWS region, Netflix moved from a single-region design to serving members from multiple AWS regions, any of which can take over another's traffic. Their described approach combined DNS and edge traffic steering, Cassandra replicated across regions with eventually consistent writes, and an emphasis on making every region able to serve any member, so that a failing region's traffic could be evacuated to the others. *Evidence: Primary* — [Meshenberg et al. 2013]

Common misconceptions

COMMON MISTAKE

Mistake — "Active-active means every region can write every record." Most production "active–active" systems are read-local/write-global or home-region designs: every region *serves*, but each record has one writer. Full multi-writer is reserved for data whose conflicts can be merged.

44.7 Geo-replication

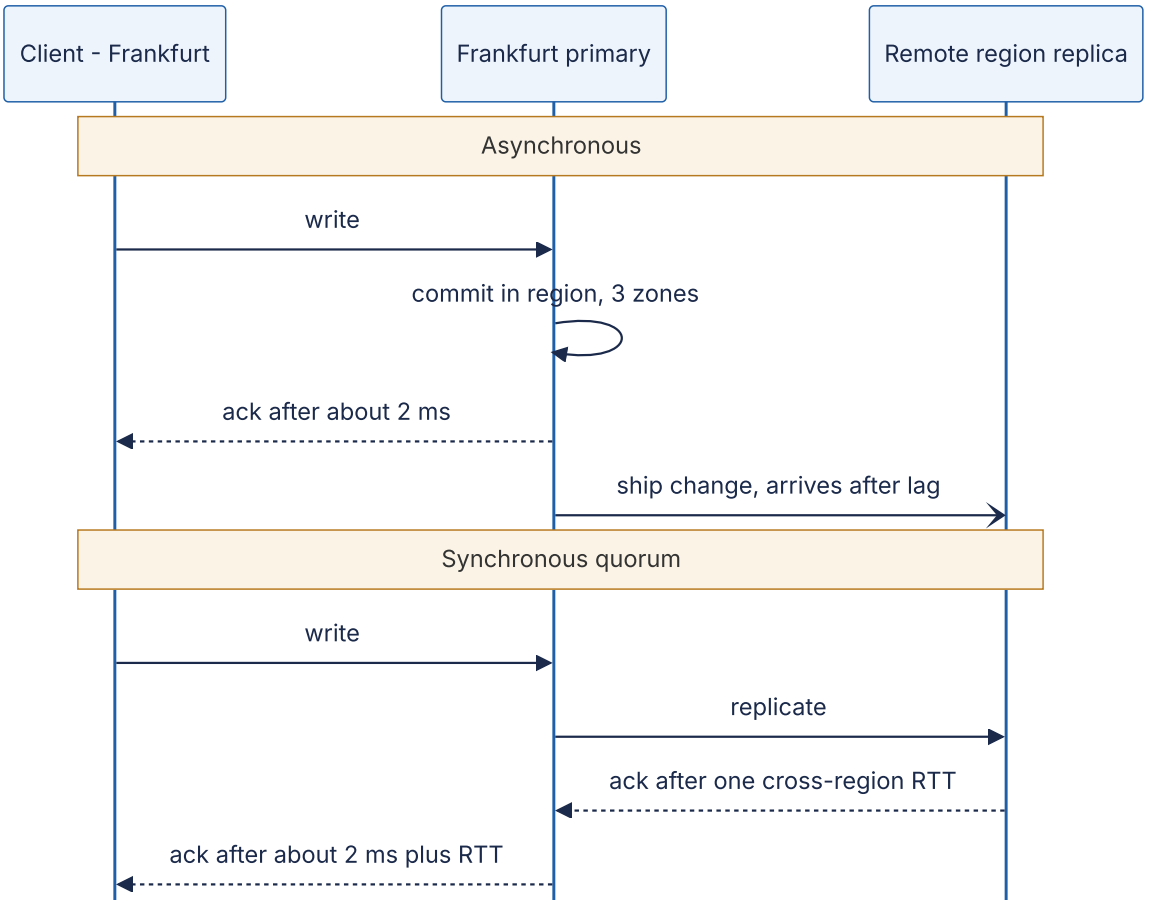
44.7.1 Asynchronous versus synchronous across regions

DEFINITION

Definition — Geo-replication; replication lag. Geo-replication copies data between regions. It is **synchronous** when a write is acknowledged only after a copy (or a quorum of copies) in another region has it, and **asynchronous** when the write is acknowledged locally and shipped afterward. **Replication lag** ℓ is the time between a write's local commit and its application in a given remote replica.

Synchronous geo-replication gives RPO = 0 for region loss and costs at least one cross-region RTT per write (§44.4.3). Asynchronous geo-replication costs nothing on the write path and loses whatever is in flight when a region dies. Most systems use both: synchronous *within* a region across zones, asynchronous *between* regions, with synchronous cross-region consensus only for the small set of data that cannot tolerate loss or conflict.

Figure 44.10 — Asynchronous versus synchronous cross-region writes.



Reading the diagram. In the asynchronous half, the Frankfurt primary commits across its own zones and answers the client in about 2 ms; the change travels to the remote region afterward (open arrowhead), arriving after the lag ℓ. If Frankfurt is lost before it arrives, the acknowledged write is gone. In the synchronous half, the primary waits for the remote acknowledgment before answering, so every write pays a cross-region RTT, and a remote-region outage blocks writes unless a quorum of other regions remains. Storage boundaries: the primary's zones and the remote replica. Scaling: asynchronous throughput is limited by shipping bandwidth; synchronous throughput by pipelining, since latency, not bandwidth, is the bound.

44.7.2 Replication-lag budgets and the data-loss window

With asynchronous replication, the RPO is not a configuration value; it is the lag at the moment of failure. Lag is not constant: it grows when the replication link is congested, when the remote replica is slow to apply, or, crucially, when the source region is *already degrading*, which is exactly when failures happen.

FORMULA

Data-loss window for asynchronous geo-replication

$$\mathrm{RPO}_{\mathrm{actual}} = \ell(t_f), \qquad W_{\mathrm{lost}} \approx \lambda_w \cdot \ell(t_f), \qquad \ell(t) \approx \ell_0 + \frac{\max(0,\ \lambda_w - \mu_r)\, t}{\lambda_w}$$

Symbol	Meaning	Units
t_f	Time of the regional failure	s
$\ell(t)$	Replication lag at time t	s
ℓ_0	Steady-state lag (batching plus one-way transit plus apply)	s
λ_w	Write rate in the failed region	writes/s
μ_r	Replication throughput (ship and apply)	writes/s
t	Time since replication throughput fell below the write rate	s
W_{lost}	Acknowledged writes lost if the region never returns	writes

WORKED EXAMPLE

Worked example — QuickBite EU orders. The EU region writes $\lambda_w = 400$ order-state changes per second at dinner peak. Changes ship in 100 ms batches with 45 ms one-way transit to the DR region and about 5 ms apply, so $\ell_0 \approx 50 + 45 + 5 = 100$ ms on average (half a batch waits, on average).

1. *Steady state:* $W_{\text{lost}} = 400 \times 0.1 = 40$ order changes.
2. *Degrading region:* 10 minutes before the outage, a failing network device halves cross-region throughput to $\mu_r = 200$ writes/s while writes continue. Backlog grows by 200 writes/s for 600 s: 120,000 writes. Lag: $0.1 + 120,000/400 = 300.1$ s, five minutes.
3. $W_{\text{lost}} \approx 400 \times 300 = 120,000$ order changes: thousands of orders in unknown states.

Interpretation. The steady-state RPO of 100 ms is a fair-weather number; the RPO that matters is the lag during the incident, which here is 3,000 times larger.
Engineering implication. Alert on replication lag and backlog, set a **lag budget** (for example, “lag above 5 s for 1 minute pages the on-call engineer; above 30 s the region stops accepting new orders” — an RPO guard that trades availability for bounded loss), and reconcile lost writes when the region returns rather than discarding them (§44.11.4).

44.7.3 Conflict-free by construction: home-region ownership

If each record has exactly one home region that accepts its writes (§44.6.4), asynchronous replication creates no conflicts: replicas elsewhere are read-only copies that lag. Conflicts reappear only during a failover, when the DR copy is promoted and the old home may hold writes the DR copy never received. Treat those as a reconciliation job, not as a merge.

44.7.4 Managed geo-replicated databases (as of 2026)

Table 44.7 — Managed geo-replication options (published facts as of 2026; check current documentation).

Product	Write model	Cross-region consistency	Conflict handling	Notes
DynamoDB global tables, multi-Region eventual consistency (default)	Any replica Region accepts writes	Asynchronous; AWS states changes usually propagate within a second	Last-writer-wins on concurrent updates	PA/EL; RPO > 0
DynamoDB global tables, multi-Region strong consistency	Writes replicated to another Region before success	Strongly consistent reads available in each Region	Concurrent conflicting writes are rejected with an error, not merged	Exactly three Regions: three replicas, or two replicas plus a witness; RPO 0; mode fixed at table creation
Spanner multi-region	Paxos leader per split, default leader region	External consistency (§28.8); stale reads local	No conflicts (single leader per split)	Base configs: two read-write regions with two replicas each plus a witness region; five voters; optional read-only replicas
CockroachDB multi-region	Raft leaseholder per range; table localities	Serializable; follower reads stale and local	No conflicts	Survival goal zone (default) or region (needs ≥ 3 regions); `REGIONAL BY TABLE`, `REGIONAL BY ROW`, `GLOBAL`
Aurora Global Database	One primary Region; secondaries read-only	Asynchronous storage-level replication	No conflicts (one writer); write forwarding available	Planned switchover has no data loss; unplanned failover RPO typically seconds

Sources: [AWS Docs: DynamoDB global tables], [Google Cloud Docs: Spanner instance configurations], [Cockroach Labs Docs: Multi-region overview], [AWS Docs: Aurora Global Database].

A few details matter when choosing:

- **DynamoDB global tables** in the default mode resolve concurrent writes with last-writer-wins, so make each item single-owner or an idempotent overwrite (§44.8). The strong mode (generally available since 2025) trades write latency for RPO 0 [AWS Docs: DynamoDB global tables].
- **Spanner** multi-region instances put a write quorum within the leader region and the second read-write region or nearby witness, so writes cost a regional RTT (tens of milliseconds), not an intercontinental one, while reads anywhere can use stale (bounded or exact timestamp) reads served by local replicas [Corbett et al. 2012; Google Cloud Docs: Spanner instance configurations]. Brewer argues that Spanner is technically CP but, because Google's private network makes partitions rare, delivers availability high enough that users can treat it as CA [Brewer 2017].

- **CockroachDB** expresses placement declaratively. `REGIONAL BY ROW` stores a hidden region column per row and homes each row's leaseholder in that region: home-region ownership inside one SQL database. `GLOBAL` tables serve consistent, low-latency reads from every region by writing at future timestamps, so writes are slower [Taft et al. 2020; VanBenschoten et al. 2022]. A region survival goal places voters so that a region loss keeps a quorum, at the cost of cross-region writes (§44.4.3).
- **Aurora Global Database** distinguishes a planned *switchover*, which waits for the secondary to catch up and suits drills, from an unplanned *failover*, which accepts the lag as data loss [AWS Docs: Aurora Global Database].

44.7.5 Code example: simulating write latency and failover loss

The program below models clients in Virginia, Frankfurt and Tokyo writing 2,000 times per second. It compares an active–passive pair (Virginia primary, Oregon standby, asynchronous batched replication) with consensus groups of three and five regions, and kills the primary or leader region at $t = 15$ s. For each design it reports write latency by client region and the number of *acknowledged* writes that no surviving replica holds.

```
        """Write latency and failover data loss: active-passive async vs multi-region
quorum."""
        import random
        import statistics

        RTT_MS = {  # approximate inter-region round-trip times, ms (illustrative)
            ("virginia", "ohio"): 12, ("virginia", "oregon"): 65,
            ("virginia", "frankfurt"): 90, ("virginia", "tokyo"): 150,
            ("ohio", "oregon"): 50, ("ohio", "frankfurt"): 100, ("ohio", "tokyo"): 140,

What to notice:

- **Durability is checked, not assumed.** For each committed write, `quorum` records when every follower received it and verifies that some replica outside the failed region holds it at the moment of failure. The count is 0 for every placement: a majority commit cannot be lost to one region failure.
- **Async loses the batch in flight.** The 188 lost writes are those committed in the last 100 ms batch, sealed but not yet delivered: close to $\lambda_w \ell$ from §44.7.2. Raise `batch_ms` or slow the link and the loss grows proportionally.
- **Virginia clients see the order statistic.** 2 ms (local commit), 14.5 ms (Ohio is the nearest follower), 69 ms (second-nearest of four is Oregon), 95 ms (nearest of Frankfurt and Tokyo), matching §44.4.3.
- **Distant clients pay the client-to-leader RTT in every design.** Frankfurt and Tokyo clients are slow even in the active–passive case; only home-region data (§44.6.4) or moving the leader helps them.
- **The model is deliberately small.** It ignores leader election time, apply delay and correlated network jitter; extend it in the exercises (§44.16).

44.8 Conflict handling across regions

44.8.1 Where conflicts come from and how often

DEFINITION

Definition — Cross-region write conflict. Two writes to the same record, accepted in different regions, neither of which had seen the other when it was accepted. Such writes are **concurrent** in the happens-before sense (§24.10); a system must either prevent them (ownership, consensus) or resolve them after the fact.

Inside one region, conflicts are prevented cheaply by a single leader. Across regions, the window in which two writes can be concurrent is the replication lag, tens of milliseconds to minutes, so conflict rates that were negligible become routine for hot records.

FORMULA

Expected conflict rate on one record under multi-writer replication

$$c \approx 2 r_A r_B \ell \qquad (\text{for } r \ell \ll 1)$$

Symbol	Meaning	Units
r_A, r_B	Write rates to the record in regions A and B	writes/s
ℓ	Replication lag between the regions (assumed equal both ways)	s
c	Rate of conflicting write pairs	conflicts/s

A write in A conflicts with any write in B that lands within ℓ before or after it, a window of 2ℓ; with B's writes arriving at rate r_B, each A write conflicts with probability about $2 r_B \ell$.

WORKED EXAMPLE

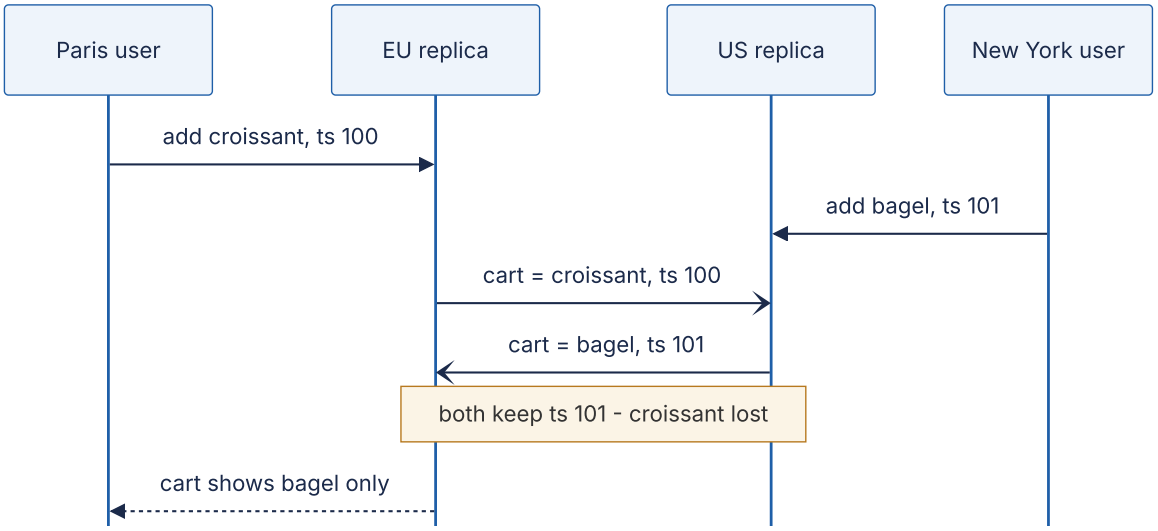
Worked example — A shared group-order cart. A group order from friends in Paris (EU region) and New York (US region) receives 0.2 edits/s from each side during the 5-minute ordering window; lag is 0.5 s at peak.

1. $c = 2 \times 0.2 \times 0.2 \times 0.5 = 0.04$ conflicts/s.
2. Over 300 s: $0.04 \times 300 = 12$ conflicting pairs per group order.
3. Under last-writer-wins on the whole cart, up to 12 edits silently vanish per order.
4. For a user profile edited once a month from one device, $r_A r_B \approx 0$: conflicts essentially never happen.

Interpretation. Conflict rate scales with the *product* of the two regions' write rates and with lag, so it is concentrated on a few hot, shared records. **Engineering implication.** Classify records: single-owner records tolerate LWW; shared, frequently edited records need ownership, a merge function or a CRDT.

44.8.2 Strategies

Figure 44.11 — A lost update under last-writer-wins across regions.



Reading the diagram. Each user writes the whole cart to the replica in their own region, and each write is acknowledged locally. The replicas then exchange states asynchronously (open arrowheads). Last-writer-wins compares timestamps, keeps the cart stamped 101 in both regions and discards the croissant, even though both writes were acknowledged and neither user removed anything. The storage boundary is each regional replica; the failure point is the merge rule, which treats two concurrent *additions* as competing *replacements*. A CRDT set or a per-item write would keep both.

The options, from most to least preferred for shared mutable data:

1. **Avoid conflicts by ownership.** Give each record a home region (§44.6.4) or route all writes for a shared object to one region, such as the region of the group order's creator. Cost: remote users pay the RTT.
2. **CRDTs.** Model the cart as an observed-remove set and quantities as counters, so concurrent operations merge deterministically (§27.14.3). Cost: data-model constraints and tombstone metadata; invariants such as "stock ≥ 0" cannot be enforced by merging alone.
3. **Application-level merge.** Keep siblings with version vectors (§27.14.2) and merge with domain rules: union of cart lines, maximum of order status in its state machine, flag for human review if a refund and a charge collide. Cosmos DB, for example, offers a custom conflict-resolution procedure or a conflicts feed for this purpose, alongside its LWW default [Azure Docs: Cosmos DB conflict resolution].
4. **Last-writer-wins.** Acceptable for single-writer or idempotent-overwrite data: a device's last-seen location, a cache entry, a preference toggle. Remember that clock skew can make the earlier write win (§27.14.1).

Some invariants cannot be merged at all: a username must be unique, a seat may be sold once, an account must not go negative. Route those operations through a single owner or a cross-region consensus group, and keep everything else local. The pattern of "local for most, global for the few operations that need it" recurs throughout this chapter.

COMMON MISTAKE

Mistake — "We use timestamps, so the latest write wins." "Latest" by whose clock? With skew ε, writes closer than ε can be misordered, and LWW discards concurrent writes even with perfect clocks. LWW is a resolution rule, not a correctness guarantee.

44.9 Data residency and sovereignty

44.9.1 Residency as a placement constraint

DEFINITION

Definition — Data residency, localization, sovereignty. Data residency is a requirement, from law, contract or customer policy, about the geographic location where data is stored and processed. **Data localization** is the stricter form: data (or a copy) must remain inside a country. **Data sovereignty** is the broader principle that data is subject to the laws of the place where it is collected or stored, which raises the question of which governments can compel access to it.

NOTE

Note — This section is architecture, not legal advice. Requirements differ by jurisdiction, sector and contract and change over time. Engineers should design for configurable placement and work with counsel on what each data class actually requires.

The constraint at an architectural level

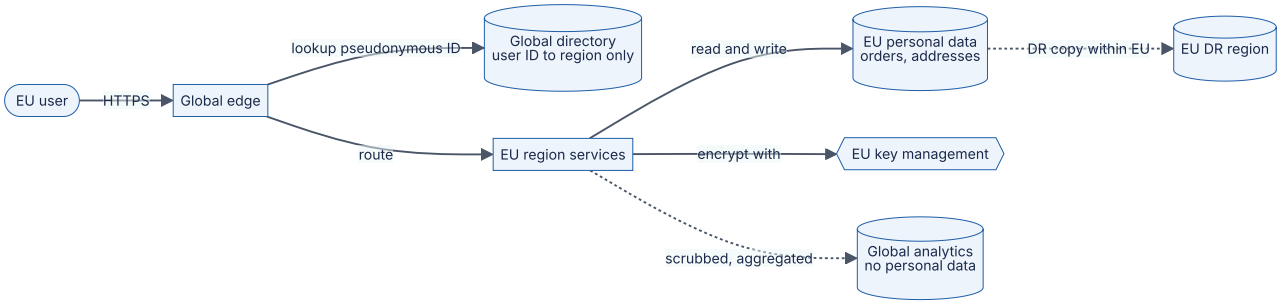
The EU General Data Protection Regulation (GDPR) does not, in general, require personal data to stay inside the EU. Its Chapter V (Articles 44–49) restricts *transfers* of personal data to countries outside the European Economic Area unless a legal basis applies: an adequacy decision by the European Commission (Article 45), appropriate safeguards such as standard contractual clauses or binding corporate rules (Articles 46–47), or narrow derogations (Article 49) [EU 2016]. In *Schrems II* (2020) the Court of Justice of the EU invalidated the EU–US Privacy Shield and required transfers under standard contractual clauses to be assessed for whether the destination's law undermines the protection, possibly with supplementary technical measures [CJEU 2020]. A new EU–US Data Privacy Framework adequacy decision followed in July 2023 [European Commission 2023]. The engineering lesson: the legal basis for a cross-border flow can change within a product's

lifetime, so architectures that can *keep* data in a region, and prove it, are worth building. Stricter national localization rules become placement policies.

How it works internally

1. **Classify data.** Personal content (orders, addresses, messages), personal metadata (account ID, home region), non-personal reference data (menus, restaurant catalogs) and derived data (logs, metrics, analytics, ML features, backups).
2. **Regional data stores.** Personal data lives in the user's home region (§44.6.4), with its DR copy in a region inside the same jurisdiction (for QuickBite's EU data, Frankfurt with DR in another EU region).
3. **Split metadata from content.** A global directory stores only a pseudonymous user ID and the home region, which is what routing needs; names, addresses and order history stay regional.
4. **Keep keys regional.** Encrypt regional data with keys held in a key-management service in the same jurisdiction, so a copy that leaks outside is unreadable; supplementary-measure discussions often turn on exactly this.
5. **Cover the side channels.** Logs, traces, crash dumps, support tooling, analytics pipelines, backups and ML training sets are where residency is usually broken. Scrub or regionalize them, and treat remote administrative access from another country as a potential transfer too.

Figure 44.12 — Metadata versus content split for residency.



Reading the diagram. The global edge needs only to know where a user lives, so the global directory holds a pseudonymous ID and a region code, nothing else. The request is routed synchronously to EU services, which read and write personal data in the EU store, encrypted with keys from an EU key-management service (hexagon, an external trust boundary). Asynchronous flows (dotted) carry only scrubbed, aggregated data to global analytics and a DR copy to another EU region. Storage boundaries: the directory (global), the personal store and its DR copy (EU only) and analytics (global, non-personal). Failure points: a log line or support export that copies personal data out; a directory field that quietly grows into a profile. Scaling: adding a jurisdiction means adding a region set and a placement rule, not redesigning.

COMMON MISTAKE

Mistake — "Our database is in Frankfurt, so we are compliant." Residency is broken more often by everything around the database: application logs shipped to a global log cluster, a support tool in another country with read access, nightly back-ups to a cheaper region, a feature pipeline that copies orders into a global training set.

44.10 Cell-based and region-isolated architectures at global scale

44.10.1 Regional independence

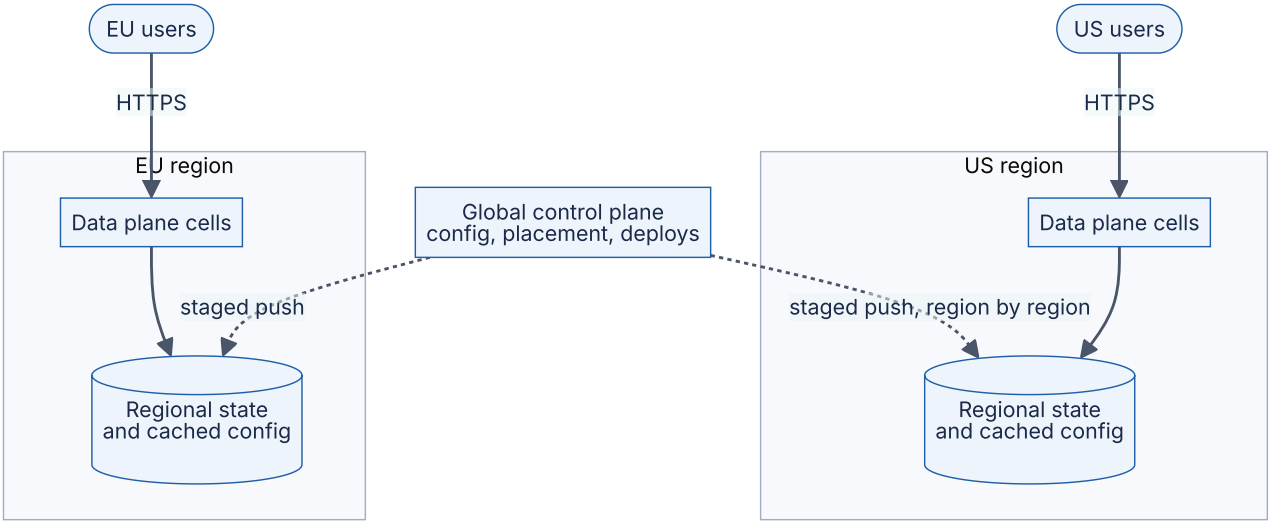
DEFINITION

Definition — Regional independence; static stability. A design is **regionally independent** when each region can serve its users with no synchronous dependency on any other region or on a global service. It is **statically stable** when it keeps working through a failure *without making changes*: no scaling, no reconfiguration and no control-plane calls are needed to survive [Weiss and Furr 2020].

Cells (§33.12) bound the blast radius of faults inside a region. At global scale the same idea applies one level up: each region is a set of cells, and regions share as little as possible. The usual culprits for shared fate are *global* components: a single global control plane, a global configuration or feature-flag service, a global identity provider, a single DNS provider, a global database for sessions, and deployment pipelines that push to every region at once.

The AWS Builders' Library article "Minimizing correlated failures in distributed systems" frames the problem: redundancy is only as good as the independence of what is redundant, and shared infrastructure, shared software and shared timing all correlate failures [AWS Builders' Library: Minimizing correlated failures]. The AWS whitepaper on fault isolation boundaries describes the provider's own split: regional services keep their control and data planes within the region, while a few global services have their control plane in one region but data planes distributed worldwide, and it recommends that recovery depend only on data-plane operations [AWS 2022].

Figure 44.13 — Regional data planes with a non-critical global control plane.



Reading the diagram. Users call each region's data-plane cells synchronously; the cells depend only on regional state, including a locally cached copy of configuration. The global control plane writes configuration, placement and deployments asynchronously (dotted), one region at a time. If the control plane fails, every region keeps serving from its last known-good configuration: static stability. Storage boundaries: one per region; there is no global store on the request path. Failure points: a bad configuration that passes validation can still reach every region, which is why pushes are staged with health checks between regions (§43.6), and a region's cached configuration must survive restarts. Scaling: add regions independently.

How to get there

1. **Inventory global dependencies** on the request path and the *recovery* path; a failover that needs a control-plane API in the failed region will not run.
2. **Pre-provision** capacity, certificates, credentials and DNS records, so failover is a data-plane change (flipping a routing control).
3. **Cache with stale-OK semantics:** tokens verified with cached keys, configuration from local snapshots.
4. **Stage every global change** by region and cell (§43.6), including configuration and certificates.
5. **Diversify the truly global**, for example two DNS providers.

INDUSTRY EXAMPLE

AWS us-east-1, 7 December 2021. AWS's published summary describes an automated capacity-scaling activity that triggered unexpected behavior in internal network clients, congesting the devices connecting AWS's internal network to the main network in the Northern Virginia region. Many services' control planes and APIs in that region were impaired for hours, while some already-running resources continued to work. AWS noted that the event also impaired its own monitoring and its ability to update the Service Health Dashboard. Lesson for designers: running resources (data plane) were more resilient than anything that needed control-plane actions, and dependencies on a single region's tooling hurt communication during the incident. *Evidence: Primary* — [AWS 2021b]

44.11 Regional failover and evacuation

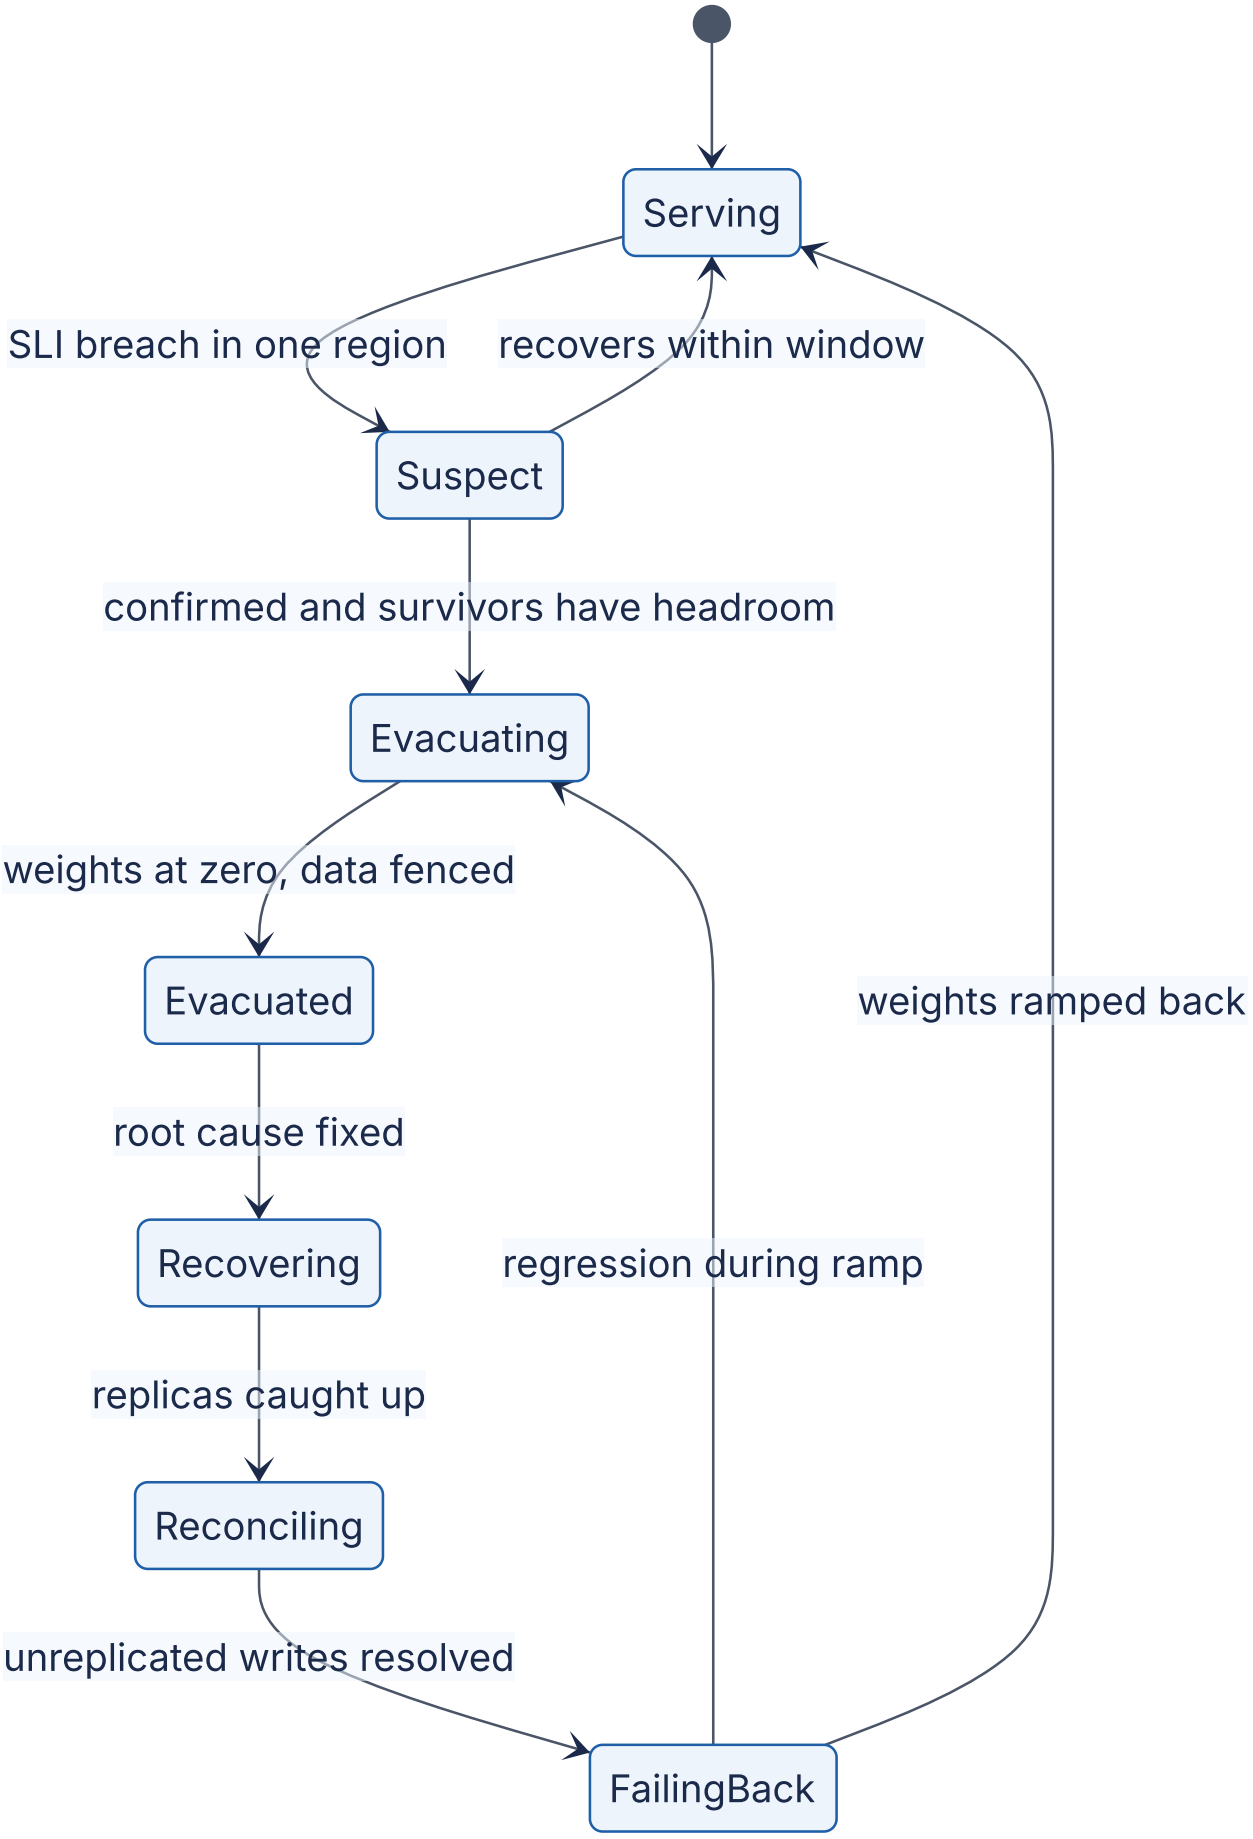
44.11.1 Detection, decision, traffic shift

DEFINITION

Definition — Regional evacuation. Deliberately moving all traffic, and where necessary data ownership, out of a region that is failing or under maintenance, onto the remaining regions, without waiting for the region to fail completely.

1. **Detection.** Use user-facing signals per region: request success rate and latency at the edge, plus synthetic probes from outside. Regional failures are often *gray* (§24.8.2): the region is partly up, and internal health checks pass while users fail.
2. **Decision.** Automate the decision for clear signals with guard rails (never evacuate more than one region automatically; require survivors to have headroom). Keep a single, rehearsed human command for ambiguous cases. Evacuating early is usually cheaper than waiting for certainty.
3. **Traffic shift.** Ramp weights (for example 25% steps every 30 s) so survivors' caches and autoscalers warm, and shed low-priority load if needed (§22.9).
4. **Data.** For home-region data, promote DR copies (fenced, §44.6.1) or serve those users read-only until the home returns.

Figure 44.14 — Regional evacuation and failback as a state machine.



Serving
SLI breach in one region
recovers within window
Suspect
confirmed and survivors have headroom
Evacuating
weights at zero, data fenced
Evacuated
root cause fixed
Recovering
replicas caught up
Reconciling
unreplicated writes resolved
FailingBack
regression during ramp
weights ramped back

Reading the diagram. A region moves from *Serving* to *Suspect* when its user-facing SLIs breach a threshold, and back if it recovers within a confirmation window. Confirmed failure with enough headroom elsewhere starts *Evacuating*: weights ramp to zero and the region's writers are fenced. Return is deliberately slower than exit: after the fix, replicas catch up, writes accepted in the region but never replicated are reconciled, and only then do weights ramp back, with an automatic return to evacuation on regression. Storage boundaries are the region's data stores, whose state gates each step. The riskiest transitions are *Evacuating* (survivor overload) and *Reconciling* (lost or duplicated writes).

44.11.2 Capacity headroom to absorb a region

FORMULA

Regional capacity to survive the loss of one of N regions

$$C_{\text{region}} = \frac{D}{(N-1)\,u_{\text{fail}}}, \qquad C_{\text{total}} = N\,C_{\text{region}}, \qquad u_{\text{normal}} = \frac{N-1}{N}\,u_{\text{fail}}, \qquad \text{overhead} = \frac{N}{N-1} - 1$$

Symbol	Meaning	Units
D	Global peak demand, spread evenly over regions	RPS
N	Number of active regions	regions
u_{fail}	Highest acceptable utilization after absorbing a region	fraction
C_{region}	Capacity to provision in each region	RPS
C_{total}	Total provisioned capacity	RPS
u_{normal}	Utilization in normal operation	fraction
overhead	Extra capacity compared with D/u_{fail} with no regional failure headroom	fraction

WORKED EXAMPLE

Worked example — QuickBite's N + 1 regions. Global peak $D = 30,000$ RPS; after a failover, regions may run at $u_{\text{fail}} = 0.8$. Without regional headroom you need $30,000/0.8 = 37,500$ RPS of capacity.

1. $N = 2$: $C_{\text{region}} = 30,000/(1 \times 0.8) = 37,500$; total 75,000; normal utilization $0.5 \times 0.8 = 40\%$; overhead 100%.
2. $N = 3$: $30,000/(2 \times 0.8) = 18,750$; total 56,250; normal 53%; overhead 50%.
3. $N = 4$: $12,500$ each; total 50,000; normal 60%; overhead 33%.
4. $N = 5$: $9,375$ each; total 46,875; normal 64%; overhead 25%.
5. *Uneven, proximity-routed traffic.* With three regions carrying US 50%, EU 30%, APAC 20%, and US traffic failing over 80% to EU and 20% to APAC, the EU region must absorb $30\% + 0.8 \times 50\% = 70\%$ of global demand: $0.7 \times 30,000/0.8 = 26,250$ RPS, 40% more than the even-split 18,750.

Interpretation. More, smaller regions make regional redundancy cheaper, but the even-split formula is optimistic when users fail over to the *nearest* survivor. **Engineering implication.** Compute the worst-case survivor load for each failure, using the real failover routing, and either size for it or steer part of the evacuated traffic to a farther region and accept extra latency. Time-zone diversity helps: if markets peak at different hours, size for the peak of the *sum*, not the sum of peaks. Reserve or pre-provision this capacity; on-demand capacity may be scarce in a regional event when every customer fails over at once [Weiss and Furr 2020].

44.11.3 Game days and continuous evacuation

A failover path that is not exercised does not work when needed. Run **game days**: planned evacuations of a production region during business hours, with the on-call team using the real runbook, measuring T_{fo}, survivor utilization and data reconciled. Mature teams evacuate regions routinely, for maintenance as well as practice, so the path stays warm.

INDUSTRY EXAMPLE

Netflix region evacuation. Netflix has described evacuating an entire AWS region's traffic to its other regions as a routine resilience exercise, and later re-engineering the process (pre-scaled capacity in the receiving regions and faster traffic steering) so that an evacuation completes in minutes rather than the better part of an hour. *Evidence: Primary* — [Netflix Technology Blog 2018]

44.11.4 Failback

Failback is a second, planned failover in reverse and deserves the same care. Wait until the recovered region's replicas have caught up; reconcile writes that the region acknowledged before it failed but never replicated (replay them where safe, or route them to human review: an order that was paid for but never dispatched matters); then ramp traffic back gradually. Never fail back automatically just because health checks turn green.

44.12 Global consistency options and the user-visible consequences

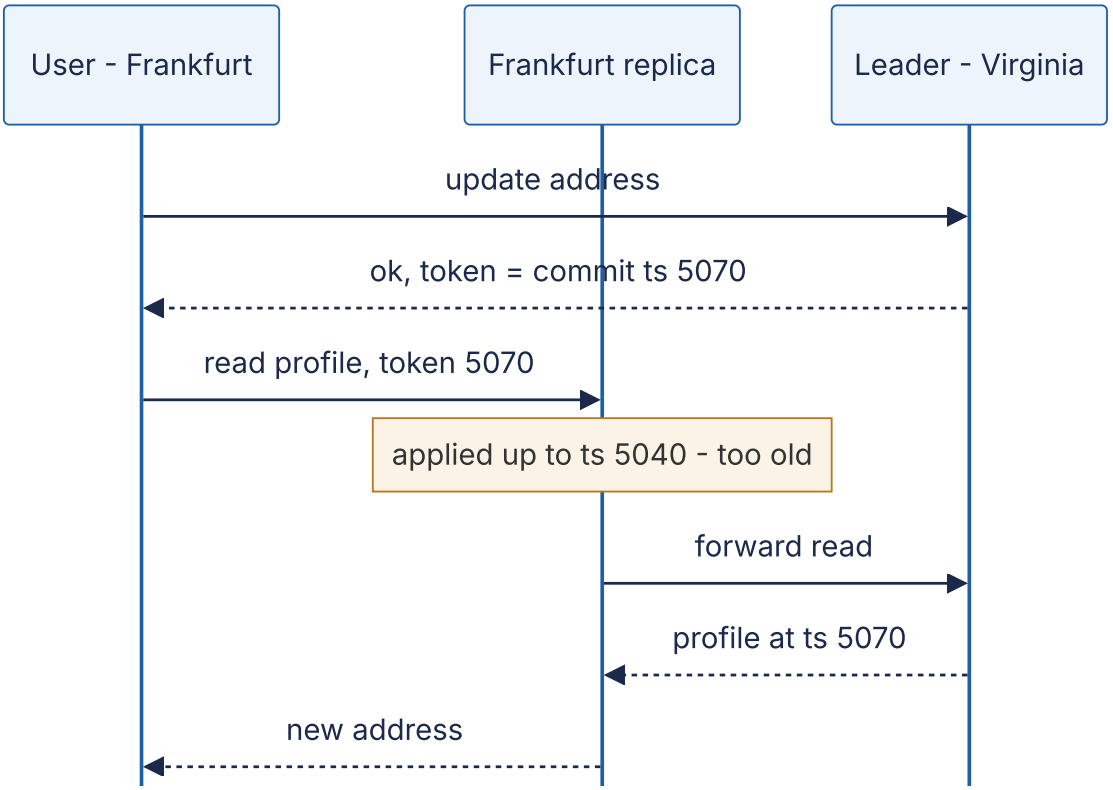
44.12.1 What users notice

Users do not see consistency models; they see symptoms. "I changed my address and the old one came back." "My friend's order shows *delivered* but mine still says *cooking*." Most of these are violations of session guarantees (§25.6) across regions, and above all of **read-your-writes (RYW)**: after a user's write is acknowledged, that user's subsequent reads must reflect it.

In a read-local/write-global design, a Frankfurt user writes to a Virginia leader and then reads from the Frankfurt replica, which may lag. Three fixes, in increasing cost:

1. **Session stickiness to the home region.** Route each user's reads and writes to their home region (§44.6.4), where reads are strongly consistent. Simple, and correct as long as stickiness holds; it breaks during failover or when a traveller hits another region.
2. **Session tokens.** Each write returns a position: a commit timestamp, log sequence number or version vector. The client sends its latest token with every read; a replica serves the read only if it has applied up to that position, otherwise it waits briefly or forwards to the leader (§25.6.2).
3. **Strong reads.** Read from the leader or use a linearizable read (Spanner strong reads, DynamoDB strongly consistent reads where offered), paying the cross-region RTT on every read.

Figure 44.15 — Read-your-writes across regions with a session token.



Reading the diagram. The user's write goes synchronously to the Virginia leader, which returns a token holding the commit timestamp. The next read goes to the nearby Frankfurt replica with the token. The replica has applied changes only up to 5040, so serving locally would show the old address; it forwards the read to the leader (or waits for replication to pass 5070), then answers. Storage boundaries: the leader and the replica. Failure point: if the token is lost (a new device, a cleared app), RYW quietly degrades to eventual consistency. Scaling: most reads carry tokens that the local replica already satisfies, so the forward path is rare.

Table 44.8 — Global consistency options and what users see.

Option	Read latency	Write latency	What the user may see
Eventual, read local	Local	Local or +RTT	Own edits disappear briefly; others' edits arrive late
Session token (RYW, monotonic reads)	Local, occasionally +RTT	+RTT to leader	Own edits always visible; others' may lag
Home-region sticky	Local for home users	Local for home users	Consistent at home; travellers pay RTT
Bounded-staleness reads	Local	+RTT	Data at most Δ old
Strong (linearizable) everywhere	+RTT	+ quorum RTT	Always current; slower and less available in partitions

INTERVIEW TIP

Interview tip — Name the user-visible anomaly. When asked about global consistency, start from what a user would notice and choose the weakest guarantee that prevents it, per operation: RYW for profile edits, strong for payments and uniqueness, eventual for view counts.

44.13 Summary and revision notes

SUMMARY

- Go multi-region for latency, regional availability, data residency or blast radius; each leads to a different design, and all cost capacity, transfer fees, write latency and complexity.
- Fiber RTT floor $= 2d/v$ at about 5 µs/km; observed RTTs are 1.3–2× the floor. A user action costs (sequential round trips) × RTT, so move data with compute.
- Quorum write latency $\approx \mathrm{RTT}(c, \ell) + \mathrm{RTT}_{(q-1)}(\ell)$. Place the usual quorum near the leader and the leader near writers; a region survives loss of r if $N - n_r \geq q$.
- Steer with geo/latency DNS, anycast front doors and client-side selection. DNS failover $= T_{\text{detect}} + T_{\text{decide}} + T_{\text{TTL}} + T_{\text{reconnect}}$; anycast removes the TTL term.
- Topologies: active–passive; read-local/write-global; multi-writer; home region per record. Most “active–active” systems still have one writer per record.
- Active–active turns regional downtime into $f T_{\text{shift}}$; global dependencies ($f_g T_g$) then dominate.
- Asynchronous RPO is the lag at failure, $W_{\text{lost}} \approx \lambda_w \ell(t_f)$, and lag grows when regions degrade. Synchronous quorums give RPO 0 for one region loss at the cost of cross-region RTTs.
- Conflict rate $\approx 2 r_A r_B \ell$: prefer ownership, then CRDTs, then application merge; use LWW only for single-writer data.
- Residency: home regions, metadata/content split, regional keys, and regionalized logs, backups and analytics.
- Regional independence and static stability: no global component on the request or recovery path; stage global changes by region.
- Headroom to lose one of N regions: overhead $N/(N-1) - 1$, plus extra for proximity-based failover. Rehearse evacuation; fail back slowly after reconciliation.
- Read-your-writes across regions needs home-region stickiness, session tokens or strong reads.

44.14 Knowledge checkpoint

1. Compute the fiber RTT floor for 8,000 km.
2. Why can moving only the stateless tier to a nearer region make requests slower?
3. Five voters with follower RTTs 12, 65, 90, 150 ms from the leader: what is the commit latency, and if the 12 ms follower fails?
4. Five replicas placed 2 + 2 + 1 across three regions: which single-region losses keep a quorum?
5. Detection 30 s, decision 0 s, TTL 300 s, reconnect 20 s: worst-case DNS failover time?
6. Why does an anycast front door fail over faster than DNS?
7. Distinguish read-local/write-global from multi-writer active–active.
8. With $f = 2$, $T_{\text{shift}} = 3$ min and one 30-minute global incident per year, compute active–active downtime.
9. A region writes 500 writes/s with 2 s of lag at failure. How many acknowledged writes are at risk?
10. Two regions each edit a record 0.1 times/s with 1 s lag. Estimate the conflict rate.
11. Why is LWW unsafe for a shared cart?
12. Name three places personal data escapes a regional store.
13. Define static stability.
14. How much capacity overhead does surviving one region loss cost with four equal regions?
15. Why should failback not be automatic?
16. How does a session token give read-your-writes?

Answers

1. $2 \times 8,000/200,000 = 80$ ms.
2. The backend still makes sequential cross-region round trips to the data, which now cost the long RTT each time (§44.4.2).
3. Second-smallest: 65 ms. Without the 12 ms follower: second-smallest of 65, 90, 150 is 90 ms.
4. All: losing a 2-replica region leaves 3; losing the 1-replica region leaves 4; $q = 3$.
5. $30 + 0 + 300 + 20 = 350$ s.
6. The address does not change; edges re-route to another backend without waiting for resolver caches.
7. In the first, every region serves reads but each record has one write location; in the second, any region writes any record and conflicts must be resolved.
8. $2 \times 3 + 30 = 36$ min/year.
9. $500 \times 2 = 1,000$ writes.
10. $2 \times 0.1 \times 0.1 \times 1 = 0.02$ conflicts/s.
11. Concurrent additions are treated as replacements; one is silently discarded.
12. Logs and traces, backups, support tools, analytics or ML pipelines (any three).

13. Continuing to work through a failure without making any changes such as scaling or control-plane calls.
14. $4/3 - 1 = 33\%$.
15. Unreplicated writes must be reconciled and replicas caught up first; green health checks do not prove data is consistent.
16. The write returns its commit position; a replica serves the read only once it has applied that position, otherwise it waits or forwards.

44.15 Interview questions

Basic

Q1. Why can't a database give strongly consistent writes between Virginia and Singapore in 20 ms? Answer. The fiber floor is about $2 \times 15,500/200,000 = 155$ ms and observed RTTs are about 220 ms. A strongly consistent cross-region write needs at least one round trip to a replica in the other region. Only avoiding that round trip (home-region data, asynchronous replication) can be faster.

Q2. Active–passive or active–active for a new SaaS product? Answer. Start from requirements. If users are in one geography and an RTO of tens of minutes is acceptable, active–passive with a warm standby and tested failover is simpler and cheaper. Choose active–active when latency for distant users or a near-zero RTO matters, and design data ownership first.

Intermediate

Q3. Design QuickBite's order storage for US, EU and APAC. Answer. Home orders in the restaurant's region; synchronous replication across zones within the region (RPO 0 for zone loss); asynchronous copy to a DR region in the same jurisdiction with lag alerts and a lag budget; global directory with IDs and region codes only; a small cross-region consensus store for global uniqueness (accounts, payment tokens); RYW via home-region stickiness; headroom sized for worst-case survivor load.

Q4. Your DNS failover took 12 minutes although the TTL is 60 s. Why? Answer. Resolvers or runtimes ignoring TTLs, clients holding connections to dead addresses with long timeouts, slow detection or a manual decision step. Measure each term of T_{fo}; add an anycast VIP or server-directed client steering, shorten timeouts and automate the decision.

Advanced

Q5. A global feature-flag service outage took down all regions. Redesign. Answer. Make flags a data-plane-local concern: each region serves flags from a local snapshot with a safe default, refreshed asynchronously; the global service is control plane only. Stage flag changes region by region with health checks. Test static stability by blocking the global service during a game day.

Q6. How would you choose between DynamoDB global tables' two consistency modes? Answer. Default eventual mode gives local writes everywhere with LWW conflicts and RPO > 0: fine for single-writer items or idempotent overwrites. The strong mode needs three Regions (or two plus a witness), adds cross-Region write latency, rejects conflicting concurrent writes and gives RPO 0: use it for data where loss or silent overwrite is unacceptable. The mode is fixed at table creation, so classify data first.

44.16 Practical exercises

1. Run the §44.7.5 simulation with `batch_ms` of 10, 100 and 1,000 ms and plot lost writes; compare with $\lambda_w \ell$.
2. Add leader election to `quorum` (a 3 s outage after leader loss) and report the write-availability gap.
3. Use public inter-region latency data for your cloud provider to recompute Table 44.2's inflation factors.
4. Lower a test domain's TTL to 30 s, fail over with your DNS provider's health checks and measure the client-observed tail.
5. Compute worst-case survivor load for your own traffic split and failover routing.

44.17 Design challenges

1. **Global ticketing.** Sell seats for events in any market from any region, never oversell, and keep browsing local. Decide what is consensus-backed and where its voters sit.
2. **Residency-first messaging.** A chat product must keep EU message content in the EU while supporting chats between EU and US users. Design storage, routing and key management.
3. **Region-independent identity.** Login must work in every region during a total outage of the identity service's primary region.

Chapter 45 — Advanced Consistency and Byzantine Fault Tolerance

> **Level:** 5 · **Track:** A (Traditional) · **Estimated reading time:** 7 h

Two customers share a checking and a savings account. A read-only report shows a deposit one of them just made, yet a withdrawal that committed a moment later was charged an overdraft fee as if the deposit had never happened. Everything ran under snapshot isolation and nothing failed; the report saw a state that no serial order could produce. Remove the report and the history is serializable again.

Chapters 11 and 24–27 gave you the working vocabulary: isolation levels (§11.13), system models and FLP (§24.6, §24.13), consistency models and CAP (Chapter 25), consensus (Chapter 26) and CRDTs in practice (§27.14). This chapter goes underneath it: Adya's dependency graphs, which let you *prove* whether a history is serializable; serializable snapshot isolation as PostgreSQL implements it; an Elle-style checker; and the lattice theory behind CRDTs, with its limits (the CALM theorem).

The second half drops the assumption that nodes are honest. Byzantine faults need $3f + 1$ replicas and protocols such as PBFT, Tendermint and HotStuff; you will count their messages, compute the probability that a Bitcoin payment is reversed, and finish with a decision table. Three runnable Python programs accompany the chapter: a dependency-graph cycle detector, an exhaustive CRDT lattice checker and a Nakamoto confirmation calculator.

45.1 Learning objectives

After this chapter you should be able to:

- Place any guarantee in the combined consistency hierarchy, state the Adya phenomena it proscribes and give its availability class under partition.
- Construct write-skew and read-only-anomaly histories under snapshot isolation, draw their direct serialization graphs and identify the dangerous structure that serializable snapshot isolation (SSI) detects.
- Explain how PostgreSQL implements SSI and estimate how often an anomaly or a serialization failure will occur.
- Build a direct serialization graph from a list-append history, detect G0, G1c, G-single and G2-item cycles in linear time, and explain why Elle avoids the NP-complete-

ness of general serializability checking.
- Sketch the convergence proof for state-based CRDTs, state op-based delivery requirements, size delta-CRDT savings, and use invariant confluence and CALM to decide when coordination is unavoidable.
- Explain where Byzantine faults occur in real infrastructure and derive $n \geq 3f + 1$ and the $2f + 1$ quorum intersection for partially synchronous Byzantine consensus.
- Walk through PBFT's normal case and view change and compute its message count for $n = 4$, 7 and 10; compare it with Tendermint and chained HotStuff.
- Compute Nakamoto's confirmation probability, contrast probabilistic and deterministic finality, and decide when a permissioned BFT system, a crash-tolerant database or a tamper-evident log is the right tool.

45.2 Prerequisites

- Isolation anomalies, snapshot isolation, MVCC and PostgreSQL's SERIALIZABLE level — §11.13–§11.15 (this chapter formalizes them).
- Timing models, failure models and the $2f + 1$ versus $3f + 1$ preview — §24.6 (BFT bounds start there).
- FLP impossibility and how partial synchrony escapes it — §24.13 (recapped only).
- Linearizability, causal consistency, session guarantees, the consistency map, CAP and Jepsen testing — Chapter 25, especially §25.7.5 and §25.11 (owned there; not repeated).
- Quorums, Paxos and Raft — §26.4, §26.6, §26.7 (PBFT and HotStuff are their Byzantine counterparts).
- CRDT designs and their merge laws in code — §27.14.3 (this chapter supplies the theory).
- Cross-partition isolation and distributed SQL — §28.3.3 and §28.10 (why SSI is hard to distribute).

45.3 The full consistency hierarchy

45.3.1 Two vocabularies, one partial order

DEFINITION

Definition — Consistency hierarchy. The partial order on guarantees in which model A is **stronger** than model B when every history A allows is also allowed by B. It joins two families: **transactional isolation levels**, which constrain how groups of operations on many objects interleave, and **non-transactional consistency models**, which constrain which values single operations on single objects may return.

First-principles explanation

Think of a guarantee as a sieve: pour in every possible execution and it keeps only those the guarantee permits. A finer sieve is stronger; two sieves are **incomparable** when each keeps an execution the other rejects. Figure 25.10 drew the map of sieves after Jepsen [Kingsbury: Consistency Models]. Here you add what the map lacks: implementation-independent *definitions* and a *proof* of which levels survive a partition.

Why does this exist?

Berenson et al. showed that the ANSI SQL phenomena were ambiguous, missed lost update, read skew and write skew, and had no place for snapshot isolation [Berenson et al. 1995]. Their fix (P0–P3, A5A, A5B) was precise but **preventative**: it forbade operation patterns such as "T2 writes x after T1 read it, before T1 commits", which outlaws correct optimistic and multi-version executions. Adya replaced operation patterns with graph properties of the committed history, so a level means the same thing whether implemented with locks, versions or validation [Adya 1999; Adya et al. 2000].

How it works internally: Adya's portable levels

Adya represents a committed history as a **direct serialization graph (DSG)**: one node per committed transaction and a directed edge for each direct conflict (the edge types are defined precisely in §45.4.1). Each **portable level** (PL) is defined by the graph patterns it **proscribes**:

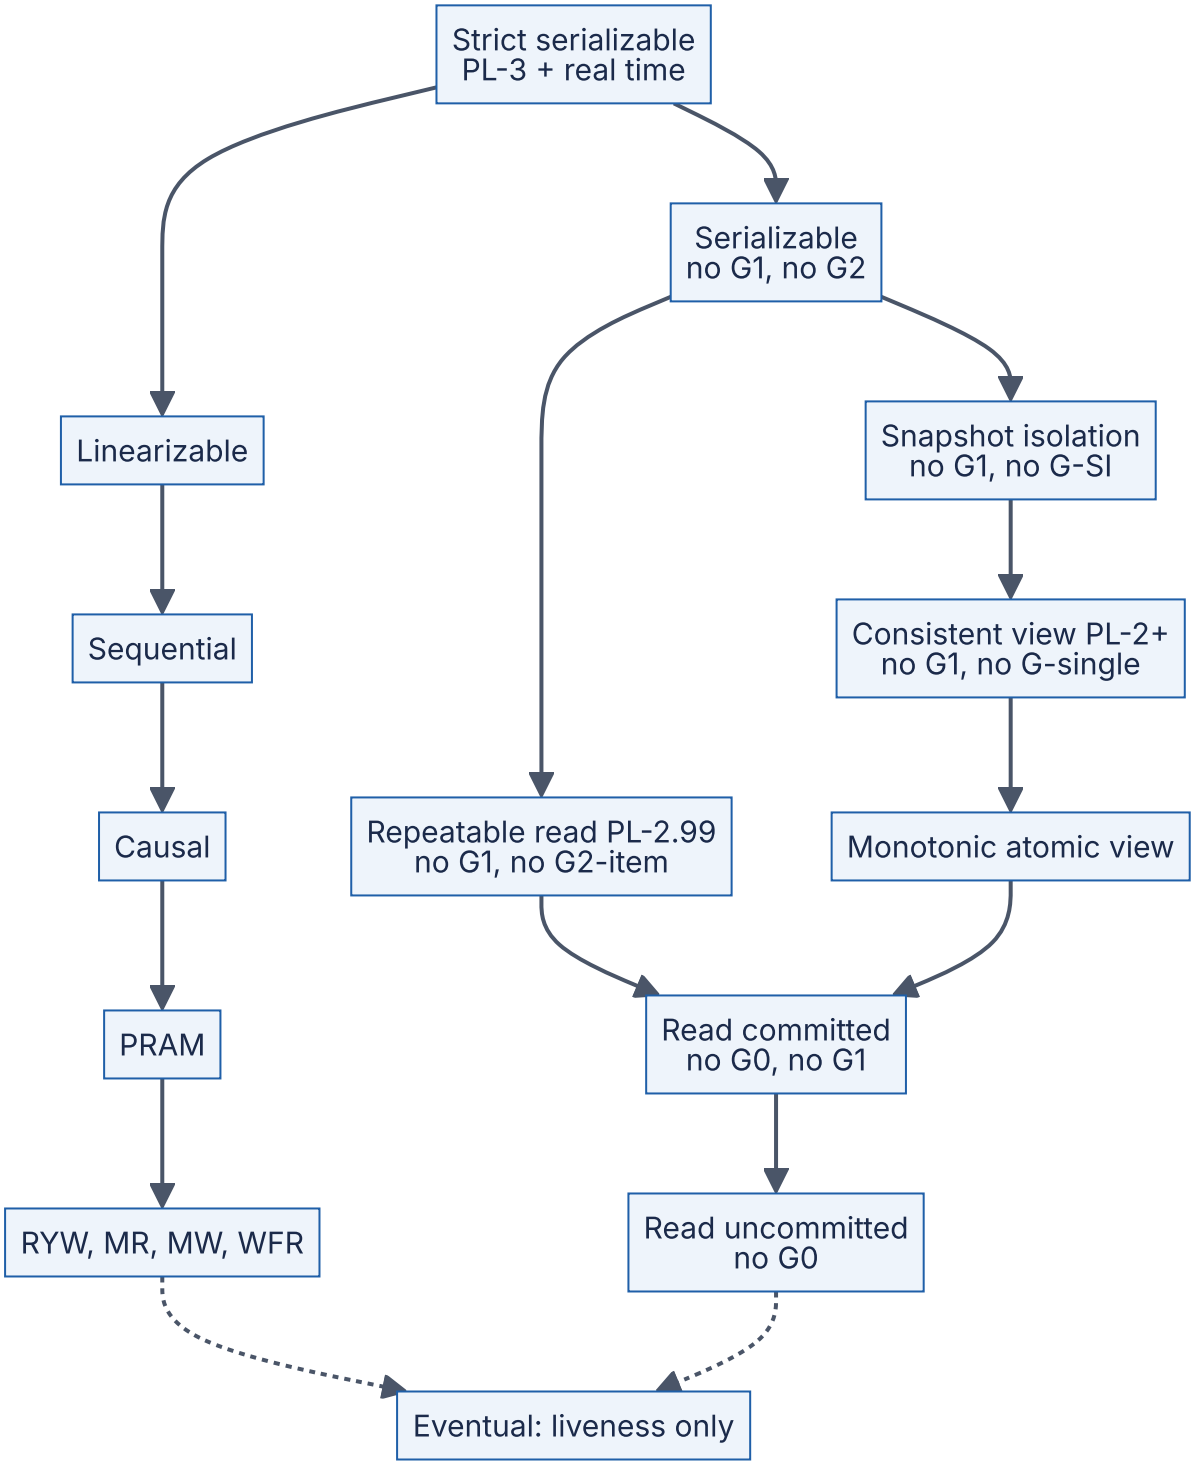
Table 45.1 — Adya's portable isolation levels and the phenomena each proscribes.

Portable level	Proscribes	Closest common name	Anomalies it still allows
PL-1	G0	Read uncommitted	Dirty reads, everything above
PL-2	G0, G1 (G1a, G1b, G1c)	Read committed	Fuzzy reads, read skew, lost update, write skew
PL-2+	G1, G-single	Consistent view	Cycles with two or more anti-dependencies (write skew)
PL-SI	G1, G-SI (G-SIa, G-SIb)	Snapshot isolation	Write skew on rows and on predicates
PL-2.99	G1, G2-item	Repeatable read (item level)	Phantoms (predicate G2)
PL-3	G1, G2	Serializable	None, apart from real-time order
PL-3 + real time	G1, G2, and cycles through real-time edges	Strict serializable	None

Three consequences explain most confusion in practice:

1. **Snapshot isolation and repeatable read are incomparable.** PL-SI forbids cycles with exactly one anti-dependency (read skew) but allows two (write skew); PL-2.99 forbids write skew on rows but allows predicate cycles (phantoms) that SI forbids.
2. **“Repeatable read” means at least three things**: the ANSI level, Adya’s PL-2.99, and vendor behavior (PostgreSQL’s is SI; MySQL’s is a snapshot for plain reads plus current-row writes, Table 11.9).
3. **Serializability ignores real time.** Strict serializability adds it, and on single-operation, single-object transactions it coincides with linearizability (§25.3): one apex for both families.

Figure 45.1 — The combined hierarchy, annotated with the phenomena each transactional level proscribes.



Reading the diagram. A solid arrow from *A* to *B* means every *A* history is a *B* history; strength decreases downward. The left column is transactional, labeled with Adya's proscribed phenomena; the right is single-object (Chapter 25). Repeatable read and SI are incomparable siblings. Dotted arrows mean "can be combined with": eventual consistency is a liveness property beside the safety properties. The figure has no protocols, flows or storage boundaries; the failure it guards against is choosing a level by name. Session variants (strong session SI, strong session serializable) add per-client order and sit just above their base level [Daudjee & Salem 2006; Kingsbury & Alvaro 2020].

45.3.2 Availability classes: what survives a partition

DEFINITION

Definition — Availability classes (Bailis et al.). A guarantee is **totally available** if every non-failing replica can commit every transaction without contacting any other replica, even when the network is arbitrarily partitioned. It is **sticky available** if this holds whenever each client keeps talking to replicas that have seen all of that client's previous operations. It is **unavailable** if some partition forces some transaction to block or abort [Bailis et al. 2014a].

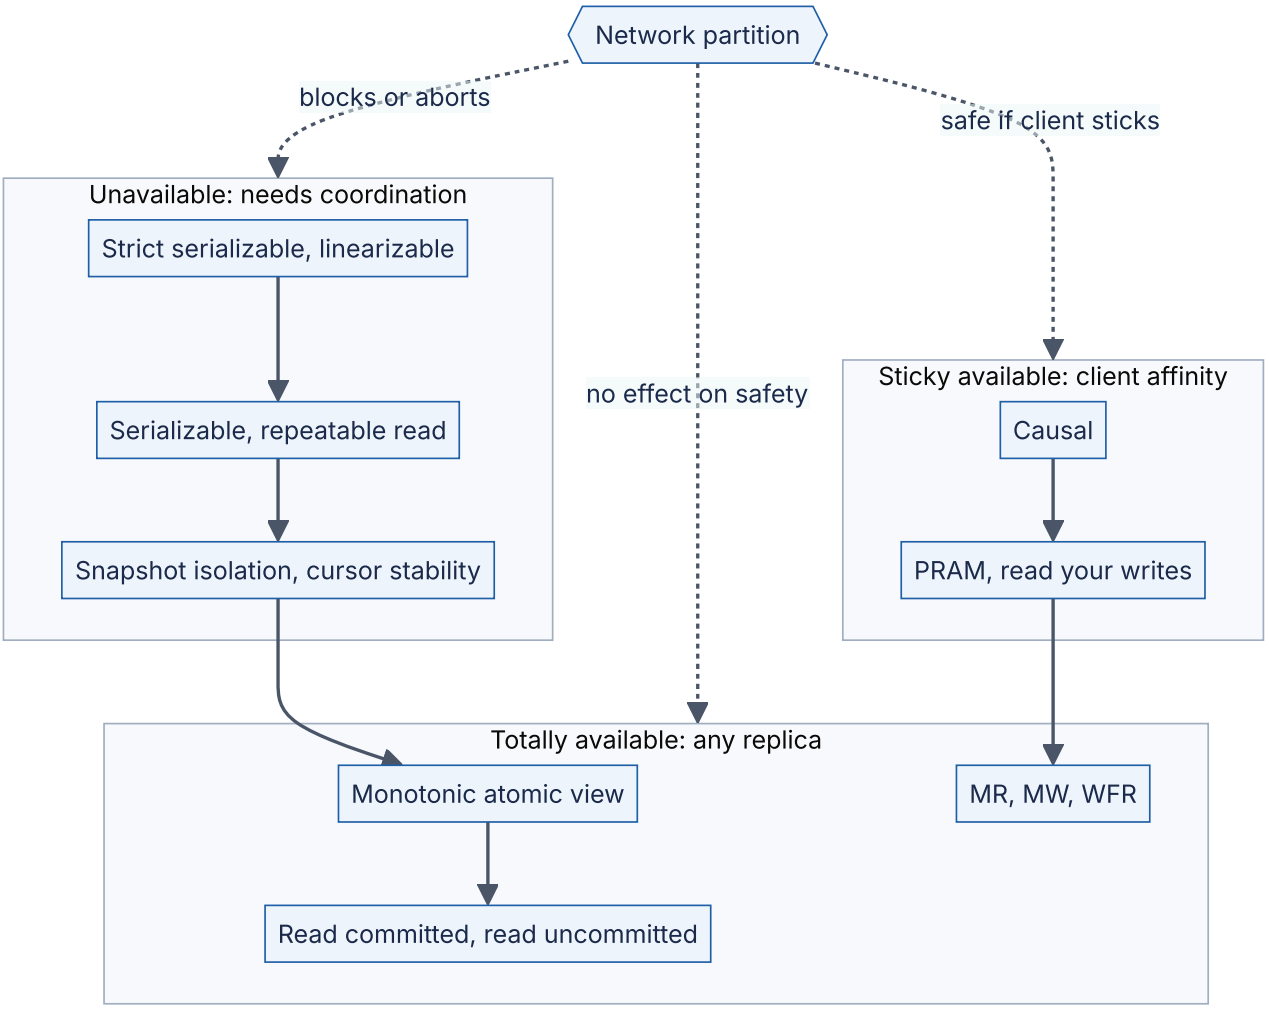
Bailis and colleagues called the first two classes **highly available transactions (HATs)**. Their classification rests on arguments you can reconstruct:

1. **Preventing lost update needs coordination.** Clients on opposite sides of a partition each read a counter at 10 and write 11; a totally available system commits both and loses one. SI, cursor stability, repeatable read and serializability are therefore unavailable.
2. **Preventing write skew needs coordination**, by the same argument with two rows.
3. **Recency needs coordination**: an isolated replica cannot promise the latest write (CAP, §25.8).

Table 45.2 — Availability class of each guarantee under partition [Bailis et al. 2014a].

Class	Guarantees	Why
Totally available	Read uncommitted, read committed, monotonic atomic view, item cut and predicate cut isolation, monotonic reads, monotonic writes, writes follow reads	Each can be enforced with data a replica already has: buffered writes, version metadata, causal tags
Sticky available	Read your writes, PRAM, causal	The client must keep reaching replicas that hold its own past writes
Unavailable	Cursor stability, snapshot isolation, repeatable read, serializable, linearizable, strict serializable	They prevent lost update or write skew, or promise recency

Figure 45.2 — The three availability classes as bands of the hierarchy.



Reading the diagram. The subgraphs are the bands of Table 45.2; solid arrows repeat the strength order of Figure 45.1. The hexagon is a network partition, and its dotted (asynchronous) arrows show its effect: unavailable levels block or abort on the minority side, sticky levels survive while clients keep reaching replicas with their history, totally available levels are unaffected. The partition is the failure point; only the lower two bands scale writes across regions without cross-region round trips.

KEY CONCEPT

Key insight — Monotonic atomic view is the most useful transactional guarantee in the totally available band. It guarantees that once you see one of a transaction's writes you see all of them, which prevents the "half-applied transaction" anomaly that read committed allows. It can be built with nothing more than buffered writes and per-transaction metadata, so it is the natural ceiling for a multi-region, always-writable store [Bailis et al. 2014a].

INDUSTRY EXAMPLE

Default isolation in shipping databases. Surveying 18 popular databases, Bailis et al. reported that only three defaulted to serializability and eight did not offer it at all; read committed was the most common default, the level that keeps latency low and stays available. *Evidence: Primary* — [Bailis et al. 2014a]

COMMON MISTAKE

Mistake — "Our database is ACID, so it is serializable." The I in ACID is whatever the default level is, which is usually read committed or snapshot isolation. Map the level to its proscribed phenomena (Table 45.1) and check which anomalies your invariants can tolerate.

45.4 Snapshot isolation versus serializability

45.4.1 Adya's dependency-graph formalism

DEFINITION

Definition — Direct serialization graph (DSG). For a history of committed transactions with a known **version order** for each object (the order in which versions of x were installed), the DSG has a node per committed transaction and an edge $T_i \to T_j$ whenever T_j directly conflicts with T_i in one of three ways [Adya 1999]:

- **Write dependency** ($T_i \overset{ww}{\to} T_j$): T_i installs a version of x and T_j installs the *next* version of x.
- **Read dependency** ($T_i \overset{wr}{\to} T_j$): T_i installs a version of x and T_j reads that version. (A predicate read that observes T_i's change to the set of matching rows also counts.)
- **Anti-dependency** ($T_i \overset{rw}{\to} T_j$): T_i reads a version of x and T_j installs the next version, so T_i did not see T_j's write. Predicate anti-dependencies arise when T_j changes the set of rows matching a predicate T_i read.

First-principles explanation

Each edge is an unavoidable "must come before" fact: a reader of T_i's write must follow T_i; a reader of a version T_j later replaced must precede T_j. A history is **conflict serializable** exactly when the DSG is acyclic, and a topological sort is then an equivalent serial order [Papadimitriou 1979; Adya 1999]. Every anomaly of §11.13 is a *shape of cycle*.

Table 45.3 — Adya's phenomena as graph properties.

Phenomenon	Formal condition	Informal name	Forbidden by
G0	DSG cycle of ww edges only	Write cycle; dirty write interleaving	Every level from PL-1 up
G1a	A committed transaction read a version written by an aborted one	Aborted read	PL-2 and up
G1b	A committed transaction read a non-final version of another's write	Intermediate read	PL-2 and up
G1c	DSG cycle of ww and wr edges only	Circular information flow	PL-2 and up
G-single	DSG cycle with exactly one rw edge	Read skew, non-atomic view	PL-2+, PL-SI, PL-3; PL-2.99 for items
G2-item	DSG cycle with at least one item rw edge	Write skew on rows	PL-2.99, PL-3
G2	DSG cycle with at least one rw edge, item or predicate	Write skew, phantoms	PL-3

For snapshot isolation, Adya's **start-ordered serialization graph (SSG)** adds an edge $T_i \overset{s}{\rightarrow} T_j$ when T_i commits before T_j begins. **G-SIa (interference)** is a ww or wr edge without the matching start edge: T_j saw or overwrote a write not committed when it started. **G-SIb (missed effects)** is an SSG cycle with exactly one anti-dependency. PL-SI proscribes G1, G-SIa and G-SIb [Adya 1999].

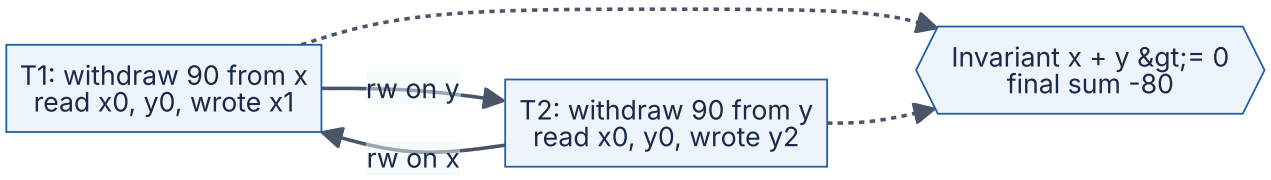
45.4.2 Write skew as a formal history

Figure 11.8 showed write skew with doctors; here it is as a history. One customer's accounts x and y hold 50 each, the invariant is $x + y \geq 0$, and T_1 and T_2 each withdraw 90 from a different account after checking the sum. Version subscripts name the writer; c_i is a commit.

$$H_{ws}: r_1(x_0 = 50)\, r_1(y_0 = 50)\, r_2(x_0 = 50)\, r_2(y_0 = 50)\, w_1(x_1 = -40)\, w_2(y_2 = -40)\, c_1\, c_2$$

The write sets are disjoint, so SI's first-committer-wins rule rejects nothing; both commit and $x + y = -80$. T_1 read y_0, which T_2 replaced, and T_2 read x_0, which T_1 replaced: two anti-dependencies.

Figure 45.3 — The DSG of write skew: a cycle of two anti-dependencies.



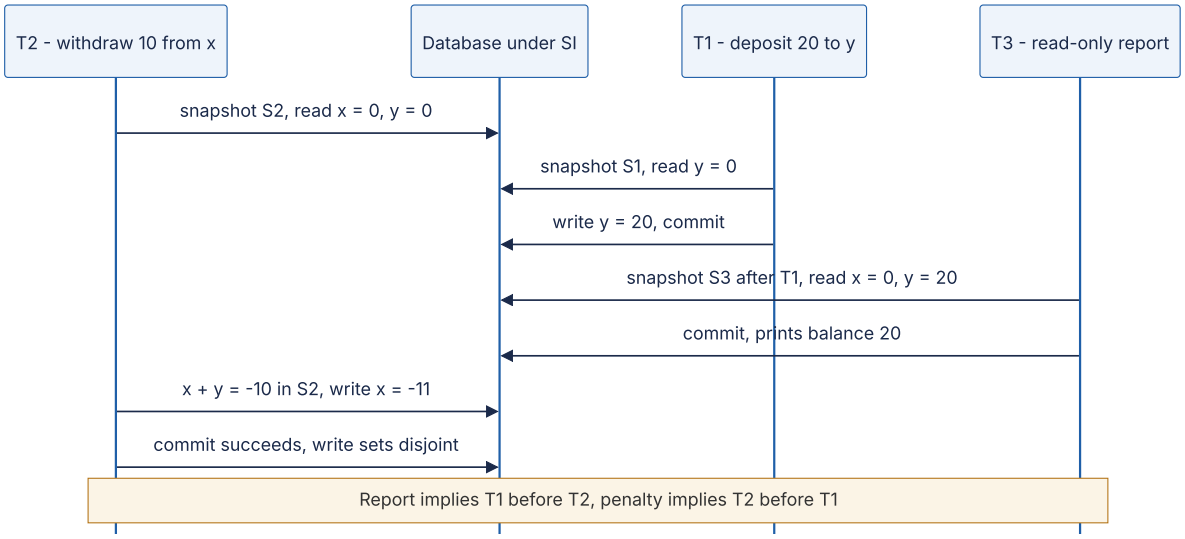
Reading the diagram. Rectangles are committed transactions on one database; arrows are logical dependencies, not messages. Each solid arrow is an anti-dependency (the source read a version the target overwrote), so together they demand T_1 before T_2 and T_2 before T_1: a G2-item cycle. Dotted arrows show both effects reaching the invariant, the failure point. SI checks only write–write conflicts and never sees these edges; SSI (§45.4.5) exists to notice them.

45.4.3 The read-only anomaly

Fekete, O'Neil and O'Neil showed that under SI a transaction that writes *nothing* can observe a state no serial execution produces, even when the writers alone are serializable [Fekete et al. 2004]. Checking x and savings y start at 0. T_1 deposits 20 into y. T_2 withdraws 10 from x and charges a penalty of 1 if its snapshot shows $x + y < 0$ afterwards. T_3 prints a statement.

$$H_{ro}\colon\ r_2(x_0 = 0)\ r_2(y_0 = 0)\ r_1(y_0 = 0)\ w_1(y_1 = 20)\ c_1\ r_3(x_0 = 0)\ r_3(y_1 = 20)\ c_3\ w_2(x_2 = -11)\ c_2$$

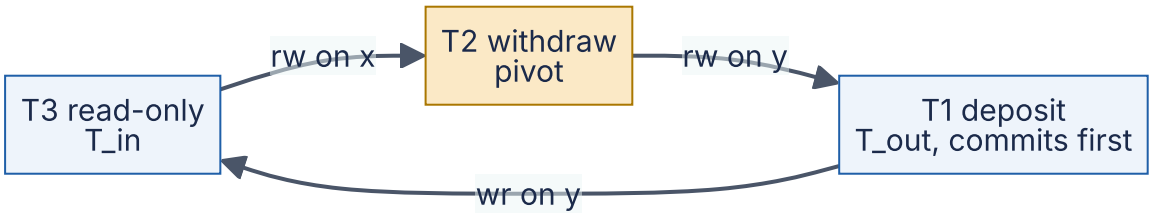
Figure 45.4 — The read-only anomaly under snapshot isolation.



Reading the diagram. Three transactions make synchronous SQL calls to one SI database; time runs downward. T_2's snapshot predates T_1's commit, so it charges the penalty; T_3's snapshot falls between the two commits, so it shows the deposit without the withdrawal. The multi-version store, holding y_0 and y_1 at once, is the storage boundary. The failure point is T_2's commit, accepted because the write sets are disjoint. Without T_3 the outcome equals the serial order T_2, T_1; with it, no order.

In the DSG, T_3 read y_1 (wr from T_1), T_3 read x_0 which T_2 replaced (rw to T_2), and T_2 read y_0 which T_1 replaced (rw to T_1): a cycle with two anti-dependencies *in a row*.

Figure 45.5 — DSG of the read-only anomaly, with the dangerous structure highlighted.



Reading the diagram. Nodes are committed transactions; edges are dependencies, not messages. The consecutive anti-dependencies into and out of T_2 form the **dangerous structure**, with T_2 the **pivot** (amber); T_1, the outgoing end, committed first; the wr edge closes the cycle. Aborting the pivot breaks it. When the three transactions live on different partitions no single node sees the structure, which is why SSI is hard to distribute (§28.3.3).

45.4.4 Why two consecutive anti-dependencies are the signature

KEY CONCEPT

Key insight — The dangerous-structure theorem. Under snapshot isolation, every cycle in the DSG contains two consecutive anti-dependency edges $T_{in} \xrightarrow{rw} T_{pivot} \xrightarrow{rw} T_{out}$ in which each pair of adjacent transactions ran concurrently [Fekete et al. 2005]. Moreover, in some such structure on the cycle, T_{out} is the first transaction of the cycle to commit [Ports & Grittner 2012].

Proof sketch: under SI a ww or wr edge $T_i \to T_j$ requires T_i to have committed before T_j started (G-SIa is forbidden), so such edges point **forward in time**. An rw edge means T_j's write was not in T_i's snapshot, so the two overlapped. A cycle must return to its start, so it needs a non-forward edge; a single rw edge among forward edges yields G-SIb, which SI forbids; case analysis leaves two adjacent rw edges between overlapping transactions.

The theorem gives a **runtime test** (detect the pattern, not the cycle: SSI), a **static test** (Fekete et al. analyzed application programs this way, showed TPC-C serializable under SI, and fixed other programs by **promotion** with `SELECT ... FOR UPDATE` or by **materializing the conflict** in a shared row [Fekete et al. 2005]) and a **diagnosis** (a G2-item cycle on an SI database is expected; a G-single cycle means SI itself is broken).

45.4.5 Serializable snapshot isolation

DEFINITION

Definition — Serializable snapshot isolation (SSI). A concurrency-control algorithm that runs transactions under snapshot isolation, tracks anti-dependencies between concurrent transactions at run time, and aborts a transaction whenever a dangerous structure could form, so every committed history is serializable [Cahill et al. 2008].

Why does this exist?

Under SI readers and writers never block each other; two-phase locking is serializable but lets a long report block every writer it touches. Cahill, Röhm and Fekete kept SI's non-blocking reads and aborted only transactions at a dangerous structure.

How it works internally

1. **Record reads without blocking.** Each read takes a **SIREAD lock**, a non-blocking note that "this transaction read this item or range".
2. **Detect rw edges from both sides.** A writer that finds a concurrent reader's SIREAD lock, or a reader whose visibility check skips a concurrent writer's newer version, records $T_r \overset{rw}{\Rightarrow} T_w$.
3. **Mark and abort.** Each transaction has `inConflict` and `outConflict` flags; one with both set may be a pivot, and a member of the structure is aborted.
4. **Keep SIREAD locks after commit**, until every concurrent transaction has finished, because a committed reader can still source a new rw edge.

The algorithm is **conservative**: two flags do not prove a cycle, so some serializable histories are aborted (**false positives**), the price of not building the full graph.

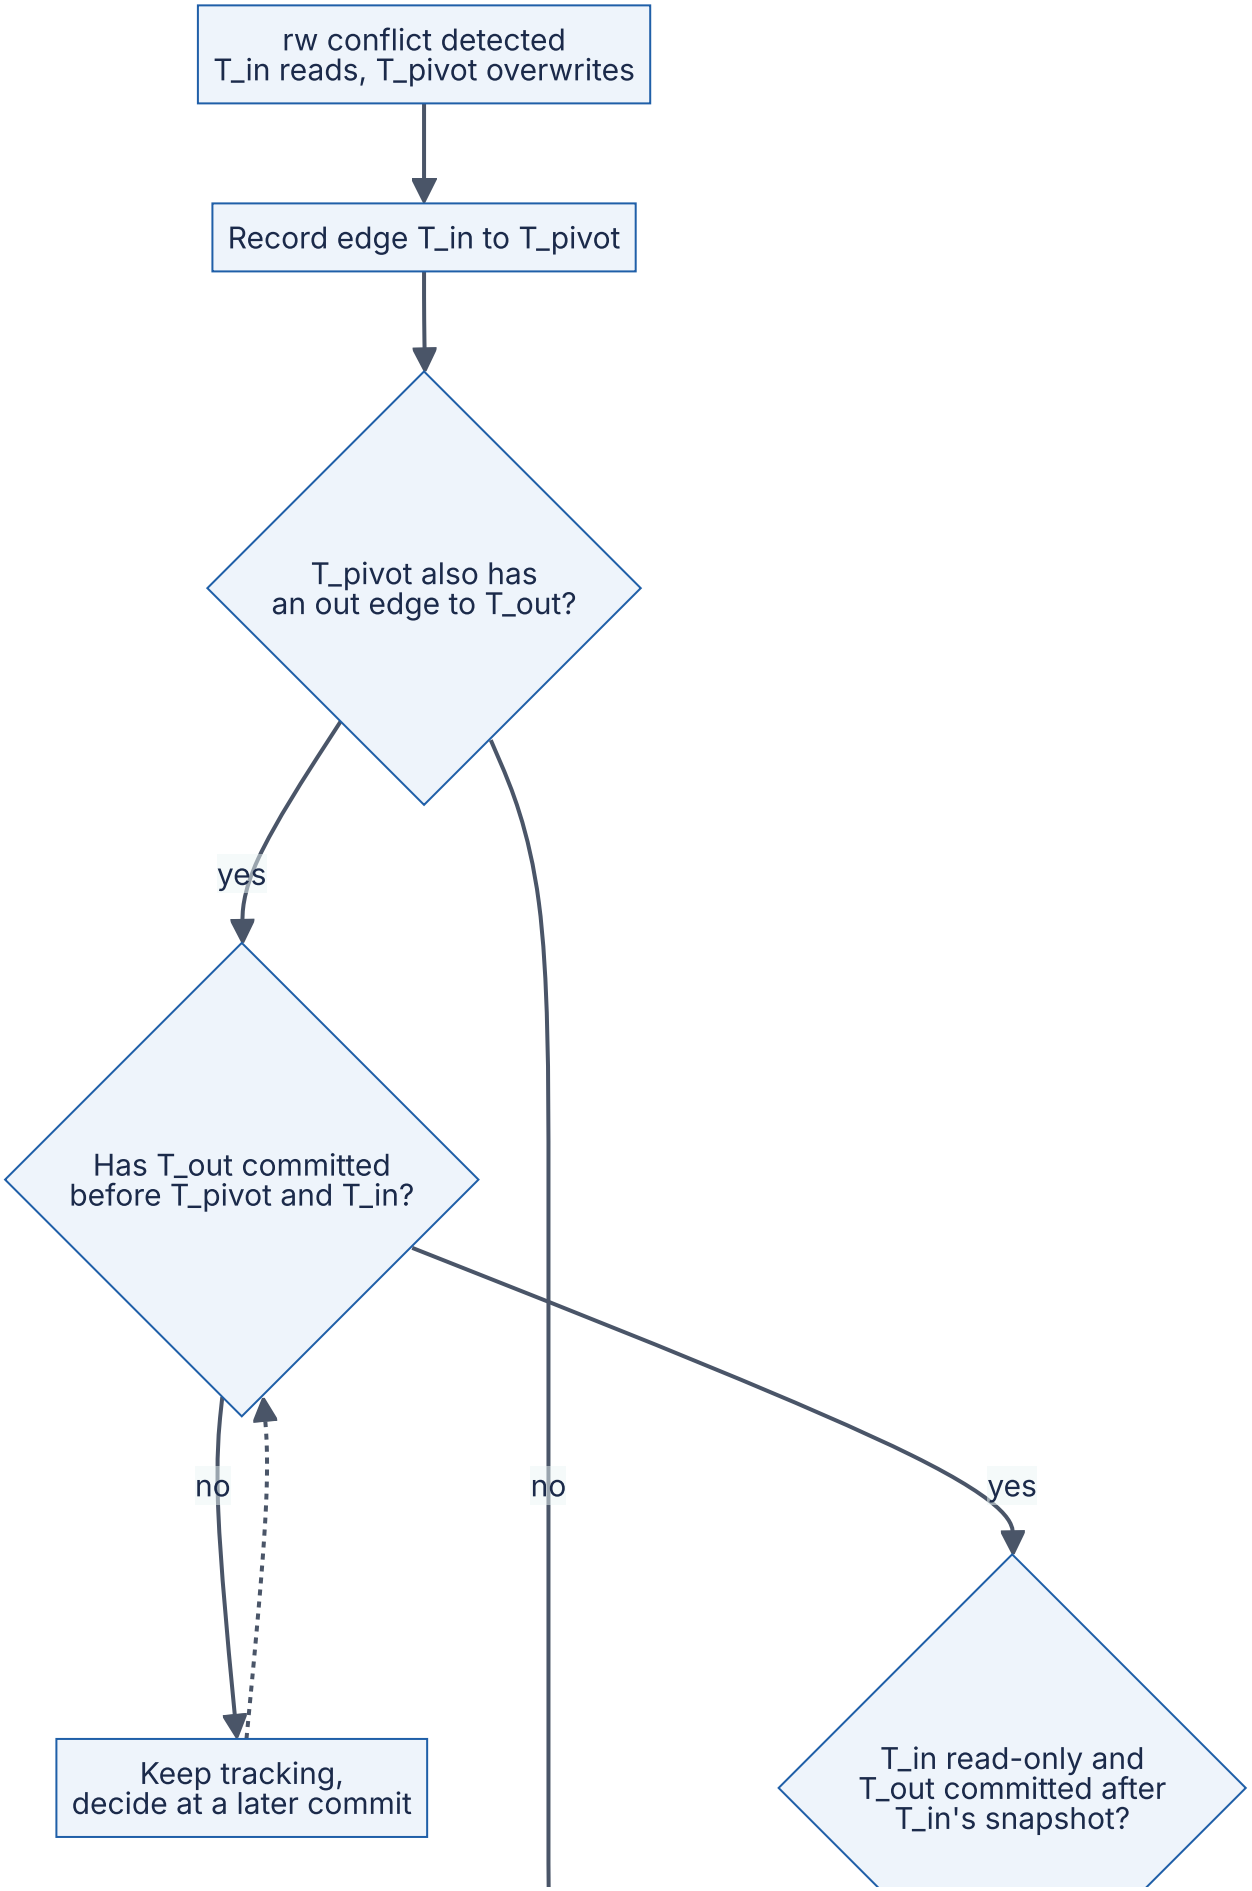
45.4.6 SSI in PostgreSQL

PostgreSQL 9.1 shipped SSI as SERIALIZABLE, the first implementation in a production database, with several improvements [Ports & Grittner 2012]:

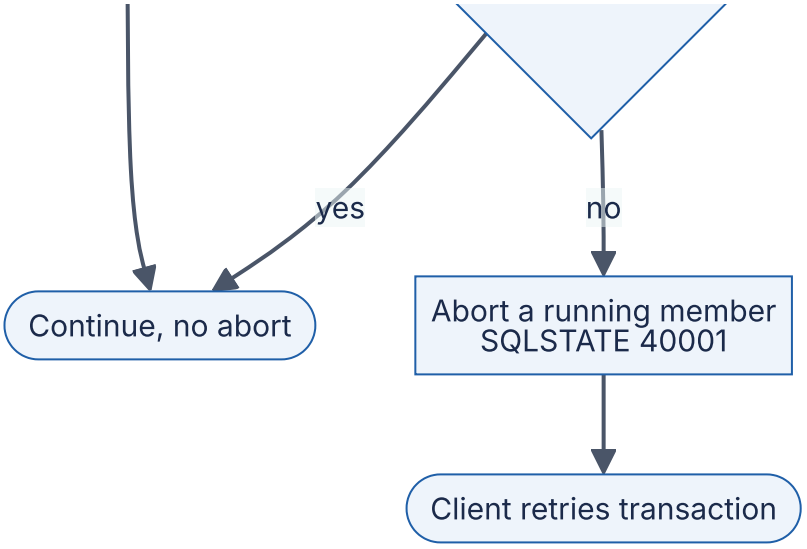
- **Edges, not flags**, which enable the **commit-ordering optimization**: a structure is dangerous only if T_{out} commits first, so PostgreSQL waits for that before aborting.
- **Read-only optimization:** with a read-only T_{in}, the structure matters only if T_{out} committed before T_{in}'s snapshot, as in Figure 45.4.
- **Safe snapshots:** a read-only snapshot that no concurrent writer can make dangerous needs no SIREAD locks and cannot fail; `SERIALIZABLE READ ONLY DEFERRABLE` waits for one.

- **Multi-granularity SIREAD locks** on tuples, index pages or relations, **promoted** to coarser locks under memory pressure (more false positives), and **summarization** of old committed transactions to bound memory.
- **Application contract:** failures return SQLSTATE `40001` and must be retried; the guarantee holds only among transactions that all run at SERIALIZABLE.

Figure 45.6 — How PostgreSQL's SSI decides whether to abort.



rw conflict detected
T_in reads, T_pivot overwrites
Record edge T_in to T_pivot
T_pivot also has
an out edge to T_out?
yes
Has T_out committed
before T_pivot and T_in?
no
Keep tracking,
decide at a later commit
no
yes
T_in read-only and
T_out committed after
T_in's snapshot?



Reading the diagram. The flow runs inside one database on each rw conflict and at commit; nothing crosses the network. Rectangles update the lock and conflict tables in shared memory, the storage boundary. Diamonds are the three tests: dangerous structure, T_{out} first, read-only exemption. The dotted arrow is asynchronous: the decision is revisited at a later commit. The failure point is the abort, surfacing as `40001`. Under high concurrency, lock promotion coarsens detection, so aborts rise faster than linearly with contention.

> INDUSTRY EXAMPLE
>
> **PostgreSQL SERIALIZABLE.** SERIALIZABLE has been SSI since 9.1; REPEATABLE READ is plain SI. Ports and Grittner report SSI throughput close to SI and well above strict two-phase locking on read-heavy workloads. In 2020 Jepsen found G2-item cycles at SERIALIZABLE in PostgreSQL 12.3, a bug since fixed (§25.11.3). *Evidence: Primary* — [Ports & Grittner 2012; PostgreSQL Docs: Transaction Isolation; Kingsbury 2020]

Mathematical foundations: how often does an anomaly happen?

An anomaly needs transactions on the *same* invariant group (one customer's accounts) to overlap in time.

FORMULA

Overlap probability and expected anomalies under snapshot isolation

$$P_{\text{overlap}} = 1 - e^{-2\lambda T} \approx 2\lambda T \qquad E[\text{anomalies per day}] \approx G \cdot \lambda^2 \cdot T \cdot s \cdot 86\,400$$

Symbol	Meaning	Units
λ	Arrival rate of invariant-checking transactions on one group, assumed Poisson	transactions/s
T	Transaction duration from snapshot to commit	s
P_{overlap}	Probability that a given transaction overlaps another on the same group	dimensionless
G	Number of independent invariant groups	count
s	Fraction of overlapping pairs whose reads and writes actually form write skew	dimensionless
$86\,400$	Seconds per day	s/day

Another transaction overlaps yours if it starts within a window of $2T$ around your start. Each group starts $\lambda \cdot 86\,400$ transactions a day, each overlapping a later one with probability about λT; a fraction s of pairs are dangerous.

WORKED EXAMPLE

Worked example — Overdrafts at a retail bank.

1. A bank has $G = 10^6$ customers with linked accounts. Each makes 20 balance-checked withdrawals a day: $\lambda = 20/86\,400 = 2.31 \times 10^{-4}$ per second. Each transaction lasts $T = 50$ ms.
2. Overlap probability per transaction: $2\lambda T = 2 \times 2.31 \times 10^{-4} \times 0.05 = 2.31 \times 10^{-5}$, about 1 in 43,000.
3. Overlapping pairs per day: $G\lambda^2 T \cdot 86\,400 = 10^6 \times (2.31 \times 10^{-4})^2 \times 0.05 \times 86\,400 = 10^6 \times 5.36 \times 10^{-8} \times 0.05 \times 86\,400 \approx 231$.
4. If $s = 0.05$ of those pairs both pass a near-limit check and write different accounts, expect about $231 \times 0.05 \approx 12$ overdrafts a day that no serial execution would allow.

Interpretation. One in 43,000 per transaction is a daily event at scale, and Poisson is optimistic: double-clicks, retries and batch jobs correlate arrivals on one group. **Engineering implication.** Under SSI the 231 pairs (plus false positives) size your retry budget; under SI they size your incident rate.

Alternatives and trade-offs

Table 45.4 — Ways to obtain serializability, compared.

Approach	How it works	Readers block writers?	Main cost	Distributes well?	Example
Strict two-phase locking	Shared read locks, exclusive write locks, held to commit	Yes	Blocking, deadlocks	Yes, with lock managers per partition	MySQL SERIALIZABLE; Spanner read-write transactions (§28.8)
SSI	SI plus rw-conflict tracking	No	Aborts, including false positives; memory for SIREAD locks	Poorly: the dangerous structure spans partitions	PostgreSQL SERIALIZABLE
Optimistic validation of reads	Re-check read set at commit time	No	Aborts under contention	Yes, with timestamps	CockroachDB read refresh (§28.10)
Deterministic ordering	Agree on order first, then execute	No	Must know read/write sets in advance	Yes	Calvin (§28.9)
SI plus application fixes	Promotion with `FOR UPDATE`, materialized conflict rows, static analysis	Only on promoted rows	Developer discipline; easy to miss a path	Yes	Any SI database

Failure scenarios

Table 45.5 — Failure scenarios around snapshot isolation and SSI.

What goes wrong	Why	Detection	Recovery	Prevention
Invariant broken at REPEATABLE READ	SI allows write skew	Reconciliation queries	Compensate	SERIALIZABLE or conflict row
Burst of `40001` errors	Hot group; lock promotion	Errors by SQLSTATE	Jittered retry	Split hot groups; more lock memory
Anomaly despite SERIALIZABLE	Some sessions at a lower level	Elle-style test	Fix, reconcile	Server-side default level
Retries duplicate side effects	Work outside the database	Duplicate e-mails	Deduplicate	Idempotency keys (§22.15)

COMMON MISTAKE

Mistake — "Read-only transactions are always safe under snapshot isolation." Figure 45.4 is the counterexample, and decisions made from such a report inherit the anomaly. Under SSI the reader may itself be aborted unless it runs `DEFERRABLE`.

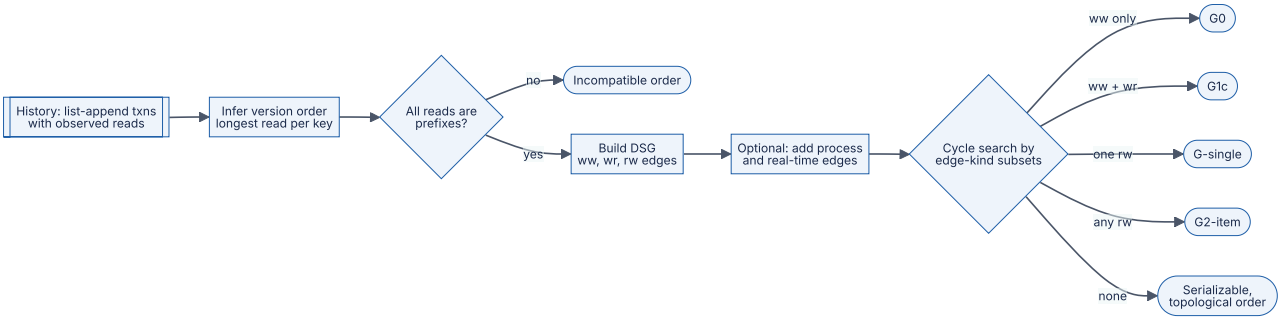
45.5 Formalizing histories and checking them

45.5.1 From observations to a graph

Chapter 25 introduced Jepsen's checkers (§25.11.2); here you build the core of one. The DSG needs each object's **version order**, which a black-box test cannot see. With registers many version orders fit the observations, and deciding whether any makes the history serializable is NP-complete [Papadimitriou 1979]; 20 transactions already have $20! \approx 2.4 \times 10^{18}$ serial orders. Elle designs the workload so observations *reveal* the order [Kingsbury & Alvaro 2020]:

1. **Recoverability.** Every write appends a unique value, so every read traces to its writer.
2. **Traceability.** A read of list `[1, 2, 5]` exhibits the key's version history; every read must be a prefix of the longest, or the history has an **incompatible order** anomaly.
3. **Edges by lookup**, then cycle detection in $O(V + E)$ with Tarjan's algorithm or breadth-first search.
4. **Classification by restriction:** search ww-only cycles (G0), then ww+wr (G1c), then one rw edge closed by ww/wr (G-single), then any cycle (G2-item).
5. **Optional edges:** per-client process order checks *strong session* variants; real-time edges check *strict* serializability.

Figure 45.7 — An Elle-style checker pipeline.



Reading the diagram. The recorded history (subroutine shape) is the storage boundary between test and analysis; everything after it runs offline in one process as synchronous steps. The prefix test can reject a history before any graph exists; the optional stage changes which level is checked. Terminals are verdicts from most to least severe. The failure point is an unobserved write, whose position is unknown, so a cycle through it can be missed. Cost grows roughly linearly with history length.

45.5.2 A runnable DSG cycle detector

The program implements the pipeline and runs it on write skew, the read-only anomaly with and without its reader, read skew, circular information flow, a write cycle and inconsistent reads.

```
        """Elle-style checker for list-append histories: infer each key's version
        order, build Adya's direct serialization graph (DSG) with ww, wr and rw
        edges, then search for cycles and name the anomaly (G0, G1c, G-single, G2)."""
        from collections import defaultdict, deque

        def version_orders(history):
            """Per key, the longest list any transaction read. Every other read of
            that key must be a prefix of it, or no version order explains the reads."""
            orders, problems = {}, []
            for txn in history:
                for op, key, val in txn["ops"]:
                    if op == "r" and len(val) >= len(orders.get(key, [])):

Output:

```
write skew        : G2-item (anti-dependency cycle)
   cycle: T1 -[rw y]-> T2  T2 -[rw x]-> T1
read-only anomaly : G2-item (anti-dependency cycle)
   cycle: T1 -[wr y]-> T3  T3 -[rw x]-> T2  T2 -[rw y]-> T1
same, without T3  : serializable
   equivalent serial order: T2 -> T1 -> T4
read skew         : G-single (read skew)
   cycle: T2 -[rw x]-> T1  T1 -[wr y]-> T2
circular info flow: G1c (circular information flow)
   cycle: T1 -[wr x]-> T2  T2 -[wr y]-> T1
write cycle       : G0 (write cycle)
   cycle: T1 -[ww x]-> T2  T2 -[ww y]-> T1
bad prefix        : incompatible-order
   T4 read x=[2]: not a prefix of [1, 2]
```

What to notice:

- `version_orders` is the whole trick: with unique values and growing lists, the longest read *is* the version order. The last history fails there.
- An rw edge points from a reader to the writer of the *next* version (`order[len(val)]`).
- The read-only history is serializable without `T3` and a G2-item cycle with it (Figure 45.5). SI allows both G2-item histories but must never produce the G-single one.
- The read-skew history needs the final read `T3`; without it the append to `x` is unobserved and the anomaly invisible.
- Each `find_path` query is $O(V + E)$; production checkers run Tarjan's algorithm once and search inside strongly connected components.

INDUSTRY EXAMPLE

Elle in Jepsen analyses. Jepsen has used Elle in its transactional analyses since 2020, including the PostgreSQL 12.3 report. The paper's evaluation shows checking time growing roughly linearly with history length, unlike search-based checkers. *Evidence: Primary* — [Kingsbury & Alvaro 2020; Kingsbury 2020]

RECOMMENDATION

Recommendation — Make your own integration tests checkable. Add a list-append table in staging, run concurrent append-and-read transactions under fault injection and feed the history to Elle. It tests the level you actually run, including connection-pool defaults that change it.

45.6 CRDT theory

§27.14.3 built CRDTs and tested their merge laws on random histories. This section explains *why* those laws are right and what no CRDT can do.

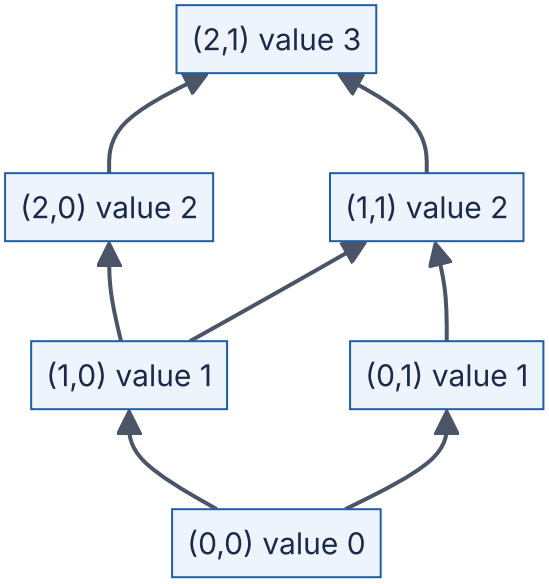
45.6.1 Join-semilattices and monotonicity

DEFINITION

Definition — Join-semilattice. A set S with a partial order $\leq$ in which every pair of elements x, y has a **least upper bound** (join) $x \sqcup y$: an element with $x \leq x \sqcup y$ and $y \leq x \sqcup y$, and $x \sqcup y \leq z$ for every other upper bound z. Any join is commutative, associative and idempotent (ACI). A function m on S is **inflationary** if $x \leq m(x)$ and **monotone** if $x \leq y$ implies $m(x) \leq m(y)$.

The ACI laws of §27.14.3 are what "least upper bound" means. The order says which state "knows more"; for a G-Counter it is slot-wise $\leq$ and the join is the slot-wise maximum.

Figure 45.8 — Hasse diagram of a two-replica G-Counter lattice.



Reading the diagram. Nodes are states (slot A, slot B); an arrow means one step up the order, toward "knows more". An increment moves up one arrow; a merge moves to the lowest node above both inputs, so (2,0) and (1,1), incomparable results of concurrent increments, merge to (2,1). In a deployment each replica holds one node and gossip carries nodes between replicas. The failure point is a merge that misses the least upper bound, such as summing slots, which double-counts duplicates.

45.6.2 Why state-based CRDTs converge: a proof sketch

KEY CONCEPT

Key insight — Strong eventual consistency from three assumptions. If (1) states form a join-semilattice, (2) merge is the join and (3) every update is inflationary, then any two replicas that have received the same set of updates are in the same state, regardless of delivery order or duplication; if (4) every update eventually reaches every replica, all replicas converge [Shapiro et al. 2011a].

The proof is a short induction. For each replica i, let C_i be its **causal history**, the set of updates whose effects it has received, and for each update u let δ_u be the state produced by u at its origin. Claim: at all times $x_i = \bigsqcup_{u \in C_i} \delta_u$ (with the empty join equal to the bottom state $\bot$).

1. **Base.** Initially $C_i = \varnothing$ and $x_i = \bot$.
2. **Local update.** Replica i applies u and gets $m(x_i)$. Because m is inflationary, $x_i \le m(x_i)$, so $m(x_i) = x_i \sqcup m(x_i)$. Taking $\delta_u = m(x_i)$ gives $x_i' = x_i \sqcup \delta_u$ and $C_i' = C_i \cup \{u\}$.
3. **Merge.** Replica i receives x_j and computes $x_i \sqcup x_j = \bigsqcup_{C_i} \delta \sqcup \bigsqcup_{C_j} \delta = \bigsqcup_{C_i \cup C_j} \delta$ by associativity and commutativity, and idempotence absorbs updates in both sets; its new causal history is $C_i \cup C_j$.

So a replica's state depends only on its causal history: strong eventual consistency. The proof needed no message ordering, no exactly-once delivery and no clocks, which is why state-based CRDTs ride on lossy, duplicating gossip.

45.6.3 Operation-based CRDTs

Operation-based CRDTs ship operations, which is cheaper for large states but moves requirements into the network [Shapiro et al. 2011b]: each operation splits into a *prepare* phase at the origin (an OR-Set remove collects the tags it observed) and an *effect* applied everywhere; **concurrent effects must commute**; and delivery must be **reliable, exactly once and causally ordered**, typically by causal broadcast with vector clocks (§24.11). Each style can emulate the other, so the choice is about the network you have.

45.6.4 Delta-CRDTs

Delta-state CRDTs take the middle path [Almeida et al. 2018]. A **delta-mutator** m^δ returns only the changed part, with $m(x) = x \sqcup m^\delta(x)$. Deltas are lattice states, so they join into **delta-intervals** that can be gossiped, duplicated and reordered like full states. A replica sends each peer the deltas it has not acknowledged, falling back to full state after long disconnections; some types, the OR-Set among them, need a causal delta-merging condition to keep their semantics.

FORMULA

Gossip bandwidth: full state versus delta-intervals

$$B_{\text{full}} = k \cdot r \cdot n \cdot b \qquad B_{\delta} = k \cdot r \cdot d \cdot b$$

Symbol	Meaning	Units
B_{full}, B_{δ}	Bytes sent per second by one replica	bytes/s
k	Peers contacted per gossip round	count
r	Gossip rounds per second	1/s
n	Entries in the full state (for a G-Counter, one per replica)	entries
d	Entries changed since the last exchange with that peer	entries
b	Bytes per entry (replica ID plus count)	bytes

WORKED EXAMPLE

Worked example — A page-view counter on 1,000 edge nodes.

1. Each of $n = 1,000$ edge nodes counts views in a G-Counter. An entry is an 8-byte node ID plus an 8-byte count: $b = 16$ bytes. Each node gossips with $k = 3$ peers once a second ($r = 1$).
2. Full state: $B_{\text{full}} = 3 \times 1 \times 1,000 \times 16 = 48,000$ bytes/s per node, or 48 MB/s across the fleet.
3. Suppose that between two exchanges with a given peer, only $d = 20$ slots have changed in what a node knows (its own plus those forwarded from recently active nodes). Then $B_{\delta} = 3 \times 1 \times 20 \times 16 = 960$ bytes/s per node, about 0.96 MB/s across the fleet.

Interpretation. Deltas save $n/d = 50\times$ here, but only with *update locality*: if every node is busy every second, $d \to n$. **Engineering implication.** Measure d before relying on the saving, and keep full-state anti-entropy as the fallback.

45.6.5 Checking the lattice laws exhaustively

On small state spaces you can enumerate *every* state and check the definitions directly, then exhibit two limits that §45.6.6 explains.

```
        """Exhaustive lattice checks on small finite state spaces (Ch 27's random
        tests sample histories; here every state is enumerated). For a G-Counter and
        an OR-Set we check that merge is the least upper bound of the partial order,
        that every mutator is inflationary, and that each delta-mutator satisfies
        m(x) == x JOIN delta(x)."""
        from itertools import product, combinations

        # ---- G-Counter for replicas A and B, slots bounded to 0..2 -----------------
        GC_STATES = list(product(range(3), repeat=2))
        gc_leq  = lambda x, y: all(a <= b for a, b in zip(x, y))
        gc_join = lambda x, y: tuple(max(a, b) for a, b in zip(x, y))
        def gc_mutators(x):                          # (full result, delta) per enabled op
            for i in range(2):
                if x[i] < 2:
                    yield (tuple(v + (k == i) for k, v in enumerate(x)),
                           tuple(x[i] + 1 if k == i else 0 for k in range(2)))

        # ---- OR-Set over three tags (element, unique id); state = (adds, removes) --
        TAGS = [("milk", 1), ("milk", 2), ("eggs", 3)]
        def subsets(items):
            return [frozenset(c) for r in range(len(items) + 1) for c in

        or_join = lambda x, y: (x[0] | y[0], x[1] | y[1])
        or_value = lambda x: {e for e, _ in x[0] - x[1]}
        def or_mutators(x):
            adds, removes = x
            for t in TAGS:                           # add(e) with a fresh tag
                if t not in adds:
                    yield (adds | {t}, removes), (frozenset({t}), frozenset())
            for e in {e for e, _ in TAGS}:           # remove(e): tombstone observed tags
                seen = frozenset(t for t in adds if t[0] == e)
                yield (adds, removes | seen), (frozenset(), seen)

        def check(name, states, leq, join, mutators):
            for x, y in product(states, repeat=2):
                j = join(x, y)
                assert leq(x, j) and leq(y, j), "join is an upper bound"
                assert all(leq(j, z) for z in states if leq(x, z) and leq(y, z)),
"least"
                assert j == join(y, x) and join(x, x) == x, "commutative, idempotent"
                for z in states:
                    assert join(join(x, y), z) == join(x, join(y, z)), "associative"
            for x in states:
                for full, delta in mutators(x):
                    assert leq(x, full), "mutator is inflationary"
                    assert full == join(x, delta), "m(x) == x JOIN delta(x)"
            print(f"{name}: {len(states)} states, join is the LUB, mutators inflation-
ary, deltas exact")

        check("G-Counter", GC_STATES, gc_leq, gc_join, gc_mutators)
        check("OR-Set   ", OR_STATES, or_leq, or_join, or_mutators)

        # The state grows monotonically, but the *query* need not be monotone:
        x = (frozenset({("milk", 1)}), frozenset())
```

```
        y = (frozenset({("milk", 1)}), frozenset({("milk", 1)}))
        print("OR-Set: x <= y:", or_leq(x, y), "| value(x) =", or_value(x), "| value(y)
=", or_value(y))

        # An invariant a lattice cannot protect: stock >= 0 checked only locally.
        p, n = {"A": 1, "B": 0}, {"A": 0, "B": 0}       # PN-Counter: one unit in stock
        replica = {r: (dict(p), dict(n)) for r in "AB"}  # both replicas have seen it
        for r in "AB":                                    # each sells it: local check
passes
            pr, nr = replica[r]
            if sum(pr.values()) - sum(nr.values()) >= 1:
                nr[r] += 1
        merged_p = {k: max(replica["A"][0][k], replica["B"][0][k]) for k in "AB"}
        merged_n = {k: max(replica["A"][1][k], replica["B"][1][k]) for k in "AB"}
        print("PN-Counter stock after merge:", sum(merged_p.values()) -
sum(merged_n.values()))
```

Output:

```
G-Counter: 9 states, join is the LUB, mutators inflationary, deltas exact
OR-Set   : 27 states, join is the LUB, mutators inflationary, deltas exact
OR-Set: x <= y: True | value(x) = {'milk'} | value(y) = set()
PN-Counter stock after merge: -1
```

What to notice:

- The “least” check, `all(leq(j, z) ...)`, proves no smaller upper bound exists: merge loses and invents no information.
- `full == join(x, delta)` is the delta contract; an OR-Set remove delta carries only observed tombstones, hence add-wins.
- The OR-Set *state* grows but its *value* shrinks (`{'milk'}` then `set()`): “is milk absent?” is a non-monotone query.
- The PN-Counter converges perfectly, to −1: each local check passed, and convergence says nothing about invariants.

45.6.6 Limits: invariants and the CALM theorem

Convergence concerns the *data*; correctness usually concerns *invariants*. Transactions are **invariant confluent** (I-confluent) for invariant *I* if merging any two divergent *I*-valid states with a common *I*-valid ancestor always yields an *I*-valid state; exactly then can replicas avoid coordination without ever violating *I* [Bailis et al. 2014b].

Table 45.6 — Invariant confluence of common invariants.

Invariant	Operations	I-confluent?	Why
Counter ≥ 0	Increments only	Yes	Merging two non-negative growths stays non-negative
Counter ≥ 0	Decrements	No	Two replicas each take the last unit (the program above)
Unique ID	Insert with replica-chosen ID from disjoint ranges	Yes	Ranges never collide
Unique username	Insert any chosen value	No	Both sides can pick the same name
Foreign key	Insert child with existing parent	Yes	Merge keeps both rows
Foreign key	Delete parent concurrently with insert child	No	Merge has an orphan

For counters the usual escape is **escrow**: pre-partition the allowance (each region may sell 50 of 100 seats) and coordinate only to rebalance [Balegas et al. 2015].

DEFINITION

Definition — CALM theorem. *Consistency As Logical Monotonicity*: a problem has a consistent, coordination-free distributed implementation if and only if it is **monotonic**, meaning that adding inputs can only add outputs, never retract one [Hellerstein & Alvaro 2020; Ameloot et al. 2013].

CALM lifts the lattice story to whole programs. Set union, reachability and deadlock detection (a waits-for cycle, once found, persists) are monotone, so replicas may act on partial views. Garbage collection ("no references exist") and checkout ("no more items will arrive") assert *absence*, which a late message can refute, so they need a barrier, sealed epoch or consensus. Write as much as possible in monotone form (Bloom and its lattice extension make this checkable [Alvaro et al. 2011; Conway et al. 2012]) and coordinate only at the non-monotone points.

COMMON MISTAKE

Mistake — "Use a CRDT and you will never need consensus." CRDTs remove coordination for *merging*; non-monotone decisions (did we oversell? is this name free?) still need it.

45.7 Byzantine faults and why they matter

45.7.1 Arbitrary failures and where they come from

DEFINITION

Definition — Byzantine fault. A fault in which a node deviates arbitrarily from its protocol: it may send wrong values, send *different* values to different peers (**equivocation**), replay or delay messages, or collude with other faulty nodes. The name comes from Lamport, Shostak and Pease's allegory of generals, some of them traitors, who must agree on a battle plan by messenger [Lamport et al. 1982].

First-principles explanation

Crash-tolerant consensus assumes a faulty node is *silent*. A Byzantine node is a committee member who signs two contradictory minutes and hands one to each half of the room. Counting votes still works, but you must count enough that liars cannot tip the outcome.

Why does this exist? Where Byzantine faults occur in practice

Most Byzantine behavior in data centers is accidental, and crash-tolerant protocols turn it into data loss because they trust every message.

Table 45.7 — Sources of Byzantine behavior.

Source	What it looks like	Published evidence
Silent data corruption in CPUs	A core computes wrong results, deterministically or intermittently, without any error signal	Google reports “mercurial cores” at a rate of a few per several thousand machines [Hochschild et al. 2021]; Meta reports silent data corruptions across its fleet [Dixit et al. 2021]
Corrupted messages	A bit flip that slips past TCP’s 16-bit checksum and changes protocol state	Amazon S3’s July 2008 outage: corrupted gossip messages spread through the cluster until MD5 checks were added [AWS 2008]
Corrupted storage	A single bad block or misdirected write on one replica	Ganesan et al. found that one corrupted block on one node could cause data loss or unavailability in widely used replicated stores [Ganesan et al. 2017]
Nondeterministic replicas	Replicas of a state machine diverge because of hash-map iteration order, time or threads	Appears to peers as a replica sending wrong answers
Faulty sensors and buses	A slightly-out-of-specification signal read differently by different receivers	Driscoll et al. document such failures in safety-critical avionics [Driscoll et al. 2003]
Mutually distrustful parties	Banks, companies or anonymous participants who each control nodes	Permissioned ledgers and public blockchains (§45.11)

RECOMMENDATION

Recommendation — Convert arbitrary faults into crashes where you can. End-to-end checksums, background comparison of replica-state digests, deterministic state machines and CPU screening turn “wrong answer” into “detected error”, which crash-tolerant protocols handle (§24.14). Pay for full BFT when the *parties* cannot trust each other.

COMMON MISTAKE

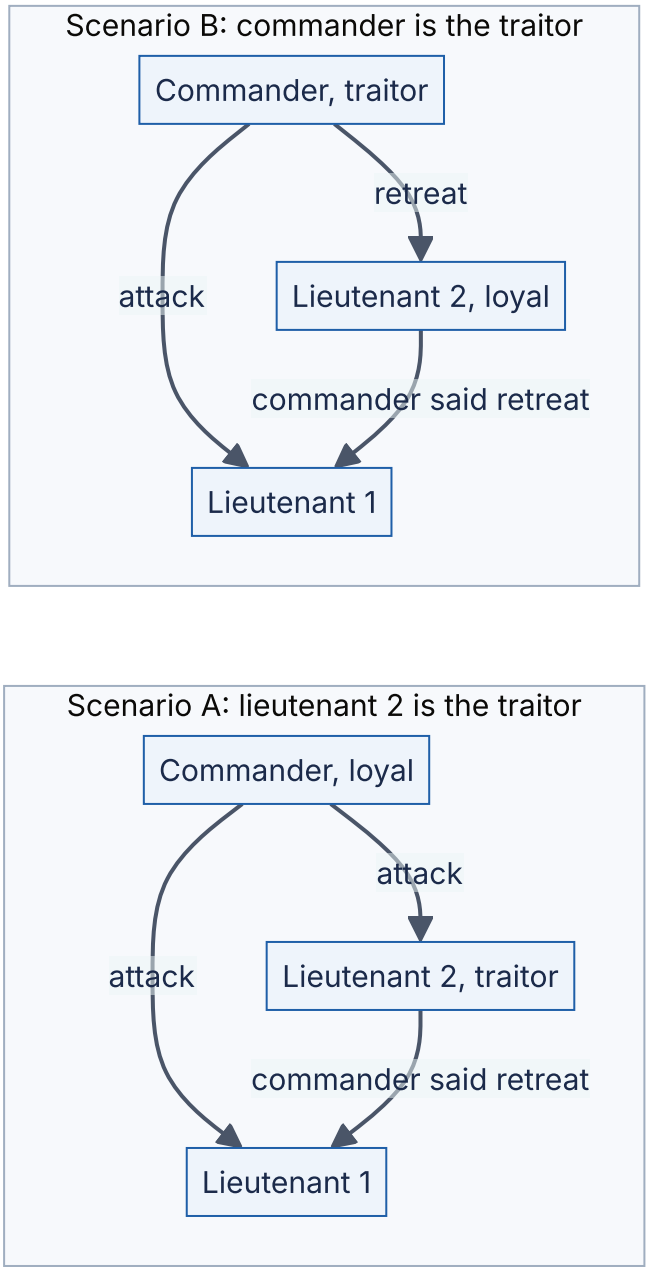
Mistake — “Byzantine fault tolerance protects against hackers.” One exploit that works on identical software compromises every replica at once. BFT needs **independent failures** (diverse implementations, keys and administrators) and does nothing about a valid but malicious client request.

45.8 BFT lower bounds

45.8.1 Why three generals cannot tolerate one traitor

With unsigned messages, three generals cannot agree if one is a traitor [Lamport et al. 1982]. A commander sends an order to two lieutenants, who relay what they heard to each other.

Figure 45.9 — The indistinguishable scenarios behind the three-generals impossibility.



Reading the diagram. Each subgraph is a possible world; arrows are unsigned messages delivered synchronously in rounds. Lieutenant 1 receives identical messages in

both. In A, validity forces it to attack. In B, loyal lieutenant 2 sees the mirror-image pattern and, by the same rule, follows the commander: retreat; agreement then forces lieutenant 1 to retreat. No rule does both. The failure point is the unverifiable relay. Simulating each general with f nodes extends the impossibility to any $n \le 3f$.

With unforgeable signatures *and synchrony*, the relay can be verified and Byzantine broadcast is solvable for any number of traitors [Lamport et al. 1982; Dolev & Strong 1983]. Signatures do not lower the bound in partial synchrony, where real protocols live.

45.8.2 The partially synchronous bound and quorum intersection

In partial synchrony (§24.6.2) a protocol must act after hearing from $n - f$ replicas, since f may be silent; up to f of those heard may be Byzantine, and the silent ones may be *honest but slow*. Two requirements follow:

1. **Liveness:** a quorum must be obtainable without the f silent nodes: $q \le n - f$.
2. **Safety:** any two quorums must share at least one *honest* node, so they cannot certify conflicting values. Two quorums of size q in n nodes overlap in at least $2q - n$ nodes, of which up to f may be Byzantine: $2q - n \ge f + 1$.

Substituting the largest allowed quorum, $2(n - f) - n \ge f + 1$, gives $n \ge 3f + 1$. Dwork, Lynch and Stockmeyer proved this is tight for partial synchrony even with signatures [Dwork et al. 1988].

FORMULA

Byzantine fault tolerance and quorum size

$$n \ge 3f + 1 \qquad f_{\max} = \left\lfloor \frac{n-1}{3} \right\rfloor \qquad q = \left\lceil \frac{n+f+1}{2} \right\rceil \qquad |Q_1 \cap Q_2| \ge 2q - n \ge f + 1$$

Symbol	Meaning	Units
n	Number of replicas	count
f	Byzantine replicas tolerated	count
q	Quorum (certificate) size	count
Q_1, Q_2	Any two quorums	sets of replicas
$2q - n$	Minimum overlap of two quorums	count

For $n = 3f + 1$ the quorum is $q = 2f + 1$ and the overlap is exactly $f + 1$: at least one honest replica sits in every overlap and will not vote for two conflicting values.

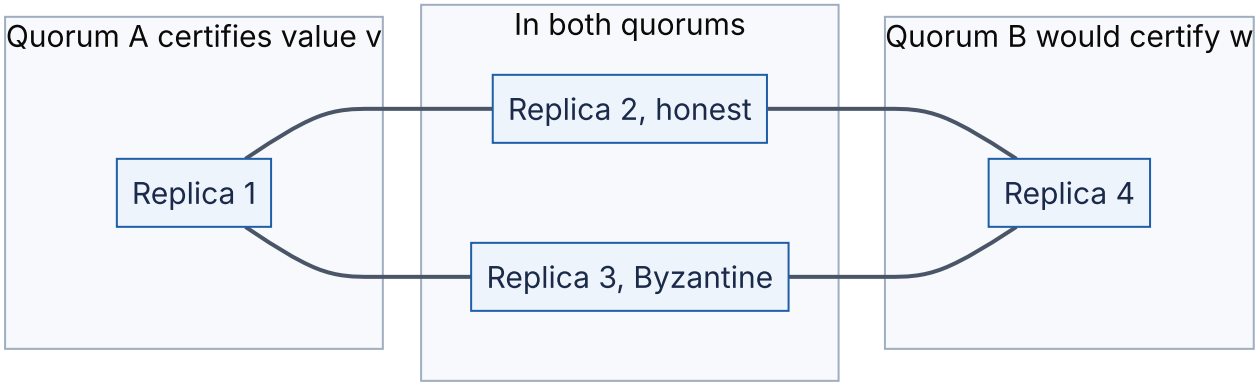
WORKED EXAMPLE

Worked example — Sizing BFT clusters with 4, 5, 7 and 10 replicas.

1. $n = 4$: $f = \lfloor 3/3 \rfloor = 1$; $q = \lceil 6/2 \rceil = 3$; overlap $2 \cdot 3 - 4 = 2 \geq f + 1 = 2$. Liveness: $q = 3 \leq n - f = 3$.
2. $n = 5$: $f = \lfloor 4/3 \rfloor = 1$; $q = \lceil 7/2 \rceil = 4$; overlap 3; liveness $4 \leq 4$. The fifth replica tolerates no extra fault and *raises* the quorum.
3. $n = 7$: $f = 2$; $q = \lceil 10/2 \rceil = 5$; overlap $3 = f + 1$; liveness $5 \leq 5$.
4. $n = 10$: $f = 3$; $q = \lceil 14/2 \rceil = 7$; overlap $4 = f + 1$; liveness $7 \leq 7$.

Interpretation. As with odd Raft sizes (§26.4.1), only $3f + 1$ is efficient: 5 and 6 replicas tolerate the same fault as 4. BFT needs f more replicas than crash tolerance and larger quorum fractions (3 of 4 versus 2 of 3). **Engineering implication.** Use $3f + 1$ replicas in independent failure *and administrative* domains; at $n = 3f + 1$ liveness has no slack, so one crashed honest replica plus f Byzantine ones halts progress.

Figure 45.10 — Quorum intersection with n = 4, f = 1: two quorums of three share an honest replica.



Reading the diagram. Quorum A is replicas 1–3; quorum B would be 2–4; lines show membership, not messages. Even if replica 3 equivocates (the failure point), honest replica 2 voted for v and will not vote for w, so B never reaches three votes. With $n = 3$ and quorums of 2, the single-replica overlap could be the liar and both quorums could form.

45.8.3 Synchrony assumptions, summarized

Table 45.8 — Byzantine agreement bounds by timing model.

Timing model	Messages	Replicas needed	Notes	Source
Synchronous	Oral (unsigned)	$n \geq 3f + 1$	Needs $f + 1$ rounds in the worst case	[Lamport et al. 1982; Fischer & Lynch 1982]
Synchronous	Signed	Broadcast for any $f < n$; agreement on inputs for $f < n/2$	Still $f + 1$ rounds	[Dolev & Strong 1983]
Partially synchronous	Either	$n \geq 3f + 1$	Safe always, live after GST; basis of PBFT, Tendermint, HotStuff	[Dwork et al. 1988]
Asynchronous, deterministic	Either	Impossible even for one crash	FLP	[Fischer et al. 1985]
Asynchronous, randomized	Either	$n \geq 3f + 1$	Terminates with probability 1	[Ben-Or 1983; Bracha 1987; Miller et al. 2016]

FLP (§24.13) applies in full, so BFT protocols take Paxos's escape: safety in every execution, liveness from timeouts and view changes after GST. Randomized asynchronous protocols such as HoneyBadgerBFT avoid timing assumptions at the cost of heavier cryptography and latency [Miller et al. 2016].

45.9 PBFT

45.9.1 The normal case

DEFINITION

Definition — Practical Byzantine Fault Tolerance (PBFT). A state-machine replication protocol for $n = 3f + 1$ replicas that tolerates f Byzantine replicas and any number of faulty clients, is safe under asynchrony and live under partial synchrony, and orders requests with three phases (pre-prepare, prepare, commit) led by a **primary** that is replaced through a **view change** when it misbehaves [Castro & Liskov 1999; Castro & Liskov 2002].

First-principles explanation

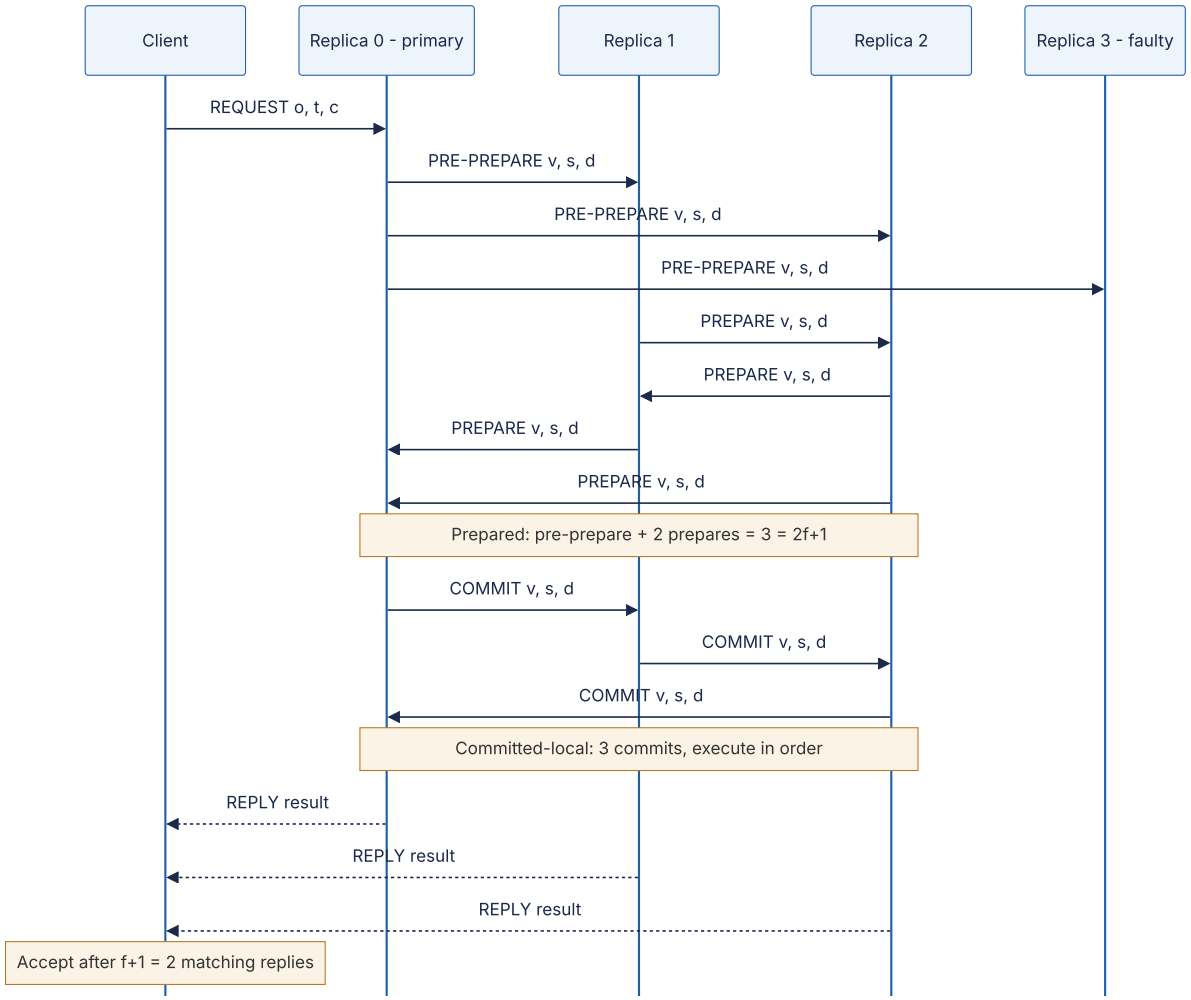
Picture Multi-Paxos (§26.6.2) with a leader who might lie. Nobody acts on its word alone: replicas first confirm with each other that they received the *same* proposal for a slot, then confirm that enough of them know it, each time with a quorum of $2f + 1$.

How it works internally

Views are numbered $v = 0, 1, 2, \ldots$ and the primary of view v is replica $v \bmod n$.

1. **Request.** A client sends a signed request ⟨REQUEST, o, t, c⟩ (operation, timestamp, client) to the primary.
2. **Pre-prepare.** The primary assigns sequence number s and multicasts ⟨PRE-PREPARE, v, s, d⟩ with the request, where d is its digest. A backup accepts it if it is in view v, s lies between the low and high **watermarks**, and it has not accepted a different digest for (v, s).
3. **Prepare.** Each backup that accepts multicasts ⟨PREPARE, v, s, d, i⟩ to all replicas. A replica is **prepared** for (v, s, d) when it has the pre-prepare and $2f$ matching prepares from different backups: a **prepared certificate** of $2f + 1$ statements. Two honest replicas can never be prepared for different digests in the same (v, s), by quorum intersection.
4. **Commit.** A prepared replica multicasts ⟨COMMIT, v, s, d, i⟩. It is **committed-local** once it is prepared and holds $2f + 1$ matching commits (its own included).
5. **Execute and reply.** Replicas execute requests in sequence-number order and reply directly to the client, which accepts a result once it has $f + 1$ matching replies: at least one is honest.
6. **Checkpoint.** Every K requests, replicas multicast a digest of their state. $2f + 1$ matching checkpoint messages make a **stable checkpoint**, which lets replicas discard older log entries and advance the watermarks.

Figure 45.11 — PBFT normal case with n = 4, f = 1 and a silent replica 3.



Reading the diagram. Authenticated point-to-point messages; time runs downward. Only a subset of solid arrows is drawn: every prepare and commit is really multicast to all replicas. Dashed arrows are replies to the client. Silent replica 3 is the failure point, yet replicas 0–2 still assemble $2f + 1 = 3$ statements per phase. Each replica's log, pruned at stable checkpoints, is the storage boundary. All-to-all phases make traffic grow with n^2.

Why three phases?

Pre-prepare and prepare fix the **order within a view**. They do not make it **survive a view change**: a lone prepared replica could be outvoted by a new primary. The commit phase ensures that before any honest replica executes, $2f + 1$ replicas hold a prepared certificate, so any view-change quorum of $2f + 1$ contains at least one honest holder.

45.9.2 View change

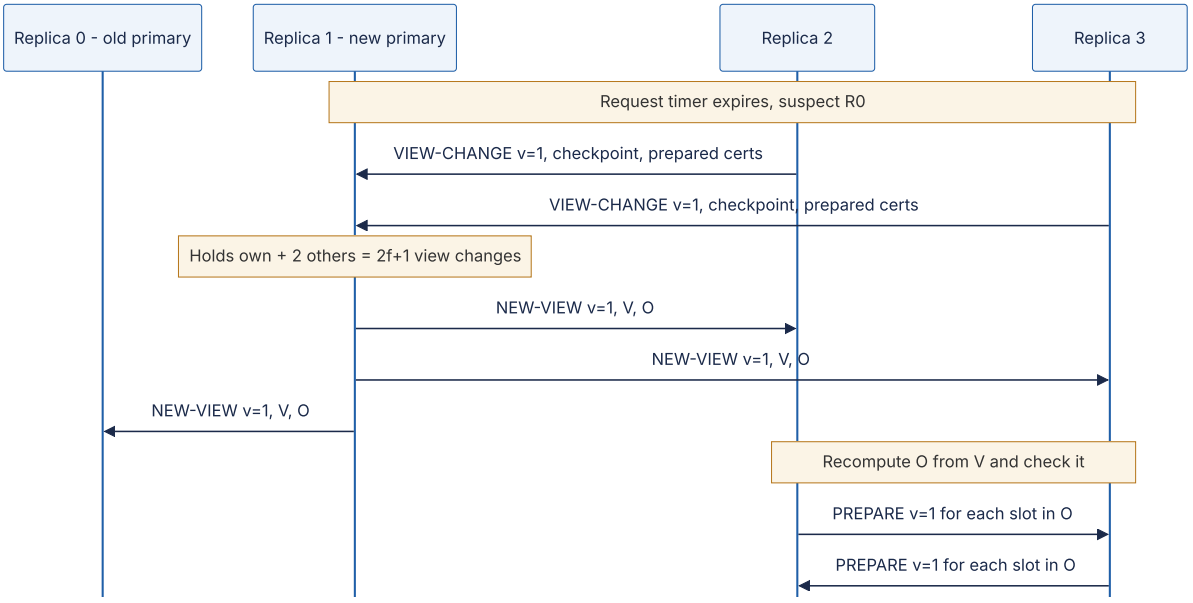
When a backup's timer for a pending request expires, it suspects the primary and stops accepting messages in view v.

1. **VIEW-CHANGE.** It multicasts $\langle$VIEW-CHANGE, $v + 1$, s_c, $\mathscr{C}$, $\mathscr{P}$, $i\rangle$: its last stable checkpoint s_c with $2f + 1$ checkpoint proofs $\mathscr{C}$, and $\mathscr{P}$, a prepared certificate for every

request prepared after s_c.

2. **NEW-VIEW.** The primary of view $v+1$ waits for $2f$ valid view-change messages from other replicas (plus its own, $2f+1$ in all) and multicasts ⟨NEW-VIEW, $v+1$, $\mathcal{V}$, $\mathcal{O}$⟩, where $\mathcal{V}$ is the set of view-change messages and $\mathcal{O}$ re-issues a pre-prepare for every slot after the checkpoint: the request with a prepared certificate from the highest view, or a **null request** if none exists.
3. **Verify and resume.** Backups check that $\mathcal{O}$ was computed correctly from $\mathcal{V}$, so a faulty new primary cannot rewrite history, and the protocol continues with prepares in view $v+1$.
4. **Escalate.** If the new primary also fails, timers double and the next view begins, which is how liveness is restored after GST.

Figure 45.12 — PBFT view change from view 0 to view 1 (n = 4).



Reading the diagram. Suspected primary R0 is the failure point; the others time out independently and multicast view changes (only those to the new primary are drawn). R1 leads view 1 because $1 \bmod 4 = 1$. NEW-VIEW carries the evidence $\mathcal{V}$, so backups recompute $\mathcal{O}$ and reject forged histories. Prepared certificates carry committed requests across views. Each view-change message holds $O(n)$ certificates of $O(n)$ signatures and NEW-VIEW holds $2f+1$ of them, so view changes grow much faster than the normal case.

45.9.3 Message complexity

FORMULA

PBFT normal-case message count per request (no batching)

$$M_{\text{replicas}} = \underbrace{(n-1)}_{\text{pre-prepare}} + \underbrace{(n-1)^2}_{\text{prepare}} + \underbrace{n(n-1)}_{\text{commit}} = 2n(n-1) \qquad M_{\text{total}} = 2n(n-1) + n + 1$$

Symbol	Meaning	Units
n	Replicas, $n = 3f + 1$	count
M_{replicas}	Replica-to-replica messages per request	messages
M_{total}	Including 1 request and n replies	messages

WORKED EXAMPLE

Worked example — PBFT messages for n = 4, 7 and 10.

1. $n = 4$ ($f = 1$): $3 + 9 + 12 = 24$ replica messages; with the request and 4 replies, 29.
2. $n = 7$ ($f = 2$): $6 + 36 + 42 = 84$; total $84 + 8 = 92$.
3. $n = 10$ ($f = 3$): $9 + 81 + 90 = 180$; total $180 + 11 = 191$.
4. At 1,000 requests/s unbatched, a 10-replica cluster exchanges $180,000$ replica messages per second. Batching 100 requests per protocol instance cuts that to $1,800$ per second.

Interpretation. Going from 1 to 3 tolerated faults multiplies traffic by $180/24 = 7.5$: the n^2 term. **Engineering implication.** PBFT with batching is excellent at $n = 4$ or 7 and a bottleneck at tens or hundreds of replicas, the regime that motivated HotStuff.

Table 45.9 — PBFT costs at three cluster sizes.

n	f	Quorum $2f + 1$	Pre-prepare	Prepare	Commit	Replica total	With client
4	1	3	3	9	12	24	29
7	2	5	6	36	42	84	92
10	3	7	9	81	90	180	191

PBFT's normal case also uses **MAC vectors** instead of signatures, **batching**, **tentative execution** (execute once prepared; the client waits for $2f + 1$ matching replies) and direct **read-only requests** answered by $2f + 1$ matching replies.

INDUSTRY EXAMPLE

BFS and BFT-SMaRt. Castro and Liskov built BFS, a Byzantine-fault-tolerant NFS service on PBFT, and reported it only 3% slower than an unreplicated NFS on the Andrew benchmark, the result that made BFT look practical. BFT-SMaRt is a widely used open-source library in the same lineage, and Hyperledger Fabric 3.0 added a BFT ordering service based on the SmartBFT library, alongside its crash-tolerant Raft orderer (as of 2024). *Evidence: Primary* — [Castro & Liskov 1999; Bessani et al. 2014; Hyperledger Fabric Docs]

WARNING / TRADE-OFF

Warning — A correct protocol can still crawl under attack. A Byzantine primary can delay each request to just under the timeout. Clement et al. showed several BFT protocols losing most of their throughput this way and designed Aardvark to bound the damage with regular primary rotation and performance monitoring [Clement et al. 2009].

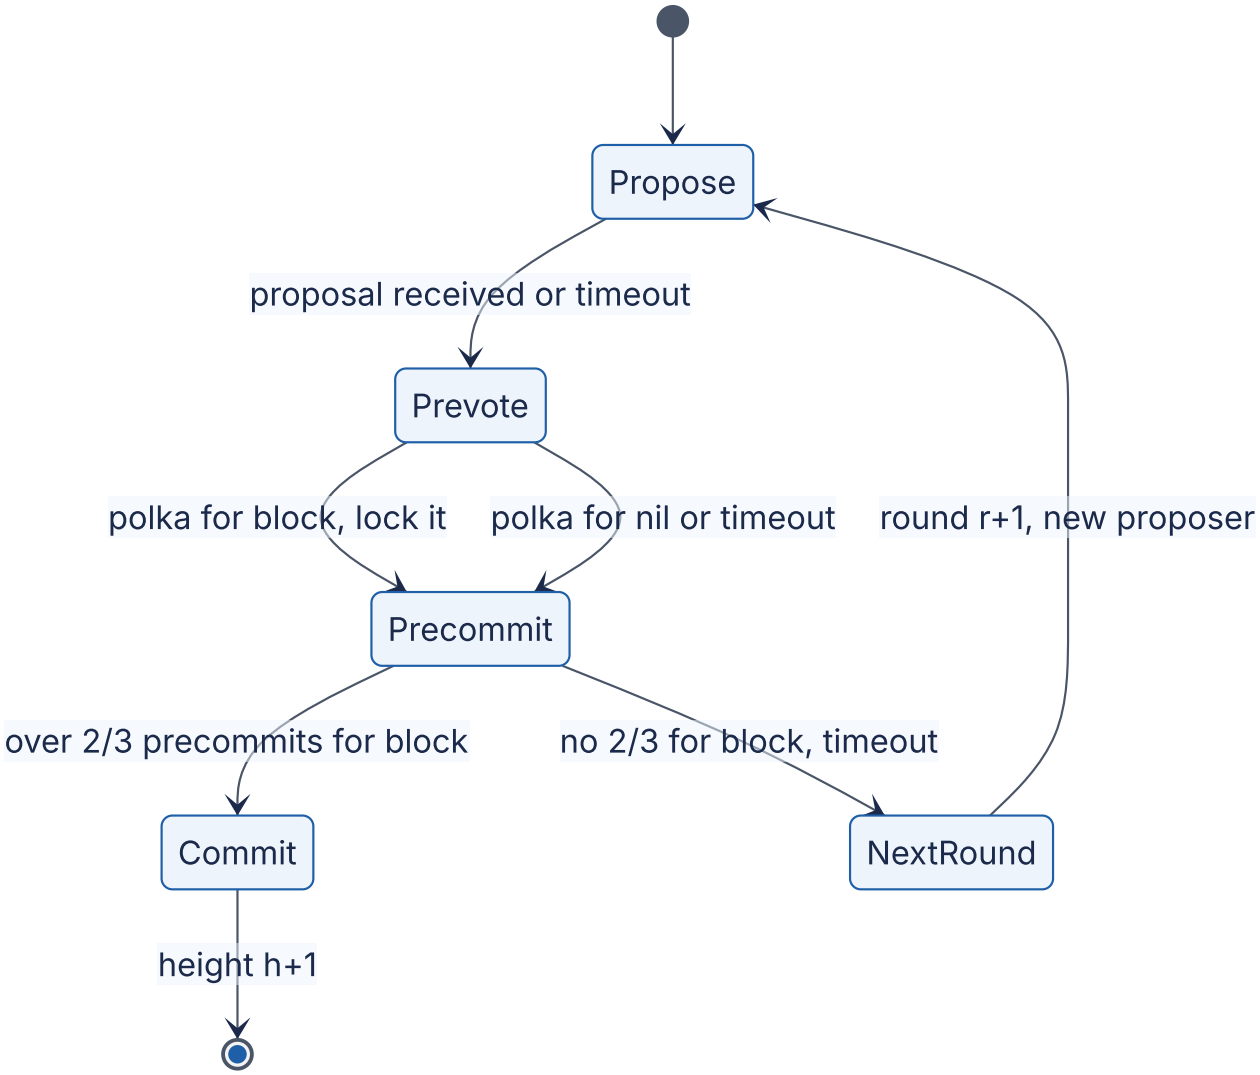
45.10 Modern BFT: Tendermint and HotStuff

45.10.1 Tendermint

Tendermint, introduced in Buchman's thesis and refined in a 2018 paper, rebuilt PBFT-style consensus for blockchains: a validator set weighted by stake, a fresh decision per block height, gossip instead of point-to-point multicast, and a proposer that rotates every round [Buchman 2016; Buchman et al. 2018]. Each height runs one or more **rounds** of three steps; "+2/3" means more than two-thirds of voting power.

1. **Propose.** The round's proposer (weighted round-robin) gossips a block.
2. **Prevote.** Each validator prevotes for the block if it is valid and compatible with its lock, otherwise for nil. More than two-thirds of prevotes for one block form a **polka**.
3. **Precommit.** On seeing a polka a validator **locks** on the block and precommits it. More than two-thirds of precommits **commit** the block at this height, with immediate finality.
4. **Next round.** If a step times out, validators move to round $r + 1$ with a longer timeout. A locked validator prevotes only its locked block in later rounds unless it sees a polka for a different block in a later round, which is what keeps two rounds from committing different blocks.

Figure 45.13 — One Tendermint height as a state machine.



Reading the diagram. States are one validator's steps at one height; transitions fire on asynchronously gossiped votes or local timeouts. The only exit is Commit, after which the block is final. A faulty proposer or a network split (the failure points) leads through NextRound with growing timeouts. Locks persisted in local state carry safety across rounds. All-to-all gossip makes each round quadratic in validators.

45.10.2 HotStuff

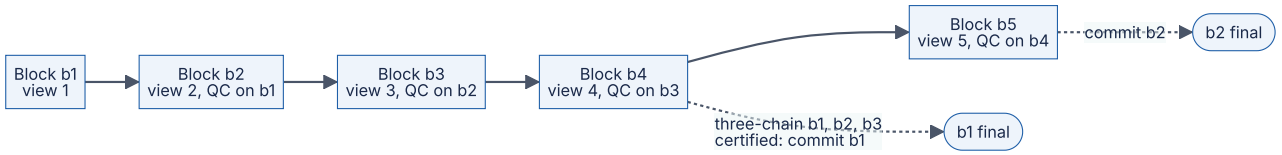
A new leader in a two-phase protocol must show its proposal conflicts with nothing that *might* have committed: by forwarding everyone's certificates (PBFT) or by waiting the maximum delay Δ to hear the highest lock (Tendermint, which is therefore not **optimistically responsive**: it cannot proceed at actual network speed after a leader change). HotStuff adds a third voting phase so that the highest quorum certificate reported by $n - f$ replicas suffices [Yin et al. 2019].

1. **Star topology:** votes go to the leader, which broadcasts; each phase costs $O(n)$ messages.

2. **Quorum certificates (QCs):** $n - f$ votes combined, in the paper by a threshold signature, into a constant-size authenticator.
3. **Phases:** PREPARE (propose a block extending the highest QC), PRE-COMMIT, COMMIT (replicas **lock**), DECIDE (execute).
4. **Voting rule:** vote if the proposal extends the locked block (safety) *or* its QC is from a higher view than the lock (liveness).
5. **Pacemaker:** leader rotation and timeouts live in a separate module, so safety never depends on timing.

Chained HotStuff pipelines the phases: each view's block carries a QC on its parent, and that single QC is the prepare QC for the parent, the pre-commit QC for the grandparent and the commit QC for the great-grandparent. A block commits once it is the first of a **three-chain**, three blocks certified in consecutive views, and leaders can rotate every block for free.

Figure 45.14 — Chained HotStuff: each block's QC advances three earlier blocks.



Reading the diagram. Each block is proposed by a different leader in consecutive views; a solid arrow means the later block carries a QC, built from $n - f$ votes sent to that leader, on the earlier one. When b4 arrives with the QC on b3, b1, b2 and b3 are certified in consecutive views, so b1 commits; dotted arrows are these asynchronous consequences. Blocks live in each replica's block tree. A failed leader breaks the chain (the failure point) and commits wait for a new three-chain. One broadcast and one vote round per view keep throughput high.

FORMULA

Messages per decision: PBFT versus HotStuff

$$M_{\text{PBFT}} = 2n(n-1) \qquad M_{\text{HS-basic}} = 8(n-1) \qquad M_{\text{HS-chained}} \approx 2(n-1)$$

Symbol	Meaning	Units
n	Replicas	count
M_{PBFT}	Replica messages per PBFT decision (§45.9.3)	messages
$M_{\text{HS-basic}}$	NEW-VIEW plus four leader broadcasts plus three vote rounds	messages
$M_{\text{HS-chained}}$	One proposal broadcast plus one vote round per block, steady state	messages

WORKED EXAMPLE

Worked example — When does linearity pay?

1. $n = 4$: PBFT $2 \cdot 4 \cdot 3 = 24$; basic HotStuff $8 \cdot 3 = 24$; chained 6.
2. $n = 10$: PBFT 180; basic 72; chained 18.
3. $n = 100$ ($f = 33$): PBFT $2 \cdot 100 \cdot 99 = 19,800$; basic 792; chained 198, a $100\times$ reduction.

Interpretation. At four replicas basic HotStuff saves nothing and needs more message delays (about seven one-way delays from proposal to DECIDE, against PBFT's three). The win is at large n and in view changes, which stay linear while PBFT's reach $O(n^3)$ authenticators. **Engineering implication.** PBFT-style protocols suit 4–7 replicas; a 100-validator set with per-block rotation needs a linear, pipelined protocol.

Table 45.10 — PBFT, Tendermint and HotStuff compared.

	PBFT	Tendermint	HotStuff (chained)
Voting phases	2 after pre-prepare	2 (prevote, precommit)	3, pipelined
Communication	All-to-all	All-to-all gossip	Star via leader
Authenticators, correct leader	$O(n^2)$	$O(n^2)$	$O(n)$
Authenticators, view change	$O(n^3)$	$O(n^2)$	$O(n)$
Optimistically responsive	Yes	No	Yes
Leader	Stable until suspected	Rotates per round	Rotates per block
Typical home	Permissioned, small n	Proof-of-stake chains	Proof-of-stake and permissioned chains

Complexities follow the comparison in the HotStuff paper [Yin et al. 2019].

INDUSTRY EXAMPLE

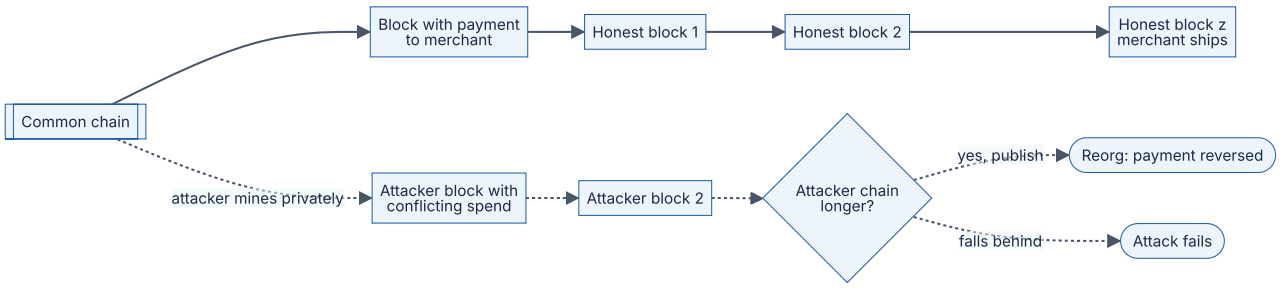
CometBFT and LibraBFT. Tendermint Core, maintained since 2023 as CometBFT, runs the Cosmos Hub and many Cosmos SDK chains. The Libra (later Diem) blockchain specified LibraBFT, a HotStuff variant with an explicit pacemaker; Diem was wound down in 2022. *Evidence: Primary* — [CometBFT Docs; Baudet et al. 2019]

45.11 Blockchain consensus overview

45.11.1 Nakamoto consensus and probabilistic finality

Classical BFT needs known membership: votes mean nothing if anyone can create a million identities (a **Sybil attack**). Nakamoto replaced votes with *work* [Nakamoto 2008]: miners race for a block hash below a target, about 10 minutes of network-wide hashing on average, and nodes follow the chain with the most cumulative work. Near-simultaneous blocks create **forks** that resolve as one branch grows. A transaction is never final; it becomes exponentially less likely to be reversed as blocks accumulate.

Figure 45.15 — A double-spend race against z confirmations.



Reading the diagram. The common chain is the log every node stores. Solid arrows are honest blocks; dotted arrows are the attacker's private branch, published only if it overtakes. The merchant ships after z blocks; the failure point is the diamond, where a lucky or powerful attacker triggers a reorganization that erases the payment. Throughput is bounded by block size and interval, so the system scales in participants but not transactions.

FORMULA

Probability that an attacker ever overtakes after z confirmations [Nakamoto 2008, section 11]

$$P(q,z) = 1 - \sum_{k=0}^{z} \frac{\lambda^k e^{-\lambda}}{k!}\left(1 - \left(\frac{q}{p}\right)^{z-k}\right), \qquad \lambda = z\frac{q}{p}, \quad p = 1 - q$$

Symbol	Meaning	Units
q	Attacker's share of total hash power	dimensionless
p	Honest share, $1 - q$	dimensionless
z	Confirmations: honest blocks on top of the payment	blocks
λ	Expected attacker blocks mined while honest miners find z	blocks
k	Attacker blocks actually mined, Poisson-distributed	blocks
$(q/p)^{z-k}$	Gambler's-ruin probability of closing a gap of $z - k$ blocks	dimensionless

The program reproduces the whitepaper's tables (it is a direct translation of the C function given there):

```
        """Probability that an attacker with hash-power share q ever overtakes the
        honest chain once the merchant has waited for z confirmations
        (Nakamoto 2008, section 11), plus the z needed for P < 0.1%."""
        from math import exp

        def attacker_success(q, z):
            p = 1.0 - q
            if q >= p:
                return 1.0                      # a majority attacker always catches up
            lam = z * q / p                     # expected attacker progress meanwhile
            total, poisson = 1.0, exp(-lam)     # poisson = P(attacker mined k blocks)
            for k in range(z + 1):              # attacker has k blocks: still z-k be-
hind
                if k > 0:
                    poisson *= lam / k          # incremental form avoids overflow
                total -= poisson * (1 - (q / p) ** (z - k))
            return total

        if __name__ == "__main__":
            for q in (0.1, 0.3):
                print(f"q = {q}:", "  ".join(f"z={z}: {attacker_success(q, z):.7f}"
                                             for z in ((0, 1, 2, 3, 6, 10) if q == 0.1
else (0, 5, 10, 20, 30))))
            for q in (0.10, 0.15, 0.20, 0.25, 0.30, 0.35, 0.40, 0.45):
                z = 0
                while attacker_success(q, z) >= 0.001:
                    z += 1
                print(f"q = {q:.2f}: z = {z:3d} confirmations for P < 0.1%"
                      f"  (about {z * 10 / 60:.1f} h at 10 min per block)")
```

Output:

```
q = 0.1: z=0: 1.0000000  z=1: 0.2045873  z=2: 0.0509779  z=3: 0.0131722  z=6: 0.0002428
z=10: 0.0000012
q = 0.3: z=0: 1.0000000  z=5: 0.1773523  z=10: 0.0416605  z=20: 0.0024804  z=30:
0.0001522
q = 0.10: z =   5 confirmations for P < 0.1%  (about 0.8 h at 10 min per block)
q = 0.15: z =   8 confirmations for P < 0.1%  (about 1.3 h at 10 min per block)
q = 0.20: z =  11 confirmations for P < 0.1%  (about 1.8 h at 10 min per block)
q = 0.25: z =  15 confirmations for P < 0.1%  (about 2.5 h at 10 min per block)
q = 0.30: z =  24 confirmations for P < 0.1%  (about 4.0 h at 10 min per block)
q = 0.35: z =  41 confirmations for P < 0.1%  (about 6.8 h at 10 min per block)
q = 0.40: z =  89 confirmations for P < 0.1%  (about 14.8 h at 10 min per block)
q = 0.45: z = 340 confirmations for P < 0.1%  (about 56.7 h at 10 min per block)
```

What to notice: the values match the whitepaper digit for digit, and the required z explodes as q approaches $1/2$.

WORKED EXAMPLE

Worked example — How long should a merchant wait?

1. Attacker share $q = 0.1$, so $p = 0.9$ and $q/p = 0.111$. For $z = 6$: $\lambda = 6 \times 0.111 = 0.667$.
2. The program gives $P(0.1, 6) = 0.0002428$, about 1 in 4,100.
3. At 10 minutes per block, 6 confirmations take 60 minutes on average. Block times are exponential, so the wait is Erlang-distributed: the probability that 6 blocks take longer than 90 minutes is the probability of at most 5 blocks in 90 minutes, $\sum_{k=0}^{5} e^{-9} 9^k / k! \approx 0.116$.
4. Against $q = 0.3$, reaching $P < 0.1\%$ needs $z = 24$, about 4 hours.

Interpretation. Finality is a risk dial that trades latency for reversal probability, set by an estimate of attacker hash power. **Engineering implication.** Size z to the value at risk and treat the formula as optimistic: it ignores network delay and strategies such as selfish mining, profitable below half the hash power [Eyal & Sirer 2014]; later analyses refine its Poisson approximation [Rosenfeld 2014].

Throughput follows from the parameters: 2,000–4,000 transactions per block every 600 s is about 3–7 transactions per second (illustrative). Bigger or faster blocks propagate more slowly relative to the interval, causing more forks and weaker security.

45.11.2 Proof of stake and finality gadgets

Proof of stake weights validators by locked-up currency and punishes misbehavior by destroying (**slashing**) it, restoring a known, weighted membership for BFT techniques. A **finality gadget** layers BFT-style voting on top of block production. Casper FFG has validators vote on checkpoint links; a checkpoint is **justified** by more than two-thirds of stake and **finalized** when its direct child checkpoint is justified. Two slashing conditions (never cast two votes for the same target epoch, never cast a vote that surrounds another) give **accountable safety**: if two conflicting checkpoints are ever finalized, at least one-third of stake provably broke a rule and can be slashed [Buterin & Griffith 2017]. Ethereum combines Casper FFG with the LMD-GHOST fork-choice rule (Gasper); with 12-second slots and 32-slot epochs, blocks typically finalize after two epochs, about 12.8 minutes (as of 2026) [Buterin et al. 2020; Ethereum Docs: Proof-of-stake].

Table 45.11 — Consensus families compared.

	Nakamoto proof of work	Proof of stake with finality gadget	BFT chain (Tendermint, HotStuff)	Permissioned BFT
Membership	Open, anonymous	Open, weighted by stake	Bounded validator set, weighted	Fixed, known identities
Fault threshold	Less than 1/2 of hash power, lower with selfish mining	Less than 1/3 of stake for finality	Less than 1/3 of voting power	$f < n/3$ replicas
Finality	Probabilistic	Probabilistic per block, final per checkpoint	Immediate on commit	Immediate on commit
Typical latency to finality	About an hour at 6 confirmations	Minutes (about 12.8 min on Ethereum)	Seconds	Milliseconds to seconds
Accountability	None	Slashing	Slashing (chain-dependent)	Operators' legal identity

45.11.3 When is a permissioned BFT system the right tool?

Most "we need a blockchain" proposals need no Byzantine consensus. Ask four questions [Wüst & Gervais 2018]:

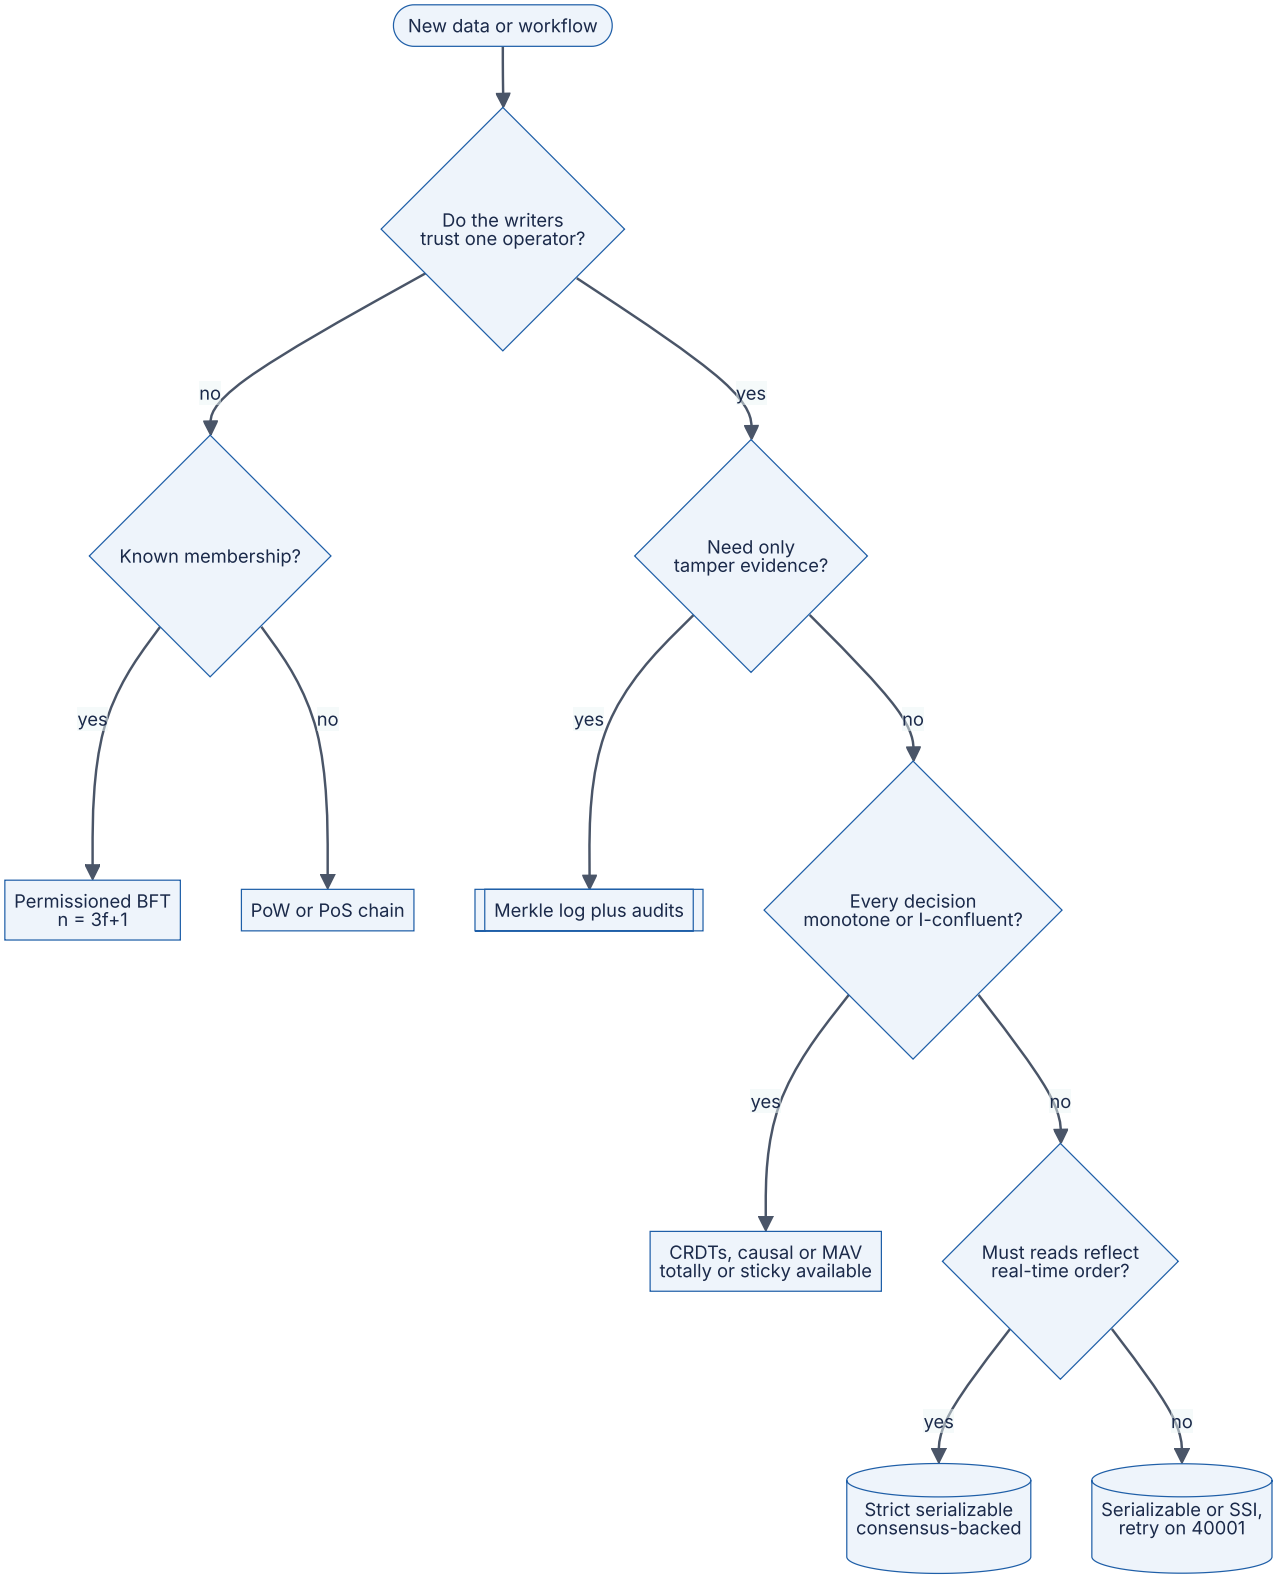
1. **Is there shared state written by several parties?** If only one organization writes, use a database.
2. **Do the writers distrust each other and refuse a trusted operator?** If a trusted operator is acceptable (a clearing house, a cloud provider, a regulator), a crash-tolerant replicated database with signed audit logs is cheaper and faster.
3. **Is the membership known?** If yes, permissioned BFT (PBFT, BFT-SMaRt, HotStuff) gives immediate finality with a handful of replicas. If not, you need Sybil resistance: proof of work or proof of stake.
4. **Do you need tolerance or only evidence?** If participants only need to *detect* tampering, a **tamper-evident log** suffices: a Merkle-tree log whose operator publishes signed tree heads and inclusion proofs, as Certificate Transparency does for TLS certificates [Laurie et al. 2013]. Detection plus legal accountability is often the real requirement.

45.12 Choosing guarantees in practice

45.12.1 A decision procedure

Start from invariants and the trust boundary: *who might lie?* and *which decisions are non-monotone?*

Figure 45.16 — Choosing a guarantee.



Reading the diagram. Diamonds are design questions answered in order; terminals are guarantee families. The first two settle the trust boundary (Byzantine tolerance, then permissioned versus open). Inside one trust domain the monotonicity test (§45.6.6) decides whether coordination-free replication suffices. Cylinders are consensus-replicated stores, unavailable in a minority partition. There are no runtime flows; the failure point is skipping a question, usually by assuming every decision is monotone.

Table 45.12 — Decision table: requirement, guarantee and mechanism.

Requirement	Weakest sufficient guarantee	Mechanism	Cost	Example
Counters, likes, presence, carts	Strong eventual consistency	State or delta CRDTs	Metadata growth	Multi-region counters
User sees own edits, ordered comments	Causal plus read your writes	Version vectors, sticky sessions	Sticky routing	Social feeds
Never see half a transaction	Monotonic atomic view	Buffered writes plus metadata	Storage overhead	Multi-row updates in AP stores
Reports and analytics on live data	Snapshot isolation, read-only deferrable	MVCC snapshots	Stale by seconds	Dashboards
Cross-row invariants (balance, roster, quota)	Serializable	SSI, 2PL or validation	Aborts or blocking	Payments, bookings
Uniqueness, global ordering, locks	Linearizable or strict serializable	Consensus (§26)	Quorum round trip, unavailable in minority	Usernames, leader election
Mutually distrustful operators, known set	BFT state machine replication	PBFT, HotStuff, $n = 3f + 1$	f more replicas, $O(n)$ to $O(n^2)$ messages	Consortium ledgers
Open participation	Probabilistic or gadget finality	Proof of work or stake	Minutes to an hour, low throughput	Public chains
Detect tampering only	Tamper-evident log	Merkle tree, signed heads	Auditors must check	Certificate Transparency

RECOMMENDATION

Recommendation — Mix guarantees per operation, and write the choice down. One service may use CRDT counters for likes, serializable transactions for payments and a consensus-backed lock for its cron leader. Record each operation’s guarantee, test it with list-append histories under faults (§45.5), and retry `40001` idempotently.

45.13 Summary and revision notes

SUMMARY

- **One hierarchy, defined by graphs.** Adya defines isolation levels by the DSG cycles they proscribe: G0 (PL-1), G1 (PL-2), G-single (PL-2+), G-SI (PL-SI), G2-item (PL-2.99), G2 (PL-3). Strict serializability adds real time and meets linearizability at the top. SI and repeatable read are incomparable.
- **Availability classes.** Totally available: up to read committed and MAV, plus MR, MW, WFR. Sticky available: RYW, PRAM, causal. Unavailable: anything that prevents lost update or write skew, or promises recency.
- **SI anomalies.** Write skew and the read-only anomaly are cycles with two consecutive rw edges around a pivot; SI forbids single-rw cycles (read skew).
- **SSI** tracks rw edges with non-blocking SIREAD locks and aborts at dangerous structures; PostgreSQL adds commit ordering, read-only optimization, safe snapshots and lock promotion. Clients must retry `40001`. Overlap rate $\approx 2\lambda T$ per transaction, about $G\lambda^2 T$ pairs per second.
- **Checking.** With unique list appends, version order is observable, edges are lookups and cycle search is $O(V + E)$, avoiding NP-complete serializability checking.
- **CRDT theory.** Join-semilattice, merge = join, inflationary updates give convergence by induction on causal histories. Op-based needs causal exactly-once delivery; deltas satisfy $m(x) = x \sqcup m^{\delta}(x)$ and save bandwidth in proportion to update locality.
- **Limits.** Convergence is not invariant preservation: use I-confluence and CALM to place coordination at non-monotone decisions; escrow for bounded counters.
- **Byzantine faults** are mostly accidental in data centers (CPU corruption, bit flips, bad blocks) and deliberate across organizations.
- **Bounds.** Partial synchrony needs $n \geq 3f + 1$; quorums of $2f + 1$ intersect in $f + 1$; signatures help only under synchrony; FLP still holds.
- **PBFT** = pre-prepare, prepare, commit plus view change; $2n(n - 1)$ replica messages per request (24, 84, 180 for $n = 4, 7, 10$).
- **HotStuff** adds a phase to get linear, responsive view changes and pipelines phases in chained form; Tendermint uses two phases with gossip and waits on timeouts.
- **Nakamoto** finality is probabilistic: $P(0.1, 6) \approx 2.4 \times 10^{-4}$. Proof of stake with finality gadgets restores BFT-style finality with slashing.
- **Choose per operation**: monotone → CRDT; invariants → serializable; real time → strict serializable; distrust → BFT; evidence only → Merkle log.

45.14 Knowledge checkpoint

1. Why are snapshot isolation and Adya's PL-2.99 incomparable?
2. Which Adya phenomenon is read skew, and which levels forbid it?
3. Draw the DSG of the read-only anomaly and name the pivot.
4. Why do ww and wr edges under SI always point forward in time?
5. What does PostgreSQL's commit-ordering optimization check?
6. What is a safe snapshot, and how does `DEFERRABLE` use it?
7. How does a list-append workload make version order observable?
8. In the overdraft example, what happens to the expected anomaly count if T doubles?
9. State the induction invariant in the CRDT convergence proof.
10. What delivery guarantees does an operation-based CRDT need that a state-based one does not?
11. Is "username is unique" I-confluent under concurrent inserts? Why?
12. Why is garbage collection non-monotone in CALM's sense?
13. Derive $n \geq 3f + 1$ from liveness and safety requirements on quorums.
14. Count PBFT replica messages for $n = 7$.
15. Why does Tendermint lack optimistic responsiveness?
16. Compute the confirmations needed for $P < 0.1\%$ against $q = 0.25$.

Answers

1. SI allows write skew (G2-item with two rw edges), which PL-2.99 forbids; PL-2.99 allows predicate anti-dependency cycles (phantoms), which SI forbids.
2. G-single (a cycle with exactly one rw edge); forbidden by PL-2+, SI, PL-2.99 and serializable.
3. $T_1 \xrightarrow{wr} T_3 \xrightarrow{rw} T_2 \xrightarrow{rw} T_1$; the pivot is T_2, the withdrawal.
4. SI lets a transaction see or overwrite only writes committed before it started (G-SIa is forbidden), so the source committed before the target began.
5. That T_{out} committed before both T_{pivot} and T_{in}; otherwise the structure cannot lie on a cycle and no abort is needed yet.
6. A read-only snapshot that no concurrent read-write transaction can make part of an anomaly; `DEFERRABLE` waits for one, then runs without SIREAD locks and cannot fail.
7. Each append is unique and lists only grow, so the longest read lists the versions in order and every other read must be its prefix.
8. Pairs scale linearly with T, so it doubles: about 24 a day.
9. Each replica's state equals the join of the update states in its causal history: $x_i = \bigsqcup_{u \in C_i} \delta_u$.
10. Reliable, exactly-once, causally ordered delivery; state-based tolerates loss, duplication and reordering.
11. No: two replicas can each insert the same name, each state valid, and the merge violates uniqueness.

12. It asserts the absence of references; a late message can add a reference and retract the conclusion.
13. Liveness: $q \le n - f$. Safety: $2q - n \ge f + 1$. Substitute $q = n - f$: $n - 2f \ge f + 1$, so $n \ge 3f + 1$.
14. $6 + 36 + 42 = 84$, which is $2 \cdot 7 \cdot 6$.
15. A new proposer must wait a timeout bounded by the maximum delay Δ to be sure it has seen the highest lock, instead of proceeding at actual network speed.
16. $z = 15$ (about 2.5 hours at 10 minutes per block).

45.15 Interview questions

Basic

Q1. What is write skew and why does snapshot isolation allow it? Answer. Two transactions read overlapping data, check an invariant and write different rows; together they break it. SI checks only write–write conflicts, so disjoint write sets commit. It is a cycle of two anti-dependencies; SSI or a materialized conflict row prevents it.

Q2. Why does Byzantine fault tolerance need 3f+1 nodes rather than 2f+1? Answer. You must decide after hearing from $n - f$ nodes because f may be silent, and up to f of those you heard from may lie. Two such quorums must overlap in at least one honest node, $2(n - f) - n \ge f + 1$, so $n \ge 3f + 1$. Crash faults never lie, so any overlap at all suffices and $2f + 1$ is enough.

Intermediate

Q3. Your PostgreSQL service moved to SERIALIZABLE and now sees 40001 errors at peak. What do you do? Answer. Expect them: add idempotent retries with jittered backoff and a budget. Find hot invariant groups from per-type error rates; shorten transactions (pairs scale with $\lambda^2 T$); move reports to `READ ONLY DEFERRABLE`; index the predicates so SIREAD locks stay fine-grained; give the predicate-lock table enough memory to avoid promotion.

Q4. When would you choose CRDTs over a consensus-backed store? Answer. When every decision on the data is monotone or I-confluent (counters, likes, presence, collaborative text), gaining local latency and partition tolerance. Keep non-monotone decisions (overselling, uniqueness) on a coordinated path or make them local with escrow.

Advanced

Q5. Design the consensus layer for a ledger shared by 12 banks that do not trust each other. Answer. Known membership plus distrust means permissioned BFT. Run $n = 10$ replicas ($f = 3$), each operated by a different bank with its own keys, ideally on di-

verse implementations. Use a pipelined HotStuff-family protocol with per-block leader rotation so no bank controls ordering, plus batching, checkpoints and state digests; clients accept $f + 1$ matching signed replies. A public chain would add latency and Sybil machinery they do not need; a single regulated operator with a tamper-evident log may suffice if auditors accept it.

Q6. How would you test that a database really provides snapshot isolation?
Answer. Run concurrent list-append transactions under partitions, pauses and clock skew; record invocations, completions and indeterminate outcomes; build the DSG with start-order information and search for G0, G1, G-single and G-SIa. G2-item cycles are allowed under SI; G-single proves it is not SI. Elle automates this.

45.16 Practical exercises

1. Extend the DSG checker with real-time edges (each transaction gets invocation and completion times) and construct a history that is serializable but not strictly serializable.
2. Add G1a and G1b detection to the checker by recording aborted transactions and intermediate appends.
3. Add a delta-mutator for a PN-Counter to the lattice checker and verify $m(x) = x \sqcup m^{\delta}(x)$ exhaustively.
4. Simulate PBFT's normal case for $n = 4$ with one equivocating primary that sends different digests to two backups, and show that no request is prepared at two honest replicas.
5. Modify the Nakamoto calculator to report the expected waiting time and the 99th-percentile waiting time for z confirmations.

45.17 Design challenges

1. **Seat booking across three regions.** Ticket sales must never oversell, browsing must stay available during partitions, and payment confirmation must be strictly serializable. Assign a guarantee to each operation, size escrow per region, and estimate abort rates at a 50 ms transaction duration during a 10,000-request-per-second on-sale.
2. **Supply-chain ledger for five companies.** Decide between a permissioned BFT ledger, a shared database run by a neutral operator, and a tamper-evident log, and justify the choice with the four questions of §45.11.3 and the message arithmetic of §45.9.3.

45.19 Open verification items

- Bailis et al. 2014a survey: confirm “3 of 18 serializable by default, 8 without serializability” and the exact class assignments in Table 45.2 (repeatable read is listed in Adya’s sense).
- Ports & Grittner 2012: confirm the qualitative performance summary, “first production SSI” wording and index-type coverage of predicate locks across PostgreSQL versions.
- Hochschild et al. 2021: confirm the “few per several thousand machines” mercurial-core rate.

- Hyperledger Fabric 3.0 BFT orderer (SmartBFT) release date; CometBFT rename year (2023).
- Ethereum finality time (two epochs, about 12.8 min) as of 2026.
- Bitcoin transactions-per-block range used for the throughput estimate.
- Daudjee & Salem 2006 as the origin of strong session SI.

Chapter 46 — Distributed Scheduling and Cluster Management

> **Level:** 4 · **Track:** Shared · **Estimated reading time:** 6 h

Chapter 42 showed what to *configure* when Kubernetes places a pod (§42.13). This chapter is about the problem underneath: with 10,000 machines and 50,000 things to run, deciding continuously what runs where, what waits and what is evicted. Those decisions set the cluster's **utilization**, the **latency** before work starts, and whether teams get a **fair** share. At Borg's scale, a few percent of packing efficiency is thousands of machines.

Foundations (§46.3–§46.4) define the problem and five scheduler architectures. **Systems** (§46.5–§46.6) take apart Borg and the Kubernetes scheduler. **Policies** (§46.7–§46.9) cover bin packing, preemption and fairness. **Workloads** (§46.10–§46.13) cover gang scheduling, GPU placement, Slurm and cluster autoscaling; Chapters 65 (distributed training) and 80 (10,000-GPU clusters) build on §46.10 and §46.11.

46.1 Learning objectives

After this chapter you should be able to:

- Distinguish batch jobs from long-running services and state the utilization–latency–fairness trade-off a cluster scheduler makes.
- Explain why cluster scheduling is NP-hard in general and which heuristics production schedulers use instead.
- Compare monolithic, two-level, shared-state, distributed and hybrid scheduler architectures, and compute head-of-line blocking and optimistic-conflict rates.
- Describe Borg's cell architecture, priority bands, quota, allocs and scoring, and quote its published utilization results correctly.
- Trace a pod through every extension point of the Kubernetes scheduling framework, and configure profiles, `percentageOfNodesToScore` and the descheduler.
- Implement and compare first-fit, best-fit, worst-fit and dot-product placement, and measure fragmentation.
- Explain preemption victim selection, PodDisruptionBudgets and how quota interacts with priority.
- Compute max-min fair, weighted fair and DRF allocations, and configure YARN-style capacity and fair schedulers.

- Explain why distributed training needs gang scheduling, show the deadlock without it, and choose between Volcano, Kueue, the coscheduling plugin and native gang scheduling.
- Place GPU jobs with topology awareness and choose between whole GPUs, MIG and time-slicing.
- Work a Slurm backfill schedule by hand and decide between Slurm and Kubernetes for training.
- Estimate how long cluster autoscaling takes to deliver capacity, and why gangs need all-or-nothing provisioning.

46.2 Prerequisites

- CPU scheduling policies: FCFS, priority, round robin, CFS — §6.5 (a cluster scheduler is the same problem one level up, with machines instead of cores).
- Load balancing and the power of two choices — §19.4.4 (Sparrow applies it to task placement).
- Leader election and leases — §26.5, §26.11 (every centralized scheduler runs as an elected leader).
- Queueing and probability — §4.10 (M/M/1 and why waits explode near full utilization), §4.6.4 (the binomial distribution, used for sampling schedulers) and §4.9.2 (the dot product, used for alignment scoring).
- Kubernetes architecture, requests, QoS, scheduling basics and autoscaling — §42.6, §42.12, §42.13 (this chapter goes deeper and does not repeat them).
- Batch processing on a cluster manager — §29.4–§29.5 (MapReduce and Spark ask YARN or Kubernetes for executors).

46.3 The cluster scheduling problem

46.3.1 Jobs, tasks and services

> DEFINITION
>
> **Definition — Cluster scheduler.** The component that assigns units of work (**tasks**, pods, containers) to machines in a cluster, decides which work waits when capacity is short, and reclaims capacity from lower-priority work. A **cluster manager** wraps the scheduler with admission, quota, health monitoring, restarts and an API.

First-principles explanation

Think of a restaurant host seating parties at tables of different sizes. Some parties stay all evening (services), some want a quick coffee (short batch tasks), a large group must sit

together or not at all (a gang), and regulars with standing reservations (quota) expect a table. The host wants every seat filled (utilization), nobody waiting long at the door (latency), and no regular complaining (fairness). Every rule the host invents is a scheduling policy, and each helps one goal at the expense of another.

Why does this exist?

When each team owns machines, capacity bought for one team's peak sits idle while another team's batch work waits. Pooling machines into one cluster and letting a scheduler place everyone's work lets one workload's idle capacity absorb another's. Borg's authors measured what pooling buys: separating production and non-production work would have needed 20–30% more machines in the median cell [Verma et al. 2015].

Cluster workloads come in two broad kinds.

Table 46.1 — Batch jobs versus long-running services.

Property	Batch job	Long-running service
Example	ETL run, model training, video transcode	API server, database, cache
Duration	Seconds to weeks, then exits	Runs until redeployed
Success measure	Completion time, throughput	Latency SLO, availability
Sensitivity to start delay	Tolerates minutes in a queue	Needs placement in seconds during a rollout or failure
Sensitivity to eviction	Restart or resume from checkpoint	Each eviction risks errors; needs PodDisruptionBudgets
Typical priority	Low or medium; preemptible	High; rarely preempted
Resource shape	Often large, sometimes gang-scheduled	Many small replicas, spread across failure domains

Google's workload analyses show the split: most jobs are batch, but most reserved resources belong to services [Schwarzkopf et al. 2013]. In a representative Borg cell, production jobs were allocated about 70% of the CPU and represented about 60% of CPU usage, and were allocated about 55% of memory while representing about 85% of memory usage [Verma et al. 2015]. Requests and usage differ, and batch fills the gap.

46.3.2 Utilization, latency and fairness

DEFINITION

Definition — Allocation versus usage. Allocated (reserved) utilization is the fraction of capacity claimed by requests or reservations; **used utilization** is the fraction actually consumed. The difference, **slack**, is capacity that is paid for, promised to someone, and idle.

A scheduler trades three goals against each other:

1. **Utilization.** Pack tightly and fill slack with preemptible work, at the cost of headroom for spikes.
2. **Latency.** Start work quickly. Free capacity shortens waits but lowers utilization; searching every machine improves packing but slows each decision.
3. **Fairness and isolation.** Give each team its share and never starve anyone; strict fairness can leave capacity idle.

FORMULA

Allocated and used utilization, and reclaimable capacity

$$U_{\text{alloc}} = \frac{\sum_j q_j}{C} \qquad U_{\text{used}} = \frac{\sum_j u_j}{C} \qquad R_{\text{reclaim}} = \sum_j q_j - (1+m)\sum_j u_j$$

Symbol	Meaning	Units
C	Total capacity of one resource in the cluster	cores or GiB
q_j	Request (reservation) of task j	cores or GiB
u_j	Measured usage of task j (for example a recent p95)	cores or GiB
m	Safety margin on usage before reclaiming	fraction
R_{reclaim}	Capacity that can be lent to preemptible work	cores or GiB

WORKED EXAMPLE

Worked example — Slack in a 10,000-core cluster. Services request 8,000 cores and use 4,800 at p95. The operator lends out capacity above usage plus a 25% margin.

1. $U_{\text{alloc}} = 8,000/10,000 = 80\%$; $U_{\text{used}} = 4,800/10,000 = 48\%$.
2. Slack $= 8,000 - 4,800 = 3,200$ cores: reserved, idle and paid for.
3. Protected reservation $= 1.25 \times 4,800 = 6,000$ cores, so $R_{\text{reclaim}} = 8,000 - 6,000 = 2,000$ cores.
4. Unallocated capacity is $10,000 - 8,000 = 2,000$ cores. Batch can therefore use $2,000 + 2,000 = 4,000$ cores, half of them borrowed from services.

Interpretation. Reclaiming slack doubles what batch can use, at the price of evicting batch when services spike. **Engineering implication.** Lend reclaimed capacity only to work that tolerates eviction; priority, preemption (§46.8) and reclamation are designed together, as in Borg (§46.5.4).

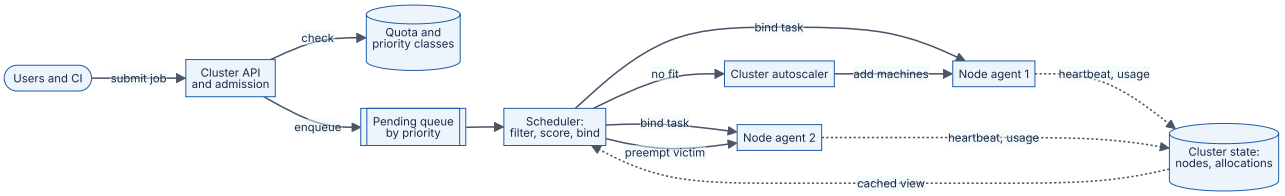
46.3.3 Why optimal scheduling is NP-hard

Ignore time for a moment and ask only: *what is the fewest machines that can hold these tasks?* That is **bin packing**: given items of sizes $s_1, \ldots, s_n$ and bins of capacity C, use as few bins as possible. Deciding whether k bins suffice is NP-complete even in one dimension [Garey and Johnson 1979]. A cluster scheduler faces a harder version:

- **Multiple dimensions.** CPU, memory, GPUs, local disk, network bandwidth and ports. This is **vector bin packing**, which is harder to approximate than the one-dimensional problem.
- **Online arrivals and departures.** Decisions are made without knowing the future and go stale as the cluster churns.
- **Constraints.** Affinity, anti-affinity, zone spread, hardware types, data locality and gangs that must be placed together.
- **Multiple objectives.** Packing, spreading for availability, fairness and start latency pull in different directions.

So every production scheduler is a set of **heuristics**: filter infeasible machines, score the rest with a weighted sum of simple rules, take the best, and correct mistakes later by preemption or descheduling. The rest of the chapter is about which heuristics, applied by which architecture.

Figure 46.1 — The cluster scheduling problem: inputs, decisions and feedback.



Reading the diagram. Users submit jobs synchronously to the API, which checks quota and priority (a storage boundary) and queues admitted work by priority. The scheduler reads a cached copy of cluster state that node agents update asynchronously (dotted); it binds each task, or preempts a lower-priority victim. Work that fits nowhere signals the autoscaler (§46.13). Failure points: a stale cache causes conflicts detected at bind time; a slow scheduler delays everything queued behind it; a lost node agent forces rescheduling. Scaling options are what §46.4's architectures differ on.

Common misconceptions

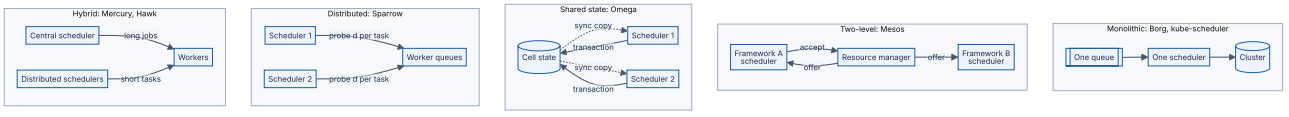
COMMON MISTAKE

"A scheduler maximizes utilization." It balances utilization, start latency, availability and fairness. A cluster 100% allocated cannot absorb a rollout surge or a failed node, so production clusters keep headroom and fill it with preemptible work.

46.4 Scheduler architectures

Schedulers differ less in their placement heuristics than in **who makes decisions and how they share the view of the cluster**. Schwarzkopf et al. classified them as monolithic, statically partitioned, two-level and shared-state [Schwarzkopf et al. 2013]; fully distributed (sampling) and hybrid designs followed.

Figure 46.2 — Five scheduler architectures.



Reading the diagram. *Monolithic*: one scheduler, one queue, full information, serial decisions. *Two-level*: a resource manager offers free capacity to framework schedulers, which accept or decline; each sees only its offers. *Shared state*: schedulers hold copies of cell state (dotted, asynchronous sync) and commit placements as transactions that the store may reject. *Distributed*: independent schedulers probe a few random workers, sharing no state. *Hybrid*: central for long jobs, distributed for short tasks. Failure points and scaling are compared in Table 46.2.

46.4.1 Monolithic schedulers

A **monolithic scheduler** is one process (replicated, with one elected leader, §26.5) applying one policy to every job, as in Borg (§46.5) and Kubernetes (§46.6). Full information makes priorities, quota, fairness and preemption easy. The cost is one decision pipeline: a constrained service job may take a second to place while a batch task needs milliseconds, so batch waits behind services. This is the convoy effect of §6.5.1 at cluster scale, called **head-of-line blocking**.

FORMULA

Mean queueing delay of a single scheduler (M/G/1, Pollaczek–Khinchine)

$$\rho = \sum_k \lambda_k \bar{S}_k \qquad W_q = \frac{\sum_k \lambda_k \bar{S^2_k}}{2(1-\rho)}$$

Symbol	Meaning	Units
λ_k	Arrival rate of jobs of class k	jobs/s
$\bar{S}_k$	Mean decision time for a class-k job	s
$\bar{S^2_k}$	Mean of the squared decision time (equals $\bar{S}_k^2$ for constant times)	s²
ρ	Fraction of time the scheduler is busy	dimensionless
W_q	Mean wait before a job's decision starts, any class	s

WORKED EXAMPLE

Worked example — Batch tasks stuck behind service jobs. Batch jobs arrive at 50 per second and take 5 ms each to place; service jobs arrive at 0.5 per second and take 1 s each (complex constraints). Treat decision times as constant.

1. Batch alone: $\rho = 50 \times 0.005 = 0.25$; $W_q = (50 \times 0.005^2)/(2 \times 0.75) = 0.00125/1.5 = 0.83$ ms.
2. Mixed: $\rho = 0.25 + 0.5 \times 1 = 0.75$.
3. Numerator: $50 \times 0.000025 + 0.5 \times 1 = 0.00125 + 0.5 = 0.50125$.
4. $W_q = 0.50125/(2 \times 0.25) = 1.0025$ s.

Interpretation. A batch task needing 5 ms of decision time now waits about 1 s, over 1,000 times longer, because of the slow class sharing the queue. **Engineering implication.** Make decisions fast (caching, sampling, §46.5.5) or separate the classes into different schedulers, Omega's motivation; Kubernetes profiles (§46.6.4) serve the same purpose.

46.4.2 Two-level schedulers: Mesos resource offers

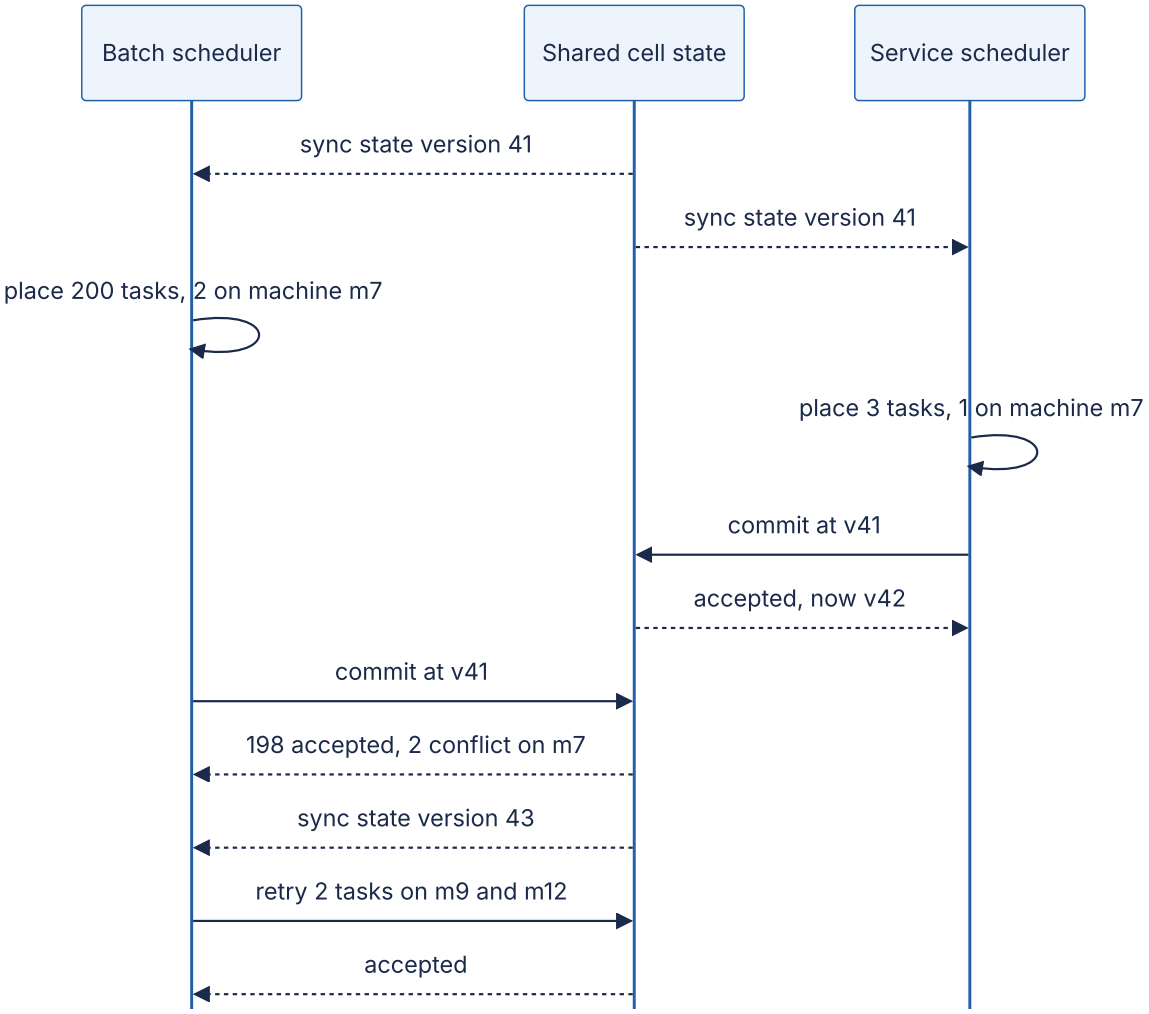
Statically partitioned clusters give each framework its own machines, reintroducing idle capacity. **Two-level scheduling** keeps one pool and splits the decision. In Mesos, a central **master** decides *how much* each framework gets and makes **resource offers** ("4 CPUs and 8 GB on node 17"); the framework's scheduler decides *which* offers to accept and what to launch; an agent on each node runs the tasks [Hindman et al. 2011]. The allocator uses Dominant Resource Fairness by default (§46.9.3). Frameworks (Hadoop, MPI, Spark, which began as a Mesos framework) keep their own placement logic, such as data locality. The weaknesses:

- **Partial view.** A framework cannot see the whole cluster, preempt others or find the best machine.
- **Pessimistic locking.** Offered resources are unavailable to others until accepted or declined.
- **Hard gangs.** A framework needing 100 machines must hoard offers until it has enough (§46.10).

46.4.3 Shared-state schedulers: Omega

Omega gives each scheduler a frequently synchronized copy of **cell state**, lets it place tasks freely, and commits placements as **optimistic transactions** [Schwarzkopf et al. 2013]. If another scheduler claimed the resources first, the conflicting part fails and is retried with fresh state: optimistic concurrency control (§11.15.3) applied to machines. Batch, service and MapReduce schedulers run different policies at different speeds without blocking one another.

Figure 46.3 — An optimistic placement conflict in a shared-state scheduler.



Reading the diagram. Both schedulers sync the same version asynchronously and decide locally, without locks. The service scheduler commits first. The batch commit conflicts on m7; with **incremental** transactions its 198 other placements stand and 2 tasks are retried, whereas an **all-or-nothing** transaction (a gang) would be rejected entirely. The storage boundary is the shared cell state. Failure points: conflicts waste work and can starve big all-or-nothing jobs. Scaling: add schedulers until conflicts dominate.

FORMULA

Conflict probability between two concurrent transactions (random placement model)

$$P_{\text{conflict}} \approx 1 - \exp\left(-\frac{c_1 c_2}{N}\right)$$

Symbol	Meaning	Units
c_1, c_2	Machines touched by each of two concurrent transactions	machines
N	Machines in the cell	machines
P_{conflict}	Probability the two transactions touch at least one common machine	probability

WORKED EXAMPLE

Worked example — Small jobs coexist, large gangs suffer. A cell has $N = 10,000$ machines.

1. Two small jobs touching 10 machines each: $c_1 c_2 / N = 100/10,000 = 0.01$; $P \approx 1 - e^{-0.01} = 0.99\%$.
2. A 1,000-machine all-or-nothing gang against one 10-machine job: $10,000/10,000 = 1$; $P \approx 1 - e^{-1} = 63\%$.
3. The same gang while five 10-machine jobs commit during its decision: exponent $5 \times 1 = 5$; $P \approx 1 - e^{-5} = 99.3\%$.

Interpretation. Optimism is nearly free for small placements but dooms a large all-or-nothing transaction while small commits keep landing; real schedulers all prefer the same "best" machines, so real conflicts exceed this model. **Engineering implication.** Commit incrementally where partial placement is acceptable, detect conflicts per resource rather than per machine, and protect large gangs with reservations or admission (§46.10). Omega's simulations found incremental transactions and fine-grained conflict detection kept conflict cost acceptable [Schwarzkopf et al. 2013].

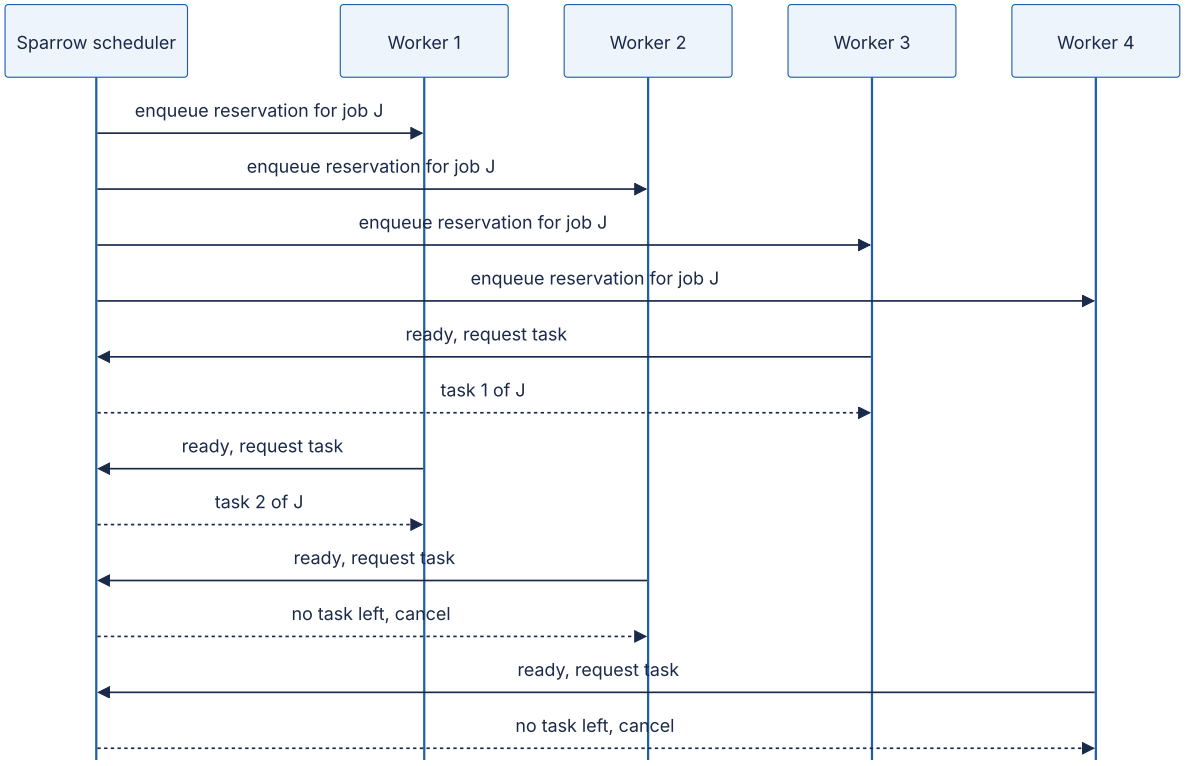
46.4.4 Distributed schedulers: Sparrow and sampling

For **sub-second tasks**, even 5 ms per central decision is a bottleneck: 100,000 tasks per second needs decisions in microseconds. Sparrow removes the central scheduler; many schedulers each handle some jobs and use the **power of two choices** of §19.4.4 [Ousterhout et al. 2013]:

1. **Per-task sampling.** For each task, probe d random workers for their queue length and place the task on the shortest queue.
2. **Batch sampling.** For a job of m tasks, probe $d \cdot m$ workers and use the m least loaded. A job finishes with its slowest task, so *all* m tasks must avoid queues; pooling probes makes that far likelier.
3. **Late binding.** Rather than trust stale queue lengths, place a **reservation** in each probed queue; workers reaching it request a task, the first m get one and the rest are canceled.

With a probe ratio of $d = 2$, Sparrow performed within 12% of an ideal scheduler on a 110-machine cluster [Ousterhout et al. 2013]. It gives up global policy: priorities and weighted sharing work per worker, but cluster-wide constraints, gangs and preemption need a full view.

Figure 46.4 — Batch sampling with late binding for a two-task job.



Reading the diagram. For $m = 2$, $d = 2$, the scheduler enqueues four reservations (synchronous RPCs). Workers 3 and 1 reach theirs first and fetch real tasks; 2 and 4 are canceled. The storage boundary is each worker's local queue. Failure points: a crashed scheduler loses only its own jobs, which clients resubmit elsewhere; late binding costs one extra round trip per task. Scaling: schedulers share nothing, so throughput grows linearly with their number.

FORMULA

Probability that a job of m tasks avoids all queueing (independent-worker model)

$$P_{\text{random}} = (1-\rho)^m \qquad P_{\text{per-task}} = (1-\rho^d)^m \qquad P_{\text{batch}} = \sum_{k=m}^{dm} \binom{dm}{k} (1-\rho)^k \rho^{dm-k}$$

$$T_{\text{sched}} \approx \text{RTT}_{\text{probe}} + t_{\text{queue}} + \text{RTT}_{\text{fetch}}$$

Symbol	Meaning	Units
ρ	Cluster load: probability a given worker is busy	fraction
m	Tasks in the job	tasks
d	Probes per task	count
P	Probability every task of the job starts on an idle worker	probability
$\text{RTT}_{\text{probe}}, \text{RTT}_{\text{fetch}}$	Round trips to place a reservation and to fetch the task	ms
t_{queue}	Time the reservation waits in the worker's queue	ms

WORKED EXAMPLE

Worked example — Why batch sampling matters for parallel jobs. Load $\rho = 0.5$, a job of $m = 10$ tasks, $d = 2$.

1. Random placement: $0.5^{10} = 0.098\%$.
2. Per-task power of two: each task finds an idle worker with $1 - 0.5^2 = 0.75$; all ten: $0.75^{10} = 5.6\%$.
3. Batch sampling: 20 probes, need at least 10 idle among them, $X \sim \text{Binomial}(20, 0.5)$: $P(X \geq 10) = 58.8\%$.
4. With $d = 3$: 30 probes, $P(X \geq 10)$ for $\text{Binomial}(30, 0.5)$ is 97.9%.
5. Latency: with 0.5 ms round trips inside a datacenter and an idle worker ($t_{\text{queue}} = 0$), $T_{\text{sched}} \approx 0.5 + 0 + 0.5 = 1$ ms.

Interpretation. Per-task sampling helps a single task ($m = 1$: 75% versus 50%) but collapses for parallel jobs, where one unlucky task delays the job; batch sampling pools the luck. The model is pessimistic, since real queues drain. **Engineering implication.** For fan-out work, sample per job and bind late; the same idea helps any request that fans out to many backends (§4.8.4).

46.4.5 Hybrid schedulers

Hybrid designs route by job type: a central scheduler places long or constrained jobs, distributed schedulers place short tasks into the remaining capacity, as in Hawk [Delgado et al. 2015] and Mercury [Karanasos et al. 2015]. Most platforms are hybrids in a looser sense: Kubernetes schedules pods centrally, and Spark or Ray schedule tasks inside them, two-level scheduling on top.

Table 46.2 — Scheduler architectures compared.

Row	Monolithic	Two-level	Shared state	Distributed	Hybrid
What it is	One scheduler, full view	Allocator offers; frameworks choose	Many schedulers, shared state	Many schedulers, no shared state	Central plus distributed
How it works	Serial filter–score–bind	Offers, accept or decline	Optimistic transactions	Random probes, late binding	Route by job class
Advantages	Global policy, simple	Framework-specific logic	Parallel, full view, per-workload policy	Millisecond decisions, no bottleneck	Quality for long jobs, speed for short
Disadvantages	Head-of-line blocking, throughput ceiling	Partial view, hoarding, hard gangs	Conflicts, hard for large gangs	No global constraints or preemption	Two systems to run and tune
Performance	Hundreds to thousands of placements/s	Bounded by offer cycle	Scales until conflicts dominate	Millisecond decisions at very high task rates	Best of both for mixed loads
Operational complexity	Low	Medium	High	Medium	High
Cost	One scheduler	Allocator plus one per framework	Shared store plus schedulers	Many cheap schedulers	Highest
Use cases	Borg, kube-scheduler, Slurm	Mesos, YARN (similar request model)	Omega, Borg's internal design	Sparrow, short analytics tasks	Research systems, large mixed clusters
Choose when	Default for most clusters	Frameworks need their own placement	Several teams need different schedulers	Sub-second tasks at huge rates	Workload is strongly bimodal

Centralization buys policy and costs throughput. Borg and Kubernetes show how far a well-engineered monolithic scheduler goes, so start there and split only when measurements show head-of-line blocking.

46.5 Borg

Borg is Google's cluster manager, described in 2015 after more than a decade in production [Verma et al. 2015], and the ancestor of Kubernetes [Burns et al. 2016]. This section reports the paper unless another source is cited; Google's systems have changed since.

46.5.1 Cells, jobs, tasks and allocs

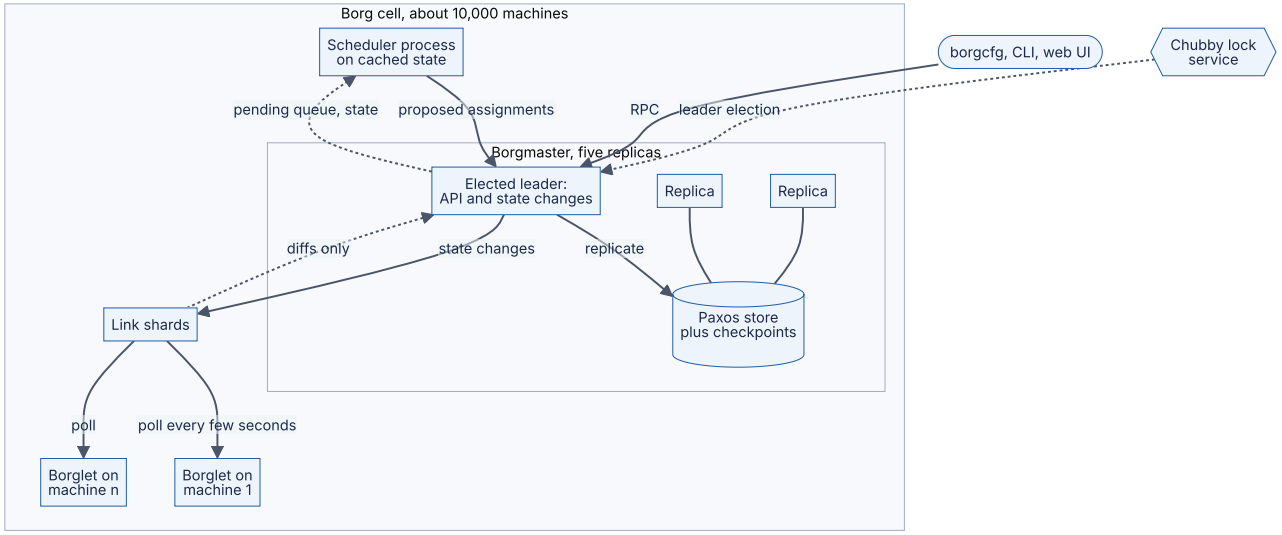
DEFINITION

Definition — Borg vocabulary. A **cell** is the set of machines managed as one unit, typically inside one datacenter building; the median cell had about 10,000 machines. A **job** is a named group of identical **tasks** (processes in containers) with a priority and resource requirements. An **alloc** is a reserved set of resources on one machine into which one or more tasks can be placed; an **alloc set** is a job-like group of allocs across machines.

A declarative job configuration names the binary, task count, per-task CPU, RAM and disk, hard and soft constraints, and a priority. Allocs let cooperating tasks, such as a web server and a log-saver, share a reserved slot: the idea Kubernetes calls the **pod** [Burns et al. 2016].

46.5.2 Architecture: Borgmaster, scheduler and Borglets

Figure 46.5 — A Borg cell.



Reading the diagram. Clients send RPCs to the elected leader, which replicates every state change to four other replicas through a Paxos-based store; checkpoints allow recovery and offline simulation (the **Fauxmaster**). Election uses Paxos and a Chubby lock (§26.14.1). The scheduler is a separate process on cached state: it proposes assignments,

which the leader accepts unless they are stale, an optimistic scheme similar in spirit to Omega. **Link shards** poll each Borglet every few seconds and forward only differences, so the Borgmaster controls the communication rate and avoids reconnection storms; a machine missing several polls is marked down and its tasks rescheduled. Failure points: a leader failover (typically about 10 s, up to a minute in a large cell) pauses changes, not running tasks; the paper reports 99.99% Borgmaster availability. Scaling: one Borgmaster per cell, more cells for more machines.

46.5.3 Priority, quota and admission

Priority decides *who is evicted* when room runs out; **quota** decides *who may submit* work at all.

Table 46.3 — Borg priority bands (from highest to lowest).

Band	Typical use	May preempt
Monitoring	Systems that watch the cell	Lower bands
Production	User-facing services, critical batch	Lower bands, but not other production tasks
Batch	Ordinary batch jobs	Best effort
Best effort (testing, free)	Experiments, opportunistic work	Nothing

Monitoring and production tasks are **prod**; the rest are **non-prod**. Production tasks do not preempt each other, which prevents **preemption cascades** (each eviction triggering one at slightly lower priority).

Quota is a resource vector at a given priority for a period, typically months; admission control rejects jobs exceeding their owner's quota at that priority. Higher-priority quota costs more; priority-zero quota is effectively unlimited but hard to use. Borg **oversells** quota at lower priorities, because users buy more than they use.

46.5.4 Resource reclamation

Borg estimates each task's likely usage plus a margin (its **reservation**), starting at the full request and decaying toward usage. Prod is scheduled against requests; non-prod may use the reclaimed difference. On CPU shortage the Borglet throttles non-prod tasks; on memory shortage it kills from the lowest priority up. §46.3.2's formula simplifies this mechanism.

46.5.5 Feasibility checking and scoring

For each pending task, the scheduler runs two phases:

1. **Feasibility checking** finds machines that satisfy the hard constraints and have enough *available* resources, counting resources held by lower-priority tasks that could be evicted.
2. **Scoring** ranks them: fewest and lowest-priority preemptions, machines that already hold the task's packages, spreading across power and failure domains, and packing quality, including mixing high- and low-priority tasks so the former can expand in a spike.

Borg first used a variant of E-PVM, which spreads load (a worst-fit tendency, §46.7) and fragments the cell; best fit packs tightly but hurts bursty work and users who underestimate. Borg's hybrid model reduces **stranded resources**, capacity unusable because another resource on the machine is exhausted, and gives about 3–5% better packing efficiency than best fit [Verma et al. 2015]. Three optimizations keep placement fast:

- **Score caching.** Scores are recomputed only when the machine or task changes.
- **Equivalence classes.** Identical tasks of a job are evaluated once.
- **Relaxed randomization.** Examine machines in random order until "enough" are feasible, then pick the best of those.

With them, scheduling a cell's whole workload from scratch typically took a few hundred seconds; without them it did not finish after more than three days. Kubernetes' `percentageOfNodesToScore` (§46.6.3) is relaxed randomization.

46.5.6 What Borg's utilization studies found

Borg's authors measured efficiency by **cell compaction**: how few machines can still fit a given workload, found by repeated Fauxmaster simulation. Their results, as stated in the paper [Verma et al. 2015]:

- **Sharing prod and non-prod.** Segregating them would need 20–30% more machines in the median cell, because prod reserves for rare spikes and non-prod fills the gap.
- **Sharing between users and large cells.** Giving large users their own cells, or splitting cells, needed more machines than sharing.
- **Fine-grained requests.** Rounding CPU and memory requests up to power-of-two buckets would need 30–50% more resources in the median case.
- **Reclamation.** A substantial fraction of the workload ran in reclaimed resources, and more aggressive reservation estimates cost little in out-of-memory events.

WORKED EXAMPLE

Worked example — What 20–30% means in machines. Take a hypothetical fleet of 20 cells of 10,000 machines each, sharing prod and non-prod as Borg does.

1. Fleet: $20 \times 10,000 = 200,000$ machines.
2. Segregated, at the paper's 20–30% median: $200,000 \times 1.2 = 240,000$ to $200,000 \times 1.3 = 260,000$ machines.
3. Extra: 40,000–60,000 machines. At an illustrative $10,000 per machine over its life, $400–600 million of hardware, before power and buildings.

Interpretation. At this scale pooling is the reason to have a cluster manager. **Engineering implication.** Proportionally the same holds for a 100-node Kubernetes cluster that keeps services and batch on separate pools "for safety": priority, preemption and reclamation let them share. The fleet and price are illustrative; only the percentages come from the paper.

46.5.7 Borg in 2019 and the lessons Kubernetes took

Tirmazi et al. compared a May 2019 trace of eight Borg cells with the 2011 trace [Tirmazi et al. 2020]. They found alloc sets used for resource-heavy workloads, automatic vertical scaling (Autopilot [Rzadca et al. 2020]) effective, and job dependencies explaining much of the high failure rates in earlier studies. The workload is heavy-tailed, so a scheduler's handling of its few largest jobs matters as much as its average case.

INDUSTRY EXAMPLE

From Borg and Omega to Kubernetes. Burns et al. describe what Kubernetes kept and changed [Burns et al. 2016]. Kept: declarative jobs, priorities, reconciliation and allocs (as pods). Changed: per-pod IPs instead of host ports; labels instead of numbered task arrays; and, following Omega, a shared store behind the API server with independent controllers and schedulers instead of a monolithic master. Trade-off: modularity brought extensibility and portability but weaker batch defaults, so gangs and queueing arrived as add-ons (§46.10). *Evidence: Primary* — [Burns et al. 2016]; [Verma et al. 2015]; [Schwarzkopf et al. 2013]

Common misconceptions

COMMON MISTAKE

"Borg proved that 'X% utilization' is achievable." The paper's claims are *relative* savings by cell compaction, not an absolute utilization figure for Google's fleet. Do not quote one unless a source states it.

46.6 The Kubernetes scheduler in depth

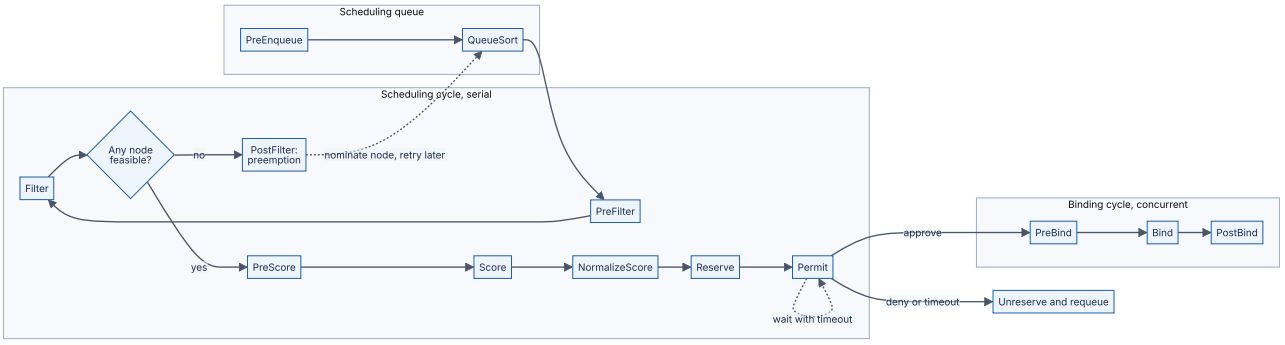
§42.13 introduced filtering, scoring and binding; this section opens the machinery. `kube-scheduler` is monolithic (§46.4.1), with one active leader elected through a `Lease` object (§26.9.2).

46.6.1 The scheduling framework

DEFINITION

Definition — Scheduling framework. The plugin architecture of `kube-scheduler`. A pod passes through a fixed sequence of **extension points**; each enabled plugin implements one or more of them. A **scheduling cycle** chooses a node for one pod and runs serially; a **binding cycle** applies the choice and may run concurrently with the next pod's scheduling cycle [Kubernetes Docs: Scheduling Framework].

Figure 46.6 — Extension points of the Kubernetes scheduling framework.



Reading the diagram. A pod enters the queue only when every PreEnqueue plugin agrees (a gang plugin can hold it until its group exists); QueueSort orders by priority. The serial cycle precomputes (PreFilter) and removes infeasible nodes (Filter); if none survive, PostFilter attempts preemption, nominates a node and requeues the pod. Otherwise nodes are scored, normalized to 0–100 and weighted, and the winner's resources are **reserved** in the cache. **Permit** approves, denies, or makes the pod *wait* with a timeout, the hook gang scheduling uses (§46.10). The binding cycle runs asynchronously: PreBind provisions volumes, Bind writes to the API server (the storage boundary). Any failure after Reserve runs Unreserve and requeues the pod. Scaling: only the scheduling cycle is serial, so slow volume binding blocks no one.

Table 46.4 — Extension points and representative default plugins.

Extension point	Purpose	Example plugin
PreEnqueue	Gate a pod before it may enter the active queue	`SchedulingGates`
QueueSort	Order pending pods	`PrioritySort`
PreFilter / Filter	Precompute; reject infeasible nodes	`NodeResourcesFit`, `NodeAffinity`, `TaintToleration`, `PodTopologySpread`, `InterPodAffinity`, `VolumeBinding`
PostFilter	Act when no node fits	`DefaultPreemption`
PreScore / Score / NormalizeScore	Rank feasible nodes	`NodeResourcesFit` (strategy), `NodeResourcesBalancedAllocation`, `ImageLocality`, `InterPodAffinity`
Reserve / Unreserve	Claim resources in the cache; roll back	`VolumeBinding`
Permit	Approve, deny or wait	Coscheduling (out of tree)
PreBind / Bind / PostBind	Prepare, write binding, clean up	`VolumeBinding`, `DefaultBinder`

Failed pods wait in an **unschedulable** pool until a relevant event (a node added, a pod deleted) could make them fit; plugins declare which events matter, so a pod short of GPUs is not retried on every ConfigMap change. Scheduling gates (`spec.schedulingGates`) let an external job queue keep pods out of the scheduler until it admits them.

46.6.2 Scores and weights

Normalized scores are multiplied by plugin weights and summed; the highest total wins, ties broken at random. Weights encode policy: a high weight on `NodeResourcesFit` with `MostAllocated` packs (§42.13.4); a heavily weighted `PodTopologySpread` spreads. For batch-heavy clusters, switching from spreading to packing is usually the most valuable cost setting; §46.7 measures why.

46.6.3 Searching only part of the cluster

In large clusters the scheduler stops filtering once it has found a fraction of feasible nodes and scores only those, resuming the next search where the last stopped, interleaved across zones.

FORMULA

Default number of feasible nodes to find (`percentageOfNodesToScore` unset)

$$p = \max\left(5,\ 50 - \frac{N}{125}\right)\% \qquad n_{\text{find}} = \min\left(N,\ \max\left(100,\ \left\lfloor N \cdot \frac{p}{100} \right\rfloor\right)\right)$$

Symbol	Meaning	Units
N	Nodes in the cluster	nodes
p	Adaptive percentage of nodes to find feasible (floor of 5%)	percent
n_{find}	Feasible nodes after which filtering stops (at least 100)	nodes

WORKED EXAMPLE

Worked example — Search size in three cluster sizes.

1. $N = 1{,}000$: $p = 50 - 8 = 42\%$; $n = 420$ nodes.
2. $N = 5{,}000$: $p = 50 - 40 = 10\%$; $n = 500$ nodes.
3. $N = 15{,}000$: $50 - 120 < 5$, so $p = 5\%$; $n = 750$ nodes.
4. Cost: if filtering and scoring cost about 20 µs per node per pod (an illustrative figure), the 5,000-node cluster spends $500 \times 20 = 10$ ms per pod instead of $5{,}000 \times 20 = 100$ ms, raising the ceiling from about 10 to about 100 pods per second for that pod type.

Interpretation. The search grows far more slowly than the cluster, keeping throughput roughly flat at the cost of sometimes missing the best node. **Engineering implication.** Lower the percentage in huge clusters of identical nodes; raise it toward 100% where placement quality matters, such as packing scarce GPU nodes. This is Borg’s relaxed randomization (§46.5.5).

46.6.4 Profiles and multiple schedulers

One `kube-scheduler` can run several **profiles**, each a named set of plugins, weights and arguments, selected by `spec.schedulerName`. Profiles share one queue and cache, so they never race, unlike separate scheduler deployments, whose conflicting bindings the kubelet rejects at admission.

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
  - schedulerName: default-scheduler          # services: default spreading
  - schedulerName: batch-packing              # batch: pack to free whole nodes
    plugins:
      score:
        disabled:
          - name: NodeResourcesBalancedAllocation
    pluginConfig:
      - name: NodeResourcesFit
        args:
          scoringStrategy:
            type: MostAllocated
            resources:
              - {name: cpu, weight: 1}
              - {name: memory, weight: 1}
              - {name: nvidia.com/gpu, weight: 5}
      - name: DefaultPreemption
        args:
          minCandidateNodesPercentage: 10
```

What to notice:

- The batch profile packs (`MostAllocated`), weighting GPUs five times CPU or memory so GPU pods consolidate first; services keep spreading.
- `NodeResourcesBalancedAllocation` favors nodes whose CPU and memory fractions are balanced; disabling it leaves packing as the dominant score.
- One shared queue means priority still orders services and batch against each other.

46.6.5 The descheduler

The scheduler decides once, but clusters drift: empty nodes join, rules change, better placements appear. The **descheduler**, a Kubernetes SIG project, periodically evicts pods that violate a policy so the scheduler can re-place them [Kubernetes SIGs: Descheduler]. Plugins include removing duplicates, `LowNodeUtilization` (drain over-used nodes into under-used ones), `HighNodeUtilization` (empty nearly idle nodes for removal), and removing pods that violate affinity, taints or topology spread, or exceed a lifetime or restart count. It uses the Eviction API and so honors PodDisruptionBudgets (§46.8.2); give either it or the node autoscaler's consolidation (§46.13) the packing job, not both, or they churn.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Pods Pending with free capacity	Fragmentation or an unsatisfiable constraint	`FailedScheduling` events naming the filter	Relax constraint; deschedule	Pack batch; check constraints in CI
Scheduler throughput collapses	Inter-pod affinity across thousands of pods	Scheduling latency histogram	Remove or narrow affinity	Prefer topology spread; lower search percentage
Two schedulers bind to one node	Separate deployments with separate caches	Kubelet admission rejections	Automatic reschedule	One binary with profiles
Pods evicted repeatedly	Descheduler and scheduler disagree	Eviction rate per workload	Disable the conflicting plugin	Align scoring and descheduler thresholds

46.7 Bin-packing heuristics

46.7.1 Four placement rules

Resource scoring reduces to a few classic online bin-packing rules over the feasible nodes:

- **First fit.** The first node, in fixed order, where the task fits. Cheap; fills low-numbered nodes first.
- **Best fit.** The node with the *least* capacity left after placement. Packs tightly, keeping empty nodes empty.
- **Worst fit.** The node with the *most* capacity left. Spreads load; Kubernetes' default `LeastAllocated` is a worst-fit rule.
- **Dot product (alignment).** Prefer the node whose normalized free-capacity vector has the largest dot product with the task's demand, so memory-heavy tasks go where memory is plentiful [Panigrahy et al. 2011]; Tetris used this score for cluster packing [Grandl et al. 2014].

Offline, **first-fit decreasing** (largest first) uses at most about 11/9 of the optimal bins plus a constant in one dimension [Garey and Johnson 1979]. Clusters are online and multi-dimensional, so you have to measure.

46.7.2 Fragmentation

DEFINITION

Definition — Fragmentation (stranded capacity). Free capacity that cannot be used by the tasks that need it, either because no single node has enough of it (**external fragmentation**), or because another resource on the same node is exhausted (**stranding**, in Borg's term).

FORMULA

Fragmentation with respect to a reference task shape s

$$F(s) = 1 - \frac{\sum_i \lfloor \min_r \frac{f_{i,r}}{s_r} \rfloor s_{r^*}}{\sum_i f_{i,r^*}}$$

Symbol	Meaning	Units
$f_{i,r}$	Free amount of resource r on node i	vCPU, GiB, GPUs
s_r	Reference task's demand for resource r	vCPU, GiB, GPUs
$\lfloor \min_r f_{i,r}/s_r \rfloor$	Copies of the reference task node i can still host	tasks
r^*	The resource in which fragmentation is reported (for example CPU)	—
$F(s)$	Fraction of free r^* unusable by tasks of shape s	fraction

WORKED EXAMPLE

Worked example — Free capacity that fits nothing. Three nodes of 32 vCPU / 128 GiB have free (10 vCPU, 8 GiB), (6, 60) and (12, 20). A task needs 8 vCPU and 32 GiB.

1. Node 1: $\min(10/8, 8/32) = \min(1.25, 0.25) \Rightarrow 0$ copies. Node 2: $\min(0.75, 1.875) \Rightarrow 0$. Node 3: $\min(1.5, 0.625) \Rightarrow 0$.
2. Free CPU $= 10 + 6 + 12 = 28$ vCPU; free memory $= 88$ GiB, which is 3.5 times the CPU and 2.75 times the memory the task needs.
3. $F = 1 - 0/28 = 100\%$.
4. For a smaller (2 vCPU, 8 GiB) task: copies $= \lfloor \min(5, 1) \rfloor + \lfloor \min(3, 7.5) \rfloor + \lfloor \min(6, 2.5) \rfloor = 1 + 3 + 2 = 6$, using 12 vCPU; $F = 1 - 12/28 = 57\%$.

Interpretation. Aggregate free capacity says there is room; per-node vectors say there is none, and large shapes suffer most. **Engineering implication.** Monitor $F(s)$ or the largest placeable task for important shapes, not total free capacity, and pack so free capacity stays concentrated.

FORMULA

Alignment (dot-product) score of node i for demand d

$$A_i = \sum_r \frac{d_r}{C_r} \cdot \frac{f_{i,r}}{C_r}$$

Symbol	Meaning	Units
d_r	Task's demand for resource r	vCPU, GiB
$f_{i,r}$	Free resource r on node i	vCPU, GiB
C_r	Node capacity of resource r (normalizer)	vCPU, GiB
A_i	Alignment score; higher is preferred	dimensionless

WORKED EXAMPLE

Worked example — Sending a memory-heavy task to the memory-rich node. Nodes of 32 vCPU / 128 GiB: X has (24, 20) free and Y has (8, 120) free. The task needs (2, 16); both nodes fit it.

1. Normalized demand: $(2/32, 16/128) = (0.0625, 0.125)$.
2. X: $(24/32, 20/128) = (0.75, 0.156)$; $A_X = 0.0625 \times 0.75 + 0.125 \times 0.156 = 0.0469 + 0.0195 = 0.0664$.
3. Y: $(0.25, 0.9375)$; $A_Y = 0.0156 + 0.1172 = 0.1328$. Choose Y.
4. Effect: X keeps 24 vCPU and 20 GiB for CPU-heavy work; placing the task there would have left 22 vCPU with only 4 GiB, stranding most of the CPU.

Interpretation. Alignment matches shapes, but A_i also grows with the *amount* free, so alone it prefers emptier nodes, like worst fit, as the simulation below shows. **Engineering implication.** Use alignment as a secondary term beside a packing term (Tetris combined several terms), not as the only rule.

46.7.3 Measuring the heuristics

The program runs a 50-node cluster at 95% offered CPU load with Poisson arrivals and exponential lifetimes; a fifth of tasks are large (half a node), and a task that fits nowhere is rejected. The tests check each rule on hand-built cases, including two half-node tasks spread so that a whole-node task cannot fit.

```
        """Compare placement heuristics on a fixed cluster with arrivals and depar-
tures."""
        import heapq
        import random

        CAP = (32.0, 128.0)                       # one node: vCPU, GiB
        SHAPES = [((1, 1), 0.20), ((4, 4), 0.20),          # CPU-heavy (1 GiB per vCPU)
                  ((1, 8), 0.20), ((2, 16), 0.20),         # memory-heavy (8 GiB per
vCPU)
                  ((16, 64), 0.20)]                        # large, node-shaped

        def norm(v):
            return [x / c for x, c in zip(v, CAP)]

        def fits(free, d):
            return all(f >= x - 1e-9 for f, x in zip(free, d))

        def score(policy, free, d):
            """Higher is better. free and d are raw vectors."""
            left = sum(norm([f - x for f, x in zip(free, d)]))   # normalized leftover
            if policy == "first-fit":
                return 0.0                                       # ties -> lowest index
            if policy == "best-fit":
                return -left                                     # least leftover
            if policy == "worst-fit":
                return left                                      # most leftover
            if policy == "dot-product":                          # Tetris-style align-
ment
                return sum(a * b for a, b in zip(norm(free), norm(d)))
            raise ValueError(policy)

        def place(nodes, d, policy):
            best, best_score = None, None
            for i, free in enumerate(nodes):                     # index order = first-
fit
                if fits(free, d):
                    s = score(policy, free, d)
                    if best is None or s > best_score + 1e-12:
                        best, best_score = i, s

rich
            assert place(skew, (2, 16), "dot-product") == 1      # memory task -> mem-
ory-rich
            assert place(skew, (4, 4), "dot-product") == 0       # CPU task -> CPU-rich
            for policy, ok in (("best-fit", True), ("worst-fit", False)):
                two = [list(CAP), list(CAP)]                     # two empty nodes
                for d in ((16, 64), (16, 64)):
                    i = place(two, d, policy)
                    two[i] = [f - x for f, x in zip(two[i], d)]
                assert (place(two, CAP, policy) is not None) == ok   # whole-node task
            print("tests passed")

        if __name__ == "__main__":
            test()
            print(f"{'policy':<12}{'CPU util':>10}{'rejected':>10}{'16-CPU
rejected':>17}")
            for p in ("first-fit", "best-fit", "worst-fit", "dot-product"):
                u, r, rb = simulate(p)
                print(f"{p:<12}{u:>10.1%}{r:>10.1%}{rb:>17.1%}")
```

```
tests passed
policy        CPU util  rejected  16-CPU rejected
first-fit        88.8%      1.9%             9.7%
best-fit         88.7%      1.9%             9.3%
worst-fit        66.0%      8.9%            44.8%
dot-product      66.3%      9.0%            44.6%
```

What to notice:

- Only `score` differs between policies, as policy is a scoring plugin in a real scheduler.
- Packing (first fit, best fit) keeps about 89% of CPU busy and rejects under 10% of large tasks. Spreading (worst fit, dot product alone) leaves nodes half full: 45% of large tasks find no node and utilization falls to 66% *although demand exceeds supply*.
- First fit and best fit are within noise (seeds 8 and 9 swap their order); the big effect is pack versus spread.

Table 46.5 — Choosing a placement rule.

Rule	Packs or spreads	Best for	Risk
First fit	Packs (by node order)	Simple batch clusters	Hot low-numbered nodes
Best fit	Packs tightly	Batch, GPU, cost-sensitive clusters; freeing nodes for scale-down	Little headroom for bursts on busy nodes
Worst fit / LeastAllocated	Spreads	Latency-sensitive services needing burst headroom	Fragmentation; large tasks stuck
Dot product	Shape-matching	Mixed CPU-heavy and memory-heavy work, as a secondary term	Spreads if used alone

Common misconceptions

> COMMON MISTAKE
>
> **“Spreading is safer, so it is the right default everywhere.”** For batch and accelerator work it creates the fragmentation that blocks large jobs. Get service availability explicitly, with topology spread constraints and PodDisruptionBudgets, and let scoring pack.

46.8 Priorities, preemption and quota

46.8.1 Preemption and victim selection

DEFINITION

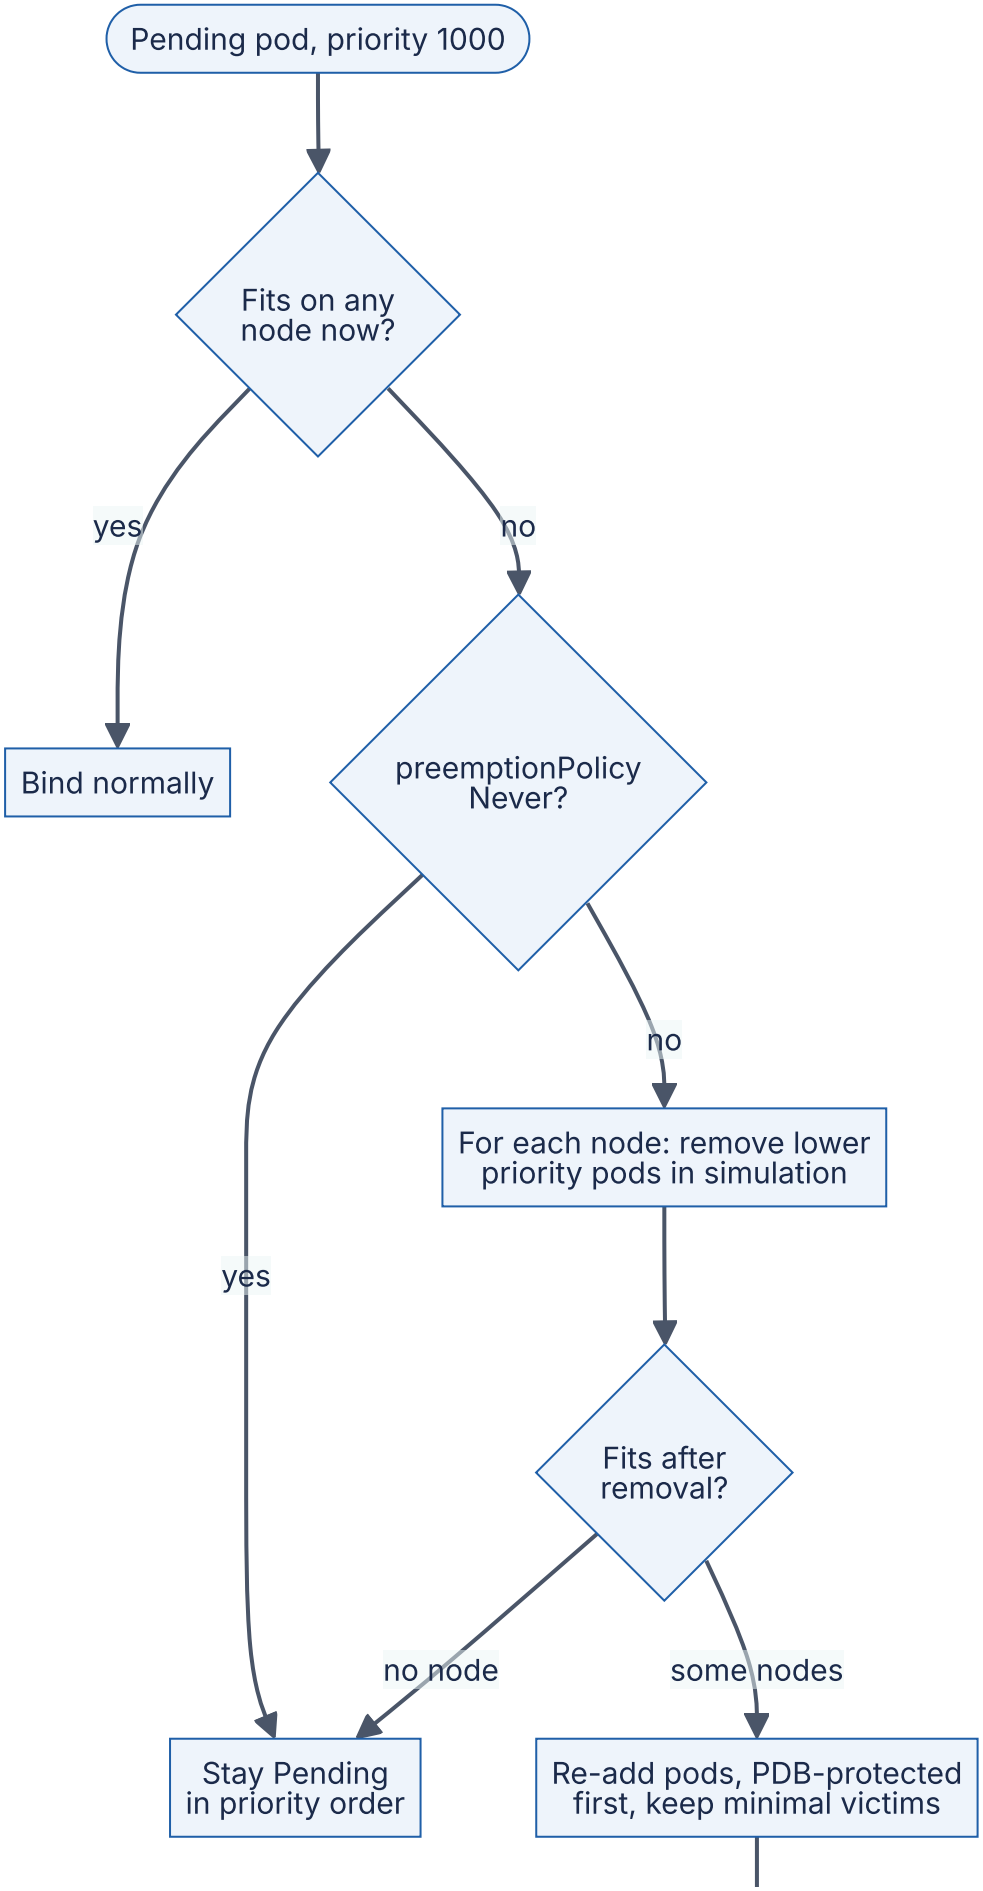
Definition — Preemption. Evicting running lower-priority work so that a pending higher-priority task can be placed. The evicted tasks are **victims**; the pending task is the **preemptor**.

Preemption lets a cluster run at high utilization *and* place urgent work quickly. The hard part is choosing victims. Kubernetes' `DefaultPreemption` plugin, at PostFilter, works in two steps [Kubernetes Docs: Pod Priority and Preemption]:

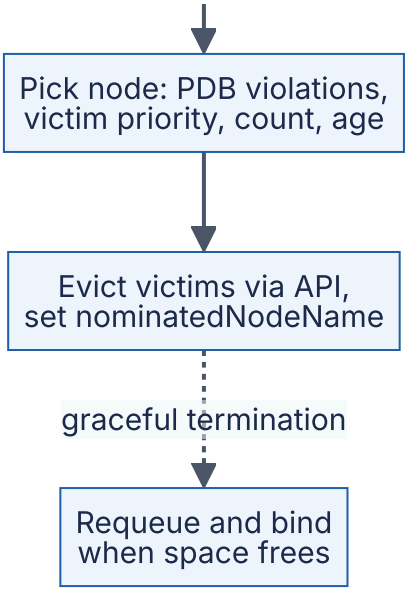
1. **For each candidate node**, remove all lower-priority pods in simulation; if the preemptor fits, add pods back, highest priority first, while it still fits. PDB-protected pods are added back first, so they are evicted only if unavoidable.
2. **Pick one node** by, in order: fewest PDB violations; lowest highest-victim priority; smallest sum of victim priorities; fewest victims; latest start time of the highest-priority victims (evict the work that has run least).

The scheduler sets `nominatedNodeName`, deletes the victims (with their grace periods) and retries. A `PriorityClass` with `preemptionPolicy: Never` queues ahead of lower priorities without evicting anyone.

Figure 46.7 — Preemption decision for one pending pod.



Pending pod, priority 1000
Fits on any node now?
yes
no
Bind normally
preemptionPolicy Never?
yes
no
For each node: remove lower priority pods in simulation
Fits after removal?
no node
some nodes
Stay Pending in priority order
Re-add pods, PDB-protected first, keep minimal victims



Reading the diagram. The decision is synchronous within one scheduling cycle; evictions complete asynchronously within grace periods, so the preemptor is requeued, not bound. The storage boundary is the API server, which records deletions and the nomination. Failure points: long grace periods delay the preemptor; PDBs are best effort here; a pod that does not fit even after evicting everything lower stays Pending. Scaling: simulation is expensive, so the plugin examines a bounded sample of candidate nodes.

46.8.2 PodDisruptionBudgets

A **PodDisruptionBudget** (PDB) limits *voluntary* disruptions of a pod set through `minAvailable` or `maxUnavailable`. Drains, the descheduler and consolidation use the Eviction API, which refuses evictions that would break a PDB; preemption treats PDBs as a preference; node failures ignore them. Trap: `maxUnavailable: 0`, or a PDB on a single-replica service, blocks every drain.

46.8.3 How quota and priority interact

If every team marks its work “critical”, priority means nothing, so quota bounds work *per priority*, as in Borg (§46.5.3). A Kubernetes `ResourceQuota` can be scoped to a `PriorityClass` with a `scopeSelector`: say 200 CPU at `production` and 2,000 at `batch-low`; `system-cluster-critical` and `system-node-critical` are reserved for cluster components. Queueing systems such as Kueue add **borrowing** of unused quota, reclaimed by preemption when the owner returns (§46.10.2).

FORMULA

Work lost to preemption for a checkpointed job

$$L = r_p\left(\frac{\tau}{2} + t_r\right)G \qquad \text{fraction lost} = \frac{L}{24G} = \frac{r_p(\tau/2 + t_r)}{24}$$

Symbol	Meaning	Units
r_p	Preemptions (or failures) per day	1/day
τ	Checkpoint interval; on average half of it is lost	h
t_r	Restart time: rescheduling, loading the checkpoint, warm-up	h
G	Accelerators (or machines) held by the job	GPUs
L	Accelerator-hours lost per day	GPU·h/day

WORKED EXAMPLE

Worked example — Preempting a 256-GPU training job. The job is preempted twice a day, checkpoints every 60 minutes, and takes 10 minutes to restart.

1. Lost per preemption: $0.5 + 10/60 = 0.667$ h; $\times 256 = 170.7$ GPU·h.
2. Per day: $2 \times 170.7 = 341$ GPU·h of $256 \times 24 = 6,144$: **5.6%**.
3. With 15-minute checkpoints: $(0.125 + 0.167) \times 256 = 74.7$ GPU·h per preemption; 149 per day: **2.4%**.

Interpretation. Lost progress and restart are multiplied by the job's whole footprint. **Engineering implication.** Preempt large gangs rarely and as a unit (evicting one worker stalls all, §46.10), checkpoint frequently and asynchronously (Chapter 65), and prefer preempting small jobs.

Common misconceptions

COMMON MISTAKE

"A PDB guarantees availability." It only throttles voluntary evictions. Crashes, OOM kills and zone outages ignore it. Availability comes from replicas and spread; the PDB stops your own tools removing them too fast.

46.9 Fairness

46.9.1 Max-min fairness and weighted fair share

DEFINITION

Definition — Max-min fairness. An allocation is max-min fair if no user's share can be increased without decreasing the share of a user who has an equal or smaller share. With one resource, it is computed by **water filling**: raise every unsatisfied user's allocation equally until each is either satisfied or the resource is exhausted. **Weighted fair share** raises allocations in proportion to weights.

FORMULA

Weighted max-min (water-filling) allocation of one resource

$$a_i = \min(d_i, w_i\,\theta) \qquad \text{with } \theta \text{ chosen so that } \sum_i a_i = C \text{ (when } \sum_i d_i \geq C)$$

Symbol	Meaning	Units
C	Capacity to share	GPUs, cores
d_i	Demand of user i	GPUs, cores
w_i	Weight of user i	dimensionless
θ	Water level: allocation per unit weight for unsatisfied users	GPUs
a_i	Allocation of user i	GPUs, cores

WORKED EXAMPLE

Worked example — Sharing 100 GPUs among three teams. Demands are 10, 40 and 80 GPUs.

1. Equal weights. Try $\theta = 45$: $10 + 40 + 45 = 95 < 100$; team 2 is satisfied at 40, so raise θ for team 3 only: $10 + 40 + \theta = 100 \Rightarrow \theta = 50$. Allocation **10, 40, 50**.
2. Weights 1, 1, 2. Try $\theta = 30$: $\min(10, 30) + \min(40, 30) + \min(80, 60) = 10 + 30 + 60 = 100$. Allocation **10, 30, 60**.

Interpretation. Small demands are met in full and the rest is shared by weight, with nothing idle while anyone wants more. **Engineering implication.** YARN's Fair Scheduler and Kueue's fair sharing apply this rule; set weights from budget.

46.9.2 Why one resource is not enough

With several resources, “equal shares” is ambiguous. Equal CPU may give a memory-hungry team almost nothing useful. Ghodsi et al. asked which multi-resource policy satisfies four properties [Ghodsi et al. 2011]: **sharing incentive** (each user is at least as well off as with $1/n$ of every resource), **strategy-proofness** (lying about demands cannot help), **envy-freeness** (no user prefers another’s allocation) and **Pareto efficiency** (no one can gain without someone losing). Their answer is Dominant Resource Fairness.

46.9.3 Dominant Resource Fairness

FORMULA

Dominant share and DRF

$$s_i = \max_r \frac{u_{i,r}}{C_r} \qquad \text{DRF: maximize allocations subject to equal } \frac{s_i}{w_i} \text{ (progressive filling)}$$

Symbol	Meaning	Units
$u_{i,r}$	Amount of resource r allocated to user i	CPUs, GB
C_r	Total capacity of resource r	CPUs, GB
s_i	User i’s dominant share: its largest share of any resource	fraction
w_i	Weight of user i (1 if unweighted)	dimensionless

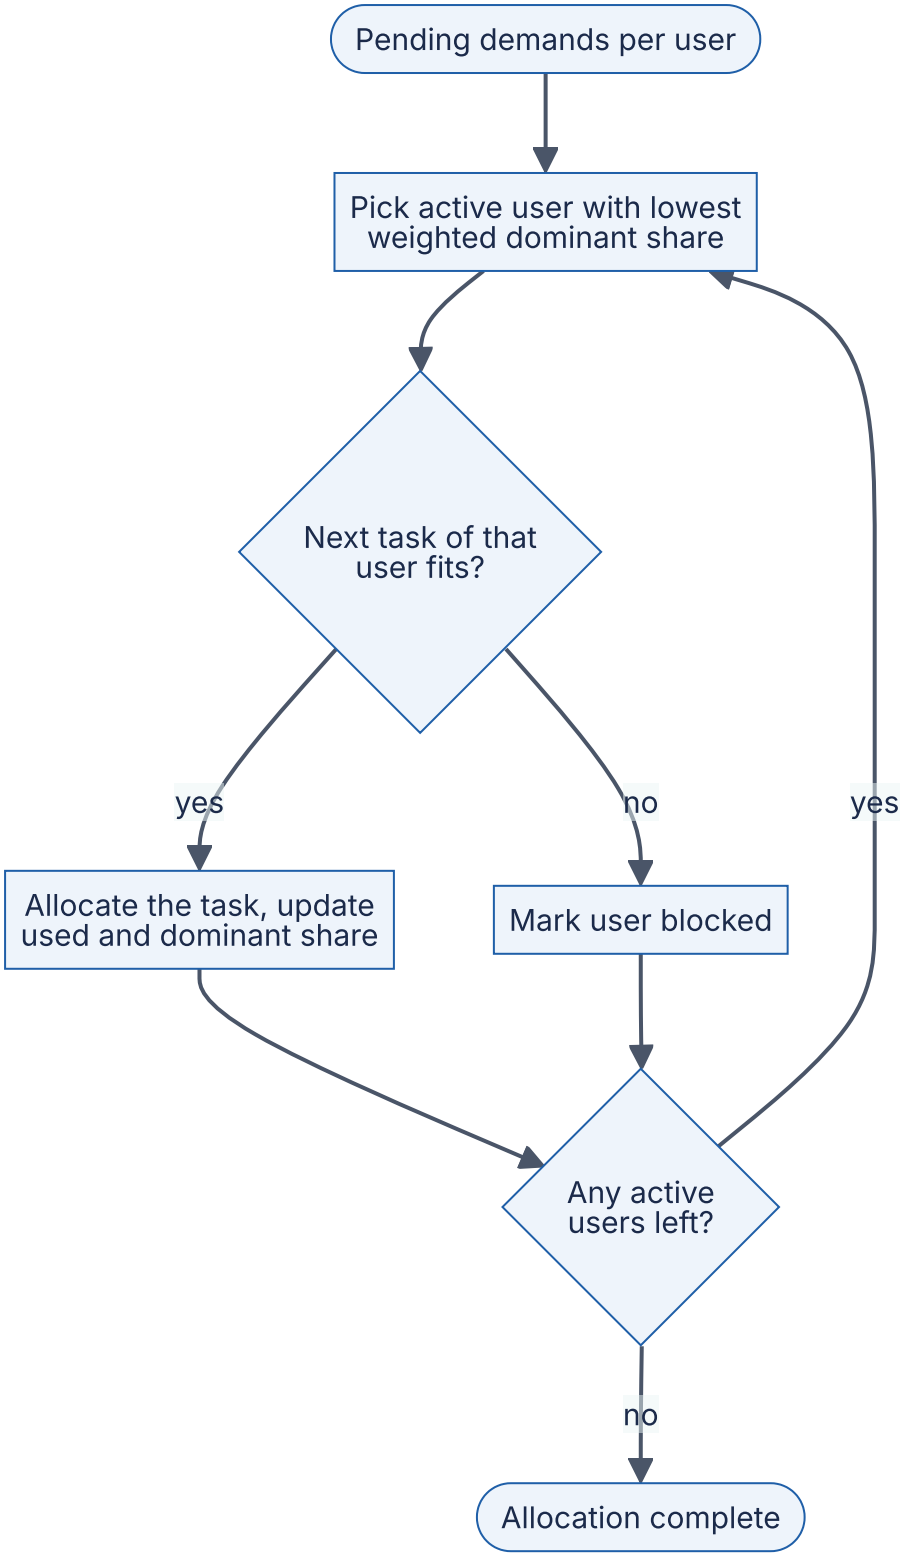
WORKED EXAMPLE

Worked example — The DRF paper's example, recomputed. A system has 9 CPUs and 18 GB. User A's tasks need ⟨1 CPU, 4 GB⟩; user B's need ⟨3 CPUs, 1 GB⟩ [Ghodsi et al. 2011].

1. Per-task shares. A: CPU $1/9$, memory $4/18 = 2/9$, so A's dominant resource is memory. B: CPU $3/9 = 1/3$, memory $1/18$, so B's is CPU.
2. Let A run x tasks and B run y. Equal dominant shares: $2x/9 = y/3 \Rightarrow y = 2x/3$.
3. CPU: $x + 3y \le 9 \Rightarrow x + 2x \le 9 \Rightarrow x \le 3$. Memory: $4x + y \le 18 \Rightarrow 4x + 2x/3 \le 18 \Rightarrow x \le 3.86$. CPU binds: $x = 3$, $y = 2$.
4. A gets ⟨3 CPUs, 12 GB⟩, B gets ⟨6 CPUs, 2 GB⟩. Dominant shares: A $12/18 = 2/3$, B $6/9 = 2/3$. All CPUs are used; 4 GB of memory is left, usable by neither user's task shape because no CPU remains.
5. Sharing incentive check: with half of everything (4.5 CPUs, 9 GB), A could run $\min(4.5, 9/4) = 2.25$ tasks and B $\min(1.5, 9) = 1.5$; DRF gives 3 and 2.

Interpretation. Each user gets the same fraction of the resource it needs most, and both beat a static split. **Engineering implication.** Use DRF where teams have different resource shapes; Mesos used it by default, YARN's Fair Scheduler offers it, and Volcano ships a `drf` plugin.

Figure 46.8 — DRF by progressive filling.



Reading the diagram. The loop serves the user furthest behind in dominant share; a user whose next task no longer fits drops out while others continue. Online, the loop runs whenever resources free (a Mesos offer cycle, a YARN heartbeat) on the allocator's in-memory state. Failure points: discrete tasks deviate from ideal shares; a user with huge tasks may be blocked by small ones, which needs reservations. Scaling: a priority queue keyed by dominant share makes each pick $O(\log n)$.

```
        """Dominant Resource Fairness by progressive filling [Ghodsi et al. 2011]."""
        from fractions import Fraction as F

        def drf(capacity, demands, weights=None):
            """capacity: {resource: amount}; demands: {user: {resource: per-task}}.
            Repeatedly launch one task for the user with the lowest weighted dominant
            share whose next task still fits. Returns tasks per user."""
            weights = weights or {u: 1 for u in demands}
            used = {r: F(0) for r in capacity}
            tasks = {u: 0 for u in demands}

            def dominant_share(u):
                return max(F(tasks[u] * demands[u][r], capacity[r]) for r in capacity)
/ weights[u]

            active = set(demands)
            while active:
                u = min(sorted(active), key=dominant_share)        # sorted: determinis-
tic ties
                if all(used[r] + demands[u][r] <= capacity[r] for r in capacity):
                    for r in capacity:
                        used[r] += demands[u][r]
                    tasks[u] += 1
                else:
                    active.discard(u)                              # u is blocked; oth-
ers may still fit
            return tasks, {u: dominant_share(u) * weights[u] for u in demands}, used

        if __name__ == "__main__":
            cap = {"cpu": 9, "mem_gb": 18}
            users = {"A": {"cpu": 1, "mem_gb": 4}, "B": {"cpu": 3, "mem_gb": 1}}
            tasks, shares, used = drf(cap, users)
            print("tasks", tasks, "dominant shares", {u: str(s) for u, s in
shares.items()},
                  "used", {r: int(v) for r, v in used.items()})
            assert tasks == {"A": 3, "B": 2} and shares["A"] == shares["B"] == F(2, 3)
            # Weighted, on a cluster ten times larger: B's weight 2 lets B's dominant
            # share grow to twice A's.
            big = {r: 10 * v for r, v in cap.items()}
            tasks_w, shares_w, _ = drf(big, users, weights={"A": 1, "B": 2})
            print("weighted", tasks_w, {u: str(s) for u, s in shares_w.items()})
            assert tasks_w == {"A": 18, "B": 24}
```

```
tasks {'A': 3, 'B': 2} dominant shares {'A': '2/3', 'B': '2/3'} used {'cpu': 9,
'mem_gb': 14}
weighted {'A': 18, 'B': 24} {'A': '2/5', 'B': '4/5'}
```

What to notice:

- `Fraction` keeps shares exact, so the 2/3 assertion is immune to rounding.
- A blocked user leaves `active` while the loop continues for others.

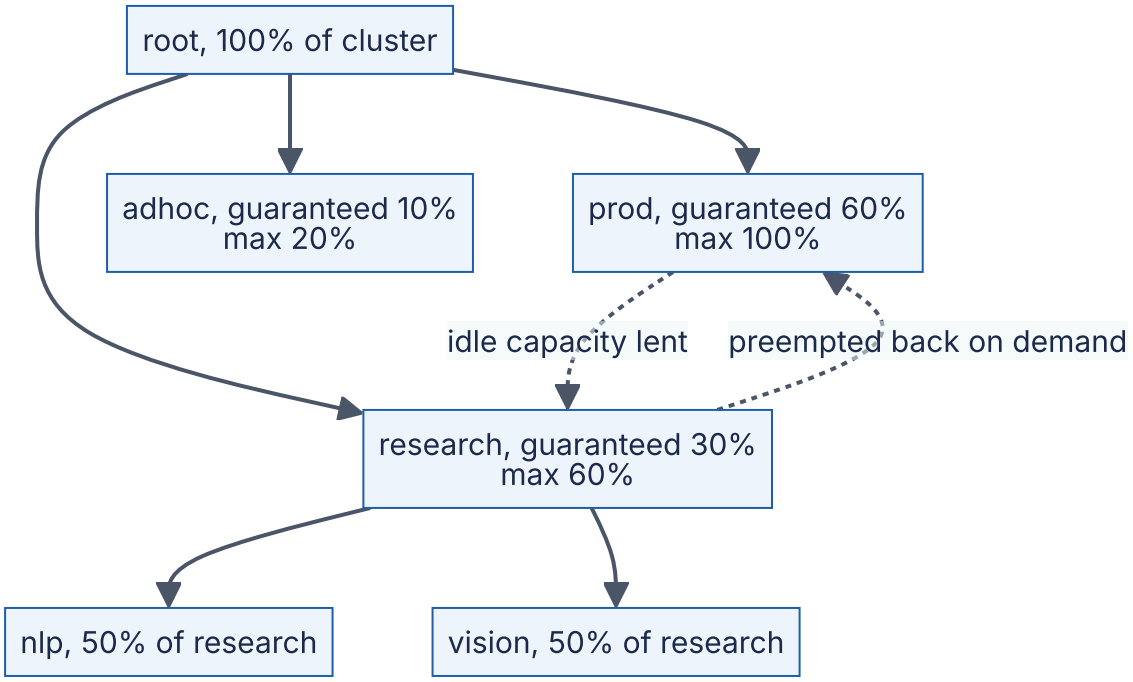
- In the weighted run, B's weight of 2 doubles its dominant share (4/5 against 2/5), matching the continuous solution of $y/30 = 2x/45$ and $x + 3y = 90$.

46.9.4 Capacity and fair schedulers in YARN

In Hadoop YARN a global **ResourceManager** allocates **containers** (CPU and memory on a node), a **NodeManager** per node launches them, and each application's **ApplicationMaster** requests containers with locality preferences (node, rack, anywhere) and runs its tasks in them [Vavilapalli et al. 2013]: two-level scheduling with requests instead of offers. Policies are pluggable:

- **Capacity Scheduler.** Hierarchical queues, each with a guaranteed **capacity** (a percentage of its parent), an elastic **maximum capacity** for borrowing, and per-user limits; preemption reclaims borrowed containers.
- **Fair Scheduler.** Queues with weights and minimum shares, using fair share, FIFO or DRF within each.

Figure 46.9 — A hierarchical capacity-queue tree with borrowing.



Reading the diagram. Guarantees nest: `nlp` gets $0.5 \times 30\% = 15\%$ of the cluster. When `prod` is idle, `research` borrows up to its 60% maximum (dotted: elastic and reversible); when `prod` returns, borrowed containers are preempted after a configured wait. The tree lives in the ResourceManager, the failure point, run as an active–standby pair. Scaling: node heartbeats drive allocation.

Table 46.6 — Fairness policies compared.

Policy	Resources	Guarantees	Weakness	Seen in
FIFO with priority	Any	None beyond order	Starvation, convoys	Simple queues
Max-min / weighted fair share	One	Equal or weighted share of one resource	Ambiguous with several resources	Fair Scheduler, Kueue fair sharing
Capacity queues	Any	Guaranteed fraction per queue, elastic borrowing	Static guarantees need tuning	YARN Capacity Scheduler, Kueue ClusterQueues
DRF	Several	Sharing incentive, strategy-proof, envy-free, Pareto	Ignores placement constraints	Mesos, Fair Scheduler, Volcano
Fair-share decay over usage history	Any	Long-run share by past consumption	Hard to explain to users	Slurm (§46.12)

46.10 Gang scheduling and co-scheduling

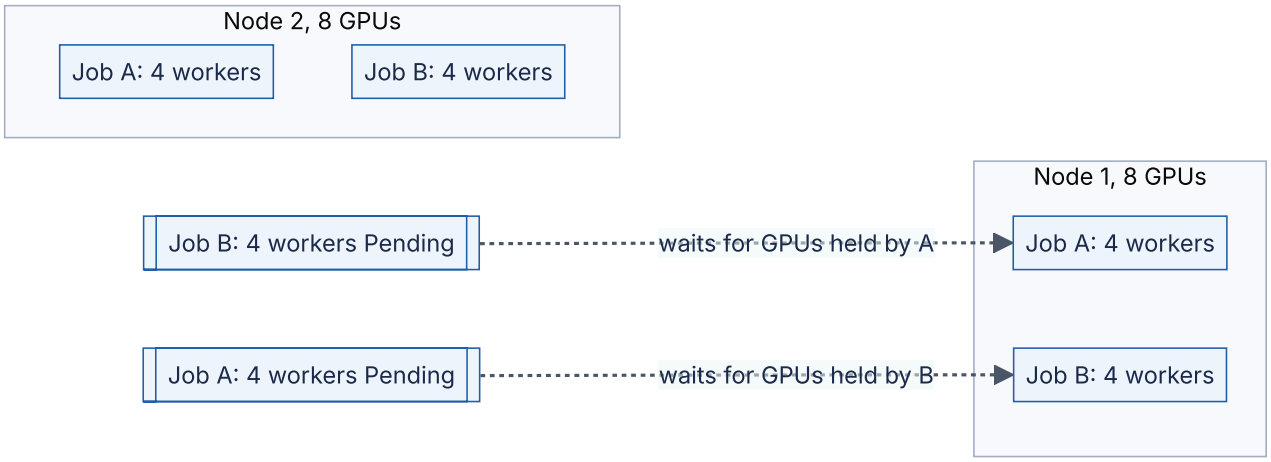
46.10.1 Why distributed training needs all-or-nothing

DEFINITION

Definition — Gang scheduling. Placing all tasks of a parallel job at the same time, or none of them. **Co-scheduling** is the weaker form: place a minimum number together and let the rest follow.

A 64-worker data-parallel training job runs collectives (all-reduce, §49.9.2 and Chapter 65) in which every worker participates at every step; with 63 running, 63 GPUs idle waiting for the 64th. A pod-at-a-time scheduler places whatever fits, so two large jobs can each get part of what they need and wait for each other forever.

Figure 46.10 — Deadlock without gang scheduling on 16 GPUs.



Reading the diagram. Jobs A and B each need 12 one-GPU workers on 16 GPUs. Interleaved placement gave each 8 GPUs and left 4 workers Pending. Neither can take a step or release GPUs, because its running pods are healthy, waiting at a barrier. Dotted arrows are waits, not data flows; in the scheduler's state every pod looks fine, so the cycle is invisible. Recovery needs someone to kill a job; gang admission would have started A with 12 GPUs and queued B.

FORMULA

Accelerator time wasted by partial allocations

$$W = \sum_j g_j^{\text{held}}\, t_j^{\text{wait}}$$

Symbol	Meaning	Units
g_j^{held}	Accelerators held by a job that cannot yet run	GPUs
t_j^{wait}	Time it holds them before starting or being killed	h
W	Wasted accelerator time	GPU·h

WORKED EXAMPLE

Worked example — A deadlock discovered after two hours. Jobs A and B of Figure 46.10 each hold 8 GPUs until an on-call engineer notices after 2 hours.

1. $W = 8 \times 2 + 8 \times 2 = 32$ GPU·h, the whole cluster for two hours.
2. At an illustrative $3 per GPU-hour, $96 for nothing, and both jobs' owners lost two hours.
3. With gang admission: A runs at once for 2 hours (24 GPU·h useful), B waits, and 4 GPUs serve small jobs: $W = 0$.

Interpretation. Partial allocation turns the scarcest resource into idle reservations; deadlock makes the waste unbounded. **Engineering implication.** Multi-worker jobs need all-or-nothing admission plus a timeout that releases partially placed gangs.

46.10.2 Gang scheduling approaches in Kubernetes

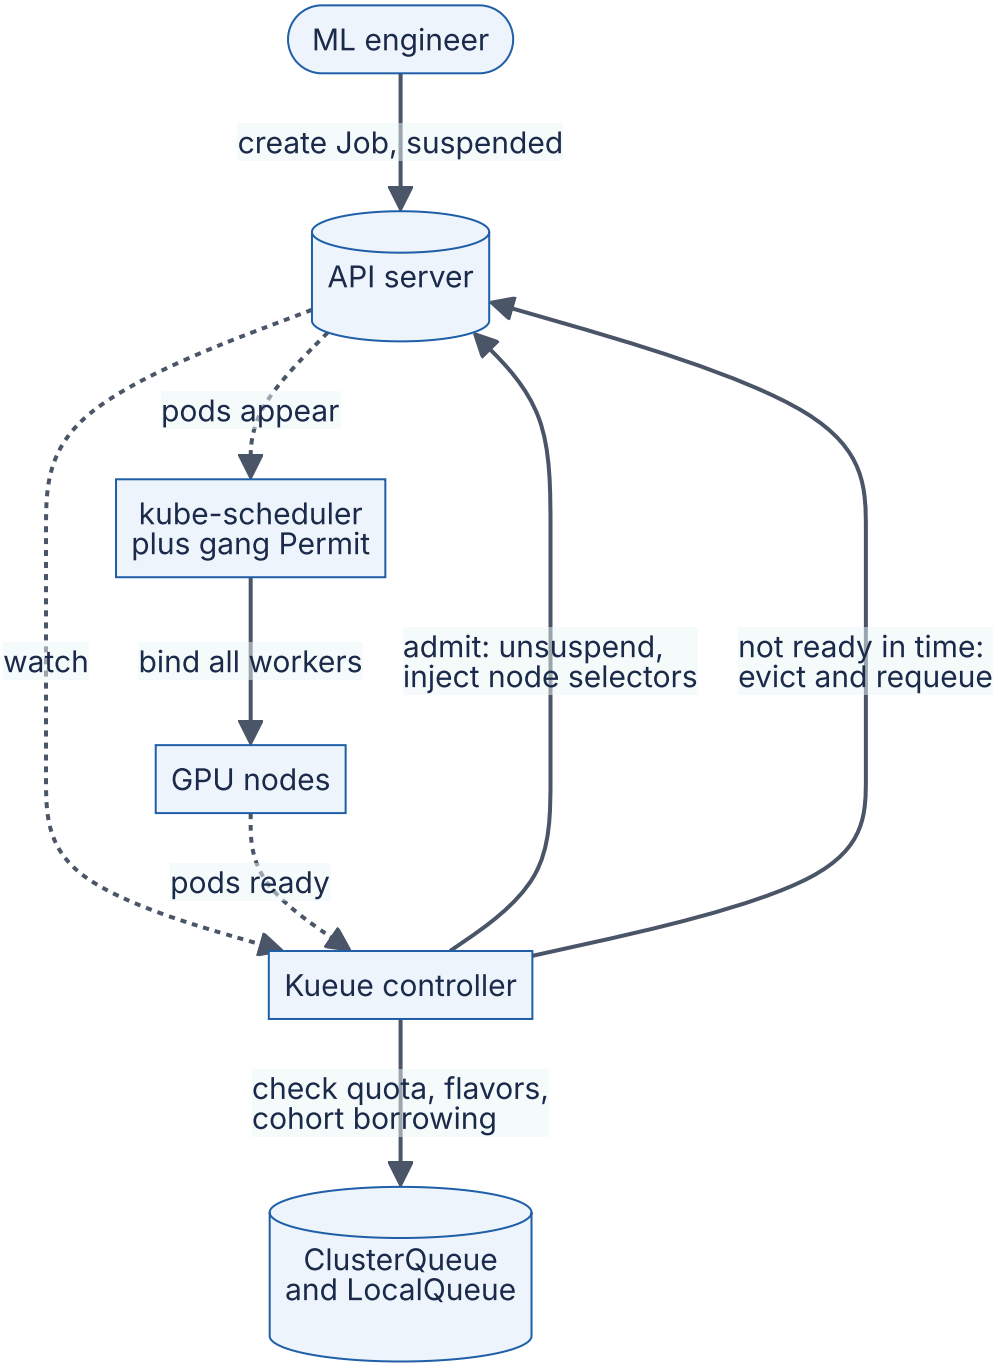
Kubernetes places one pod at a time, so gangs come from extensions; as of 2026 there are four main options:

- **Coscheduling plugin** (kubernetes-sigs `scheduler-plugins`). A `PodGroup` declares `minMember`; **Permit** holds each placed pod in *wait* until `minMember` pods have re-

served nodes, then approves them together, or on timeout rejects all and releases the reservations.

- **Volcano**, a CNCF batch system, replaces or runs alongside the default scheduler. Its scheduler runs a session per cycle with *actions* (enqueue, allocate, preempt, reclaim, backfill) and *plugins* (gang, priority, DRF, proportion, binpack and others), and adds `Queue` and `PodGroup` resources and a `Job` type for MPI, PyTorch and similar frameworks [Volcano Docs].
- **Kueue**, a Kubernetes SIG project, does **job-level admission** rather than pod placement: jobs are created suspended, and Kueue admits a whole job only when its `ClusterQueue` has quota for all of it, then lets the default scheduler place the pods [Kueue Docs]. `ResourceFlavor`s describe node types (such as GPU models or spot versus on-demand), **cohorts** let ClusterQueues borrow each other's unused quota, `waitForPodsReady` adds a timeout-based all-or-nothing guarantee (requeue the job if its pods are not all running in time), and **topology-aware scheduling** places a job's pods within one rack or block.
- **Native gang scheduling.** Kubernetes v1.35 added an alpha `Workload` API (`scheduling.k8s.io/v1alpha1`) through which pods reference a pod group with a minimum count, and a `GangScheduling` scheduler plugin behind feature gates; the design is still changing across releases [Kubernetes Docs: Gang Scheduling].

Figure 46.11 — Admission versus placement for a training job.



Reading the diagram. The job is created suspended, so no GPUs are held. Kueue watches it asynchronously, checks ClusterQueue quota (including cohort borrowing), and admits it by unsuspending it with node selectors for the chosen ResourceFlavor. Only then do pods reach the scheduler, ideally with a gang-aware Permit. If not all pods run before the timeout, Kueue evicts and requeues the job. Storage boundary: API objects. Failure points: quota without gang placement can strand a job on fragmented nodes; admission without topology awareness scatters workers (§46.11). Scaling: decisions are per job, not per pod.

Table 46.7 — Gang scheduling options on Kubernetes (as of 2026).

Option	Level	Gang mechanism	Quota and fairness	Choose when
Coscheduling plugin	Placement	Permit waits for `minMember`	None (use ResourceQuota)	Small clusters needing gangs only
Volcano	Scheduler	Gang plugin in its own scheduler	Queues, DRF, proportion, reclaim	A full batch scheduler replacing the default
Kueue	Admission	Admit whole job; `waitForPodsReady`	ClusterQueues, cohorts, borrowing, fair sharing	Multi-team quota with the default scheduler
Native Workload API	Placement	Pod group minimum count	None yet	Experiments; track for the future

Platforms often combine Kueue admission, gang-aware placement, and JobSet or a framework operator to describe the job's roles.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Two jobs each hold part of the cluster	Pod-at-a-time scheduling	Jobs with some pods Pending for long	Kill one job	Gang admission or Permit
Admitted job never runs	Quota exists but nodes are fragmented	Admitted-but-not-ready time	`waitForPodsReady` requeue	Pack GPU nodes; topology-aware admission
Large job starves behind small ones	Small jobs always fit first	Head-of-queue age	Reserve capacity for it	Strict FIFO within a queue, or reservations
One worker evicted, job stalls	Preemption of a single pod	Collective timeout	Restart job from checkpoint	Preempt whole gangs, not pods

46.11 GPU and accelerator scheduling

This section covers what the *scheduler* must know about accelerators; Chapter 64 covers GPU internals and sharing mechanisms in depth, and Chapter 80 covers clusters of 10,000 GPUs and more.

46.11.1 Making GPUs schedulable

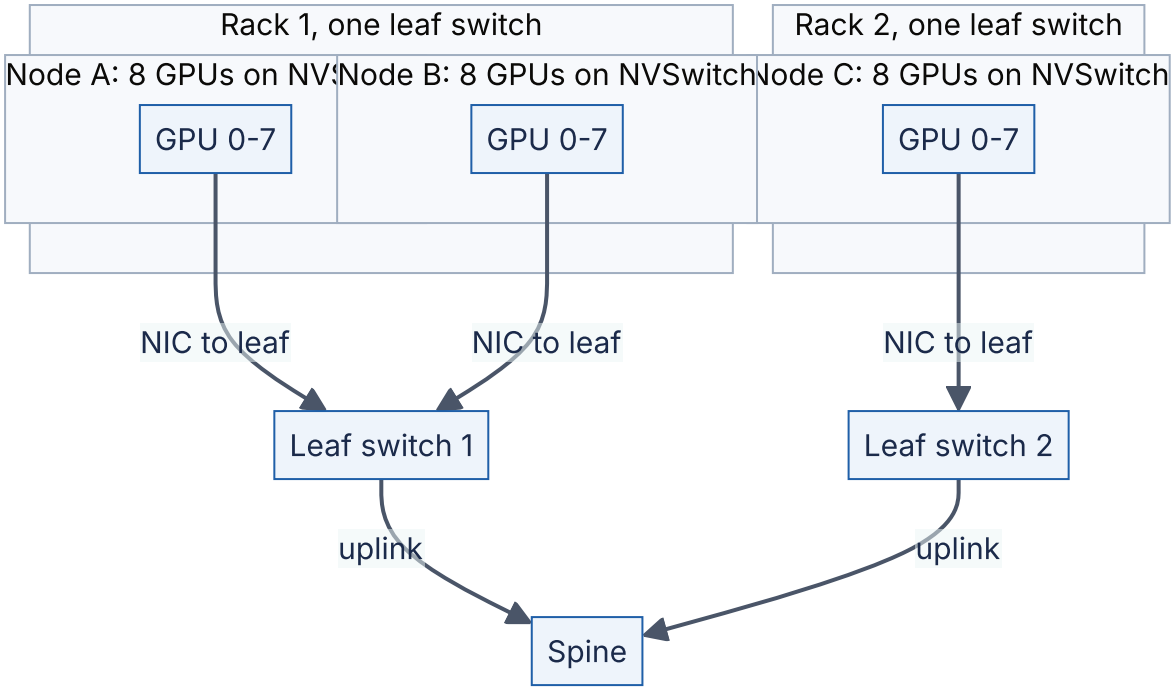
By default a container gets whole GPUs. A vendor **device plugin** on each node registers an extended resource such as `nvidia.com/gpu`, reports healthy devices to the kubelet, and says which devices each container receives [Kubernetes Docs: Device Plugins]. Extended resources are integers, requested as limits, never overcommitted: a scarce, indivisible dimension. **Dynamic Resource Allocation** (DRA), whose core became generally available

in v1.34, replaces the integer count with claims against devices that drivers publish as `ResourceSlice` objects, so a pod can ask for “one GPU with at least 40 GB of memory” or for devices sharing an interconnect [Kubernetes Docs: Dynamic Resource Allocation].

46.11.2 Topology-aware placement

GPUs in one server talk over NVLink or NVSwitch at hundreds of gigabytes per second, across servers over the network at a fraction of that, and across racks through more switch hops. Step time includes collectives across all GPUs (Chapter 65), so *where* the gang lands sets its speed.

Figure 46.12 — Placement tiers for a GPU job.



Reading the diagram. Inside a node, the 8 GPUs share NVSwitch (fastest tier). Nodes A and B share a leaf switch, so traffic between them takes one switch hop; traffic between A and C crosses the spine, adding hops and competing with other racks for oversubscribed uplinks. Preference order for a job’s GPUs: one node, then one rack (or one high-bandwidth network block), then anywhere. Failure points: one bad GPU or NIC stalls the whole gang; a congested uplink slows every cross-rack job. Scaling: schedulers express the tiers as node labels (Kueue’s topology-aware scheduling, Slurm’s topology plugin), and the kubelet’s Topology Manager aligns a pod’s CPUs, GPUs and NICs to one NUMA node inside a server.

46.11.3 Sharing a GPU

Table 46.8 — GPU sharing modes (see Chapter 64 for internals).

Mode	Isolation	Granularity	Use for
Whole GPU	Full	1 device	Training, large inference
Multi-Instance GPU (MIG)	Hardware: dedicated compute slices, memory and cache	Up to 7 instances on supported data-center GPUs	Small inference, notebooks, predictable QoS
Time-slicing	None for memory or faults; turns rotate	Configurable replicas per GPU	Dev, bursty low-utilization work
MPS (concurrent processes)	Partial limits, shared fault domain	Fraction of compute per process	Cooperating processes of one tenant

MIG partitions are scheduled as their own extended resources (for example one resource name per profile), so the scheduler again sees integers. Partitioning is a packing decision in its own right: a GPU split into seven small instances cannot run a job that needs the whole device until it is reconfigured.

WORKED EXAMPLE

Worked example — GPU fragmentation across four 8-GPU nodes. Nodes have 3, 5, 2 and 6 GPUs free: 16 free in total, half the cluster.

1. An 8-GPU job: no node has 8 free; $F(8) = 1 - 0/16 = 100\%$ by the formula of §46.7.2.
2. 4-GPU jobs: $\lfloor 3/4 \rfloor + \lfloor 5/4 \rfloor + \lfloor 2/4 \rfloor + \lfloor 6/4 \rfloor = 0 + 1 + 0 + 1 = 2$ jobs, 8 GPUs; $F(4) = 50\%$.
3. Repacked (moving one-GPU and two-GPU work so free GPUs are 8, 8, 0, 0): $F(8) = 0$, two 8-GPU jobs fit.

Interpretation. A cluster that is 50% free can be 100% full for its most valuable jobs. **Engineering implication.** Pack GPU nodes with best fit, keep small jobs on a separate pool or on MIG slices, measure F for 8-GPU and full-node shapes, and let a descheduler or checkpoint-and-migrate policy consolidate small jobs when large ones queue.

46.12 Batch and HPC schedulers: Slurm

46.12.1 Architecture and concepts

Slurm is a widely used open-source workload manager in HPC and ML training [Slurm Docs]. A central `slurmctld` (with an optional backup for failover) holds the queue and decides; `slurmd` on each node launches work; `slurmdbd` stores accounting data for fair-share. Users submit **jobs** with `sbatch` (a script) or `salloc` (an interactive allocation), and launch parallel **job steps** inside an allocation with `srun`. A job asks for nodes, tasks, CPUs, memory and generic resources such as GPUs (`--gres=gpu:8` or `--gpus`), and must state a **time limit** (`--time`), after which Slurm kills it. **Partitions** group nodes into

queues with their own limits and priorities, and **QOS** records add per-user or per-group limits and preemption rules.

Slurm is gang-scheduled by construction: a job's allocation is granted whole or not at all, and the `topology/tree` plugin, with the `--switches` option, keeps an allocation under as few switches as possible. Priority comes from the **multifactor** plugin, a weighted sum of age, job size, partition, QOS and **fair-share**, which lowers the priority of accounts that have used more than their share recently, with usage decaying over a configurable half-life.

46.12.2 Backfill scheduling

In a strict priority queue, everything waits behind a head job that cannot yet start, even jobs that would finish first. **Backfill** starts lower-priority jobs early *if they delay no higher-priority job's expected start*, which needs time limits. EASY backfilling protects only the head job's reservation; conservative backfilling protects every queued job [Mu'alem and Feitelson 2001]. Slurm's backfill plugin plans reservations for the higher-priority jobs it examines, within a planning window (`bf_window`, 1,440 minutes by default) every `bf_interval` (30 s by default) [Slurm Docs: Scheduling Configuration].

FORMULA

Backfill condition and gain

$$\text{start } j \text{ now} \iff n_j \le n_{\text{free}} \ \wedge \ (t_{\text{now}} + T_j \le t_{\text{shadow}} \ \vee \ n_j \le n_{\text{extra}}) \qquad G = \sum_{j \in \text{backfilled}} n_j \min(T_j, t_{\text{shadow}} - t_{\text{now}}$$

Symbol	Meaning	Units
n_j, T_j	Nodes and time limit of candidate job j	nodes, h
n_{free}	Nodes free now	nodes
t_{shadow}	Reserved start time of the blocked higher-priority job	h
n_{extra}	Nodes free at t_{shadow} beyond what the reservation needs	nodes
G	Node-hours of the idle hole $n_{\text{free}}(t_{\text{shadow}} - t_{\text{now}})$ filled by backfill	node·h

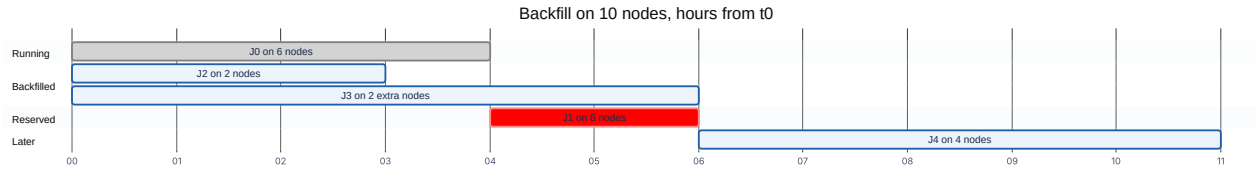
WORKED EXAMPLE

Worked example — Backfilling a 10-node cluster. At $t = 0$, J0 runs on 6 nodes until $t = 4$ h. The queue, in priority order: J1 (8 nodes, 2 h), J2 (2 nodes, 3 h), J3 (2 nodes, 6 h), J4 (4 nodes, 5 h).

1. Strict priority. J1 needs 8 nodes and only 4 are free, so nothing starts. At $t = 4$, J1 (8) and J2 (2) start; at $t = 6$, J3 and J4 start. Starts: 4, 4, 6, 6 h; **mean wait 5 h**; last job ends at 12 h.
2. Backfill. J1 is reserved at $t_{\text{shadow}} = 4$ on 8 nodes, so $n_{\text{extra}} = 10 - 8 = 2$.
3. J2: $2 \le 4$ free and $0 + 3 \le 4$: start now. Free: 2.
4. J3: $2 \le 2$ free, ends at $6 > 4$, but $2 \le n_{\text{extra}} = 2$: start now; it uses the nodes J1 will not need. Free: 0; extra: 0.
5. J4 cannot start. J1 starts on time at $t = 4$; J4 at $t = 6$. Starts: 4, 0, 0, 6 h; **mean wait 2.5 h**; last job ends at 11 h.
6. Hole: $4 \times 4 = 16$ node·h; $G = 2 \times 3 + 2 \times 4 = 14$ node·h, **88%** filled. Total work is $24 + 16 + 6 + 12 + 20 = 78$ node·h, so utilization until the last job ends rises from $78/120 = 65\%$ to $78/110 = 71\%$.

Interpretation. Backfill halved the mean wait and raised utilization without delaying the highest-priority job by a second. **Engineering implication.** Backfill works only with honest time limits: inflated limits make jobs look too long to backfill, while limits that are too short get jobs killed. Many sites reward accurate estimates, and the planning parameters (`bf_window` , `bf_resolution`) must cover your longest jobs.

Figure 46.13 — The backfill schedule of the worked example.



Reading the diagram. Hours run left to right. J1's 8-node reservation starts at hour 4 and never moves; J2 fits in the hole before it, J3 runs past it on the 2 nodes J1 does not need, and J4 waits for J1. Failure points: J2 would be killed at its 3-hour limit, so the reservation is safe, and J3 holds only extra nodes. The plan is recomputed every backfill cycle as jobs end early.

The program below plans the queue both ways and asserts the start times above.

```
        """Plan a priority-ordered queue with and without backfill on a node-count pro-
file."""

        def plan(total, running, queue, backfill):
            """running: [(nodes, end)]; queue: [(name, nodes, hours)] in priority order.
            Returns {name: start}. Without backfill no job may start before the job
            ahead of it; with backfill a job may start early if it delays no reserva-
tion."""
            busy = [(0.0, end, n) for n, end in running]          # (start, end, nodes)

            def free(t0, t1):                                     # min free nodes in
[t0, t1)
                points = {t0} | {s for s, _, _ in busy if t0 < s < t1}
                return min(total - sum(n for s, e, n in busy if s <= p < e) for p in
points)

            starts, earliest = {}, 0.0
            for name, nodes, hours in queue:
                candidates = sorted({earliest} | {e for _, e, _ in busy if e > earli-
est})
                t = next(c for c in candidates if free(c, c + hours) >= nodes)
                starts[name] = t
                busy.append((t, t + hours, nodes))                # start now, or re-
serve
                if not backfill:
                    earliest = t                                  # strict order: nobody
overtakes
            return starts

        if __name__ == "__main__":
            queue = [("J1", 8, 2), ("J2", 2, 3), ("J3", 2, 6), ("J4", 4, 5)]
            for bf in (False, True):
                s = plan(10, running=[(6, 4.0)], queue=queue, backfill=bf)
                ends = max(s[n] + h for n, _, h in queue)
                print("backfill" if bf else "strict  ", s, f"mean wait {sum(s.values())
/ 4:.2f} h,",
                      f"makespan {ends:.0f} h")
            assert plan(10, [(6, 4.0)], queue, True) == {"J1": 4, "J2": 0, "J3": 0,
"J4": 6}
            assert plan(10, [(6, 4.0)], queue, False) == {"J1": 4, "J2": 4, "J3": 6,
"J4": 6}
```

```
strict   {'J1': 4.0, 'J2': 4.0, 'J3': 6.0, 'J4': 6.0} mean wait 5.00 h, makespan 12 h
backfill {'J1': 4.0, 'J2': 0.0, 'J3': 0.0, 'J4': 6.0} mean wait 2.50 h, makespan 11 h
```

What to notice:

- Every job, started or not, is appended to `busy`: a job that cannot start now becomes a **reservation**, which is what stops later jobs from delaying it. This is conservative backfilling.

- The only difference between the two modes is `earliest`: strict mode forbids any job from starting before the job ahead of it.

46.12.3 Slurm versus Kubernetes for training

Table 46.9 — Slurm and Kubernetes for ML training.

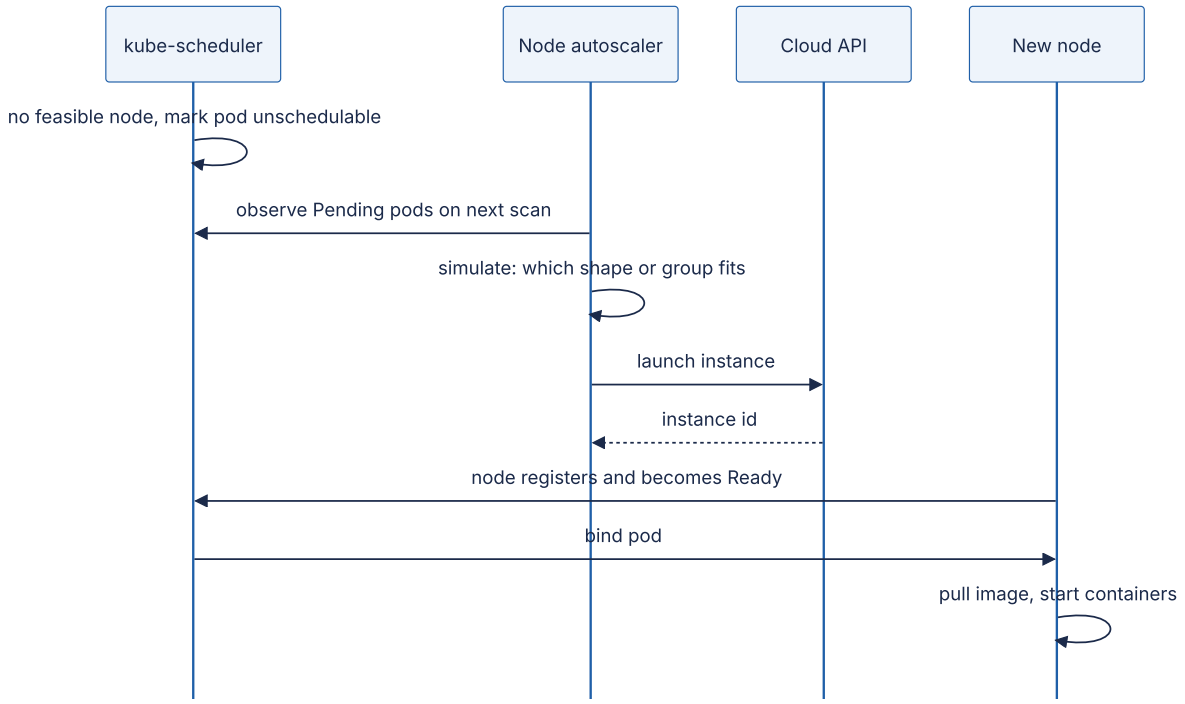
Row	Slurm	Kubernetes with batch add-ons
What it is	HPC batch workload manager	General orchestrator plus Kueue/Volcano
How it works	Whole-allocation jobs, priority, backfill	Pods, admission queues, gang plugins
Advantages	Native gangs, topology, backfill, fair-share; familiar to researchers	One platform for training, serving and data; containers, APIs, operators
Disadvantages	Weaker service and container story	Gangs, queues and topology are add-ons
Performance	Fast whole-job placement	Pod-at-a-time; tuned add-ons close the gap
Operational complexity	Low for batch; separate stack for serving	Higher; one stack for everything
Cost	Static partitions can idle	Elastic node provisioning, spot capacity
Use cases	Supercomputers, research clusters, large pretraining	Mixed training and inference fleets in the cloud
Choose when	Mostly large batch jobs, researchers on the command line	You also serve models and want one control plane

The boundary is blurring: projects run Slurm inside Kubernetes (SchedMD's Slinky) or give Kubernetes Slurm-like admission (Kueue), and Chapter 80 describes how large AI clusters combine them.

46.13 Autoscaling the cluster itself

§42.12 described the node autoscalers: the **Cluster Autoscaler** grows predefined node groups when pods are Pending and removes nodes whose requests stay low, while **Karpenter** provisions right-sized instances directly from the cloud catalog for the pending pods and consolidates continuously. Seen from the scheduler, a node autoscaler is a slow, expensive extension of placement: the scheduler's "no fit" is its input.

Figure 46.14 — From Pending to running on a new node.



Reading the diagram. The unplaced pod stays Pending; the autoscaler finds it on its next scan (asynchronously), simulates which group or instance fits, and calls the cloud API. The new node registers, the scheduler binds the pod, and the kubelet pulls images. Failure points: cloud capacity shortages (common for GPUs), autoscaler simulations that disagree with the scheduler, huge images. Scaling: each stage adds latency, summed below.

FORMULA

Time to capacity through node autoscaling

$$T = t_{\text{scan}} + t_{\text{provision}} + t_{\text{join}} + t_{\text{pull}} + t_{\text{start}}$$

Symbol	Meaning	Units
t_{scan}	Delay until the autoscaler sees the Pending pod	s
$t_{\text{provision}}$	Cloud instance launch and boot	s
t_{join}	Node registration, drivers and device plugins ready	s
t_{pull}	Image download and unpack	s
t_{start}	Application start until Ready	s

WORKED EXAMPLE

Worked example — A GPU training worker on a fresh node. Illustrative values: scan 10 s, provision 90 s, join including GPU driver and device plugin 60 s, a 15 GB image at 0.5 GB/s, start 30 s.

1. $t_{\text{pull}} = 15/0.5 = 30$ s.
2. $T = 10 + 90 + 60 + 30 + 30 = 220$ s, about 3.7 minutes.
3. For a 64-node gang, the job starts when the *last* node is ready, and if the cloud grants only 40 nodes, the 40 sit idle: by §46.10.1, $40 \times 8 = 320$ GPUs held while waiting.

Interpretation. Autoscaling turns placement latency from milliseconds into minutes, and for gangs the tail node and partial grants dominate. **Engineering implication.** Keep warm headroom with low-priority placeholder pods (§42.12), cache or pre-pull images, and for gangs ask for capacity atomically: Kueue's ProvisioningRequest integration with the Cluster Autoscaler, or a cloud's reservation and queued-capacity products, so that a job is admitted only when all of its nodes are granted.

Table 46.10 — Cluster Autoscaler versus just-in-time provisioning.

Row	Cluster Autoscaler	Karpenter-style provisioning
Unit of scaling	Predefined node groups	Individual instances chosen per batch of pods
Choice of shape	Fixed per group	From the whole catalog, including spot
Packing	Scheduler packs onto group shapes	Provisioner sizes nodes to pods, then consolidates
Gang support	Atomic scale-up via ProvisioningRequest	Batches pending pods; atomicity via the queueing layer
Choose when	Few, stable node types; on-premises-like pools	Diverse workloads, spot, frequent shape changes

46.14 Summary and revision notes

SUMMARY

- A cluster scheduler trades utilization, start latency and fairness. Services reserve for peaks; batch fills the slack. Optimal placement is NP-hard vector bin packing, so schedulers filter, score with heuristics and correct later.
- Architectures: monolithic (head-of-line blocking, $W_q = \sum \lambda \bar{S^2}/2(1-\rho)$), two-level offers (partial view), shared-state optimistic (conflicts $\approx 1 - e^{-c_1 c_2/N}$), distributed sampling (Sparrow), hybrids.
- Borg: ~10,000-machine cells, a five-replica Paxos Borgmaster, a scheduler on cached state, priority bands with quota, reclamation, hybrid scoring. Results are relative: sharing saves 20–30% of machines; fine-grained requests 30–50%.
- Kubernetes: extension points from PreEnqueue to PostBind; Permit enables gangs; `percentageOfNodesToScore` bounds search; profiles give per-workload policy; the descheduler corrects drift.
- Packing (first or best fit) beats spreading for batch and GPUs; spreading strands large tasks. Measure fragmentation $F(s)$ for the shapes you care about; use dot-product alignment only as a secondary term.
- Preemption picks nodes by PDB violations, victim priority, count and age; PDBs guard voluntary evictions only. Quota bounds work per priority. Preemption cost for big jobs is $r_p(\tau/2 + t_r)G$.
- Fairness: water filling for one resource; DRF equalizes dominant shares (the 9-CPU/18-GB example gives 3 and 2 tasks, both 2/3); YARN offers capacity and fair schedulers.
- Gangs need all-or-nothing admission, or partial allocations deadlock and waste accelerators. Options: coscheduling Permit, Volcano, Kueue admission, and the alpha native Workload API.
- GPUs are indivisible integers (device plugins) or claims (DRA); place gangs by topology (node, rack, network block); share with MIG or time-slicing; pack to avoid fragmentation.
- Slurm gives whole-job allocation, topology, fair-share and backfill; backfill starts jobs that do not delay reservations, which needs honest time limits.
- Node autoscaling adds minutes; gangs need atomic provisioning and warm headroom.

46.15 Knowledge checkpoint

1. Why do services usually dominate reserved resources while batch jobs dominate job counts?

2. A cluster has 2,000 cores; requests total 1,600 and p95 usage 900. With a 20% margin, how many cores can be reclaimed?
3. What is head-of-line blocking in a monolithic scheduler, and two ways to reduce it?
4. Why does an all-or-nothing transaction of 500 machines conflict far more often than ten 50-machine transactions in Omega?
5. For $\rho = 0.5$, $m = 4$ and $d = 2$, compute the no-queueing probability with per-task sampling.
6. What does late binding fix in Sparrow, and what does it cost?
7. What are Borg's prod bands, and why can production tasks not preempt each other?
8. Compute the default number of nodes the Kubernetes scheduler searches in a 2,500-node cluster.
9. Which extension point lets a gang plugin hold pods until the group is complete?
10. Why does a pure dot-product score behave like worst fit?
11. Recompute DRF for 18 CPUs and 36 GB, with A needing ⟨1 CPU, 4 GB⟩ and B ⟨3 CPUs, 1 GB⟩ per task.
12. Why does a PodDisruptionBudget not protect against a node crash?
13. Nodes with 8 GPUs have 7, 1, 4 and 4 GPUs free. Compute $F(8)$ and $F(4)$.
14. In the backfill example, why may J3 start at $t = 0$ although it runs past J1's reservation?

Answers

1. Services run continuously and reserve for peaks, so a few service jobs hold much capacity; batch work is many short jobs.
2. Protected $= 1.2 \times 900 = 1,080$; reclaimable $= 1,600 - 1,080 = 520$ cores.
3. Fast decisions wait behind slow ones in one queue. Make decisions faster (caching, sampling) or split classes into separate queues, profiles or schedulers.
4. $P \approx 1 - e^{-c_1 c_2 / N}$ grows with the product of transaction sizes, and the large transaction's long decision time exposes it to many commits; any single conflict rejects the whole transaction.
5. $(1 - 0.25)^4 = 0.316$.
6. Stale queue-length reports; it costs an extra round trip per task and idle time for workers whose reservation is canceled.
7. Monitoring and production. Mutual preemption would cause cascades and make high-priority services unstable.
8. $p = 50 - 2,500/125 = 30\%$, so 750 nodes.
9. Permit (with PreEnqueue to gate entry).
10. The score grows with the node's free capacity, so emptier nodes always score higher.
11. Dominant shares $4x/36 = 3y/18 \Rightarrow y = 2x/3$; CPU $x + 2x \le 18 \Rightarrow x = 6$, $y = 4$; memory $24 + 4 = 28 \le 36$. Both dominant shares are $2/3$.
12. It limits voluntary evictions through the Eviction API only; a crash is involuntary.

13. $F(8) = 100\%$ (no node has 8 free); 4-GPU copies $= 1 + 0 + 1 + 1 = 3$, so $F(4) = 1 - 12/16 = 25\%$.
14. It uses only the 2 nodes that J1's 8-node reservation does not need, so J1 still starts at $t = 4$.

46.16 Interview questions

Basic

Q1. What does a cluster scheduler do, and how is it different from a load balancer? Answer. It decides where units of work run, given multi-resource requests, constraints, priorities and quota, and reclaims capacity by preemption. A load balancer routes individual requests among running replicas; they share ideas (power of two choices), but scheduling decisions last minutes to months.

Q2. Why do production schedulers use heuristics instead of optimal placement? Answer. Placement is NP-hard multi-dimensional bin packing, made harder by online arrivals, constraints and conflicting objectives. Filter-and-score heuristics take milliseconds, are explainable and come within a few percent of optimal; preemption and descheduling fix mistakes later.

Intermediate

Q3. Batch pods take minutes to start after a large service rollout. Diagnose and fix. Answer. Likely head-of-line blocking: one serial scheduling cycle is busy with expensive service pods (inter-pod affinity, volume topology). Check scheduling latency by profile and the plugins' durations. Fixes: a separate batch profile, cheaper constraints (topology spread instead of affinity), a lower search percentage, and higher throughput settings; for very high task rates, a framework-level scheduler inside pods.

Q4. Three teams share 512 GPUs. Design quota and fairness. Answer. Kueue ClusterQueues per team with nominal quotas from budget in one cohort so idle GPUs can be borrowed; preemption reclaims borrowed GPUs when the owner returns; priority classes inside each team; fair sharing weights for borrowing; ResourceFlavors per GPU type; gang admission with `waitForPodsReady`; DRF-style accounting if teams also consume large CPU and memory.

Advanced

Q5. Design scheduling for a 4,096-GPU training cluster shared by pretraining and many small jobs. Answer. Separate the problems: an admission layer (Kueue or Slurm) with quota, fair-share and priorities; gang placement with topology awareness

(whole nodes, one network block per job); best-fit packing; small jobs on dedicated nodes or MIG slices to avoid fragmenting full nodes; backfill of short jobs into holes before large reservations, with enforced time limits; preemption of whole gangs only, with frequent checkpoints so loss stays near $r_p(\tau/2 + t_r)G$; health checks that cordon bad GPUs before placement; and fragmentation metrics for 8-GPU and multi-node shapes.

Q6. Compare Borg, Mesos and Omega, and say what Kubernetes took from each. **Answer.** Borg: monolithic with full information, priorities, quota, allocs, reclamation; Kubernetes took pods, priorities, declarative jobs and requests-based packing. Mesos: two-level offers with DRF; Kubernetes has no offers, but frameworks still schedule inside pods. Omega: shared state with optimistic concurrency; Kubernetes' API server is a shared store all controllers act on, and multiple schedulers or profiles resolve conflicts at bind or admission. Each move trades global policy for flexibility or throughput.

46.17 Practical exercises

1. Run the §46.7.3 program with 30% large tasks and with no large tasks; explain why the gap between packing and spreading changes.
2. Add a `best-fit + 0.3 × alignment` score to the program and test whether it beats best fit across five seeds.
3. Extend the DRF program to three resources (CPU, memory, GPUs) and three users, and verify the sharing-incentive property by assertion.
4. In a test cluster, create a second scheduler profile with `MostAllocated` scoring, run 200 batch pods under each profile, and compare how many nodes the node autoscaler can remove.
5. Install Kueue, create two ClusterQueues in one cohort, and show borrowing and reclamation with two Jobs.

46.18 Design challenges

1. **QuickBite's mixed cluster.** QuickBite's 120-vCPU production cluster (§42.13.4) runs at 30% real CPU utilization. Design priority classes, a batch profile and reclamation so that nightly ETL and the delivery-time model's retraining run on the slack, and compute how many nodes you avoid adding.
2. **Research GPU cloud.** Twenty research groups share 1,024 GPUs; jobs range from 1 to 512 GPUs and from minutes to weeks. Choose Slurm or Kubernetes, define quota, fair-share, gang and topology policy, and estimate fragmentation and preemption loss.

46.20 Open verification items

- Borg figures as stated in Verma et al. 2015, recalled rather than re-read: 2–16× cells and 20–150% extra machines for user segregation; about 20% of work in reclaimed resources; failover about 10 s (up to a minute); “few hundred seconds” versus “more than 3 days” without scheduler optimizations; 3–5% hybrid-scoring gain (one secondary summary names E-PVM, not best fit, as the baseline).
- Sparrow’s default probe ratio $d = 2$.
- Tirmazi et al. 2020: heavy-tail characterization (stated qualitatively here).
- Kubernetes (as of 2026): preemption node-selection order; default `percentageOfNodesToScore` formula; Workload API and `GangScheduling` alpha in v1.35 and later API changes; DRA core GA in v1.34.
- Kueue features (`waitForPodsReady`, topology-aware scheduling, ProvisioningRequest) and Volcano’s action and plugin names.
- Slurm defaults (`bf_window` 1,440 min, `bf_interval` 30 s) and Slinky status.
- Sharing modes and MIG instance limits per GPU model (Chapter 64 owns these).

Chapter 47 — Multi-Tenant Architecture and Isolation

> **Level:** 4 · **Track:** Shared · **Estimated reading time:** 5 h

Almost every system that serves more than one customer is multi-tenant. A SaaS product serves thousands of companies from one fleet; an internal Kafka or Kubernetes platform serves dozens of teams; a serverless platform runs code from strangers on the same hosts. Sharing makes these systems cheap. Isolation makes them safe to share: one tenant must not see another's data, slow the others down or take them offline.

This chapter covers pooling economics (§47.3), tenancy models (§47.4), data isolation down to PostgreSQL row-level security (§47.5), tenant placement (§47.6), noisy neighbors (§47.7), per-tenant quotas and fair queuing with a runnable simulation (§47.8), the compute isolation spectrum (§47.9), the control plane (§47.10), metering (§47.11), cross-tenant attacks (§47.12) and the tenant lifecycle (§47.13). The running example is **TaskForge**, the hypothetical project-management SaaS of §14.7.2: 40,000 tenants, a median of 15 users each, and a largest tenant with 60,000 users and about 2% of all data. Every TaskForge number is a teaching assumption. Chapter 79 applies these ideas to AI workloads.

47.1 Learning objectives

After this chapter you should be able to:

- Quantify the capacity saved by pooling tenants and explain how correlated demand erodes it.
- Compare silo, pool, bridge and tiered models, and compute blast radius per tier by tenants and revenue.
- Choose a data isolation pattern, and write and test a PostgreSQL row-level security policy.
- Design per-tenant encryption with BYOK and crypto-shredding.
- Place tenants with a directory, identify whales and compute placement imbalance.
- Diagnose noisy neighbors from per-tenant metrics.
- Combine per-tenant token buckets with weighted fair queuing, compute max–min fair shares and simulate containment of a noisy tenant.
- Rank compute isolation boundaries by security and overhead, and cost the overhead.

- Separate control plane from data plane and meter usage for showback and chargeback.
- Name cross-tenant attack classes, write isolation tests, and plan the tenant lifecycle.

47.2 Prerequisites

- Shard keys and the TaskForge example — §14.7 (tenant-aware sharding extends it).
- Rebalancing and online migration — §14.9 (tenant moves use the same machinery).
- Token buckets, load shedding and bulkheads — §22.4, §22.9, §22.14 (per-tenant limits reuse them).
- Cells and shuffle sharding — §33.12 (the main blast-radius tools).
- Metric cardinality — §40.5.3 (why `tenant_id` is a dangerous label).
- IAM policies and roles — §41.12 (the cloud's own tenant boundary).
- Namespaces, cgroups and runtime classes — §42.3 (the container isolation mechanisms).
- Envelope encryption and KMS — §10.9.2 (per-tenant keys build on it).
- Broken access control and IDOR — §10.7.1 (the most common cross-tenant bug).
- Normal distribution and percentiles — §4.7.2, §4.8 (pooling arithmetic).

47.3 What multi-tenancy is and why

47.3.1 Tenants, sharing and isolation

> DEFINITION
>
> **Definition — Tenant and multi-tenancy.** A **tenant** is the unit of ownership, billing and isolation in a shared system: usually a customer organization in a SaaS product, or a team in an internal platform. **Multi-tenancy** means serving many tenants from shared infrastructure and code while keeping each tenant's data, performance and failures separate. **Tenant isolation** is the set of mechanisms that enforce that separation.

First-principles explanation

Think of an apartment building. Tenants share the foundation, roof and plumbing, which is why an apartment costs far less than a house. Each apartment still has a locked door (data isolation), its own electricity meter (metering) and a circuit breaker that trips before one tenant's heater blacks out the floor (quotas). Some buildings have a penthouse with a private elevator for those who pay (a siloed premium tier). Multi-tenant architecture decides what to share, where the walls go and how strong each wall must be.

Isolation has three dimensions, each answered separately:

1. **Security isolation.** Tenant A can never read or change tenant B's data or configuration.
2. **Performance isolation.** A's load cannot push B's latency or errors outside B's service level objective (SLO).
3. **Fault isolation.** A failure caused by or affecting A reaches as few other tenants as possible.

Why does this exist?

Dedicated infrastructure per customer is simple but expensive: each copy is provisioned for its own peak and mostly idles, each is deployed, patched and monitored separately, and onboarding means building a stack. Multi-tenancy reverses all three: one fleet absorbs every peak, one deployment upgrades everyone, and onboarding becomes a database insert.

47.3.2 The economics of pooling

The main saving comes from **statistical multiplexing**: tenants rarely peak together, so a shared pool needs less headroom than the sum of private headrooms.

FORMULA

Capacity for siloed versus pooled tenants (normal demand)

$$C_{\text{silo}} = \sum_{i=1}^{n} (\mu_i + z\sigma_i) \qquad C_{\text{pool}} = \sum_{i=1}^{n} \mu_i + z\sqrt{\sum_{i=1}^{n} \sigma_i^2 + \sum_{i \neq j} \rho_{ij}\,\sigma_i \sigma_j} \qquad \text{Saving} = 1 - \frac{C_{\text{pool}}}{C_{\text{silo}}}$$

Symbol	Meaning	Units
n	Number of tenants	tenants
μ_i, σ_i	Mean and standard deviation of tenant i's demand	RPS
z	Standard-normal quantile for the provisioning percentile (2.33 for p99)	dimensionless
ρ_{ij}	Correlation between tenants i and j's demand	dimensionless
C_{silo}, C_{pool}	Capacity exceeded by demand only 1% of the time	RPS

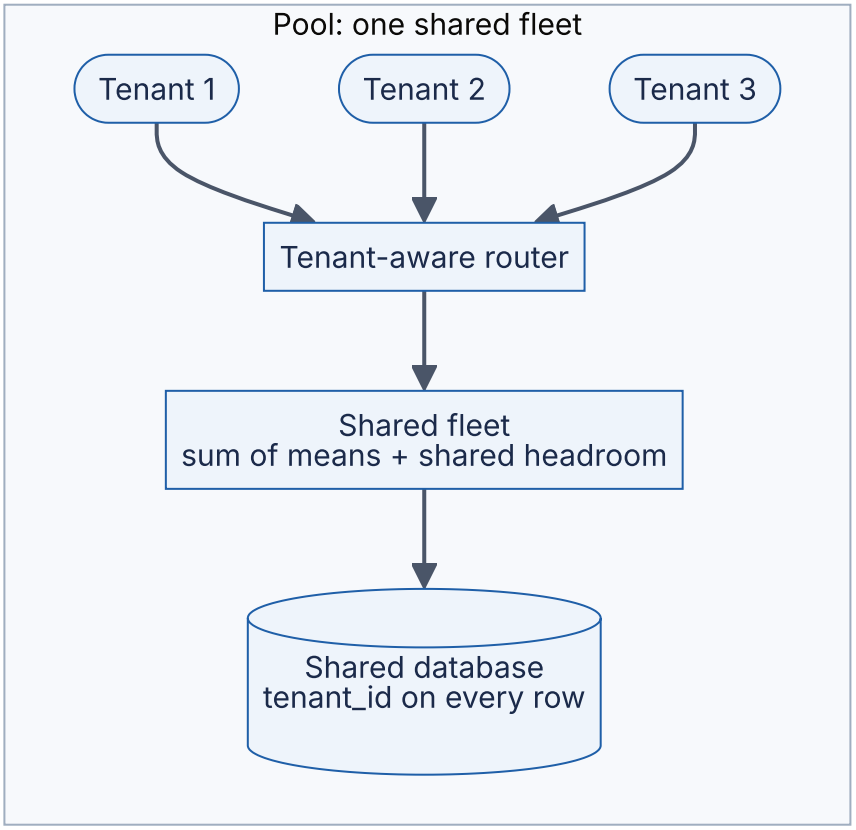
WORKED EXAMPLE

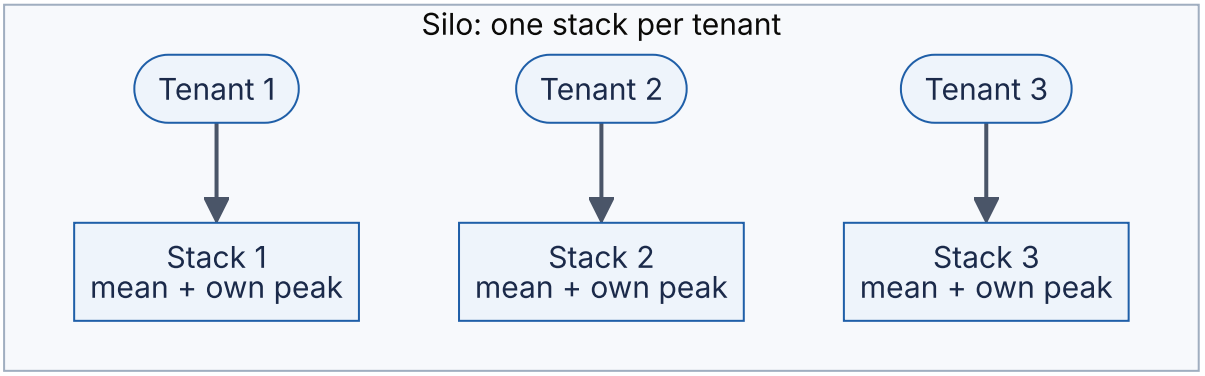
Worked example — Pooling 100 TaskForge tenants. Each tenant has $\mu = 100$ RPS and $\sigma = 50$ RPS; provision for p99, $z = 2.33$.

1. Silo: each needs $100 + 2.33 \times 50 = 216.5$ RPS, so $C_{\text{silo}} = 100 \times 216.5 = 21,650$ RPS.
2. Pool, independent ($\rho = 0$): mean $10,000$; standard deviation $\sqrt{100 \times 50^2} = 500$; $C_{\text{pool}} = 10,000 + 2.33 \times 500 = 11,165$ RPS. Saving $= 1 - 11,165/21,650 = 48.4\%$.
3. Correlated, $\rho = 0.3$ for every pair (same time zones, same 9 a.m. start): variance $= 250,000 + 0.3 \times 2,500 \times (100 \times 99) = 7,675,000$; standard deviation $2,770$; $C_{\text{pool}} = 10,000 + 2.33 \times 2,770 = 16,455$ RPS. Saving $= 24.0\%$.

Interpretation. Independent headroom grows with $\sqrt{n}$, not n, halving capacity; realistic correlation halves the saving again. **Engineering implication.** Pool tenants whose peaks differ (time zones, batch versus interactive), measure correlation from per-tenant metrics before promising savings, and count the operational saving too: one deployment instead of a hundred.

Figure 47.1 — Siloed headroom versus pooled headroom.





Reading the diagram. On the left, each tenant's synchronous requests reach its own stack and storage boundary, sized for its own peak: physical isolation, three idle head-rooms. On the right, one router forwards all tenants to a shared fleet and a database where every row carries `tenant_id`; headroom is shared, so the fleet is smaller, but router, fleet and database become shared failure points. The silo scales by adding stacks; the pool by adding capacity and, later, cells (§47.4.3).

47.3.3 SaaS products and internal platforms

Two kinds of system are multi-tenant, differing mainly in how far tenants trust each other.

- **SaaS products** serve external customers who may be competitors and who sign contracts with security and availability terms. Security isolation is non-negotiable, and some customers pay for physical separation.
- **Internal platforms** (a shared Kubernetes cluster, a company-wide Kafka) serve semi-trusted teams. Malice is unlikely, accidents (runaway jobs, retry loops, full disks) are common, so performance isolation and cost attribution dominate.

The Kubernetes documentation draws the same line between multi-team and multi-customer tenancy and treats isolation strength as a spectrum rather than a "soft" versus "hard" binary [Kubernetes Docs: Multi-tenancy]. A third case, **untrusted code** (serverless, CI runners, notebooks), needs a compute boundary that withstands a deliberate attacker (§47.9).

COMMON MISTAKE

Common misconception — "Internal tenants do not need isolation." Without per-team quotas and metrics, a shared platform has the reliability of its least careful team, and nobody can tell which team caused an outage or who should pay for capacity.

47.4 Tenancy models

47.4.1 Silo, pool and bridge

AWS's SaaS guidance names three basic models, applied per layer of the architecture [AWS SaaS Lens 2023; AWS Tenant Isolation 2020]:

DEFINITION

Definition — Silo, pool, bridge and tiered. In the **silo** model each tenant gets dedicated resources: its own stack, account, database or cluster. In the **pool** model tenants share resources and isolation is enforced logically by tenant-aware code, policies and limits. The **bridge** (hybrid) model mixes the two by layer, for example shared services with a database per tenant. A **tiered** deployment applies different models to different customer tiers, typically pooling small tenants and siloing premium ones.

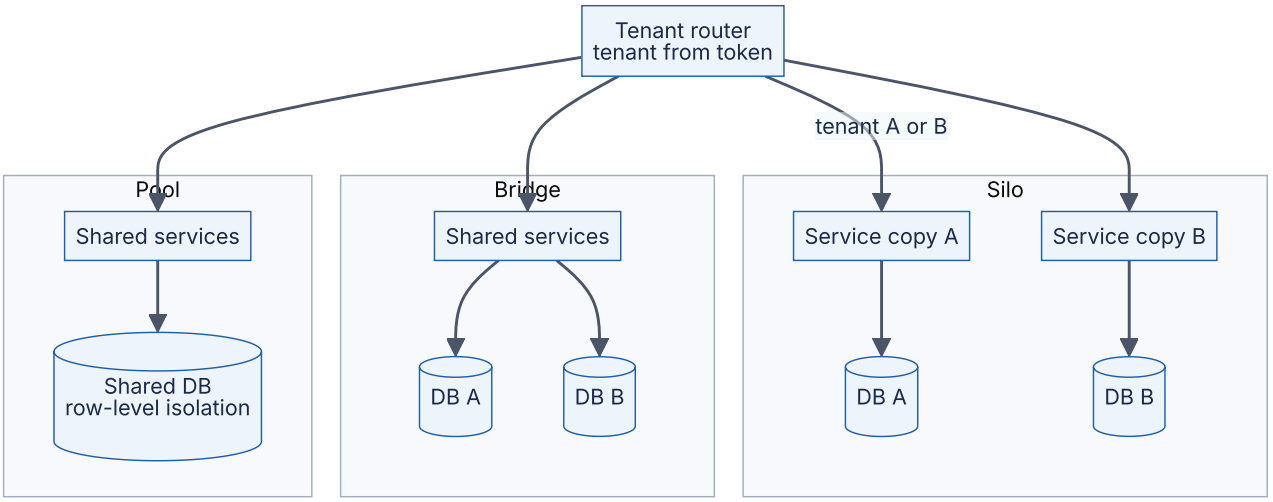
How it works internally

Choose per layer, not once for the product:

1. **Routing**: almost always pooled; one entry point resolves the tenant from the authenticated identity.

2. **Compute**: pooled stateless services by default; siloed for untrusted code or guaranteed capacity.
3. **Data**: where the choice matters most, because data is what regulators and attackers care about (§47.5).
4. **Supporting services**: caches, queues, search and object storage each need a decision; a pooled queue in front of siloed databases still lets one tenant's backlog delay others.

Figure 47.2 — Silo, pool and bridge applied per layer.



Reading the diagram. A pooled router reads the tenant from the token and forwards synchronously. In the silo, A and B each have a service copy and database: two storage boundaries, two failure domains. In the bridge, shared services write to separate databases, so a service bug affects both tenants but a database failure only one. In the pool, everything is shared and isolation depends on every query carrying the tenant predicate. Silo scales by adding copies, at linear operational cost; pool by growing or cloning the shared stack.

47.4.2 Comparing the models

Table 47.1 — Tenancy models compared.

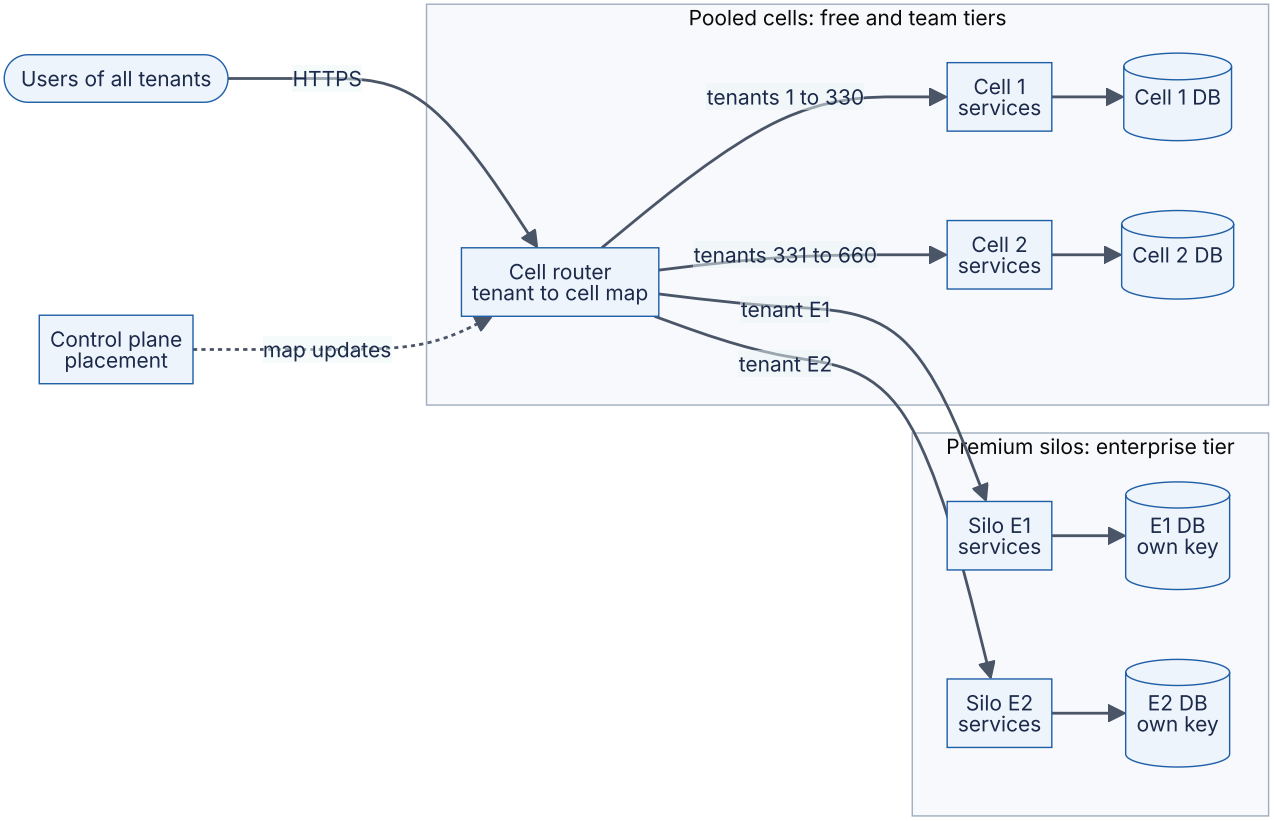
Row	Silo	Pool	Bridge	Tiered
What it is	Dedicated stack per tenant	Everything shared	Shared compute, separate data (or other per-layer mix)	Pool for most, silo for premium
How it works	Account, cluster or database per tenant	Tenant ID in every request, row and metric	Router picks the tenant's database	Router maps tier to deployment
Advantages	Strongest isolation; per-tenant upgrades and residency	Lowest cost; instant onboarding; one deploy	Data isolation at moderate cost	Matches isolation to willingness to pay
Disadvantages	Idle headroom; N deployments; slow onboarding	Noisy neighbors; one bug can leak across tenants	Connection and schema-migration fan-out	Two operating models to maintain
Performance	Predictable; no neighbors	Best utilization; needs fair-share controls	Data layer predictable; compute shared	Premium predictable; pool shared
Operational complexity	High per tenant, low per incident	Low per tenant, high blast radius	Medium	Medium to high
Cost	Highest per tenant	Lowest per tenant	Medium	Blended
Use cases	Regulated enterprise, untrusted compute	Self-serve SaaS, internal platforms	B2B SaaS with data-residency demands	B2B SaaS with free-to-enterprise tiers
Choose when	Contract or law requires separation	Many small, similar tenants	Data isolation matters more than compute	Tenants differ by orders of magnitude

Most mature SaaS products end up tiered, and the key rule is **one codebase, many deployments**: tiers differ only in configuration and placement. If silos run forked code, every fix is applied N times and the silo tier becomes the outage tier.

47.4.3 Tiers, cells and blast radius

One pooled stack maximizes utilization and blast radius alike. **Cells** (§33.12) split the pool into identical, independent stacks, each with a bounded set of tenants. A tiered design then has two kinds of compartment: silos with one premium tenant each, and pooled cells with many small tenants.

Figure 47.3 — A tiered deployment with pooled cells and premium silos.



Reading the diagram. The cell router maps each authenticated tenant to its compartment and forwards synchronously over HTTPS. Pooled cells hold hundreds of tenants on a shared database; silos hold one tenant on a database under its own key (§47.5.4). The control plane updates the mapping asynchronously (dotted), so routing continues from cache if it fails. A fault inside a cell stays there; the router is the one shared component and must stay minimal. Scale by adding cells as small tenants multiply and silos as enterprise contracts arrive.

FORMULA

Blast radius of one compartment failure, by tenants and by revenue

$$B_{\text{ten}}(k) = \frac{n_k}{N} \qquad B_{\text{rev}}(k) = \frac{R_k}{R} \qquad E[\text{impact}] = \sum_k f_k \, B_{\text{rev}}(k)$$

Symbol	Meaning	Units
n_k	Tenants in compartment k (a cell or silo)	tenants
N	Total tenants	tenants
R_k, R	Annual revenue from compartment k, and in total	dollars/year
B_{ten}, B_{rev}	Fraction of tenants, and of revenue, affected when k fails	fraction
f_k	Expected failures of compartment k per year	failures/year
$E[\text{impact}]$	Expected revenue-weighted failures per year (1.0 = one whole-company outage)	events/year

WORKED EXAMPLE

Worked example — Blast radius per TaskForge tier. One region has 2,000 paying tenants: 20 siloed enterprise tenants at $50,000/year and 1,980 team tenants at $2,000/year. Total revenue $R = 20 \times 50,000 + 1,980 \times 2,000 = 1,000,000 + 3,960,000 = \$4.96\text{M}$.

1. *One pool, no cells.* A pool failure hits 1,980 tenants: $B_{\text{ten}} = 1,980/2,000 = 99\%$, $B_{\text{rev}} = 3.96/4.96 = 79.8\%$.
2. *Six pooled cells of 330.* One cell failure: $B_{\text{ten}} = 330/2,000 = 16.5\%$; $B_{\text{rev}} = 330 \times 2,000/4,960,000 = 660,000/4,960,000 = 13.3\%$.
3. *One enterprise silo.* $B_{\text{ten}} = 1/2,000 = 0.05\%$, but $B_{\text{rev}} = 50,000/4,960,000 = 1.0\%$: twenty times its tenant share.
4. *Expected impact.* If every cell and silo fails $f = 2$ times a year, cells contribute $6 \times 2 \times 0.133 = 1.60$ revenue-weighted events per year and silos $20 \times 2 \times 0.010 = 0.40$: a total of 2.0, as if one compartment held everything and failed twice. Compartments do not cut expected loss; they make each event small, which is what contracts and reputations punish.

Interpretation. Cells cut the pool's blast radius sixfold. Silos have tiny tenant blast radius but disproportionate revenue blast radius. **Engineering implication.** Size cells by revenue at risk, canary in a pooled cell before any silo (§43.6), and automate silos exactly like cells, because each is a deployment that can fail on its own.

Table 47.2 — Tenancy-model failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Silo tier lags releases by months	Silos deployed by hand	Version skew dashboard	Automate silo rollout	Silos are cells of size one in the same pipeline
One pool outage hits every tenant	No cells	Global error spike	Restore pool	Cells sized by revenue at risk
Enterprise tenant overloads a pooled cell	Grew past the cell's tested size	Per-tenant share of cell load	Migrate to silo (§47.13)	Placement rules by tenant size (§47.6)

47.5 Data isolation patterns

47.5.1 Three ways to separate tenant data

Data isolation answers one question: what stops a query for tenant A from returning tenant B's rows?

DEFINITION

Definition — Database-per-tenant, schema-per-tenant and shared tables. In **database-per-tenant**, each tenant's data lives in its own database or cluster, and the connection selects the tenant. In **schema-per-tenant**, tenants share a server but each has its own schema, selected by the search path or qualified names. In **shared tables**, all tenants' rows share tables and are distinguished by a `tenant_id` column that every query must filter on, ideally enforced by the database with **row-level security (RLS)**.

First-principles explanation

A storage company can give each customer a separate building, a locked room in a shared building, or a labeled shelf in a shared room with a guard who checks labels on every withdrawal. The building is safest and dearest; the shelf is cheapest and only as safe as the guard.

Why does this exist?

TaskForge cannot afford 40,000 database servers, yet one forgotten `WHERE tenant_id = ?` in shared tables leaks a customer's data, the worst incident a SaaS company can have. Each pattern is a point on the cost-versus-safety curve, and products often mix them by tier.

Table 47.3 — Data isolation patterns compared.

Row	Database-per-tenant	Schema-per-tenant	Shared tables + RLS
What it is	One database or cluster per tenant	One schema per tenant in a shared server	`tenant_id` column, policy on every table
How it works	Connection string selects tenant	`search_path` or qualified names	Session variable plus policy predicate
Advantages	Physical separation; per-tenant backup, restore, residency, keys	Logical separation; simpler per-tenant restore	Cheapest; one migration; millions of tenants
Disadvantages	Cost per idle tenant; migrations fan out N times	Catalog bloat at tens of thousands of schemas	Context bug leaks data; noisy neighbors
Performance	Predictable per tenant	Shared buffer pool and I/O	Shared; needs `tenant_id`-leading indexes
Operational complexity	High (fleet of databases)	Medium-high	Low to medium
Cost	Highest	Medium	Lowest
Use cases	Enterprise and regulated tenants	Hundreds to low thousands of tenants	Self-serve SaaS, many small tenants
Choose when	Contract or residency requires it	Tenants need schema customizations	Tenants are many, small and alike

Practical limits drive the choice. At 40,000 tenants × 50 tables, schema-per-tenant puts 2 million tables in the system catalog, slowing planning, backups and migrations. Database-per-tenant multiplies connection pools (§14.13): 2,000 databases × 10 connections × 20 application instances is 400,000 connections, so it needs a multiplexing proxy. Shared tables need every index to lead with `tenant_id`, so each tenant's queries touch only its own index range.

47.5.2 Shared tables with row-level security

Filtering in application code works until one query forgets. **Row-level security** moves the predicate into the database: once enabled, every query from a non-exempt role is rewritten to include the table's policies, and with no policy the table returns nothing [PostgreSQL Docs: RLS].

How it works internally

1. Derive the tenant ID from the verified token, never from a URL, header or body field.
2. On a pooled connection, open a transaction and run `SET LOCAL app.tenant_id = '<id>'`, which lasts only until the transaction ends, so the next request cannot inherit it.

3. The policy's `USING` expression filters reads, updates and deletes; its `WITH CHECK` expression validates inserted and updated rows.
4. Connect as a role that is not a superuser, not the owner (unless `FORCE` is set) and lacks `BYPASSRLS`: those bypass policies.

The following SQL was run against PostgreSQL 16.

```
        -- Schema owned by a migration role; the application connects as app_user.
        CREATE ROLE app_owner NOLOGIN;
        CREATE ROLE app_user LOGIN;

        CREATE TABLE tasks (
          tenant_id uuid   NOT NULL,
          task_id   bigint GENERATED ALWAYS AS IDENTITY,
          title     text   NOT NULL,
          PRIMARY KEY (tenant_id, task_id)
        );
        ALTER TABLE tasks OWNER TO app_owner;
        GRANT SELECT, INSERT, UPDATE, DELETE ON tasks TO app_user;

        ALTER TABLE tasks ENABLE ROW LEVEL SECURITY;
        ALTER TABLE tasks FORCE ROW LEVEL SECURITY;   -- applies to the owner too

        CREATE POLICY tenant_isolation ON tasks
          USING      (tenant_id = NULLIF(current_setting('app.tenant_id', true),
'')::uuid)
          WITH CHECK (tenant_id = NULLIF(current_setting('app.tenant_id', true),
'')::uuid);
```

The isolation test below seeds two tenants as a superuser (which bypasses RLS) and then acts as `app_user`. Comments show the output observed.

```
INSERT INTO tasks (tenant_id, title) VALUES
  ('00000000-0000-0000-0000-00000000000a', 'A: ship release'),
  ('00000000-0000-0000-0000-00000000000a', 'A: fix login'),
  ('00000000-0000-0000-0000-00000000000b', 'B: quarterly report');

SET ROLE app_user;

-- 1. No tenant set: the predicate is NULL, so no rows.          -> 0
SELECT count(*) FROM tasks;

-- 2. Tenant A sees only its rows, with no WHERE clause.
BEGIN;
SET LOCAL app.tenant_id = '00000000-0000-0000-0000-00000000000a';
SELECT title FROM tasks ORDER BY task_id;      -- A: ship release, A: fix login
-- 3. A forged filter on B's tenant_id returns nothing.          -> 0
SELECT count(*) FROM tasks
 WHERE tenant_id = '00000000-0000-0000-0000-00000000000b';
-- 4. Updating B's rows changes nothing.                         -> UPDATE 0
UPDATE tasks SET title = 'pwned' WHERE title LIKE 'B:%';
COMMIT;

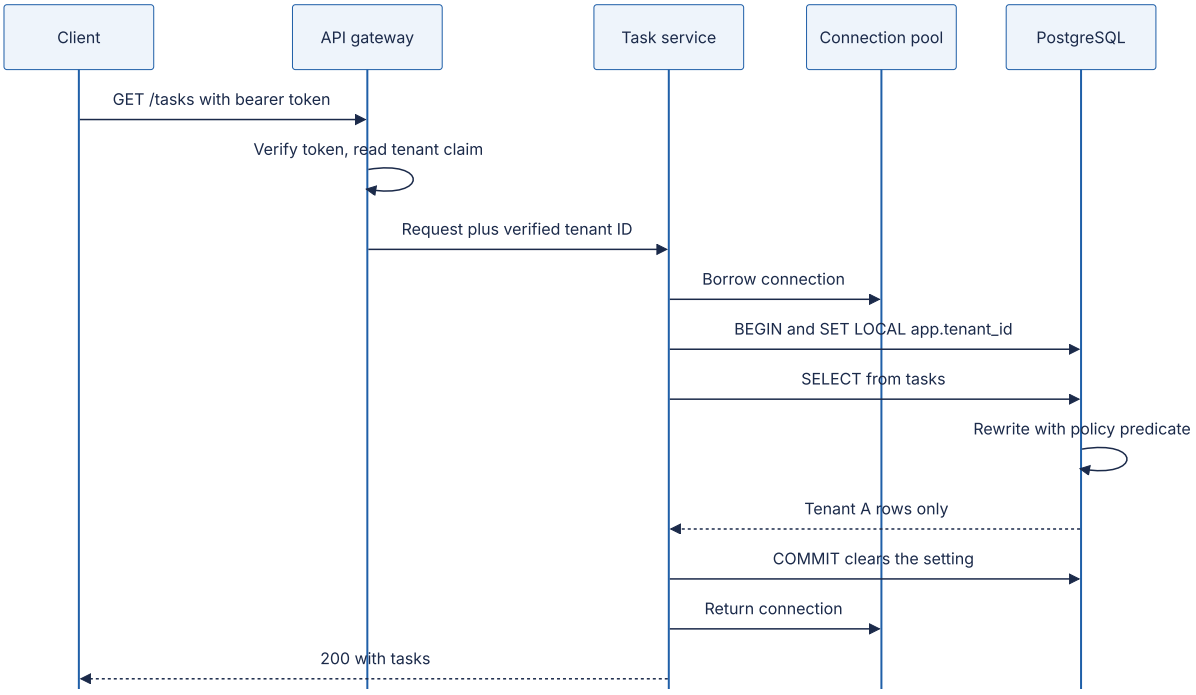
-- 5. Writing a row for another tenant is rejected by WITH CHECK.
BEGIN;
SET LOCAL app.tenant_id = '00000000-0000-0000-0000-00000000000a';
INSERT INTO tasks (tenant_id, title)
  VALUES ('00000000-0000-0000-0000-00000000000b', 'A writes into B');
-- ERROR: new row violates row-level security policy for table "tasks"
ROLLBACK;

-- 6. After the transaction, the setting is gone on this pooled
--    connection: the next request does not inherit tenant A.    -> 0
SELECT count(*) FROM tasks;
```

What to notice:

- Without `FORCE ROW LEVEL SECURITY` the owner bypasses its own policies; superusers and `BYPASSRLS` roles always do.
- `current_setting('app.tenant_id', true)` returns NULL if the setting was never defined but an **empty string** after a `SET LOCAL` has ended in the same session, and `''::uuid` raises an error. `NULLIF(..., '')` makes both cases NULL, so an unset tenant fails closed with zero rows; test 6 failed until we added it.
- Test 3 matters most: even code that explicitly asks for B's rows gets nothing.
- The primary key leads with `tenant_id`, so filtered lookups use the index; secondary indexes should too.
- Constraint checks see all rows, so a global unique constraint can reveal that a value exists in another tenant: use `UNIQUE (tenant_id, value)`. `SECURITY DEFINER` functions and views owned by bypassing roles need separate review [PostgreSQL Docs: RLS].

Figure 47.4 — Tenant context on the request path with RLS.



Reading the diagram. The gateway verifies the bearer token and extracts the tenant claim, the only trusted source of tenant identity. The service borrows a pooled connection and sets the tenant for one transaction; PostgreSQL rewrites each statement with the policy, so the storage boundary itself enforces isolation. All calls are synchronous. Failure points: session-level `SET` leaks context through the pool; connecting as owner without `FORCE`, or as superuser, bypasses the policy. Scaling: the extra predicate is negligible with tenant-leading indexes; the database scales by sharding on `tenant_id` (§47.6).

INDUSTRY EXAMPLE

Salesforce's metadata-driven multitenancy. Force.com stores all customer organizations' data in a few large shared tables, with an organization ID on every row. Customer-defined objects and fields are rows in metadata tables; their data lives in generic "flex" columns of a shared data table, with pivot tables supplying indexes and relationships. The query layer generates organization-scoped SQL from metadata, so tenants customize schemas without DDL on the shared database [Weissman and Bobrowski 2009]. The price is a sophisticated query compiler in place of native schemas, accepted because per-customer DDL on a shared database would be unworkable. *Evidence: Primary* — [Weissman and Bobrowski 2009]

47.5.3 Choosing among the patterns

1. **Default to shared tables with RLS** for thousands of similar tenants, with the policy from day one; retrofitting `tenant_id` is a full migration.
2. **Move a tenant to its own database** when contract, residency, per-tenant restore or size requires it (§47.13), keeping the same schema and `tenant_id` column so the

code path is identical.
3. **Avoid schema-per-tenant at large tenant counts** unless tenants need different schemas: it combines database-per-tenant's migration fan-out with a pool's contention.

COMMON MISTAKE

Common misconception — "RLS makes the application secure." RLS stops a query returning another tenant's rows once the tenant is set. It cannot stop the application setting the wrong tenant (say, from a client header), nor leaks through caches, search indexes, object storage, logs or jobs that never touch protected tables. Each needs its own tenant scoping (§47.12).

47.5.4 Encryption per tenant

Access controls decide who may read data; encryption decides what an attacker who bypasses them sees.

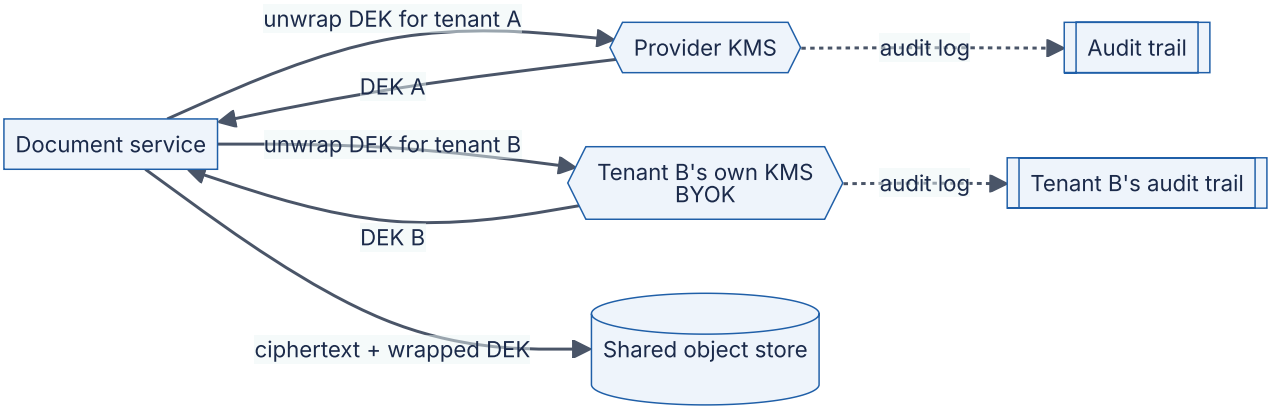
DEFINITION

Definition — Per-tenant keys, BYOK and crypto-shredding. With **per-tenant keys**, each tenant's data encryption keys (DEKs) are wrapped by a key-encryption key (KEK) unique to that tenant in a key management service (KMS), which is envelope encryption (§10.9.2). **Bring your own key (BYOK)** lets the tenant create or import the KEK in a KMS it controls, so it can audit and revoke every use; **hold your own key (HYOK)** keeps it outside the provider entirely. **Crypto-shredding** deletes data by destroying its key, making every copy, including backups, unreadable.

How it works internally

1. Onboarding creates the tenant's KEK, or records the ARN of its BYOK key and the grant allowing the service to use it.
2. On write, the service encrypts with a DEK and stores the DEK, wrapped by the tenant's KEK, beside the ciphertext.
3. On read, the KMS unwraps the DEK after checking the caller may use *this tenant's* key, and logs the call. Unwrapped DEKs are cached for minutes to keep the KMS off the hot path.
4. Revocation (BYOK) or key deletion at offboarding makes the tenant's data unreadable once caches expire.

Figure 47.5 — Per-tenant envelope encryption with an optional customer-held key.



Reading the diagram. All tenants' encrypted objects share one object store, each beside its wrapped DEK. To read, the service makes a synchronous, authenticated TLS call to unwrap the DEK: the provider KMS for A, B's own KMS for B. Audit records flow asynchronously to each key owner. The object store holds only ciphertext. Failure points: if B's KMS is down or B revokes the key, B's data is unreadable by design while A is unaffected; a long-lived DEK cache weakens revocation. Scaling: KMS request quotas are the limit, so cache and reuse DEKs.

The trade-offs are concrete. Per-tenant keys stop cross-tenant reads caused by *storage-side* mistakes (a wrong bucket path, a stolen backup), but an application tricked into serving B's request as A will unwrap A's key happily. BYOK adds a dependency the provider does not operate: a tenant's key outage is a tenant outage. Crypto-shredding fails if a DEK is logged, cached indefinitely or also wrapped by a shared key. Cloud KMSs support imported key material and external key stores (for example AWS KMS [AWS Docs: KMS]); features and quotas vary by provider (as of 2026).

Table 47.4 — Data isolation failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Tenant A sees tenant B's records	Query missing tenant filter	Customer report; cross-tenant canary test	Revoke, notify, audit access logs	RLS with `FORCE`; tenant-leading keys
Tenant context leaks through pool	Session `SET` instead of `SET LOCAL`	Isolation test on reused connection	Fix, recycle sessions	Transaction-scoped settings
Migration takes hours	Schema-per-tenant at 40,000 schemas	Migration duration per release	Batch and parallelize	Shared tables for small tenants
Tenant locked out of own data	BYOK key disabled or KMS outage	Decrypt errors for one tenant	Tenant re-enables key	Clear BYOK contract; per-tenant alerts

47.6 Tenant-aware sharding and placement

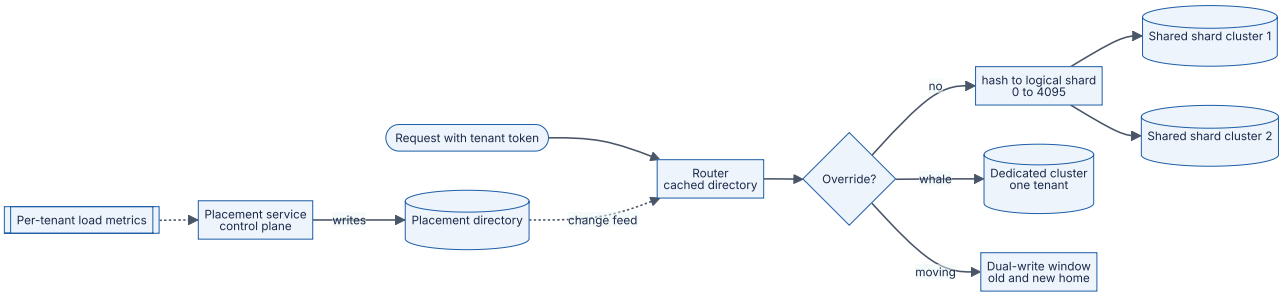
47.6.1 The tenant directory

§14.7.2 chose `tenant_id` as TaskForge's shard key, so each tenant's queries, transactions, backups and deletions stay on one shard. This section adds where each tenant goes and how big tenants are handled.

> DEFINITION
>
> **Definition — Tenant placement directory.** A small, highly available mapping from tenant ID to location (cell, shard or dedicated cluster), owned by the control plane and cached by every router. It lets the system place, move and isolate individual tenants, which pure hashing cannot.

Pure hashing (`hash(tenant_id) mod S`, or consistent hashing, §14.8) needs no lookup but puts each tenant wherever the hash says, whatever its size. A cached directory costs microseconds per lookup and buys three things: placing new tenants on the least-loaded shard, moving one tenant alone, and giving a whale its own cluster. The common hybrid (§14.7.2) hashes tenants into fixed logical shards and keeps a directory of **overrides**.

Figure 47.6 — Tenant placement with a directory, overrides and whale isolation.



Reading the diagram. The router checks the override list, otherwise hashes to a logical shard mapped to a shared cluster; both come from a cache fed asynchronously by the directory. Whales have dedicated clusters; a tenant in transit is routed through a dual-write or cutover state (§14.9.5). The placement service reads per-tenant load and writes decisions to the directory. Shard clusters are the storage boundaries. Failure points: a stale cache can send writes to a tenant's old home, so clusters must fence (reject) writes for tenants they do not own; a directory outage must not stop routing from cache. Scaling: add clusters and move logical shards, or promote a growing tenant to an override.

47.6.2 Whale tenants and placement balance

Tenant sizes are heavy-tailed: TaskForge's median tenant has 15 users, its largest 60,000. A **whale** is a tenant whose placement alone determines a shard's load.

FORMULA

Placement imbalance and the whale threshold

$$I = \frac{\max_s L_s}{L/S} \qquad \text{tenant } i \text{ is a whale if } \quad \ell_i > f \cdot \frac{L}{S}$$

Symbol	Meaning	Units
L_s	Load on shard s (data size, request rate or CPU, whichever binds)	% of total, or RPS
L	Total load across all shards	same as L_s
S	Number of physical shards	shards
I	Imbalance factor: hottest shard relative to the mean (1.0 is perfect)	dimensionless
ℓ_i	Load of tenant i	same as L_s
f	Whale threshold as a fraction of the mean shard load (a policy choice, e.g. 0.2)	dimensionless

WORKED EXAMPLE

Worked example — TaskForge's whales on 32 and 256 shards. Suppose the five largest tenants carry 2.0%, 1.5%, 1.0%, 0.8% and 0.7% of total load, and the remaining 94% is spread across 39,995 small tenants.

32 shards.

1. Mean shard load $L/S = 100\%/32 = 3.125\%$.
2. Randomly placed, the 2.0% tenant shares a shard with a typical load of small tenants, $94\%/32 = 2.94\%$, so that shard carries 4.94%: $I \approx 4.94/3.125 = 1.58$, worse if two whales collide.
3. Whale threshold with $f = 0.2$: $0.2 \times 3.125\% = 0.625\%$. All five large tenants (6.0% in total) are whales.
4. Fix: place whales first, largest first, on separate shards, then fill each shard with small tenants to 3.125% (the 2.0% whale's shard takes only 1.125%). I falls to about 1.0.

256 shards (the fleet has grown).

1. Mean shard load $= 100\%/256 = 0.39\%$.
2. The 2.0% tenant is $2.0/0.39 = 5.1$ shards' worth of load; no shared shard can hold it.
3. It needs a dedicated cluster of that size, or a split by a second key such as `(tenant_id, project_id)` (§14.7.2).

Interpretation. Whales grow relative to the fleet, because the mean shard shrinks while the largest tenant does not. **Engineering implication.** Place whales explicitly, review the whale list whenever the shard count changes, and keep the data model splittable for a tenant that outgrows the largest cluster.

47.6.3 Rebalancing, cells and placement policy

Placement is continuous:

1. **Initial placement** puts a new tenant in the cell and shard with most headroom, subject to residency region (Chapter 44), tier and anti-affinity (a reseller and its customers in different cells).
2. **Monitoring** tracks each tenant's share of its shard's CPU, storage, IOPS and request rate (§47.11).
3. **Promotion** moves a tenant that crosses the whale threshold to a larger shard or dedicated cluster in its quiet hours.
4. **Moving** applies the online migration of §14.9.5 to one tenant: snapshot, stream changes, verify, flip the directory entry with a fence, delete the old copy.

5. **Cells** (§33.12) are the outer placement unit; a tenant lives in one cell, so cell and shard are chosen together.

For stateless pooled tiers, shuffle sharding (§33.12.2) complements placement: with each tenant on a random 5 of 100 workers, a poison tenant fully disables another only if that tenant's whole subset failed, about one chance in 75 million [MacCárthaigh 2019].

INDUSTRY EXAMPLE

Citus tenant isolation. Citus, a distributed PostgreSQL extension, documents a multi-tenant pattern that distributes and co-locates tables by `tenant_id`, keeping each tenant's joins on one node, and provides a function that moves one large tenant's rows into a dedicated shard that can be placed on its own node: the directory override implemented inside the database [Citus Docs]. *Evidence: Primary* — [Citus Docs]

COMMON MISTAKE

Common misconception — "Consistent hashing balances tenants." It balances *keys*. With heavy-tailed tenants, tenant counts per shard can be even while load is badly skewed. Balance by measured load and place the largest tenants by policy.

47.7 Noisy neighbors

47.7.1 What contends, and how

DEFINITION

Definition — Noisy neighbor. A tenant whose consumption of a shared resource degrades other tenants' performance. It need not exceed any limit; it only has to consume a resource that others also need and that is not partitioned.

First-principles explanation

A colleague's loud phone call takes neither your desk nor your computer, yet you cannot work. Likewise, CPU quotas can be perfectly fair while one tenant thrashes the shared cache or fills the disk queue and everyone's latency doubles. Isolation is only as good as the *least* partitioned resource on the path.

How it works internally

Table 47.5 — Shared resources, contention mechanisms and per-tenant signals.

Resource	How a neighbor hurts you	Per-tenant signal	Isolation mechanism
CPU cores	Run-queue delay, throttling	CPU-seconds, run-queue latency	cgroup weights and quotas (§42.3.2), dedicated cores
Last-level cache, memory bandwidth	Evicts your lines; saturates memory bus	Cycles per instruction (CPI), misses	Cache and bandwidth partitioning (e.g. Intel RDT), separate hosts
Disk and network I/O	Fills device queues; burns IOPS	IOPS, bytes, queue depth	cgroup I/O weights, per-volume limits
Connection pools	Holds connections with slow queries	Connections held, wait time	Per-tenant pool partitions (§22.14)
Database	Expensive queries, locks, vacuum debt	Query time, rows scanned, lock waits	Statement timeouts, concurrency caps, sharding
Caches	Large working set evicts others	Hit ratio and bytes by tenant prefix	Per-tenant cache quotas
Queues and streams	Backlog delays everyone behind it	Lag and enqueue rate	Per-tenant queues, fair dequeue (§47.8)

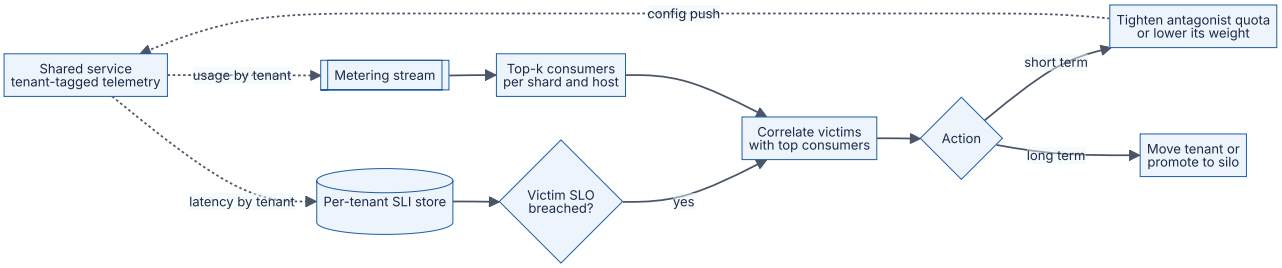
CPU, memory and pool contention show up in standard metrics. Cache and memory-bandwidth interference does not: the victim's CPU use may even fall while latency rises, because it stalls on memory. Google's CPI² learns each job's normal cycles-per-instruction distribution, flags victims whose CPI rises outside it, identifies the co-located task whose CPU use correlates with the slowdown, and can throttle it [Zhang et al. 2013]. Heracles uses cache partitioning, core isolation and network shaping to co-locate batch work beside latency-critical services within their SLOs [Lo et al. 2015].

47.7.2 Detection

You cannot fix a neighbor you cannot name. Detection needs:

1. **Per-tenant accounting at each shared resource**: requests, CPU time, rows read, bytes and cache use, tagged with tenant ID (§47.11 avoids the cardinality trap).
2. **Per-tenant SLIs**: a global p99 hides a tenant whose p99 tripled; compute SLIs per tier and for top tenants by revenue.
3. **Correlation**: when a victim degrades, rank tenants on the same shard, cell or host by change in consumption over that window.

Figure 47.7 — Detecting and containing a noisy neighbor.



Reading the diagram. The service emits tenant-tagged usage and latency asynchronously (dotted). A top-k job ranks consumers per shard and host; when a victim breaches its SLO, a correlation step matches it with the top consumers on the same resources. The short-term action tightens the antagonist's quota or weight by configuration push; the long-term action moves it (§47.6.3). Failure points: untagged telemetry makes correlation impossible, and a wrong correlation punishes an innocent tenant, so keep a human in the loop beyond quota tweaks. Heavy-hitter sketches (§17.6.2) keep ranking cheap at tens of thousands of tenants.

> WARNING / TRADE-OFF
>
> **Warning — Rate quotas do not cap cost.** A tenant within its RPS limit can still run the most expensive search or scan a million rows per call. Quota the scarce unit (rows scanned, CPU-milliseconds, bytes) or weight each request by estimated cost, as §47.8 does.

Table 47.6 — Noisy-neighbor failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
All tenants slow on one shard	One tenant's export scans full tables	Rows scanned by tenant jumps	Throttle export	Cost-based quotas; exports on replicas
p99 doubles, CPU normal	Cache or memory-bandwidth antagonist	CPI rises on victims	Move antagonist	Cache partitioning; whales on own hosts
Connection pool exhausted	One tenant's slow queries	Connections held by tenant	Statement timeout	Per-tenant pool partitions
Queue lag for everyone	One tenant enqueued a million jobs	Enqueue rate by tenant	Divert to overflow queue	Per-tenant queues, fair dequeue

47.8 Quotas, rate limits and fair share per tenant

47.8.1 Three controls, three questions

Performance isolation in a pooled service rests on three controls:

1. **Quotas**: *how much may this tenant use in total?* (projects, storage, calls per day). Business limits tied to the tier, enforced by the control plane or at write time.
2. **Rate limits**: *how fast may it send?* A per-tenant token bucket (§22.4) with rate r and burst b admits at most $b + rT$ requests in any interval T and rejects the rest with 429 and `Retry-After`.
3. **Fair scheduling**: *when the service is busy, whose admitted work goes next?* Per-tenant queues and a fair scheduler divide the capacity that exists among tenants that want it.

Rate limits alone are not enough, because per-tenant limits are always **oversubscribed**: if every tenant used its full limit at once, demand would far exceed capacity. That is the pooling saving of §47.3.2, but it means admission alone cannot guarantee prompt service to tenants within their limits.

WORKED EXAMPLE

Worked example — Per-tenant limits in one TaskForge cell. A cell with capacity $C = 20,000$ RPS holds 6,000 free tenants ($r = 10$ RPS, $b = 20$), 1,900 team tenants ($r = 100$, $b = 200$) and 10 pooled enterprise tenants ($r = 1,000$, $b = 2,000$). Measured aggregate peak: 12,000 RPS.

1. Sum of limits: $6,000 \times 10 + 1,900 \times 100 + 10 \times 1,000 = 60,000 + 190,000 + 10,000 = 260,000$ RPS.
2. Oversubscription: $260,000/20,000 = 13\times$.
3. Largest tenant: $1,000/20,000 = 5\%$ of the cell, so no single tenant at its limit can overload it.
4. Headroom at peak: $20,000 - 12,000 = 8,000$ RPS, consumed by eight enterprise tenants bursting together, or 80 team tenants.
5. Bursts: 80 team tenants emptying full buckets send $80 \times 200 = 16,000$ requests at once, two seconds of headroom.

Interpretation. Rate limits bound what *one* tenant can do. Correlated bursts within limits need fair queuing, which divides a shortage fairly, and shedding by priority (§22.9.2), which decides who loses when fair shares cannot be met. **Engineering implication.** Keep each limit a small fraction of cell capacity, track oversubscription and aggregate p99.9 against capacity as cell-health metrics, and split cells before correlated bursts become routine.

47.8.2 Fair queuing

DEFINITION

Definition — Fair queuing and weighted fair queuing. Fair queuing keeps a queue per flow (here, per tenant) and serves them so that each backlogged flow gets an equal share of capacity, however much any one flow sends [Demers et al. 1989]. **Weighted fair queuing (WFQ)** gives flow i a share proportional to weight w_i. The allocation is **max–min fair**: no tenant can get more without taking from one that has less.

First-principles explanation

At one checkout with a shared line, a shopper with 500 items ahead of you makes you wait however few items you have. Give every shopper a line and let the cashier take one item from each line in turn: the big shopper still progresses, one item per round, and your three items are done in three rounds. Weighting lets a premium line contribute several items per round.

How it works internally

Demers, Keshav and Shenker emulated an ideal bit-by-bit round robin: each packet is stamped with the time it *would* finish under that ideal, and the gateway sends the smallest stamp first [Demers et al. 1989]. Generalized Processor Sharing extends the ideal to weights [Parekh and Gallager 1993]. Practical approximations:

1. **Finish tags (self-clocked fair queuing).** Request k of tenant i gets tag $F_{i,k} = \max(V, F_{i,k-1}) + c_k / w_i$, with c_k its cost and V the tag last served; the smallest tag goes next [Golestani 1994]. A flooding tenant's tags run far into the future, so other tenants' new requests overtake them.
2. **Deficit round robin (DRR).** Visit queues in turn, add a quantum proportional to w_i to each tenant's deficit, and serve while costs fit: $O(1)$ per request [Shreedhar and Varghese 1995].
3. **Bounded per-tenant queues.** A full queue sheds that tenant's requests (503) only, so the backlog itself becomes a bulkhead.

FORMULA

Weighted max-min fair share (water-filling, as in §46.9.1)

$$a_i = \min(d_i, w_i\,\theta), \qquad \text{with } \theta \text{ chosen so that } \sum_i a_i = C \quad (\text{if } \sum_i d_i > C)$$

Symbol	Meaning	Units
C	Service capacity	RPS (or cost units/s)
d_i	Admitted demand of tenant i (after its rate limit)	RPS
w_i	Weight of tenant i (for example by tier)	dimensionless
θ	Fair-share level per unit of weight (the “water level”)	RPS per unit weight
a_i	Throughput allocated to tenant i	RPS

WORKED EXAMPLE

Worked example — One noisy tenant, and one weighted pair.

Equal weights. $C = 1,000$ RPS. After rate limits, acme presents 500 RPS and beta, gamma and delta 200 each: 1,100 RPS in total.

1. Try $\theta = 250$: $\min(500, 250) + 3 \times 200 = 850 < 1,000$, so raise θ.
2. The three small tenants stay satisfied at 200 each; acme gets the rest: $\theta + 600 = 1,000$, so $\theta = 400$.
3. Allocation: 200 each for beta, gamma and delta (100% of demand); 400 for acme (80%). Acme’s surplus queues, then is shed.

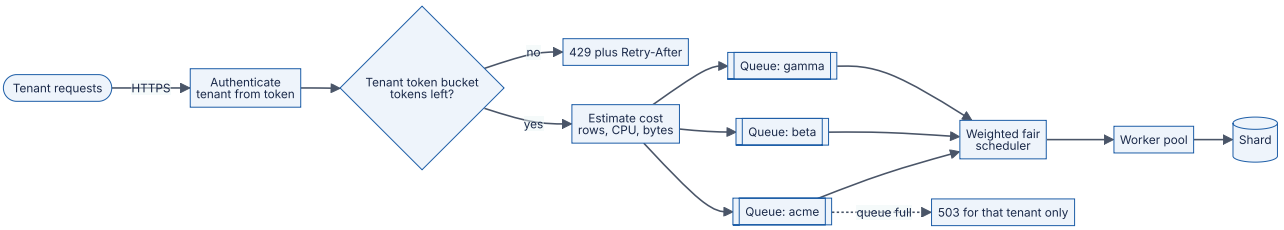
Weights 3:1. Gold ($w = 3$) and free ($w = 1$) each demand 2,000 RPS with $C = 1,000$: $3\theta + \theta = 1,000$, $\theta = 250$, so gold gets 750 RPS and free 250.

Interpretation. Tenants asking for less than their share get all of it; only those asking for more are cut, and unused shares flow to them. **Engineering implication.** A well-behaved tenant’s service no longer depends on the noisy one, which the simulation below confirms.

One-dimensional fairness is not the whole story: a tenant may be light on CPU and heavy on memory. **Dominant Resource Fairness (DRF)** equalizes each tenant’s share of its most-used resource [Ghodsi et al. 2011]; §46.9.3 covers it.

47.8.3 Admission control as a pipeline

Figure 47.8 — Per-tenant admission: rate limit, cost, fair queue, workers.



Reading the diagram. Authentication identifies the tenant before any shared resource is spent. The tenant's token bucket rejects excess rate cheaply with 429. Admitted requests get a cost estimate and join their tenant's bounded queue; the weighted fair scheduler feeds the shared workers, which call the shard synchronously. A full queue sheds only its own tenant (dotted). Failure points: per-node buckets drift from the global limit unless quota is distributed (§22.8.3); underestimated costs let expensive requests through. Scaling: a few numbers per tenant fit tens of thousands of tenants in memory; add workers to raise C.

47.8.4 Simulation: containing a noisy tenant

The program simulates a 1,000 RPS service (one request per millisecond) shared by four tenants for 10 s. Each sends 200 RPS of Poisson traffic; acme bursts to 2,500 RPS from $t = 2$ s to $t = 6$ s. Policies: a shared FIFO queue; per-tenant token buckets ($r = 500$, $b = 100$) before the FIFO; and the same buckets before bounded per-tenant queues with self-clocked WFQ. A final test checks a 3:1 weighted split.

```

Table 47.7 — What each policy does to the quiet tenants (beta, gamma, delta).

Policy	Quiet tenants' requests shed	Quiet tenants' p99 latency	Who absorbs acme's burst
Shared FIFO, no limits	28% (563–586 of about 2,000 each)	2,000 ms	Everyone, equally
Token buckets + FIFO	0	about 480 ms	Everyone, through a shared backlog
Token buckets + WFQ	0	16–28 ms	Acme only (429s, then 503s from its own queue)

What to notice:

- **FIFO** lets acme fill the shared 2,000-slot queue: everyone waits 2 s and loses over a quarter of requests, and acme gets the most service because it sends the most.
- **Token buckets alone** cut acme to 500 RPS (7,892 rejections), but $500 + 3 \times 200 = 1,100$ RPS still exceeds capacity because limits are oversubscribed; the shared queue grows about 100 requests per second for 4 s, and everyone sees about 480 ms of delay.
- **Buckets plus WFQ** confine the excess to acme's queue: acme gets the 400 RPS predicted in §47.8.2, sheds 285 requests with 503 and reaches 589 ms p99; the quiet tenants lose nothing.
- Quiet tenants' p99 under WFQ (16–28 ms) exceeds the no-burst baseline (about 10 ms, same seed) because, while acme is backlogged, each is guaranteed only 250

RPS and uses 200. An M/D/1 queue at $\rho = 0.8$ and service rate 250/s has mean wait $\rho/(2\mu(1-\rho)) = 0.8/(2 \times 250 \times 0.2) = 8$ ms. Fair queuing bounds latency by a tenant's share, not the whole server.

- The weighted test confirms the 750:250 split. Production schedulers put the request's cost in place of the constant 1 in the tag.

RECOMMENDATION

Recommendation — Layer the controls. Use per-tenant token buckets at the edge, cost-weighted fair queuing before each scarce resource, bounded per-tenant queues, and shedding by tier as the last line (§22.9.2). Each handles a failure the others cannot.

47.9 The compute isolation spectrum

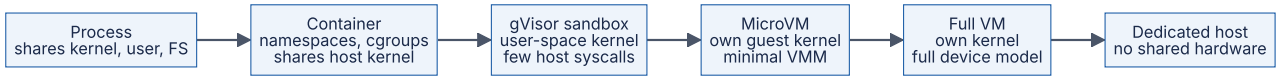
47.9.1 What each boundary shares

When tenants run *code* (functions, CI jobs, notebooks, TaskForge's tenant-written automation scripts), the compute boundary must stop a deliberately malicious program. For each option ask: what does the code share with its neighbors, and how much of it can it attack?

DEFINITION

Definition — Isolation boundary and attack surface. An **isolation boundary** separates one tenant's running code from others': a process, container, user-space kernel, hypervisor or separate hardware. Its **shared attack surface** is the interface callable across it: for a container, the host kernel's several hundred system calls; for a VM, the far smaller virtual-hardware interface.

Figure 47.9 — The compute isolation spectrum, from most shared to least.



Reading the diagram. Each step right removes a shared layer and costs more memory, start time or money per tenant; the arrows show increasing isolation, not data flow. A **process** shares the kernel, users and file system. A **container** gets its own view of processes, mounts and network from namespaces and resource caps from cgroups (§42.3), but every system call reaches the shared host kernel, so one kernel bug can become an escape. **gVisor** handles system calls in a user-space kernel, exposing only a small filtered set to the host. A **microVM** gives each tenant a guest kernel behind hardware virtualiza-

tion with a minimal device model; a **full VM** does so with a general-purpose one. A **dedicated host** shares no hardware, which also removes microarchitectural side channels (§47.12.3).

47.9.2 How gVisor and Firecracker work

gVisor interposes an application kernel, the **Sentry**, written in Go. A platform mechanism (the default **systrap** uses seccomp to trap system calls; a KVM platform also exists) redirects the application's system calls to the Sentry, which implements them in user space and makes only a restricted, seccomp-filtered set of host calls; a separate **Gofer** can mediate file access [gVisor Docs]. System-call-heavy and I/O-heavy workloads pay overhead; CPU-bound code runs near native speed.

Firecracker is a KVM-based virtual machine monitor written in Rust for serverless workloads [Agache et al. 2020]. It emulates only a few devices (virtio network and block, a serial console, a minimal keyboard controller for reset), with no BIOS or PCI, keeping attack surface and boot path small. A **jailer** further confines each Firecracker process with namespaces, cgroups and seccomp, so escaping the guest lands in a restricted process. The paper reports boot to application code in as little as 125 ms, under 5 MiB of VMM memory overhead per microVM, and up to 150 microVMs created per second per host.

> INDUSTRY EXAMPLE
>
> **AWS Lambda and Firecracker.** Lambda needed VM-grade isolation for untrusted code from many customers at container-like density and start-up speed. The paper explains that Lambda originally used containers to separate functions and separate VMs to separate customer accounts, which wasted capacity; Firecracker let it run each execution environment in its own microVM and pack microVMs of different customers onto one host, trading generality (a minimal device model, a jailer, KVM rather than a new hypervisor) for a small trusted code base [Agache et al. 2020]. Chapter 48 covers Lambda's internals. *Evidence: Primary* — [Agache et al. 2020]

47.9.3 Comparing boundaries and their cost

Table 47.8 — Compute isolation spectrum (figures as of 2026; verify for your versions).

Boundary	Shared attack surface	Start time	Per-instance overhead	Density	Untrusted multi-tenant code?
Process	Kernel, user, file system	~ms	~0	Highest	No
Container (runc)	Full host kernel syscall interface	~0.1–1 s	~MiB (shim, runtime)	Very high	No, unless hardened and tenants semi-trusted
gVisor (runsc)	Sentry plus a small filtered set of host syscalls	Slightly slower than runc	Tens of MiB (Sentry, Gofer), syscall CPU overhead	High	Yes, for many workloads
MicroVM (Firecracker, Kata)	Minimal virtual devices, KVM	~125 ms boot (Firecracker)	< 5 MiB VMM plus guest kernel memory	High	Yes
Full VM	Virtual devices, hypervisor	Tens of seconds	Hundreds of MiB (guest OS)	Medium	Yes
Dedicated host	None (except provider control plane)	Minutes	Whole host	Lowest	Yes, including side-channel concerns

FORMULA

Hosts and cost per tenant for an isolation choice

$$H = \left\lceil \frac{N\,(m + o)}{M} \right\rceil \qquad c = \frac{H\,p}{N}$$

Symbol	Meaning	Units
N	Tenant workloads to run concurrently	workloads
m	Memory a workload needs for itself	MiB
o	Isolation overhead per workload (runtime, sandbox, guest kernel)	MiB
M	Usable memory per host	MiB
H	Hosts required (memory-bound case)	hosts
p	Cost per host per month	dollars/month
c	Isolation-inclusive cost per tenant workload per month	dollars/month

WORKED EXAMPLE

Worked example — Hosting TaskForge Automations. 10,000 concurrently active tenant scripts each need $m = 128$ MiB. Hosts offer $M = 256$ GiB $= 262,144$ MiB usable at $p = \$3$/hour $\times$ 730 h $= \$2,190$/month. Overheads are illustrative planning assumptions, not vendor figures: container 2 MiB, gVisor 30 MiB, microVM 40 MiB (VMM plus trimmed guest kernel), full VM 512 MiB.

1. Container: $10,000 \times 130 = 1,300,000$ MiB; $1,300,000/262,144 = 4.96$, so $H = 5$; $c = 5 \times 2,190/10,000 = \$1.10$.
2. gVisor: $10,000 \times 158 = 1,580,000$; $6.03 \Rightarrow H = 7$; $c = 7 \times 2,190/10,000 = \$1.53$.
3. MicroVM: $10,000 \times 168 = 1,680,000$; $6.41 \Rightarrow H = 7$; $c = \$1.53$.
4. Full VM: $10,000 \times 640 = 6,400,000$; $24.41 \Rightarrow H = 25$; $c = 25 \times 2,190/10,000 = \$5.48$.
5. Dedicated host per tenant: $H = 10,000$; $c = \$2,190$.

Interpretation. For small workloads, overhead dominates: a microVM costs about 40% more than a container but runs untrusted code safely; a full VM costs five times as much, a dedicated host 2,000 times. **Engineering implication.** Sandboxes and microVMs suit numerous small untrusted workloads; price dedicated hosts for the contracts that need them. Repeat the sum for CPU: if a syscall-heavy workload loses, say, 20% throughput under gVisor, CPU may bind before memory.

47.9.4 Isolation in Kubernetes

The Kubernetes documentation lists the layers to combine on a shared cluster [Kubernetes Docs: Multi-tenancy]:

1. **Namespace per tenant**, with RBAC granting each tenant rights only in its namespaces.
2. **ResourceQuota** per namespace (CPU, memory, storage, object counts) and **LimitRange** for default and maximum pod requests.
3. **NetworkPolicy** denying traffic between namespaces by default (otherwise every pod reaches every pod, §42.9).
4. **RuntimeClass** to run untrusted pods under gVisor or Kata Containers (§42.3.4).
5. **Dedicated node pools** through taints, tolerations and affinity (§42.13.2).
6. **Control-plane isolation**: tenants share one API server, so use API priority and fairness, object-count quotas or a **virtual control plane** per tenant.

WARNING / TRADE-OFF

Warning — The shared kernel is the line. Namespaces, cgroups, quotas and network policies isolate semi-trusted teams. They do not make one kernel safe for mutually hostile tenants: put untrusted code behind gVisor, a microVM or a VM, away from nodes running privileged platform components.

47.10 Control plane and data plane

47.10.1 Two planes with different jobs

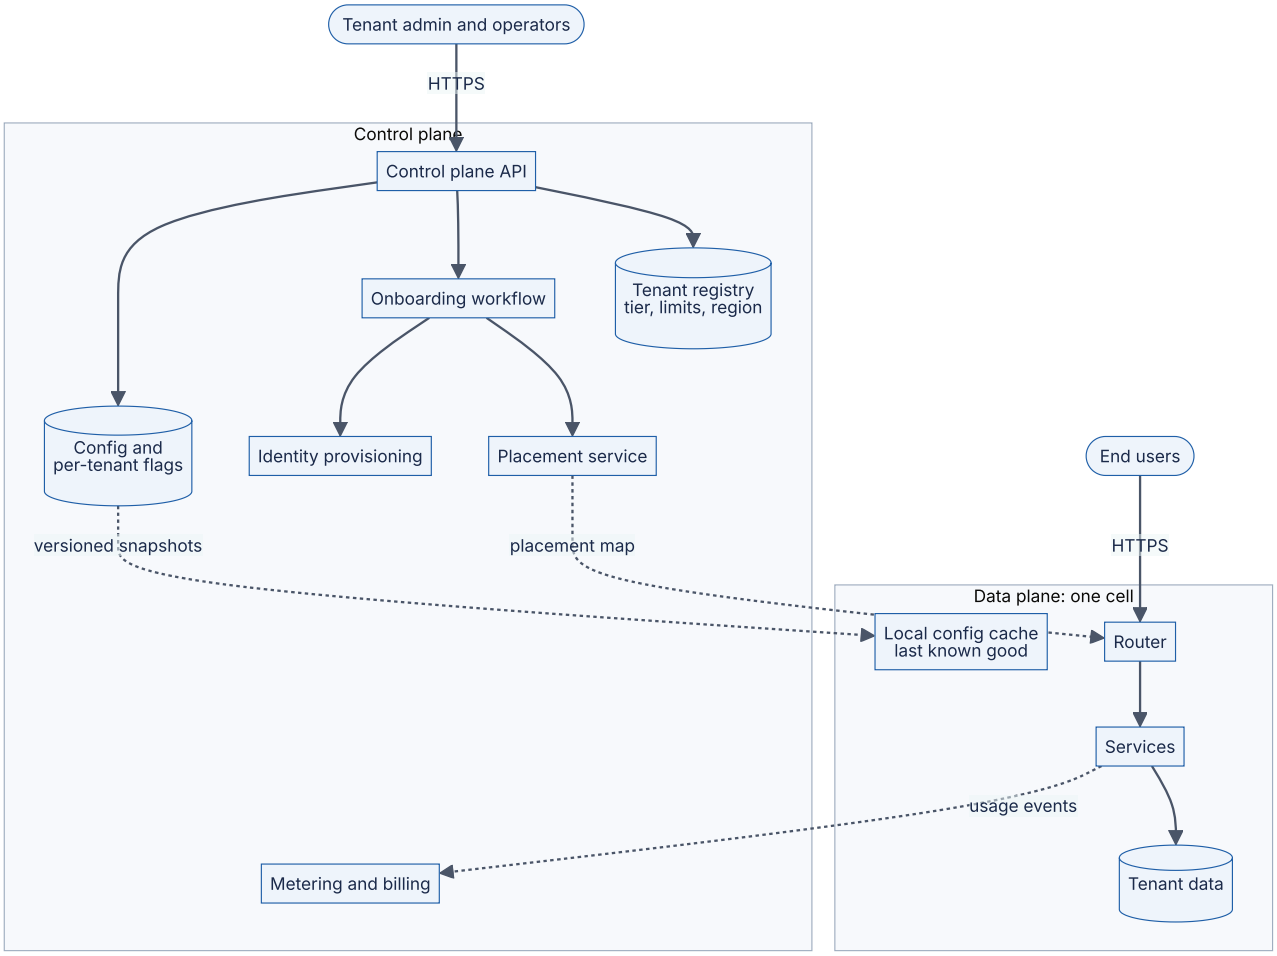
DEFINITION

Definition — Control plane and data plane (multi-tenant). The **data plane** serves tenants' requests: routers, services, caches and databases. The **control plane** manages tenants: onboarding and offboarding, provisioning and placement, configuration, tiers and limits, identities, and metering for billing. It serves operators and tenant administrators, not end-user traffic [AWS SaaS Fundamentals 2022].

Why does this exist?

Tenant management needs rich, slow workflows (approvals, provisioning, billing); request serving needs low latency and very high availability. Mixed together, a billing bug can stop request serving and one enterprise tenant's provisioning can slow everyone. Separated, each is built and scaled for its job, and the data plane keeps running when the control plane is down: **static stability** [Weiss and Furr 2020].

Figure 47.10 — Multi-tenant control plane and data plane.



Reading the diagram. Administrators use the control plane API, which records tenants in the registry and runs onboarding workflows calling placement and identity provisioning. Configuration, limits and flags are pushed asynchronously (dotted) as versioned snapshots into each cell's cache, and the placement map to routers. End-user requests stay in the data plane, synchronously; usage events flow back to metering asynchronously. Failure points: if the control plane fails, existing tenants keep working from cache but onboarding and limit changes stop; a bad snapshot is the main way the control plane can hurt the data plane, so snapshots are validated and rolled out cell by cell. The control plane scales with tenants and changes, the data plane with requests.

47.10.2 Onboarding, configuration and per-tenant flags

Onboarding is an automated, idempotent (§22.15), checkpointed workflow:

1. Create the tenant record (ID, tier, region, limits).
2. Place it: cell and shard if pooled; provision a silo from infrastructure code (§43.8) if premium.
3. Provision identity: an identity-provider organization, an admin user, token claims carrying the tenant ID.
4. Provision a KMS key (§47.5.4), storage prefixes, default configuration and quotas.

5. Publish placement and configuration, wait for the cell to acknowledge, then mark the tenant active.

A pooled tenant should be live in seconds, a silo in minutes. **Per-tenant configuration** (limits, weights, modules, retention) is stored centrally and distributed as versioned, validated snapshots; on a bad or missing snapshot the data plane keeps the last known good one.

Per-tenant feature flags (§43.7) are the main release tool: evaluate flags with the tenant as context, enabling a feature for internal tenants, then an early-access cohort, then a percentage of tenants, with change-controlled enterprise tenants in a later ring. A per-tenant kill switch disables a feature for one tenant without a deploy. Flags that change data formats cannot simply be turned off again, and every long-lived per-tenant flag is a fork that tests must cover, so retire them.

47.11 Observability and cost attribution per tenant

47.11.1 Tenant context everywhere, labels carefully

The questions you will be asked are per tenant: “why is Acme slow?”, “who filled shard 7?”, “what does Beta cost?” Answering them needs **tenant context propagation**: the tenant ID, taken once from the verified token, travels through RPC metadata, message headers and job payloads. OpenTelemetry **baggage** can carry it into traces and logs, but only as a telemetry label, never an authorization input, because any upstream hop can set it.

Where the tenant ID goes depends on the signal:

- **Logs and traces:** always. High-cardinality attributes are what logs and traces are for (§40.3.3).
- **Metrics:** carefully. A latency histogram labeled with route (25 values) and tenant (40,000) has $25 \times 40,000 \times 14 = 14$ million series before adding pod or status labels, far beyond what a Prometheus-style system holds comfortably (§40.5.3).

Three patterns keep per-tenant metrics affordable:

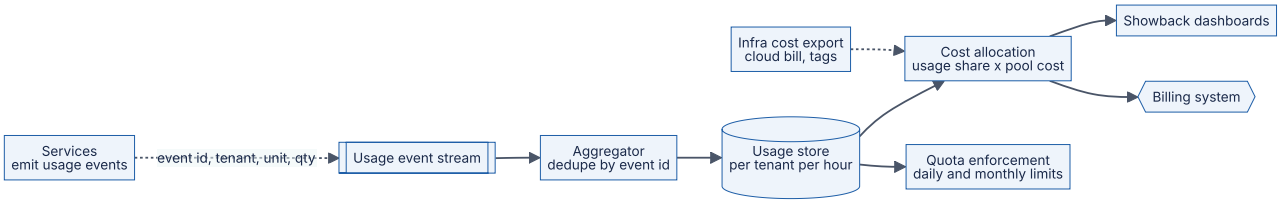
1. **Usage counters with few labels**: one per tenant per resource type (five types) is $40,000 \times 5 = 200,000$ series, manageable.
2. **Top-N plus “other”**: tenant-labeled histograms only for the top few hundred tenants; the rest fold into `tenant="other"` or a tier label.
3. **Wide events to a columnar store**: one event per request, with per-tenant percentiles computed by query where cardinality is cheap (§40.3.3).

47.11.2 Metering, showback and chargeback

DEFINITION

Definition — Metering, showback and chargeback. Metering records each tenant's consumption of billable or scarce resources as durable usage events. **Showback** reports the cost attributed to each tenant (or internal team) without billing it. **Chargeback** bills that cost to the tenant or team's budget. External SaaS turns metering into invoices; internal platforms use showback or chargeback to make teams see the cost of what they consume.

Figure 47.11 — Per-tenant metering pipeline.



Reading the diagram. Services emit usage events (event ID, tenant, unit, quantity) asynchronously to a durable stream. The aggregator deduplicates by event ID, because delivery is at least once (§30.8), and writes hourly per-tenant totals to the usage store. Cost allocation joins usage with the tagged cloud bill to produce showback and invoices; quota enforcement reads the same totals. Failure points: lost events under-bill and duplicates over-bill, so aggregation must be idempotent and reconciled against independent counts; emitting only on success misses the cost of failures. Scaling: partition the stream by tenant ID.

FORMULA

Usage-based cost allocation

$$C_i = \sum_r K_r \frac{u_{i,r}}{\sum_j u_{j,r}} + D_i \qquad \text{Margin}_i = \frac{P_i - C_i}{P_i}$$

Symbol	Meaning	Units
K_r	Total cost of shared resource pool r for the period (compute, database, observability)	dollars/month
$u_{i,r}$	Tenant i's metered usage of resource r	resource units (CPU-s, IO, GB)
D_i	Direct costs dedicated to tenant i (silo resources, own key, own index)	dollars/month
C_i	Cost attributed to tenant i	dollars/month
P_i	Price tenant i pays	dollars/month

WORKED EXAMPLE

Worked example — Is TaskForge's tenant "Northwind" profitable? One pooled cell costs $70,000/month in compute, $40,000 in its database and $10,000 in observability. Northwind's metered share is 3% of CPU-seconds, 5% of database I/O and 2% of log bytes. It also has a dedicated search index costing $300/month. It pays $3,500/month.

1. Compute: $70,000 \times 0.03 = \$2,100$.
2. Database: $40,000 \times 0.05 = \$2,000$.
3. Observability: $10,000 \times 0.02 = \$200$.
4. Direct: $D = \$300$. Total $C = 2,100 + 2,000 + 200 + 300 = \$4,600$.
5. Margin $= (3,500 - 4,600)/3,500 = -31\%$.

Interpretation. Northwind pays for a mid-size plan but consumes like a large one, mostly in database I/O. Dividing by *metered* usage spreads idle headroom over all tenants; reporting it separately as platform cost makes tenants look cheaper but hides the headroom. **Engineering implication.** Metering makes this tenant visible, so the team can re-tier it, add a cost-based quota or optimize the expensive path. Chapter 51 covers unit economics.

47.12 Security boundaries and cross-tenant attacks

47.12.1 Attack classes

In a pooled system the most damaging security failure is one legitimate tenant reaching another's data. Design and test against these classes:

Table 47.9 — Cross-tenant attack classes and the controls and tests that address them.

Attack class	How it works	Primary control	Test that proves isolation
Cross-tenant IDOR	Tenant A requests `/projects/9001`, which belongs to B; handler checks login, not ownership (§10.7.1)	Tenant-scoped data access layer; RLS	Two-tenant test: A's token on every B object ID returns 404
Tenant ID from client input	Handler trusts `X-Tenant-Id` header or body field	Tenant only from verified token	Forged header test: response unchanged
Confused deputy	Service uses its own broad privileges on an object a tenant named	Act with the tenant's scoped credentials; external IDs	Tenant supplies another tenant's resource ARN; call fails
Shared cache or index leak	Cache key or search query lacks tenant	Tenant prefix in every key; tenant filter enforced by the index layer	Same query string from A and B returns different results
Background job without context	Batch job runs as a privileged role across all tenants	Jobs carry tenant ID and run with tenant-scoped role	Job for A cannot read B's rows
Object storage path abuse	Path traversal or guessable keys under a shared bucket	Server-generated keys under per-tenant prefixes; scoped short-lived URLs	`../` and other-tenant prefixes rejected
Resource exhaustion	Tenant consumes shared capacity	Quotas, fair queuing (§47.8)	Load test one tenant; others' SLOs hold
Microarchitectural side channel	Co-resident code infers secrets via shared caches or predictors	Patched hosts; no cross-tenant core sharing; dedicated hosts for sensitive tiers	Placement audit: tenants never share physical cores

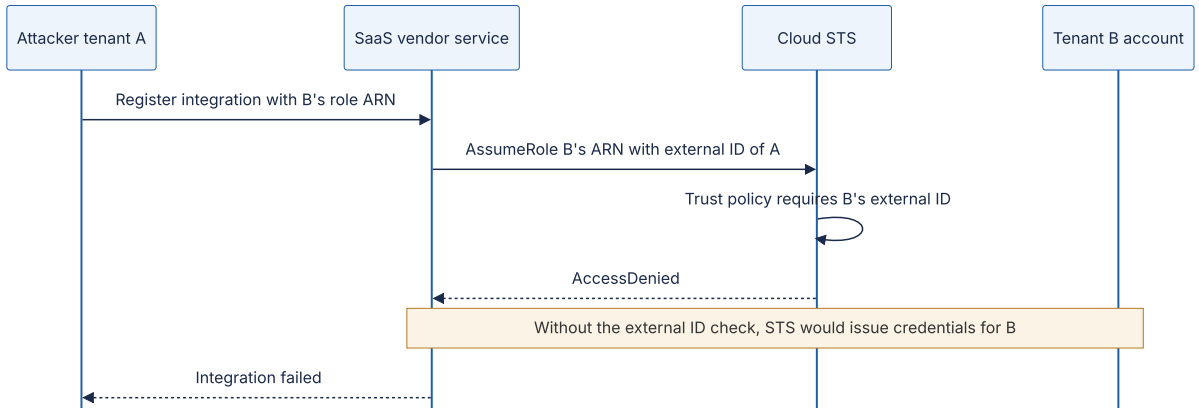
47.12.2 The confused deputy

DEFINITION

Definition — Confused deputy. A program (the deputy) that holds authority from several sources and is tricked into using one principal's authority on behalf of another. Hardy named it after a compiler that, given an output file name by a user, overwrote a billing file the compiler itself had permission to write [Hardy 1988].

Multi-tenant services are deputies by design, holding permissions into every tenant's resources. Take a SaaS integration that assumes a role in each customer's cloud account. Tenant A registers an integration but supplies the role ARN that tenant B created for the same vendor; if the vendor assumes whatever role it is given, it reads B's account on A's behalf. AWS documents the fix, an **external ID**: the vendor generates a unique value per tenant, the customer requires it in its role's trust policy, and the vendor always passes the requesting tenant's external ID. For AWS service principals, the `aws:SourceArn` and `aws:SourceAccount` condition keys play the same role [AWS Docs: IAM].

Figure 47.12 — A confused deputy attack and the external-ID defense.



Reading the diagram. Attacker A names tenant B's role. The vendor calls the cloud's security token service (STS) synchronously, passing the external ID it generated for *A*, the requester, never a tenant-supplied value. B's trust policy accepts only B's external ID, so STS denies the call; without that condition, STS would issue credentials and the vendor would read B's account for A. The failure point is the deputy's logic, not the cloud's.

The general rule: a multi-tenant service should act *with the requesting tenant's authority*, not its own, by scoping credentials per request (a tenant-scoped role conditioned on a tenant tag, or RLS with a tenant session), so even a logic bug cannot reach another tenant.

47.12.3 Side channels, conceptually

Tenants sharing hardware may infer each other's secrets from timing differences in shared microarchitectural state: caches, branch predictors and sibling hyperthreads. Ristenpart et al. showed that an attacker could place VMs on a target's physical host in a public cloud and measure cache-based signals across the VM boundary [Ristenpart et al. 2009]; Spectre showed that speculative execution leaks data across boundaries software considered sound [Kocher et al. 2019]. Mitigations, cheapest first:

1. Keep hosts, hypervisors and microcode patched, and use constant-time cryptographic code.

2. Never schedule two tenants on sibling hyperthreads of one physical core; Linux **core scheduling** lets the kernel enforce that only mutually trusting tasks share a core [Linux Docs: Core Scheduling].
3. Use hardware-virtualized boundaries (microVMs, VMs) rather than shared kernels for untrusted code.
4. Offer dedicated hosts for tenants whose threat model includes a well-funded co-resident attacker, and price them as such.

47.12.4 Tests that prove isolation

Every new endpoint, table, cache and job can break isolation, so test it continuously:

1. **Two-tenant fixture tests.** For every endpoint, try each of B's objects with A's token. Expect 404, not 403, so responses do not confirm the object exists.

2. **Database policy tests.** Run the RLS script of §47.5.2 in CI, plus a catalog check that fails if any table with a `tenant_id` column lacks forced RLS:

   ```
   SELECT c.relname AS unprotected_table
   FROM pg_class c
   JOIN pg_namespace n ON n.oid = c.relnamespace
   JOIN pg_attribute a ON a.attrelid = c.oid AND a.attname = 'tenant_id'
   WHERE n.nspname = 'public'
     AND c.relkind IN ('r', 'p')
     AND NOT (c.relrowsecurity AND c.relforcerowsecurity);
   ```

   On the example database plus a new `projects` table without a policy, it returned exactly one row, `projects`; CI fails on any non-empty result.

3. **Noisy-neighbor load tests.** Drive one synthetic tenant far past its limits in staging and assert the others stay within SLO, as §47.8.4 does in miniature.

4. **Production canary tenants** continuously attempt cross-tenant reads; any success pages security.

5. **Placement audits** verify that silos use only their resources and untrusted code never shares a kernel.

6. **Penetration tests and bug bounties** that target cross-tenant access.

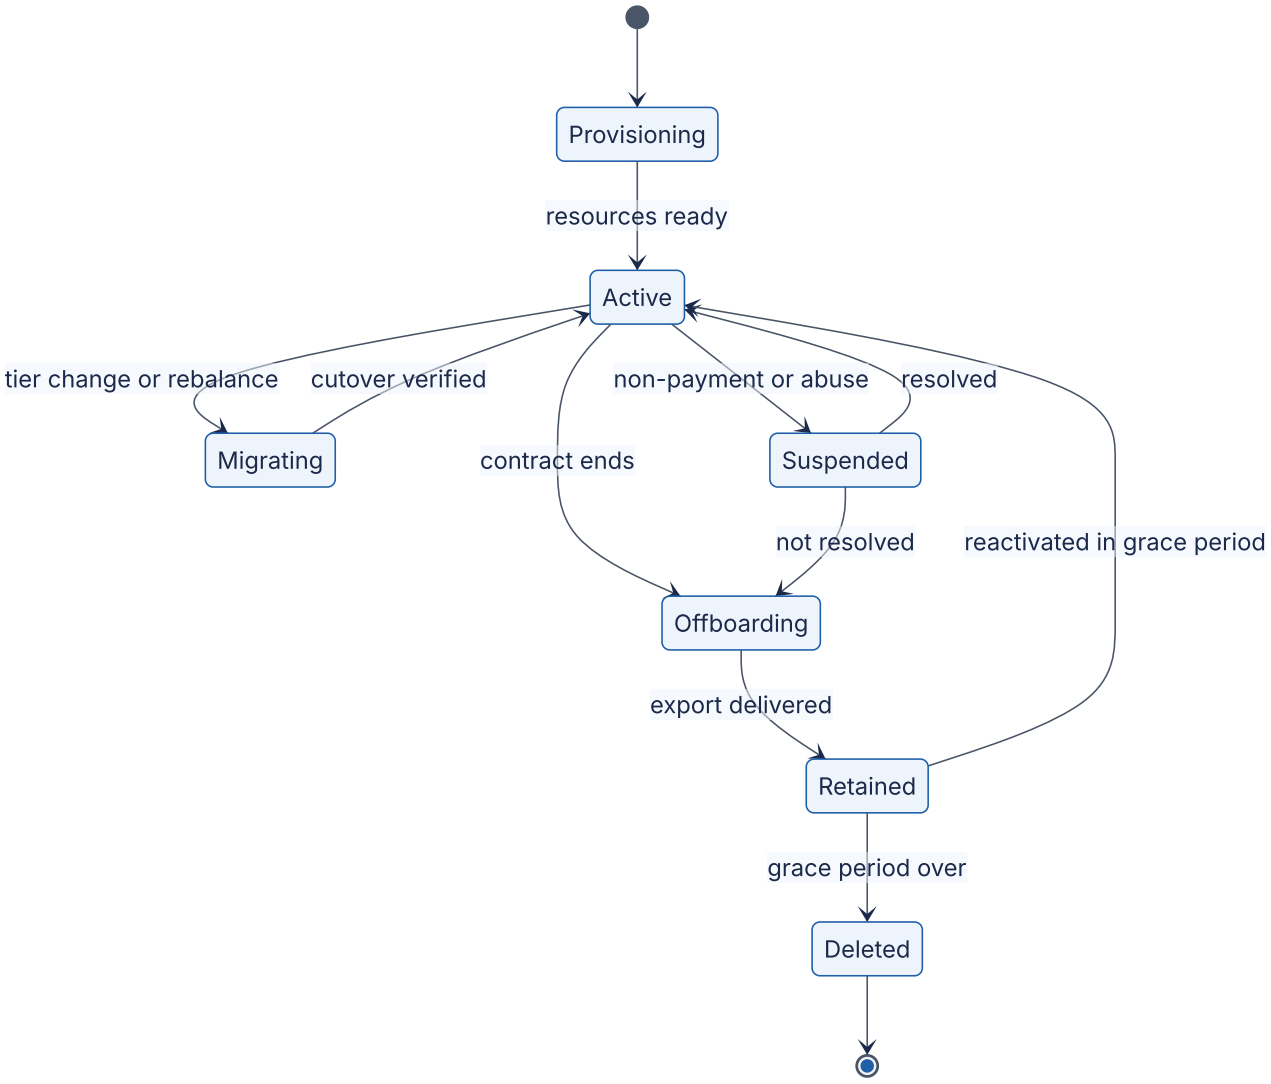
> COMMON MISTAKE
>
> **Common misconception — "Our tenant IDs are UUIDs, so they cannot be guessed."** Unguessable IDs slow enumeration but are not access control; IDs leak through URLs, logs, links and tickets. Every access must check ownership.

47.13 Tenant lifecycle

47.13.1 States and transitions

Each lifecycle transition is a control-plane workflow: idempotent, audited and reversible until the final step.

Figure 47.13 — Tenant lifecycle.



Reading the diagram. States live in the tenant registry; each arrow is an asynchronous control-plane workflow. *Provisioning* creates resources (§47.10.2); *Migrating* moves data while the tenant stays online; *Suspended* blocks access but keeps data; *Offboarding* exports data; *Retained* keeps it disabled for a grace period; *Deleted* is the one irreversible state. Failure points: a failed migration must roll back to the old placement, and a deletion that misses a store leaves data behind. Rare per tenant but frequent across 40,000 tenants, these workflows must be fully automated.

47.13.2 Migration between tiers

Moving a tenant from a pooled cell to a silo applies the online migration of §14.9.5 to one tenant:

1. **Provision** the target (silo database, keys, services) from the same infrastructure code as every other silo.
2. **Copy** a consistent snapshot of the tenant's rows. Shared tables with a leading `tenant_id` make this a range scan.
3. **Stream changes** made since the snapshot, using change data capture filtered by tenant.
4. **Verify** row counts and checksums per table for that tenant.
5. **Cut over**: briefly block writes for that tenant (seconds), apply the final changes, flip its directory entry, and fence the old location so it rejects writes for that tenant.
6. **Keep the old copy** read-only for a rollback window, then delete it.

Downgrades run the same steps in reverse. Rehearse tier migration on synthetic tenants weekly: an unexercised path fails exactly when a sales deal depends on it.

47.13.3 Offboarding and data deletion

Offboarding must remove the tenant's data from *every* store, provably, within a contractual or legal deadline (Chapter 50 covers GDPR):

1. **Export** data in a documented format if the contract requires portability.
2. **Disable** access, jobs and integrations.
3. After the grace period, **delete** from primary stores, replicas, caches, search indexes, analytics copies, object storage and queues, driven by an inventory of every store holding tenant data.
4. **Backups** cannot practically be edited per tenant: let them expire (and document the deadline) or crypto-shred by destroying the tenant key that wraps every copy (§47.5.4).
5. **Logs**: keep tenant data out of long-retention logs, or apply the same limits.
6. **Record** a deletion certificate: what, where, when, and the key-destruction event.

WORKED EXAMPLE

Worked example — Deletion deadline with and without crypto-shredding. TaskForge keeps daily backups for 35 days and archives monthly snapshots for 12 months. A tenant's 30-day grace period ends today.

1. Without per-tenant keys, the tenant's data is fully gone only when the last monthly archive containing it expires: up to 12 months from the end of the grace period.
2. With a per-tenant KEK and every DEK wrapped by it, scheduling the KEK for deletion (many KMSs impose a waiting period, commonly 7 to 30 days, as of 2026) makes every backup copy unreadable within that waiting period.
3. If the contract promises deletion within 30 days, only design 2 can meet it without restoring and rewriting a year of archives.

Interpretation. Crypto-shredding turns a 12-month deletion tail into days. **Engineering implication.** Choose per-tenant keys at design time; retrofitting means re-encrypting everything and still waiting for old backups to expire.

Table 47.10 — Lifecycle failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Onboarding half-completes	Step failed, workflow not idempotent	Tenant stuck in Provisioning	Resume from last completed step	Idempotent, checkpointed workflow
Writes lost during tier migration	Router cache stale after cutover	Row-count mismatch	Replay from change stream	Fence old location; verify before delete
Deleted tenant's data found in search	Index not in data inventory	Post-deletion scan	Purge index	Inventory every store; deletion tests
Shared backup prevents timely deletion	No per-tenant keys	Deletion deadline audit	Wait for expiry; disclose	Per-tenant keys and crypto-shredding

47.14 Summary and revision notes

SUMMARY

- Multi-tenancy trades isolation for pooling. Headroom for independent tenants grows with $\sqrt{n}$, not n; correlated demand shrinks the saving (48% falls to 24% at $\rho = 0.3$ in §47.3.2).
- Isolation has three dimensions: security, performance and fault. Decide each one per layer.
- Silo, pool and bridge are per-layer choices. Tiered products pool small tenants in cells and silo premium ones, from one codebase. Measure blast radius by revenue as well as by tenant count.
- Data isolation runs from database-per-tenant through schema-per-tenant to shared tables. Shared tables need forced row-level security, transaction-scoped tenant settings and indexes that lead with `tenant_id`. Per-tenant keys add BYOK and crypto-shredding.
- Place tenants through a directory. Whales grow relative to the fleet as shard count rises, so place or split them explicitly.
- Noisy neighbors contend for whichever resource is least partitioned, often caches, memory bandwidth, connections or queues. Detect them with per-tenant usage and per-tenant SLIs.
- Per-tenant rate limits are always oversubscribed. They bound one tenant; weighted fair queuing splits real capacity max–min fairly; shedding by priority decides who loses when fair shares are not enough.
- Compute isolation runs from process, container, gVisor and microVM to VM and dedicated host. Untrusted code needs at least a sandbox or microVM. Overhead per tenant decides the cost.
- Keep the control plane (onboarding, placement, configuration, flags, metering) apart from the data plane, and keep the data plane statically stable.
- Meter usage per tenant for showback, chargeback and margin. Keep `tenant_id` out of high-cardinality metric labels.
- Test cross-tenant attacks continuously: IDOR, trusting a client-supplied tenant ID, confused deputies, shared caches and side channels.
- Lifecycle workflows (onboarding, tier migration, offboarding) must be idempotent and rehearsed. Deletion must reach every store, including backups.

47.15 Knowledge checkpoint

1. Name the three dimensions of tenant isolation.
2. Why does pooling save less capacity than the independent-tenant formula predicts?

3. Why can an enterprise silo have a revenue blast radius twenty times its tenant blast radius?
4. What three PostgreSQL settings or role choices are needed for RLS to protect a table against the application role?
5. Why use `SET LOCAL` rather than `SET` for the tenant ID?
6. What does crypto-shredding achieve that deleting rows does not?
7. Why does a whale become harder to place as the shard count grows?
8. Why can a noisy neighbor slow a victim whose CPU usage falls?
9. Why do per-tenant token buckets alone fail to protect quiet tenants?
10. Compute the max–min fair allocation for $C = 900$ and demands 600, 200, 200 with equal weights.
11. What is the main security difference between a container and a microVM?
12. How does an external ID defend against a confused deputy?

Answers

1. Security isolation (no cross-tenant data access), performance isolation (no SLO impact from neighbors) and fault isolation (failures stay within one compartment).
2. Real tenants' demand is positively correlated (same time zones, same events), and correlation adds covariance terms to pooled variance.
3. Because blast radius by revenue weights each tenant by what it pays: one $50,000 tenant out of 2,000 is 0.05% of tenants but 1% of revenue.
4. `ENABLE ROW LEVEL SECURITY` with a policy, `FORCE ROW LEVEL SECURITY` (so the owner is also subject), and an application role that is not a superuser and lacks `BYPASSRLS`.
5. `SET LOCAL` ends with the transaction, so a pooled connection cannot carry one tenant's context into another tenant's request.
6. It makes every copy unreadable at once, including backups and replicas that cannot practically be edited.
7. The mean shard load shrinks as $1/S$ while the whale's load stays the same, so the whale becomes a larger multiple of a shard.
8. The antagonist evicts the victim's cache lines or saturates memory bandwidth, so the victim stalls on memory: lower CPU utilization, higher latency. CPI reveals it.
9. Limits are oversubscribed, so the sum of admitted traffic can still exceed capacity, and a shared FIFO queue spreads the resulting delay over everyone.
10. Try 300 each: the two 200s are satisfied, so the large tenant gets $900 - 400 = 500$. The allocation is 500, 200, 200.
11. A container shares the host kernel's full system-call interface. A microVM has its own guest kernel behind hardware virtualization and a minimal device model.
12. The vendor passes a unique, vendor-generated external ID for the requesting tenant, and each customer's role trusts only its own external ID, so naming another customer's role fails.

47.16 Interview questions

Basic

Q1. What is the difference between silo and pool tenancy, and when would you choose each? **Answer.** Silo gives each tenant dedicated resources: strongest isolation, per-tenant upgrades and residency, but idle headroom and N deployments. Pool shares everything and isolates logically: lowest cost and instant onboarding, but noisy neighbors and a larger blast radius. Choose silo when contracts, regulations or untrusted compute require it. Choose pool for many small, similar tenants. Most products are tiered and use both.

Q2. How would you stop one tenant from reading another's rows in a shared PostgreSQL table? **Answer.** Derive the tenant from the verified token. Set it per transaction with `SET LOCAL`. Enforce it with a forced RLS policy on every tenant table, and connect as a role without bypass rights. Lead every index with `tenant_id`, scope unique constraints by tenant, and test with two-tenant fixtures and a catalog check in CI.

Intermediate

Q3. A pooled cell's p99 latency doubled, but CPU and request rate are flat. How do you investigate? **Answer.** Compare per-tenant SLIs to find the victims, then rank tenants on the same shard or host by change in usage: rows scanned, cache bytes, I/O, connections held. Check CPI for cache or memory-bandwidth interference. Check connection-pool wait and queue lag by tenant. Contain the antagonist with a tighter cost-based quota or lower weight, then move it or add a per-tenant bulkhead.

Q4. Design per-tenant rate limiting for a 20,000 RPS cell with 8,000 tenants. **Answer.** Use tier-based token buckets, each well under the cell's capacity (at most about 5%), enforced at the gateway with distributed quota (§22.8). Behind them, use cost-weighted per-tenant fair queues in front of the scarce resources, bounded queues per tenant, and shedding by tier. Expect 10–15× oversubscription, and track aggregate peak against capacity to decide when to split the cell.

Advanced

Q5. Design isolation for a platform that runs customers' arbitrary code next to their data. **Answer.** Run each tenant's code in a microVM or gVisor sandbox with a per-tenant identity, never a shared kernel. Give the sandbox network access only to a tenant-scoped data API, and enforce tenant identity in that API and in the database (RLS or a database per tenant). Add per-tenant CPU, memory and I/O limits, plus a fair scheduler for invocations. Keep tenants off sibling hyperthreads, and offer dedicated hosts for sensitive tenants. Meter CPU-milliseconds and memory per invocation for billing. Test escape and cross-tenant access continuously.

Q6. An enterprise customer wants to move from your pooled tier to a dedicated silo with its own key, without downtime. Walk through it. **Answer.** Provision the silo from the standard infrastructure code, and create a KEK in the customer's KMS with a grant to your service. Snapshot the tenant's rows (a `tenant_id` range scan), re-encrypting under the new key. Stream changes by CDC filtered by tenant, then verify counts and checksums. Cut over with a seconds-long write block: flip the directory entry and fence the old location. Keep the old copy read-only through a rollback window, then delete it. Afterwards, check metering and alerts for the new placement.

47.17 Practical exercises

1. Run the RLS script of §47.5.2 on PostgreSQL. Then remove `FORCE ROW LEVEL SECURITY` and repeat the tests as the table owner. Record what changes.
2. Extend the simulation of §47.8.4 so that each request has a cost of 1–10 units, and use cost in the finish tag. Show that a tenant sending few but expensive requests is contained.
3. Repeat the pooling calculation of §47.3.2 using a week of real per-tenant request counts from any system you can access. Estimate ρ.
4. Design the Prometheus metrics for a 40,000-tenant service using the top-N-plus-other pattern, and compute the series count.
5. Write a two-tenant integration test harness that calls every endpoint in an OpenAPI specification with the other tenant's object IDs.

47.18 Design challenges

1. **Multi-tenant analytics warehouse.** 3,000 internal teams share one warehouse. Design quotas, fair scheduling of queries (by slot-seconds), cost showback and isolation of a runaway query. Estimate the oversubscription ratio.
2. **Tiered SaaS across regions.** TaskForge must offer EU data residency and enterprise silos. Combine cells, placement constraints and per-tenant keys, and compute blast radius by revenue for your design (Chapter 44 covers multi-region).
3. **Serverless code platform.** Run 50,000 concurrent tenant functions of 256 MiB each. Choose an isolation boundary, compute host count and cost per tenant with the formula of §47.9.3, and describe how you would detect and contain a crypto-mining tenant.

- Google production use of gVisor (App Engine standard, Cloud Functions, first-generation Cloud Run). Reported by secondary sources; gvisor.dev was unreachable.
- gVisor platform details: systrap as default since mid-2023, and the Gofer and directfs behavior. Taken from search summaries of the platform guide.
- The Citus function name and current behavior for isolating a single tenant to its own shard.
- KMS key-deletion waiting periods (7–30 days) and request quotas, as of 2026.
- The isolation-overhead figures in §47.9.3 are labeled planning assumptions. Replace them with measured values if a source is found.

Chapter 48 — Edge Computing and Serverless at Scale

> **Level:** 4 · **Track:** A (Traditional) · **Estimated reading time:** 4.5 h

Two ideas share this chapter. **Serverless** lets you hand the provider a function and stop thinking about machines: the platform starts a sandbox when an event arrives, bills you for the milliseconds it ran and reclaims it when traffic stops. **Edge computing** moves small pieces of that code out of the region and into hundreds of points of presence a few milliseconds from users. Both trade control for elasticity, and both hide costs: cold starts, concurrency limits, databases that cannot keep up, eventually consistent edge storage and bills linear in traffic.

Section 33.9 introduced serverless and its break-even cost, §21.9 previewed edge runtimes, and §41.8.4 and §47.9 explained Firecracker and the isolation spectrum. This chapter opens those boxes: Lambda's published internals, cold-start arithmetic with a fleet simulation, concurrency limits, data patterns, edge runtimes and edge data, latency and cost models, and operations. The running example is **PhotoShare**, the hypothetical photo app of Chapter 1, at 10 million daily users with about 70 photo uploads per second and 17,400 photo views per second at peak (§1.9). Every PhotoShare number is a teaching assumption.

48.1 Learning objectives

After this chapter you should be able to:

- Define serverless by its three properties and distinguish FaaS from managed backend services.
- Trace a Lambda invocation through frontend, placement and worker, and explain slots, on-demand image loading and snapshot restore.
- Break a cold start into its phases, compute how a cold-start fraction changes a latency percentile, and choose among mitigations.
- Compute required concurrency with Little's Law, the time to scale under a scaling-rate limit, and the database connections a function fleet will open.
- Design event-driven pipelines with batching, partial failures, idempotency and orchestration, and recognize serverless anti-patterns.
- Compare V8 isolates, WebAssembly sandboxes and microVMs as edge runtimes, including their security models and limits.

- Choose an edge data store by its consistency model and compute edge-versus-origin latency for a request.
- Build cost curves for functions, containers and VMs, including memory–duration pricing, front-door charges and egress.
- Operate serverless systems: asynchronous tracing, aliases, testing and lock-in.

48.2 Prerequisites

- Little's Law — §4.11 (concurrency = arrival rate × duration drives every sizing calculation here).
- Percentiles and tail latency — §4.8, §23.6 (cold starts live in the tail).
- CDN edge, shield and origin — §21.3, §21.9 (edge compute runs inside the CDN).
- Serverless basics, cold starts and break-even cost — §33.9 (this chapter builds on them).
- Firecracker and the isolation spectrum — §41.8.4, §47.9 (the sandbox under each function).
- Containers and images — §42.3, §42.4 (Lambda and Cloud Run load container images).
- Queues, delivery guarantees and dead-letter queues — §30.4, §30.8, §30.11 (the backbone of serverless pipelines).
- Idempotency keys — §22.15 (every event-driven function must be idempotent).
- Workflow engines and Step Functions — §32.11 (orchestration instead of function chains).
- Distributed tracing — §40.6 (following a request across asynchronous hops).

48.3 What "serverless" really means

48.3.1 FaaS plus managed backends

DEFINITION

Definition — Serverless computing. A cloud programming model with three properties: the developer **does not manage resource allocation** (no servers, clusters or capacity plans), the platform **scales automatically, including to zero**, and billing is **in proportion to resources used** rather than resources reserved [Jonas et al. 2019]. In practice it combines **functions as a service (FaaS)**, which run developer code in short-lived sandboxes triggered by events, with **backend as a service (BaaS)**: managed object storage, databases, queues, authentication and so on, which hold all the state.

First-principles explanation

A kitchen can hire cooks for every shift, paid whether or not orders arrive, or use an agency that sends a cook per order, bills by the minute and supplies the pantry. Agency cooks remember nothing between orders, so everything lives in the shared pantry, and the first cook of the evening takes a while to arrive: a **cold start**. FaaS is the agency cooks; BaaS is the pantry.

Why does this exist?

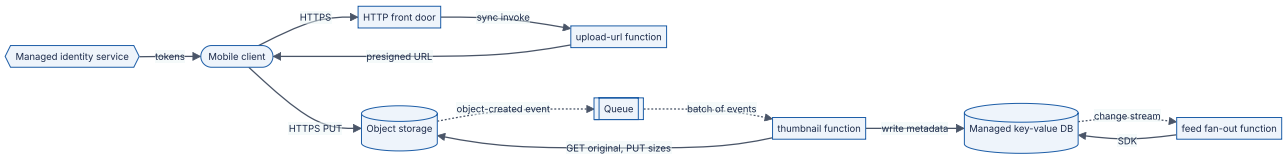
The Berkeley view argued that the early cloud copied the server too literally: users still provisioned, patched and scaled virtual machines that mostly idled [Jonas et al. 2019]. Serverless is to that what high-level languages were to assembly: you state *what* to run; the platform decides *where* and *on how much*. The authors also listed what early serverless lacked: fast storage for fine-grained state, coordination, efficient communication and predictable performance (cold starts). Much of this chapter is about how those gaps are answered.

Hellerstein et al. added the data-systems critique: isolated functions **ship data to code** through slow storage hops, so FaaS excels at embarrassingly parallel, event-driven work and struggles with chatty, stateful, coordinated computation [Hellerstein et al. 2019].

How it works internally

1. An **event source** (HTTP front door, queue, object upload, schedule, change stream) produces an event.
2. A **trigger** routes it to a function version, synchronously (the caller waits) or asynchronously (the platform queues and retries).
3. The platform finds or creates an **execution environment** (a sandbox with the runtime and your initialized code) and runs the **handler**, which keeps state only in managed services.
4. The environment stays warm for later events, then is reclaimed.

Figure 48.1 — A serverless application: functions for logic, managed services for state.



Reading the diagram. PhotoShare's upload path uses three functions and four managed services. The client gets a token from the identity service, asks the synchronous `upload-url` function for a presigned URL and uploads directly to object storage, so large bytes never pass through a function. The rest is asynchronous (dotted): the object-created

event lands in a queue that invokes the thumbnail function in batches, and the metadata write emits a change stream that triggers feed fan-out. Storage boundaries are object storage and the key-value database; no function keeps state. Failure points: duplicate deliveries from retries (§48.7.2), cold starts on the synchronous path, and database capacity when functions scale out. Each function scales independently up to the account limit (§48.6).

48.3.2 Scale to zero and the billing model

Scale to zero means that with no events, no environments run and compute costs nothing. It makes serverless cheap for spiky or rare workloads, and it creates cold starts. Lambda's billing shows the common shape (as of 2026) [AWS Lambda Pricing]:

- A **request charge** per invocation, $0.20 per million in us-east-1.
- A **duration charge** in **GB-seconds**: configured memory × billed duration, rounded up to the nearest millisecond, $0.0000166667 per GB-second for x86 and about 20% less for Arm (Graviton).
- **CPU is proportional to memory**: 1,769 MB gets one vCPU, the 10,240 MB maximum gets six [AWS Docs: Lambda]. For CPU-bound code, doubling memory halves duration: same GB-seconds, half the latency.
- The **initialization phase** is billed as duration. Since 1 August 2025 this includes managed-runtime functions packaged as ZIP archives, whose init time was previously free [AWS Compute Blog 2025].
- Optional **provisioned concurrency** bills pre-initialized environments per GB-second while they exist, whether or not they serve requests (§48.5.3).

Cloud Run and Azure Functions' Flex Consumption plan bill similarly, by instance vCPU-seconds and GiB-seconds plus requests, with optional warm minimums [Google Cloud Docs: Cloud Run]; [Microsoft Learn: Azure Functions]. Cost is linear in traffic and idle time is free, so the comparison with servers depends on utilization (§48.11).

COMMON MISTAKE

Common misconception — "Serverless means no servers" or "serverless equals FaaS." There are servers; the provider manages them. You still own code, concurrency limits, every non-elastic dependency, idempotency and the bill. And managed queues, storage, databases and workflow engines are serverless too: good serverless designs often wire services together directly and use functions only for logic no service provides.

48.4 Inside a FaaS platform

This section uses only published material: papers by AWS engineers and product documentation. Internals change; read it as a model of the design problem (as of 2026), not a current blueprint.

48.4.1 AWS Lambda's invoke path

> DEFINITION
>
> **Definition — Execution environment, slot and worker.** An **execution environment** is an isolated sandbox containing one function version's runtime and initialized code. The Firecracker paper calls a ready environment on a host a **slot**: it serves one function, one invocation at a time, but many invocations in sequence. A **worker** is a bare-metal host that runs hundreds or thousands of slots, each in its own microVM [Agache et al. 2020].

First-principles explanation

A taxi dispatcher first looks for an idle taxi nearby (a warm slot); if none is free, a fleet planner sends a new one from a garage chosen to keep garages balanced (placement). Each taxi carries one party at a time but many in a row.

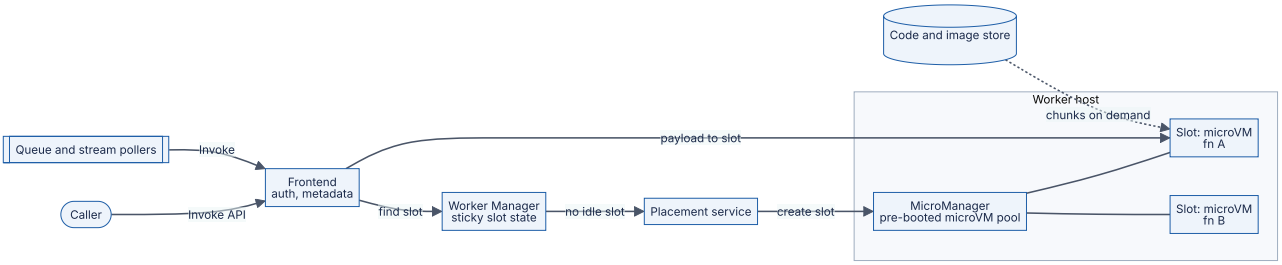
How it works internally

The NSDI 2020 Firecracker paper describes Lambda's architecture as four cooperating parts [Agache et al. 2020]:

1. **Frontend.** Receives `Invoke` (from callers, or from internal pollers reading queues and streams), authenticates it and loads function metadata.
2. **Worker Manager.** A stateful, sticky load balancer tracking which slots exist and which are idle. If one is idle, it reserves it and tells the frontend: a **warm start**.
3. **Placement service.** Otherwise Placement picks a worker that keeps CPU, memory, network and storage use even and spreads one function's slots across hosts; the paper reports this typically takes under 20 ms.
4. **Worker.** A **MicroManager** process manages the Firecracker processes and keeps a small pool of pre-booted microVMs so slot creation skips the boot. The frontend then sends the payload to the slot.

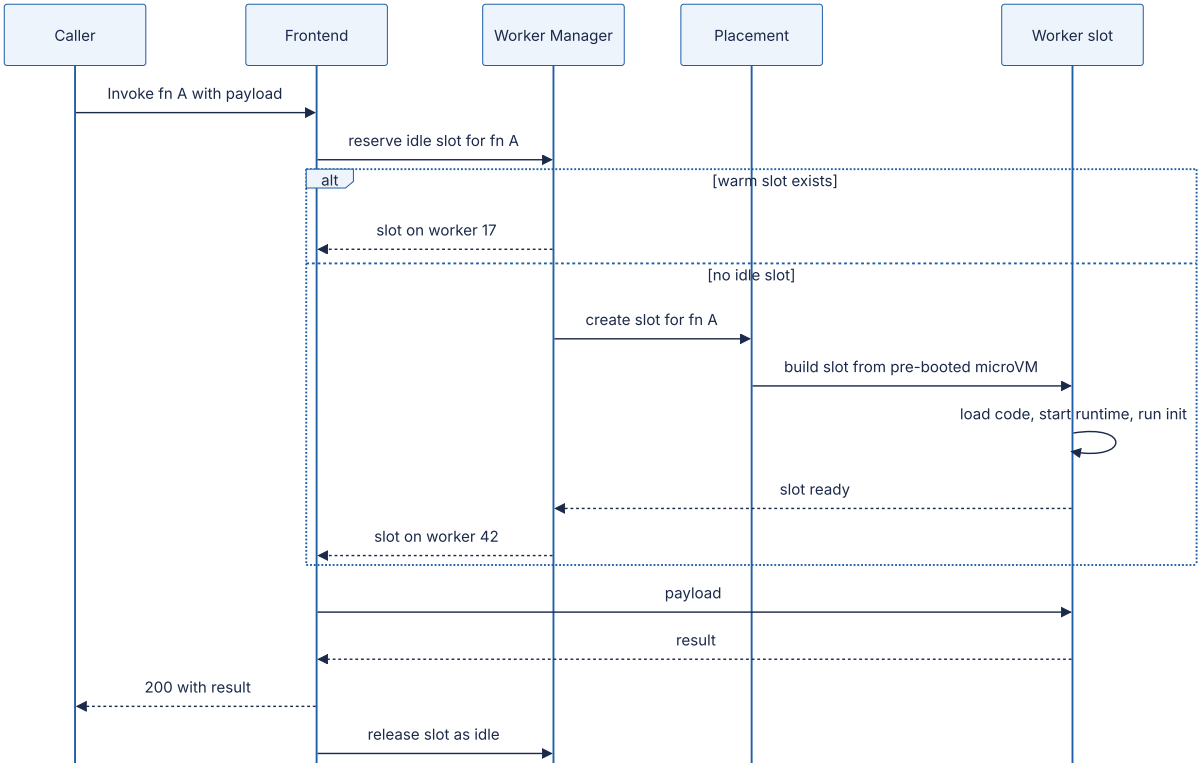
AWS engineers have since described evolving parts of this (for example, a new assignment service replacing the Worker Manager) in conference talks; the four roles remain a sound model of any FaaS control plane.

Figure 48.2 — Lambda's invoke path as described in the Firecracker paper.



Reading the diagram. Callers and Lambda's pollers enter synchronously through the frontend, which asks the Worker Manager for an idle slot. Warm: the frontend sends the payload straight to the slot. Cold: Placement picks a worker and its MicroManager turns a pre-booted microVM into a slot, while code streams in asynchronously from storage (§48.4.2). Each slot is a separate microVM, the isolation boundary between tenants. Failure points: Worker Manager state, placement capacity in a zone, and the code store on the cold path. The fleet scales by adding workers; one function scales by adding slots across workers.

Figure 48.3 — Warm and cold invocation, step by step.



Reading the diagram. All calls are synchronous. The `alt` block is the whole difference between warm and cold: cold, the caller also waits for placement, slot creation, code loading, runtime start and function initialization (§48.5). Releasing the slot returns it to the idle set until reclamation. Failure points: slot creation can be throttled (§48.6) and initialization can time out. Scaling: more concurrent invocations need more slots, which is why Lambda limits concurrency, not request rate.

INDUSTRY EXAMPLE

AWS Lambda on Firecracker. Lambda originally isolated customers with per-customer VMs, which wasted capacity. Firecracker gave each slot its own minimal microVM, so different customers' slots share one bare-metal worker and memory and CPU can be oversubscribed, since most functions are idle most of the time. The paper reports boot to user-space code in as little as 125 ms, less than 5 MiB of monitor overhead per microVM and up to 150 microVMs created per second per host, and states that Lambda processed trillions of events per month for hundreds of thousands of customers at the time [Agache et al. 2020]. §47.9 compares this boundary with containers and gVisor. *Evidence: Primary* — [Agache et al. 2020]

48.4.2 Loading code on demand

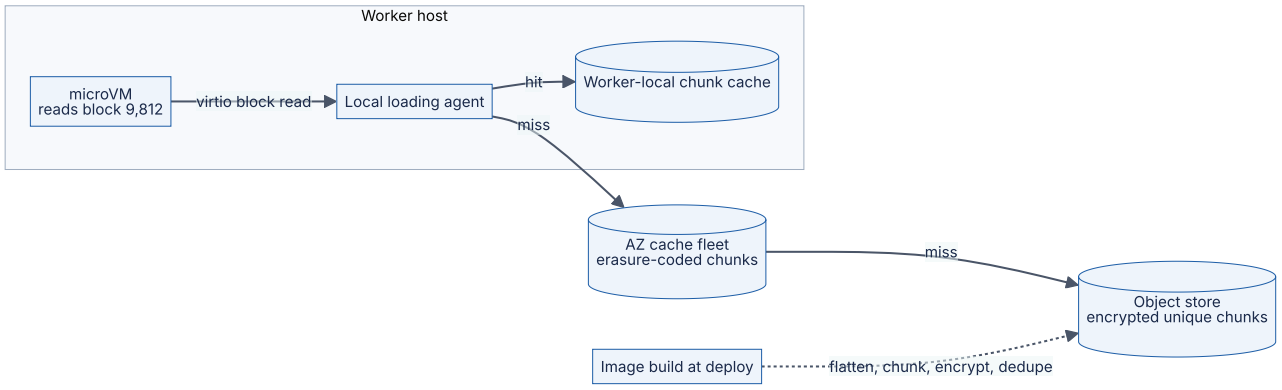
Lambda accepts container images up to 10 GiB [AWS Docs: Lambda]. Downloading that before each cold start would take tens of seconds, so Lambda loads only the bytes a function touches, when it touches them. Earlier research found that pulling accounted for 76% of container start-up time while only 6.4% of the pulled data was read [Harter et al. 2016].

Brooker et al. describe the design [Brooker et al. 2023]:

1. **Flatten and chunk.** At function creation the layers are flattened into one file-system image, split into fixed-size chunks.
2. **Deduplicate with convergent encryption.** Each chunk is encrypted with a key derived from its content, so identical chunks from different customers (shared OS and runtime layers) yield identical ciphertext, stored and cached once, unreadable without the content.
3. **Load on demand at block level.** The microVM sees a block device; a worker agent serves reads from a local cache, then an erasure-coded zone cache, then the object store.
4. **Erasure-code for tails.** A chunk can be rebuilt from any sufficient subset of fragments, masking a slow cache node.

Per the paper, this supports Lambda's goal of adding up to 15,000 new containers per second for a single customer, and the system had served hundreds of trillions of invocations for over a million customers [Brooker et al. 2023].

Figure 48.4 — Block-level on-demand loading of a container image.



Reading the diagram. At deploy time (dotted, asynchronous) the image is chunked, encrypted and deduplicated into the object store. At run time the microVM's synchronous block reads go to a local agent, which tries three storage tiers of rising latency. Only touched chunks travel: a 10 GiB image that reads 200 MB at start-up moves about 200 MB, mostly from caches. Failure points: a cold zone cache for a unique new image, and a slow cache node (masked by erasure coding). Scaling: hit ratios rise with fleet size, because more customers share base chunks.

48.4.3 Snapshot restore: SnapStart

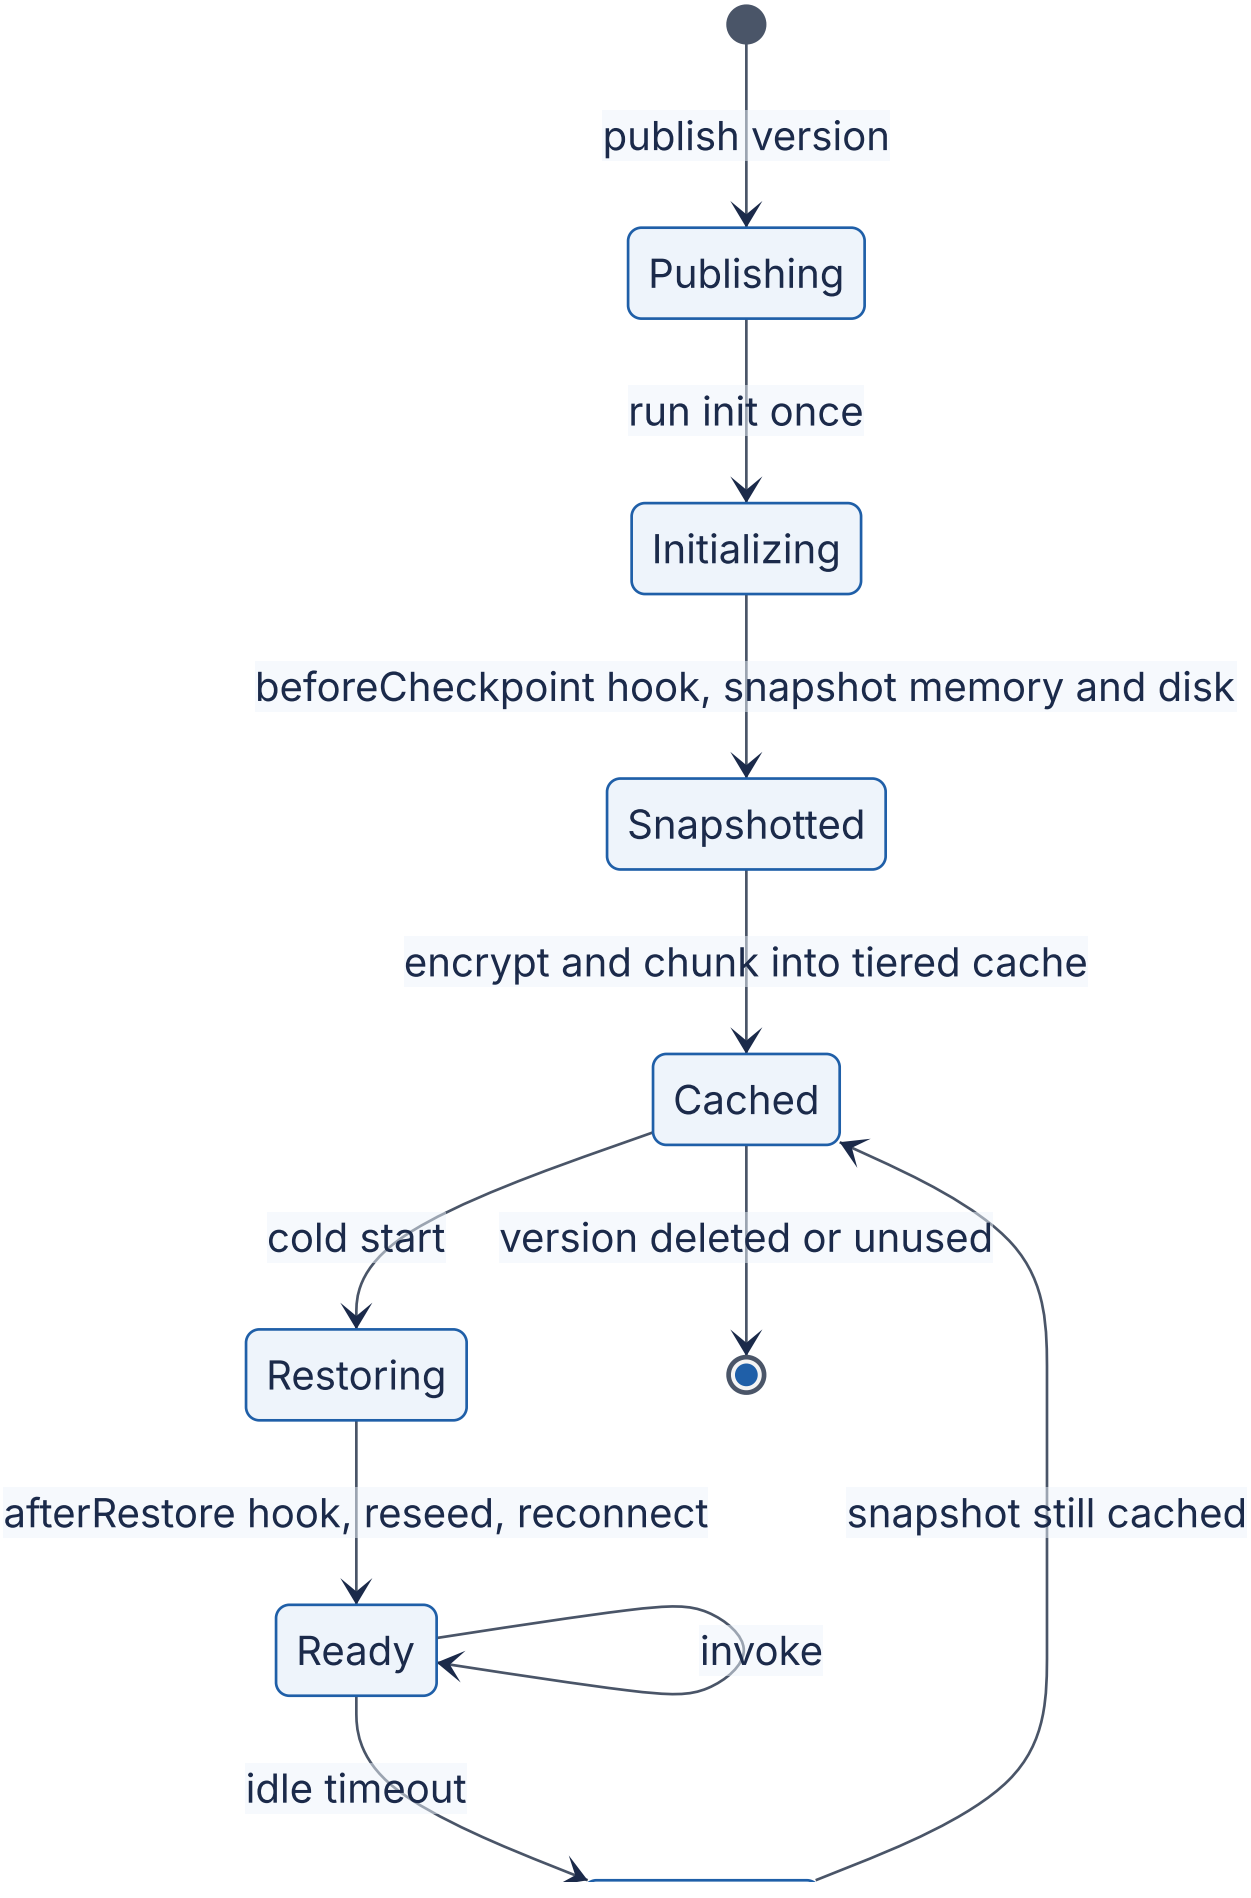
The slowest part of many cold starts is the function's own initialization. **Snapshot restore** runs it once and saves the result.

> DEFINITION
>
> **Definition — Snapshot-based start (SnapStart).** A mode in which the platform, when a function version is published, runs its initialization, takes a Firecracker snapshot of the microVM's memory and disk state, encrypts and caches it, and on each later cold start **restores** the snapshot instead of initializing from scratch [AWS Docs: Lambda].

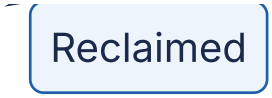
As of 2026, AWS documents SnapStart for Java, Python and .NET, with start-up improvements of up to 10× for heavy Java functions; snapshot chunks load on demand from tiered caches like images.

Snapshots raise a correctness problem: **uniqueness**. Whatever initialization created is copied into every restored environment: random seeds, UUID generators, nonces, credentials, connections whose peers have closed them. Brooker et al. analyze this for microVM snapshots and the support needed to reseed randomness after restore [Brooker et al. 2021]. **Runtime hooks** (`beforeCheckpoint` and `afterRestore` in Java's CRaC interface; registered hooks in Python) close connections before the snapshot and reconnect, refresh credentials and reseed after restore.

Figure 48.5 — Lifecycle of a snapshot-started function version.



publish version
Publishing
run init once
Initializing
beforeCheckpoint hook, snapshot memory and disk
Snapshotted
encrypt and chunk into tiered cache
Cached
cold start
version deleted or unused
Restoring
afterRestore hook, reseed, reconnect
snapshot still cached
Ready
invoke
idle timeout



Reading the diagram. States belong to one function version; deployment, invocation and idleness trigger transitions. Initialization runs once per version, not per environment; every cold start restores the cached snapshot, and `afterRestore` is the only place to repair per-environment state. Storage boundary: the snapshot cache tiers. Failure points: hooks that forget to reseed or reconnect, and snapshots evicted for long-unused versions. Scaling: restores share cached chunks, so a burst of cold starts is cheaper than a burst of full initializations.

> WARNING / TRADE-OFF
>
> **Warning — Snapshots copy secrets and randomness.** A key, seed or "random" sampling decision made during initialization is identical in every restored environment. Move such work into the handler or an after-restore hook, and test by restoring two environments and comparing outputs.

48.4.4 Google Cloud Run and Azure Functions

Other platforms make different choices, mainly about **per-instance concurrency**.

- **Google Cloud Run** runs any container image, and each instance serves many requests at once (default 80, up to 1,000), so 1,000 concurrent requests may need 13 instances rather than 1,000 environments. It scales to zero, supports **minimum instances** and a start-up CPU boost, and bills per request time or per instance lifetime [Google Cloud Docs: Cloud Run]. Its first-generation environment used gVisor, the second a microVM. **Cloud Run functions** (formerly Cloud Functions) build on it.
- **Azure Functions** offers hosting plans [Microsoft Learn: Azure Functions]: **Consumption** (scale by event load, pay per execution), **Flex Consumption** (adds per-instance concurrency, **always-ready** instances, virtual networks), **Premium** (pre-warmed instances) and dedicated plans. **Durable Functions** adds code-first orchestration.

Table 48.1 — Three FaaS platforms (published behavior, as of 2026).

Property	AWS Lambda	Google Cloud Run (and functions)	Azure Functions (Flex Consumption)
Unit of deployment	ZIP package or container image up to 10 GiB	Container image (or source built into one)	Function app (code package)
Sandbox	Firecracker microVM per environment	gVisor (gen 1) or microVM (gen 2)	Provider-managed instances
Concurrency per instance	1 request per environment	Default 80, up to 1,000	Configurable per instance
Keeping capacity warm	Provisioned concurrency	Minimum instances	Always-ready instances
Fast-start feature	SnapStart (snapshot restore)	Start-up CPU boost	Always-ready, pre-warmed
Maximum duration	15 minutes	Up to 60 minutes per HTTP request	Plan-dependent; long-running orchestration via Durable Functions
Billing basis	Requests + GB-seconds (1 ms granularity)	vCPU-seconds + GiB-seconds + requests	Execution time and memory, plus always-ready baseline

The concurrency row matters most. One request per environment means a slow dependency multiplies environments (§48.6) but requests never compete for CPU; many per instance keeps instance counts and connection pools small, but one request's CPU spike or leak hurts its neighbors.

48.5 Cold starts

48.5.1 Anatomy of a cold start

DEFINITION

Definition — Cold start. The extra latency an invocation pays when no initialized execution environment is available and the platform must create one: placement, sandbox creation, code loading, runtime start-up and the function's own initialization, all before the handler runs. An invocation served by an existing environment is a **warm start**.

First-principles explanation

A cold start is the first customer at a coffee shop that opens on demand: someone must unlock, switch on the machine and wait for it to heat before the first cup. Later customers wait only for their own cup. What matters is how often a customer finds the door locked, and how long the heating takes.

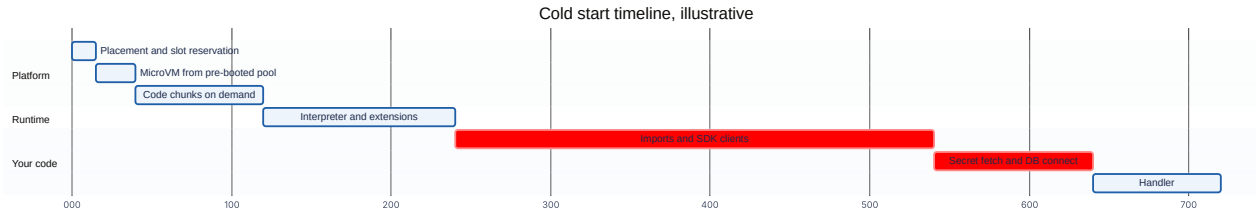
How it works internally

A Lambda cold start has five phases; other platforms differ in detail but not in shape [Agache et al. 2020]; [AWS Docs: Lambda]:

1. **Placement and slot reservation** (typically under 20 ms in the Firecracker paper).
2. **Sandbox creation**: a microVM from a pre-booted pool, a boot (as little as 125 ms) or a snapshot restore.
3. **Code loading**: ZIP packages unpacked, or images and snapshots read in chunks on demand (§48.4.2).
4. **Runtime initialization**: an interpreter in tens of milliseconds, a JVM with class loading in hundreds; Lambda **extensions** (monitoring or secrets agents) start here too.
5. **Function initialization**: imports, frameworks, SDK clients, secret fetches, database connections. Lambda limits it to 10 s on demand, and it is often the largest phase.

Phases 1–3 belong to the provider and are typically tens of milliseconds; phases 4–5 depend on your language, package and initialization code, and range from tens of milliseconds to seconds.

Figure 48.6 — An illustrative cold start for a Python function with a heavy SDK, axis in milliseconds.



Reading the diagram. Bars are phases on one synchronous path, in milliseconds from the moment no idle environment was found. Platform phases total 120 ms; the highlighted function initialization (400 ms) exceeds everything else combined; the 80 ms handler is all a warm request pays. Storage boundaries: the code store, the secrets service and the database, any of which can stall or fail the cold start. In a burst every new environment pays the full 720 ms, so cold starts cluster when load rises. Numbers are illustrative orders of magnitude, not measurements.

Measured ranges

- AWS reports that cold starts typically occur in under 1% of production invocations and last from under 100 ms to over 1 s [AWS Compute Blog 2025]; [Beswick 2021].
- Wang et al. measured Lambda, Azure Functions and Google Cloud Functions in 2017–2018: cold-start latency varied strongly with provider, language and memory,

Azure's was then far slower, and they also measured idle-instance lifetimes and co-residency [Wang et al. 2018]. Treat their numbers as history.

- Shahrad et al.'s Azure trace found invocation rates spanning eight orders of magnitude, most applications rare, so a fixed keep-alive leaves rare functions mostly cold [Shahrad et al. 2020].

48.5.2 How cold starts move percentiles

A small cold-start fraction barely moves the mean and median but can own the tail. The arithmetic is a **mixture** of two latency distributions.

FORMULA

Cold-start-weighted latency distribution and the percentile cliff

$$F(t) = (1-p)\,F_w(t) + p\,F_c(t) \qquad p > 1-q \;\Rightarrow\; L_q \geq t_{c,\,\min}$$

Symbol	Meaning	Units
$F(t)$	Fraction of all invocations with latency $\leq t$	dimensionless
$F_w(t)$, $F_c(t)$	The same fraction among warm and among cold invocations	dimensionless
p	Fraction of invocations that are cold starts	dimensionless
q	Percentile of interest as a fraction (0.99 for p99)	dimensionless
L_q	Overall q-th percentile latency, the t at which $F(t) = q$	ms
$t_{c,\,\min}$	Fastest cold-start latency (cold overhead plus fastest handler)	ms

The second expression is the **cliff**: below $t_{c,\,\min}$, $F(t) \leq 1-p < q$, so if more than $1-q$ of invocations are cold, the q-th percentile is a cold-start latency however fast warm requests are.

WORKED EXAMPLE

Worked example — PhotoShare's `upload-url` function. Warm latency has p99 = 160 ms and p99.5 = 180 ms; nothing warm exceeds 300 ms. Cold invocations add 300–700 ms of initialization (uniform) to an 80 ms handler, so cold latency runs from about 380 ms to 780 ms with a median of about 580 ms.

1. $p = 0$: $L_{0.99} = 160$ ms.
2. $p = 0.5\%$: below 380 ms no cold request has finished, so solve $(1 - 0.005)(1 - F_w(t)) + 0.005 = 0.01$. Then $1 - F_w(t) = 0.005/0.995 = 0.00503$: the warm p99.5, about 180 ms. The p99 rises 12% although only one request in 200 is cold.
3. $p = 2\%$: now $p > 1 - q = 1\%$, so $L_{0.99} \geq 380$ ms. Warm requests are all below 300 ms, so solve $0.02\,(1 - F_c(t)) = 0.01$: $F_c(t) = 0.5$, the cold median, about 580 ms.
4. Means, for comparison: with $p = 2\%$ the mean rises from about 84 ms to $0.98 \times 84 + 0.02 \times 580 \approx 94$ ms, only 12%.

Interpretation. The p99 jumps 3.6 times when the cold fraction crosses 1%, while the mean moves by 10 ms. **Engineering implication.** Compare p with $1 - q$: a p99 SLO tolerates well under 1% cold starts, a p99.9 SLO well under 0.1%. Near the cliff, remove cold starts from the path; shaving the handler will not help.

What sets p? For a function with sparse traffic, each invocation is cold if the previous one finished more than a **keep-alive window** K ago.

FORMULA

Cold-start probability and idle memory under a fixed keep-alive (sparse Poisson arrivals)

$$P_{\text{cold}} = e^{-\lambda K} \qquad I = \frac{1 - e^{-\lambda K}}{\lambda}$$

Symbol	Meaning	Units
λ	Invocation rate of the function (Poisson, rare enough that invocations do not overlap)	invocations/s
K	Keep-alive window after the last invocation before reclamation	s
P_{cold}	Probability an invocation is a cold start (gap longer than K)	dimensionless
I	Expected idle time an environment is held after each invocation, $E[\min(\text{gap}, K)]$	s

WORKED EXAMPLE

Worked example — Keep-alive for rare functions. A webhook function is invoked on average every 5 minutes ($\lambda = 1/300$ per second).

1. $K = 600$ s: $P_{\text{cold}} = e^{-2} = 13.5\%$; $I = 300\,(1 - 0.135) = 259$ s held idle per invocation.
2. $K = 1,200$ s: $P_{\text{cold}} = e^{-4} = 1.8\%$; $I = 300\,(1 - 0.018) = 295$ s.
3. An hourly function ($\lambda = 1/3,600$) with $K = 1,200$ s: $P_{\text{cold}} = e^{-1/3} = 71.7\%$, while holding $I = 3,600\,(1 - 0.717) = 1,020$ s of idle memory per invocation.

Interpretation. For the five-minute function, doubling K cuts cold starts 7.5-fold for 14% more idle memory; the hourly function wastes 17 minutes of memory per call and stays 72% cold. **Engineering implication.** No fixed window fits every function: rare functions need prediction (pre-warm before the expected arrival) or acceptance of cold starts.

INDUSTRY EXAMPLE

Azure Functions: a hybrid histogram keep-alive. Shahrad et al. characterized two weeks of the whole Azure Functions workload: 54% of applications had one function, half of functions averaged under a second, and invocation rates spanned eight orders of magnitude. Azure then used a fixed 20-minute keep-alive. The authors proposed a per-application policy that keeps a histogram of idle times, unloads an application after it runs and **pre-warms** it just before the next expected invocation, falling back to a fixed window or time-series forecasting when the histogram is not predictive. In trace-driven simulation it gave fewer cold starts with less memory, and a version was deployed in production; the trace is public as the Azure Public Dataset [Shahrad et al. 2020]. *Evidence: Primary* — [Shahrad et al. 2020]

48.5.3 Mitigations

Table 48.2 — Cold-start mitigations, in rough order of preference.

Mitigation	What it removes	Cost	Caveats
Move work off the synchronous path	User-visible cold starts entirely	Design effort	Only for work that can be asynchronous
Smaller package, fewer dependencies	Code-loading time	Engineering time	Gains shrink with on-demand loading
Lazy initialization	Function-init time for unused paths	First caller of each path pays	Do not lazy-load on the hot path
Faster-starting language	Runtime and framework init	Rewrite	Go and Rust start fastest; JVM slowest without snapshots
More memory (more CPU)	CPU-bound init time	Higher GB-second price per ms	Often cost-neutral if duration falls
Snapshot restore (SnapStart)	Function and runtime init	Small, or caching and restore charges	Uniqueness hooks (§48.4.3)
Provisioned concurrency / minimum instances	All phases, up to the provisioned level	Pay while idle	Bursts above the level still cold
Keep-warm pings	One environment's reclamation	Ping invocations	Keeps 1 warm, not the 20 a burst needs

Provisioned concurrency keeps P environments initialized and billed at all times; requests above P spill to on-demand environments with ordinary cold starts [AWS Docs: Lambda].

FORMULA

Monthly cost of keeping capacity warm

$$C_{\text{warm}} = P \times M \times T \times c_{\text{pc}}$$

Symbol	Meaning	Units
P	Provisioned environments (or minimum instances)	environments
M	Memory per environment	GB
T	Seconds provisioned per month (2,592,000 for a 30-day month)	s
c_{pc}	Price per GB-second of provisioned (idle) capacity	$/GB-s
C_{warm}	Monthly charge for warmth alone, excluding duration charges	$/month

WORKED EXAMPLE

Worked example — Removing cold starts from `upload-url`. The simulation in §48.5.4 shows that 25 provisioned environments eliminate cold starts for its bursty traffic. With $M = 0.5$ GB and an illustrative $c_{pc} = \$0.0000041667$ per GB-s (AWS's x86 us-east-1 list price as of 2026; verify) [AWS Lambda Pricing]:

1. GB provisioned: $25 \times 0.5 = 12.5$ GB.
2. GB-seconds per month: $12.5 \times 2,592,000 = 32,400,000$.
3. Cost: $32,400,000 \times 0.0000041667 \approx \$135$ per month.
4. Compare: the same traffic (about 535,000 invocations per day, 16 million per month, mean 84 ms) costs about $16 \times 10^6 \times (0.5 \times 0.084 \times 0.0000166667 + 2 \times 10^{-7}) \approx \$14.4$ per month on demand.

Interpretation. Warmth costs nine times the work, because 25 environments idle between bursts. **Engineering implication.** Provision only where cold starts break an SLO, size P from measured burst concurrency, and schedule it with an autoscaler.

48.5.4 Simulation: keep-alive and provisioned concurrency under bursty traffic

The program simulates one function for two hours: 1 RPS background traffic with a 40 RPS burst for two minutes every 15 minutes. Each environment serves one request at a time; handlers are lognormal with median 80 ms; a cold start adds 300–700 ms. On-demand environments idle longer than K are reclaimed; P provisioned ones never are. The router prefers provisioned, then the most recently used warm environment. It sweeps K and P, then runs five tests.

```
import math
import random

SIM_S = 2 * 3600          # simulate two hours
BASE_RPS = 1.0            # quiet background traffic
BURST_RPS = 40.0          # traffic during a burst
BURST_EVERY_S = 900       # a burst starts every 15 minutes...
BURST_LEN_S = 120         # ...and lasts two minutes
MU, SIGMA = math.log(0.08), 0.3   # handler: median 80 ms, p99 ~160 ms
MEAN_S = math.exp(MU + SIGMA ** 2 / 2)

def rate(t):
    """Offered load in RPS at time t (seconds)."""
    return BURST_RPS if (t % BURST_EVERY_S) < BURST_LEN_S else BASE_RPS

sparse function: cold 36.6% vs exp(-lambda K) = 36.8%
all fleet tests passed
```

What to notice:

- **The cliff is real.** At $K = 10$ s, 1.03% of requests are cold, just over $1 - q$, and p99 is 387 ms; at 60 s, 0.32% are cold and p99 is 169 ms, near the warm 162 ms. The p99.9 stays cold-dominated until nearly all cold starts are gone (§48.5.2).
- **The window must outlast the gap between bursts.** Windows of 60–600 s perform alike because bursts are 900 s apart; only $K = 1,200$ s carries environments across, at 3.5 times the idle environment-hours of $K = 60$ s.
- **Cold starts inflate concurrency.** The average burst concurrency is $40 \times 0.084 \approx 3.4$ environments, yet up to 25 on-demand environments exist: at the start of each burst, requests arrive while new environments are still initializing for 300–700 ms, so each cold request occupies an environment about seven times longer than a warm one (584 ms versus 84 ms) and triggers more cold starts. This **cold-start cascade** is why bursts need more capacity than Little's Law on warm durations suggests.
- **Provisioned concurrency trades memory for certainty.** $P = 10$ cuts cold starts tenfold; $P = 25$ removes them at 49 idle environment-hours. The tests check mono-

tonicity in K, the memory cost of warmth, Little's Law within 5%, and $e^{-\lambda K}$ for a sparse function.

Failure scenarios

Table 48.3 — Cold-start failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
p99 breaches SLO after a deploy	New version: every environment is new	Init-duration metric spikes with deploy	Shift alias traffic gradually	Pre-warm new version; canary (§48.12)
Burst times out at the gateway	Cold-start cascade plus slow init	Cold-start count vs concurrency graph	Provisioned capacity for the burst	Smaller init; asynchronous path
Init fails repeatedly	Secret or config service unreachable in init	Init errors, not handler errors	Fix dependency; retry	Timeouts and fallbacks in init
Duplicate IDs after snapshot restore	Generator seeded during init	Collisions in logs or keys	Reseed in after-restore hook	Uniqueness tests on restore
Bill jumps with no traffic change	Init now billed, heavy init code	Billed duration vs handler duration	Trim init	Measure init GB-seconds

COMMON MISTAKE

Common misconception — "Cold starts only matter for Java." Runtime choice changes phase 4, but your own initialization (phase 5) can take seconds in any language. Measure the reported init duration before blaming the runtime.

48.6 Concurrency and scaling limits

48.6.1 Concurrency is the unit

DEFINITION

Definition — Concurrency (FaaS). The number of execution environments serving invocations at the same instant. On platforms with one request per environment it equals in-flight requests. Providers limit concurrency, not request rate, because concurrency is what consumes memory on workers.

By Little's Law (§4.11), concurrency equals arrival rate times duration, so a slower function needs more environments for the same traffic: a slow database can push a fleet into its limit with no extra requests.

FORMULA

Required concurrency, time to scale and connections opened

$$C = \lambda \times D \qquad T_{\text{scale}} \approx \Delta t \times \lceil \frac{C - C_0}{r} \rceil \qquad N_{\text{conn}} = C \times k \quad \text{vs.} \quad N_{\text{pool}} = \lambda_q \times d_q$$

Symbol	Meaning	Units
C	Concurrent environments required	environments
λ	Invocation rate	invocations/s
D	Mean invocation duration, including any cold-start time	s
C_0	Concurrency already running	environments
r	Environments the platform may add per scaling step	environments/step
Δt	Length of a scaling step	s
T_{scale}	Time to reach C from C_0	s
k	Database connections each environment holds	connections
N_{conn}	Connections opened without pooling	connections
λ_q, d_q	Database query rate and mean query time	queries/s, s
N_{pool}	Connections actually busy, the pool size needed	connections

As of 2026, AWS Lambda's defaults are a **regional account limit** of 1,000 concurrent executions (raisable on request) shared by all functions, and a **scaling rate** of up to 1,000 additional environments per function every 10 seconds; invocations beyond either limit are **throttled** (HTTP 429 for synchronous calls; retried by Lambda for asynchronous events and by the poller for queues) [AWS Docs: Lambda].

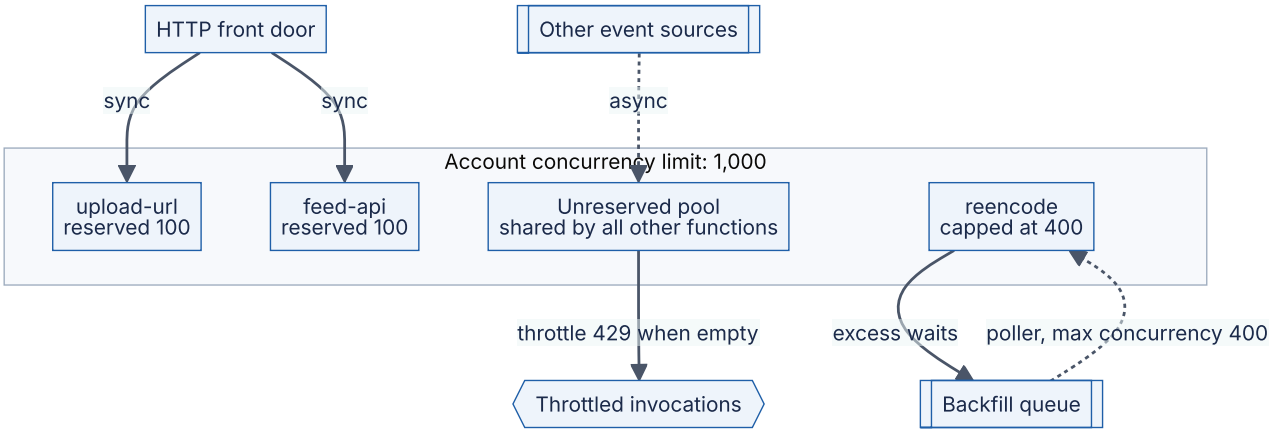
WORKED EXAMPLE

Worked example — PhotoShare re-encodes its archive. PhotoShare decides to add an AVIF rendition to 200 million stored photos. A backfill job enqueues one message per photo; the `reencode` function takes $D = 1.2$ s at 2 GB.

1. Unlimited, the queue poller would scale toward the account limit: $C = 1,000$ gives $\lambda = C/D = 833$ photos/s, but leaves nothing for the interactive functions sharing the account.
2. The live `upload-url` and feed functions need $70 \times 0.15 + 1,700 \times 0.05 = 10.5 + 85 \approx 96$ environments at peak. Reserve 200 for them, and cap `reencode` at 400 (via the SQS event source's maximum concurrency or reserved concurrency).
3. Backfill throughput: $\lambda = 400/1.2 = 333$ photos/s; duration $2 \times 10^8/333 = 600,000$ s, about 6.9 days.
4. Scaling time from zero: $T_{\text{scale}} \approx 10 \times \lceil 400/1,000 \rceil = 10$ s. A sudden need for 5,000 environments (after a limit increase) would take about $10 \times 5 = 50$ s, during which excess events wait in the queue.
5. Database: each `reencode` environment opens $k = 1$ PostgreSQL connection to update metadata, so $N_{\text{conn}} = 400$, against a `max_connections` of 500 that the API servers also use. The real need: 333 updates/s at 3 ms each gives $N_{\text{pool}} = 333 \times 0.003 = 1$ busy connection on average.

Interpretation. Concurrency is the budget, and the database has one connection's worth of work but would be offered 400 connections. **Engineering implication.** Cap high-volume asynchronous functions, reserve capacity for latency-critical ones, and pool connections to relational databases.

Figure 48.7 — Concurrency pools within one account and Region.



Reading the diagram. The account limit is one shared bucket; reserved concurrency carves guaranteed, capped slices for named functions. Synchronous front-door traffic reaches `upload-url` and `feed-api`, which the backfill cannot starve. The backfill's asyn-

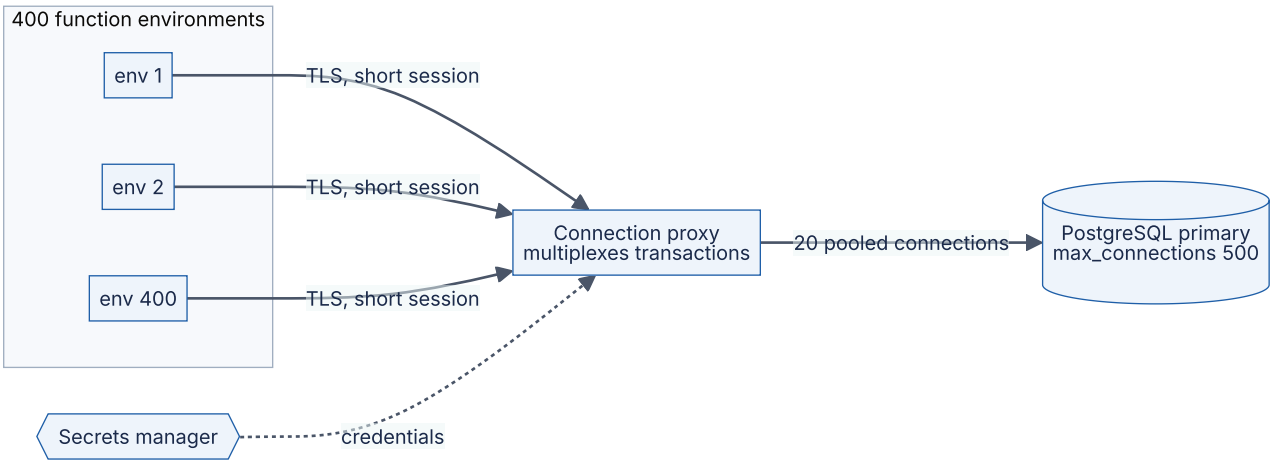
chronous poller is capped, so excess work waits in the queue (a storage boundary) instead of throttling. Other functions share the unreserved pool; when it is empty, synchronous callers get 429 and asynchronous events are retried. Failure point: over-reserving starves unplanned functions. Scaling: raise the limit or split workloads into accounts, which also limits blast radius (§47.4.3).

48.6.2 Protecting downstream systems

Functions scale in seconds; most databases and third-party APIs do not. Three tools protect them:

1. **Concurrency caps** (reserved concurrency, or a queue event source's maximum concurrency).
2. **A queue in front**, turning a burst into a backlog that drains at a controlled rate (§30.4).
3. **A connection pooler. Amazon RDS Proxy** keeps a warm pool to the database and lends a connection per transaction; session state such as temporary tables **pins** a client to a connection and defeats multiplexing [AWS Docs: RDS Proxy]. PgBouncer in transaction mode does the same for self-managed PostgreSQL; HTTP data APIs avoid connections altogether.

Figure 48.8 — A connection proxy between a function fleet and a relational database.



Reading the diagram. Each environment opens a cheap synchronous session to the proxy, which lends one of 20 pooled connections per transaction (sized by N_{pool} with headroom), so the database sees 20 connections whatever the fleet size. Credentials arrive asynchronously from a secrets manager. The database is the storage boundary and the real capacity limit; when the pool is busy the proxy queues, adding latency instead of connection errors. Failure points: pinned sessions exhausting the pool, and the proxy itself (deploy it across zones). Scaling: a larger pool helps only while the database has spare CPU and I/O.

COMMON MISTAKE

Common misconception — "Serverless scales, so my system scales." The system scales only as far as its least elastic dependency; every function calling a database or rate-limited API needs a cap or a queue.

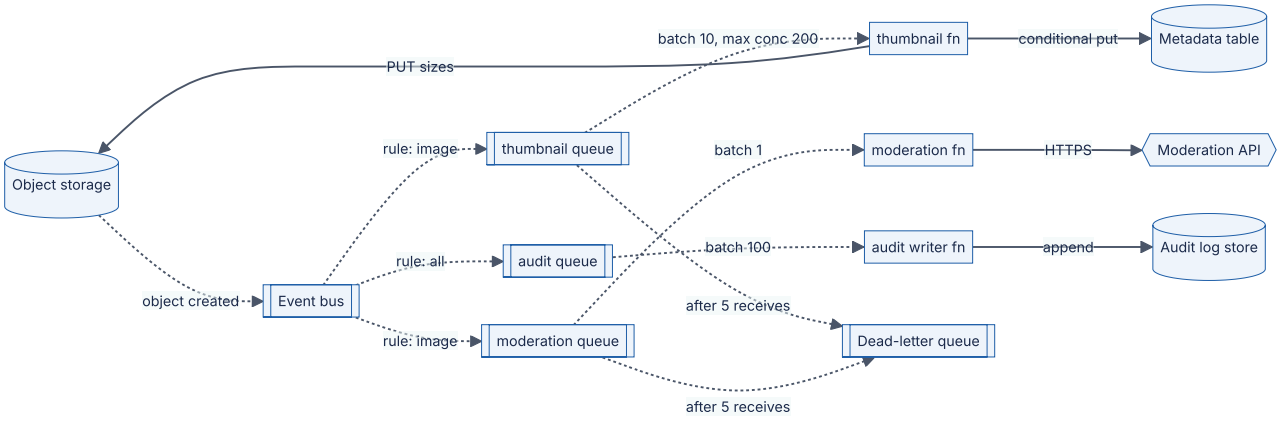
48.7 Serverless data patterns

48.7.1 Event-driven pipelines

Stateless, short-lived functions are composed into **pipelines**: a managed queue, stream or event bus carries work between them, and the event source fixes delivery semantics, ordering and retries.

- **Queues** (SQS, Pub/Sub, Service Bus). A poller invokes the function with **batches** and deletes messages on success; failed messages reappear after the visibility timeout and go to a **dead-letter queue** after a set number of receives (§30.11). **Partial batch responses** report only the failed message IDs, so one bad message does not fail its batch [AWS Docs: Lambda].
- **Streams** (Kinesis, DynamoDB Streams, Kafka). Records are ordered per shard, processed one batch per shard at a time (Lambda's **parallelization factor** allows up to 10, preserving per-key order). A failing record blocks its shard, so consumers need bisect-on-error, a retry limit and an on-failure destination.
- **Pub/sub fan-out** (SNS, EventBridge, Eventarc). One event reaches many subscribers, usually through a queue per subscriber so a slow consumer affects no one else.

Figure 48.9 — PhotoShare's upload pipeline with fan-out and failure paths.



Reading the diagram. Bus rules fan each object-created event out to one queue per consumer (dotted: asynchronous, at-least-once). Each queue sets its own batch size and concurrency: thumbnails in tens capped at 200, moderation singly because its API is slow and rate limited, audit in hundreds. Solid edges are synchronous writes to the storage

boundaries and the moderation API. Failure points: a corrupt image (retried, then dead-lettered without blocking others), the moderation rate limit (its queue absorbs the backlog) and duplicates (§48.7.2). Scaling: consumers scale independently, and a new consumer needs only a rule and a queue.

48.7.2 Idempotent handlers

Every source above delivers at least once, and asynchronous invocations are retried, so handlers must be **idempotent**. Apply §22.15: derive the **idempotency key** from the business identity of the work (bucket, key and object version, not the message ID), record completion with a conditional write, and make side effects naturally idempotent or guarded by the record.

```
        import hashlib
        import json

        class ConditionalStore:
            """Stands in for a key-value table with conditional put (put-if-absent)."""
            def __init__(self):
                self.items = {}

            def put_if_absent(self, key, value):
                if key in self.items:
                    return False
                self.items[key] = value
                return True

        def handle_batch(records, store, make_thumbnail):
            """SQS-style batch handler: idempotent per record, partial failure re-
port."""
            failures = []
            for rec in records:
                body = json.loads(rec["body"])
                # Idempotency key: the object version, not the delivery's message ID,
                # so a duplicate upload event and a redelivery both dedupe (§22.15).
                key = hashlib.sha256(f"{body['bucket']}/{body['key']}@{body['version']}"
                                     .encode()).hexdigest()
                if key in store.items:
                    continue                          # already done: skip side effects
                try:
                    sizes = make_thumbnail(body["key"])
                except Exception:
                    failures.append({"itemIdentifier": rec["messageId"]})
                    continue                          # only this record is retried
                store.put_if_absent(key, {"sizes": sizes})
            return {"batchItemFailures": failures}

        if __name__ == "__main__":
            calls = []

            def thumb(k):
                calls.append(k)
                if k == "bad.jpg":
                    raise ValueError("corrupt image")
                return [128, 512, 1080]

            ev = lambda mid, k, v: {"messageId": mid, "body": json.dumps(
                {"bucket": "photos", "key": k, "version": v})}
            store = ConditionalStore()
            batch = [ev("m1", "a.jpg", 1), ev("m2", "bad.jpg", 1), ev("m3", "a.jpg", 1)]
            out = handle_batch(batch, store, thumb)
            assert out == {"batchItemFailures": [{"itemIdentifier": "m2"}]}
            assert calls == ["a.jpg", "bad.jpg"]      # duplicate m3 did no work
            # Redelivery of the whole batch: only the failed record is attempted again.
            out = handle_batch(batch, store, thumb)
```

```
            assert calls == ["a.jpg", "bad.jpg", "bad.jpg"]
            print(out, "-> idempotency tests passed")
```

Output (Python 3.13): `{'batchItemFailures': [{'itemIdentifier': 'm2'}]} -> idempotency tests passed`.

What to notice:

- The partial-batch response returns only `m2` to the queue.
- `m3` is a different message carrying the same work; the version-derived key makes it a no-op.
- Two environments can still race between check and put. That is harmless for thumbnails, which overwrite the same keys; for non-idempotent effects (charges, emails), claim the key *before* the side effect (§22.15.3).

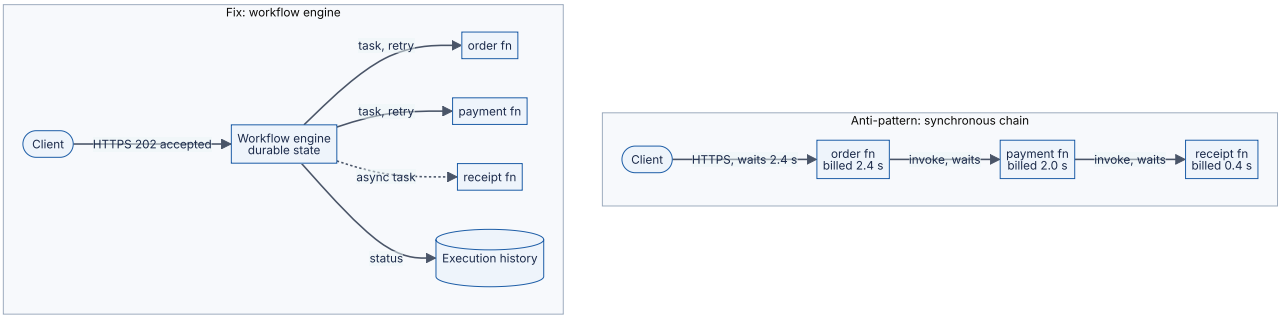
48.7.3 Orchestration instead of chains

The tempting multi-step design is a **function chain**, A calling B synchronously and B calling C. It is the main serverless anti-pattern:

1. **Double billing.** A is billed while it waits for B; the first function pays for the whole chain.
2. **Concurrency multiplication.** A three-level chain holds three environments per request.
3. **Compounding timeouts and retries** at every level (§22.12).
4. **No durable state.** If A crashes after B succeeded, nothing records B's step.

Use a queue between independent steps (choreography), or a **workflow engine** for order, branching, waits or compensation (§32.8, §32.11). Step Functions records every transition durably and retries tasks; Standard workflows run up to a year, Express up to five minutes (as of 2026). Azure Durable Functions and Google Workflows fill the same role.

Figure 48.10 — A synchronous function chain versus an orchestrated workflow.



Reading the diagram. In the chain every arrow is synchronous: the client waits 2.4 s, `order` is billed 2.4 s and `payment` 2.0 s for a fraction of that work, and three environments are held per request; a `receipt` failure surfaces through both callers with no record of

completed steps. In the orchestrated version the client gets an immediate 202; the engine invokes each function as a task with its own retries, records transitions in its execution history (the storage boundary) and runs the receipt asynchronously. The failure point becomes the managed, durable engine. Scaling: concurrency equals the work actually being done.

48.7.4 State and other anti-patterns

State lives in managed stores (tables, object storage, caches, workflow history). An environment's memory and `/tmp` are unshared caches that may vanish at any moment.

Table 48.4 — Serverless anti-patterns.

Anti-pattern	What goes wrong	Fix
Lambda calling Lambda synchronously	Double billing, concurrency × depth, compounding timeouts	Queue between steps, or a workflow engine
Recursive trigger (function writes to the bucket or queue that triggers it)	Infinite loop and a runaway bill	Separate input and output locations; loop detection; budgets
Database connections without a pooler	Connection exhaustion at scale	Proxy, caps, HTTP data APIs
Long-running or polling work in a function	Duration limit; billed idle waiting	Containers or batch; workflow waits; callbacks
One giant function with every route	Large package, slow cold starts, one broad IAM role	Functions per bounded context, or a container

Lambda stops some recursive loops itself, after about 16 repetitions through Lambda, SQS, SNS and S3 (as of 2026) [AWS Docs: Lambda]; treat that as a last line of defense.

48.8 Edge runtimes

48.8.1 Why the edge needs a different sandbox

Any server in any of a CDN's hundreds of points of presence (PoPs) may receive a request for any of millions of customer scripts. A microVM per script per server is far too much memory, and a 125 ms boot exceeds the 10–20 ms round trip the edge saves. Edge runtimes trade generality (no arbitrary binaries, no full Linux) for millisecond or microsecond starts and megabytes per tenant.

DEFINITION

Definition — V8 isolate. An instance of the V8 JavaScript engine's heap and execution state. Many isolates run inside one operating-system process, each with its own memory and globals and no access to another's objects; switching between them costs about as much as a function call, not a process context switch [Bloom 2018].

First-principles explanation

A microVM is a separate apartment; an isolate is a desk with a locked drawer in an open-plan office. Newcomers sit down in seconds, but the office is safe only if drawers are strong and nobody learns secrets by timing a neighbor's typing, hence the effort isolate platforms put into security.

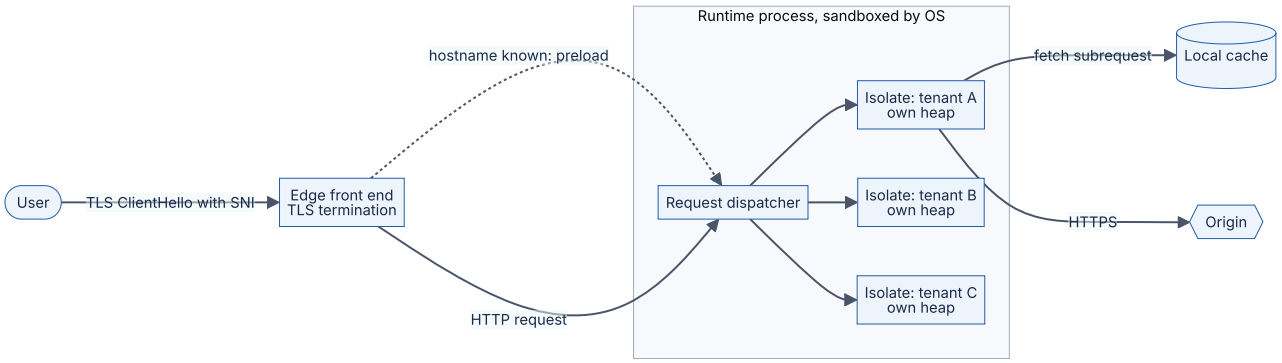
How it works internally

Cloudflare Workers. Each server's runtime process hosts thousands of isolates, one per script. Cloudflare reported in 2018 that an isolate starts in about 5 ms using a fraction of a Node.js process's memory [Bloom 2018], and later began loading the script when the TLS handshake reveals the hostname, so the isolate is usually ready when the request arrives [Partovi 2020]. Limits (as of 2026) include 128 MB per isolate and a per-request CPU-time limit (10 ms free; up to minutes on paid plans), excluding time waiting on I/O [Cloudflare Docs: Workers].

Fastly Compute. Code is compiled ahead of time to **WebAssembly** (Wasm) and run by Wasmtime, with a fresh instance per request, created in microseconds and destroyed after the response, so no state leaks between requests [Fastly Docs: Compute]. Wasm code can touch only its own bounds-checked linear memory and call only imported host functions [Haas et al. 2017]. Rust, Go and JavaScript (via an engine compiled to Wasm) all work.

AWS Lambda@Edge and CloudFront Functions [AWS Docs: CloudFront]. **CloudFront Functions** run restricted JavaScript at every edge location on viewer events only: sub-millisecond, 2 MB memory, 10 KB code, no network (header rewrites, redirects, cache keys, token checks). **Lambda@Edge** runs Node.js or Python Lambda functions in regional edge caches, on viewer events (5 s, 128 MB) and origin events (30 s, more memory), with network access.

Figure 48.11 — One edge server running many tenants' isolates.



Reading the diagram. Once the TLS handshake reveals the hostname, the front end asynchronously (dotted) tells the runtime to load that tenant's script. One OS-sandboxed process hosts many isolates with separate heaps; requests are dispatched synchronously to the right isolate, which may read the PoP cache or call the origin. Storage boundaries: the local cache and remote origins; isolates keep nothing durable. Failure points: a V8 bug (hence the second, OS-level wall), CPU-heavy scripts (bounded by limits) and origin round trips (§48.10). Scaling: every server runs every tenant, so capacity grows with PoPs and servers.

48.8.2 The isolate security model

Mutually untrusting tenants in one process need defenses beyond the language sandbox. Cloudflare's published model has several layers [Varda 2020]:

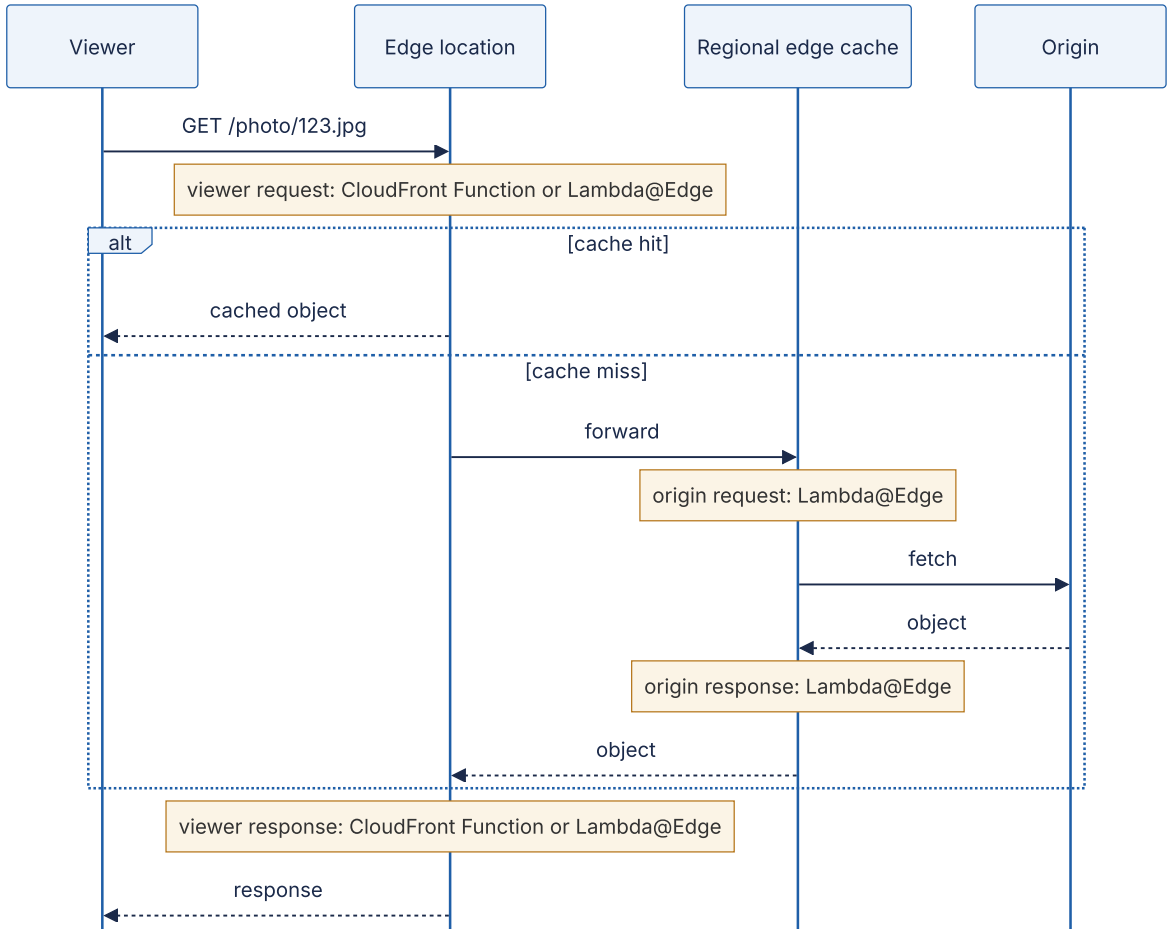
1. **The V8 sandbox**, patched rapidly when vulnerabilities appear.
2. **A process-level sandbox** around the runtime (namespaces and system-call filtering), so a V8 escape lands in a process with almost no privileges.
3. **Cordons**: tenants are grouped by trust level, so free-tier scripts never share a process with enterprise scripts.
4. **Spectre mitigations by design**: no high-resolution timers (the clock does not advance during execution), no shared memory or multithreading within a request, both of which are needed to build a precise timer; and **dynamic process isolation**, moving a script that behaves suspiciously into its own process.

Wasm platforms rely on bounds-checked linear memory, a fresh instance per request and a minimal host interface; microVM platforms such as Lambda@Edge rely on hardware virtualization (§47.9).

Table 48.5 — Edge runtimes compared (as of 2026; verify limits).

Property	V8 isolates (Cloudflare Workers)	Wasm per request (Fastly Compute)	Lightweight JS (CloudFront Functions)	MicroVM functions (Lambda@Edge)
Sandbox	Isolate in shared process + OS sandbox	Wasm instance, fresh per request	Restricted JS runtime	Firecracker microVM
Start	~ms, often hidden behind TLS	Microseconds	Sub-ms	Lambda cold start
Languages	JavaScript, TypeScript, Wasm	Anything compiling to Wasm	JavaScript subset	Node.js, Python
Where	Every PoP	Every PoP	Every edge location	Regional edge caches
Network calls	Yes	Yes	No	Yes
Typical limits	128 MB; CPU-time budget per request	Per-request memory and time budgets	2 MB, 10 KB code, sub-ms	128 MB and 5 s on viewer events
Best for	General edge logic, APIs, routing	Compute-heavy or multi-language edge logic	Header and URL manipulation at huge volume	Node or Python logic needing AWS SDKs

Figure 48.12 — Where code can run in a CloudFront request.



Reading the diagram. All messages are synchronous HTTP. Viewer-request code runs on every request before the cache lookup, so it must be cheap (token checks, cache keys). Origin events run only on misses, after the regional cache, so they can do more (origin selection, image variants) and their results are cached. Viewer-response code runs on every response. Storage boundaries: two cache tiers and the origin. Failure points: slow or failing viewer code hurts even cache hits. Scaling: origin-event work grows with the miss rate, not the request rate.

> WARNING / TRADE-OFF
>
> **Warning — Edge code is on every request.** One millisecond of viewer-request code at PhotoShare's 17,400 photo views per second is 17.4 CPU-seconds per second across the edge. Put per-request logic in the cheapest tier that can do it, and move anything cacheable to origin-facing events.

48.9 Edge data

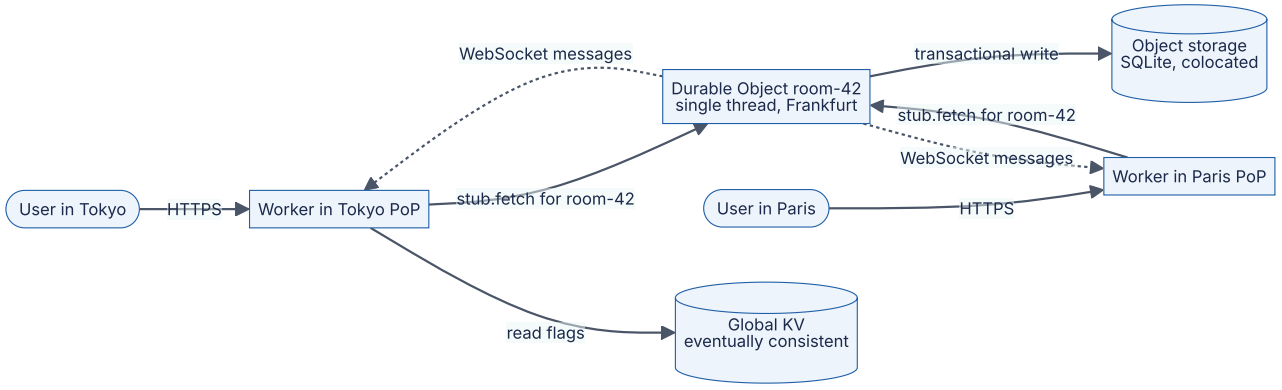
Edge code is only as fast as its data (§48.10), so edge platforms offer storage with different placements, each a different point in the consistency trade-offs of Chapter 25.

48.9.1 Four kinds of edge state

1. **Per-PoP cache (Cache API).** Code reads and writes the PoP's HTTP cache (computed responses, fetched signing keys, fragments). It is local, unreplicated and evictable; correctness must never depend on it.
2. **Global key-value stores** (Workers KV, Fastly KV Store, CloudFront KeyValueStore). Writes go to central storage and propagate to PoPs, which cache values for reads. They are **eventually consistent**: Cloudflare documents that a write is usually visible at once where it was made but may take 60 seconds or more to appear elsewhere, and limits writes to the same key to about one per second [Cloudflare Docs: Workers KV]. Concurrent writes resolve by last-write-wins. Ideal for read-heavy, rarely changing data: feature flags, redirects, A/B experiment definitions, allow-lists, public keys.
3. **Single-writer actors** (Cloudflare **Durable Objects**). Each object has a globally unique ID, and the platform guarantees at most one live instance of it in the world at a time, running single-threaded next to its own transactional, strongly consistent storage (SQLite-backed) [Cloudflare Docs: Durable Objects]. Every request for that ID is routed to that instance, so the object serializes all operations on its state without locks: a linearizable unit, in the terms of §25.3. Ideal for counters, per-user rate limiters, chat rooms, collaborative documents, game sessions and coordination.
4. **Replicated SQL at the edge** (Cloudflare D1 read replication, libSQL/Turso embedded replicas, LiteFS). A primary SQLite database takes all writes; read replicas near

users serve queries. Reads from a replica can be stale; D1 offers sessions with bookmarks so that a client's reads observe at least its own earlier writes (read-your-writes, sequential consistency within the session) [Cloudflare Docs: D1].

Figure 48.13 — Routing requests to a single-writer Durable Object.



Reading the diagram. Stateless Workers in each user's nearest PoP route requests for `room-42` synchronously to its single instance in Frankfurt, whose colocated SQLite storage is the strongly consistent boundary; broadcasts flow back asynchronously over WebSockets. Feature flags come from eventually consistent KV at the local PoP. Failure points: distance (Tokyo pays about a 230 ms round trip), one thread bounding throughput, and re-creation elsewhere if the host fails. Scaling: shard state across many objects (per room, user or document), never one global object.

48.9.2 Choosing by consistency

Table 48.6 — Edge data options and their consistency (as of 2026).

Option	Placement	Consistency	Write path	Good for	Bad for
Cache API	One PoP	None (may vanish)	Local	Memoizing fetches and renders	Anything authoritative
Global KV	Central store, cached at PoPs	Eventual, ~60 s+	Central, rate limited per key	Flags, config, redirects, keys	Counters, read-after-write, frequent writes
Durable Object	One location per object	Strong (single writer)	To the object's home	Counters, locks, rooms, sessions	Global hot keys, read-heavy global data
Edge SQLite replicas	Primary + regional replicas	Primary strong; replicas lag; sessions give read-your-writes	To primary	Read-heavy relational data	Write-heavy, globally distributed writers
Origin database	One Region	Whatever it provides	Origin	System of record	Low-latency global reads

The pattern for most products: authoritative state at the origin, read-mostly copies in KV or replicas, coordination in single-writer objects sharded by entity, and caches everywhere. PhotoShare keeps photo metadata in its regional database, experiment definitions and token-signing public keys in KV, per-user upload rate limits in Durable Objects keyed by user, and rendered thumbnails in the CDN cache.

> COMMON MISTAKE
>
> **Common misconception — "Edge KV is a globally replicated database."** It is a globally cached configuration store: concurrent increments lose updates, Sydney may read Paris's write a minute late, and per-key write rates are tiny. Count and read-back-immediately state belongs in a single-writer object or at the origin.

48.10 What to run at the edge

48.10.1 The latency budget

The edge saves round trips between user and region, and loses when edge code makes several round trips back for data (§44.4 covers the physics).

FORMULA

Edge versus origin request latency (warm connections)

$$T_{\text{origin}} = R_{ue} + R_{eo} + c_o + nR_{od} \qquad T_{\text{edge}} = R_{ue} + c_e + mR_{eo} + jR_{el}$$

Symbol	Meaning	Units
R_{ue}	Round trip between user and nearest PoP	ms
R_{eo}	Round trip between PoP and origin Region (warm connection)	ms
R_{od}	Round trip between origin service and its database (same Region)	ms
R_{el}	Round trip from edge code to edge-local data (KV, replica, cache)	ms
c_o, c_e	Compute time at origin and at the edge	ms
n	Sequential database round trips the origin service makes	count
m	Sequential round trips edge code makes to the origin	count
j	Sequential round trips edge code makes to edge-local data	count

Ignoring compute differences, moving the logic to the edge helps only if $mR_{eo} < R_{eo} + nR_{od}$. Because R_{od} is about 1 ms and R_{eo} is tens to hundreds, that means $m \leq 1$: edge code may make at most one trip to the origin, and should usually make none.

WORKED EXAMPLE

Worked example — PhotoShare in Sydney, origin in Virginia. Assume $R_{ue} = 10$ ms, $R_{eo} = 200$ ms, $R_{od} = 1$ ms, $R_{el} = 2$ ms. The profile page needs five sequential queries and 20 ms of rendering wherever it runs.

1. Origin render: $T_{\text{origin}} = 10 + 200 + 20 + 5 \times 1 = 235$ ms.
2. Edge render, data at origin ($m = 5$): $T_{\text{edge}} = 10 + 20 + 5 \times 200 = 1,030$ ms, 4.4 times slower.
3. Edge render, data in an edge replica ($m = 0$, $j = 5$): $T_{\text{edge}} = 10 + 20 + 5 \times 2 = 40$ ms, 5.9 times faster than the origin.
4. Edge token check that rejects an expired token ($m = 0$, $c_e = 1$ ms): $10 + 1 = 11$ ms, against 215 ms for a rejection by the origin, and the origin never sees the request.
5. Edge token check on a valid request, then forward: $10 + 1 + 200 + 20 + 5 = 236$ ms: 1 ms slower than no edge logic, but the origin no longer validates tokens.

Interpretation. The same code is 4.4 times slower or 5.9 times faster at the edge depending only on where its data lives. **Engineering implication.** Move logic to the edge with its data, or move only logic that needs no origin data; batch any unavoidable origin call into one request.

48.10.2 Good and bad candidates

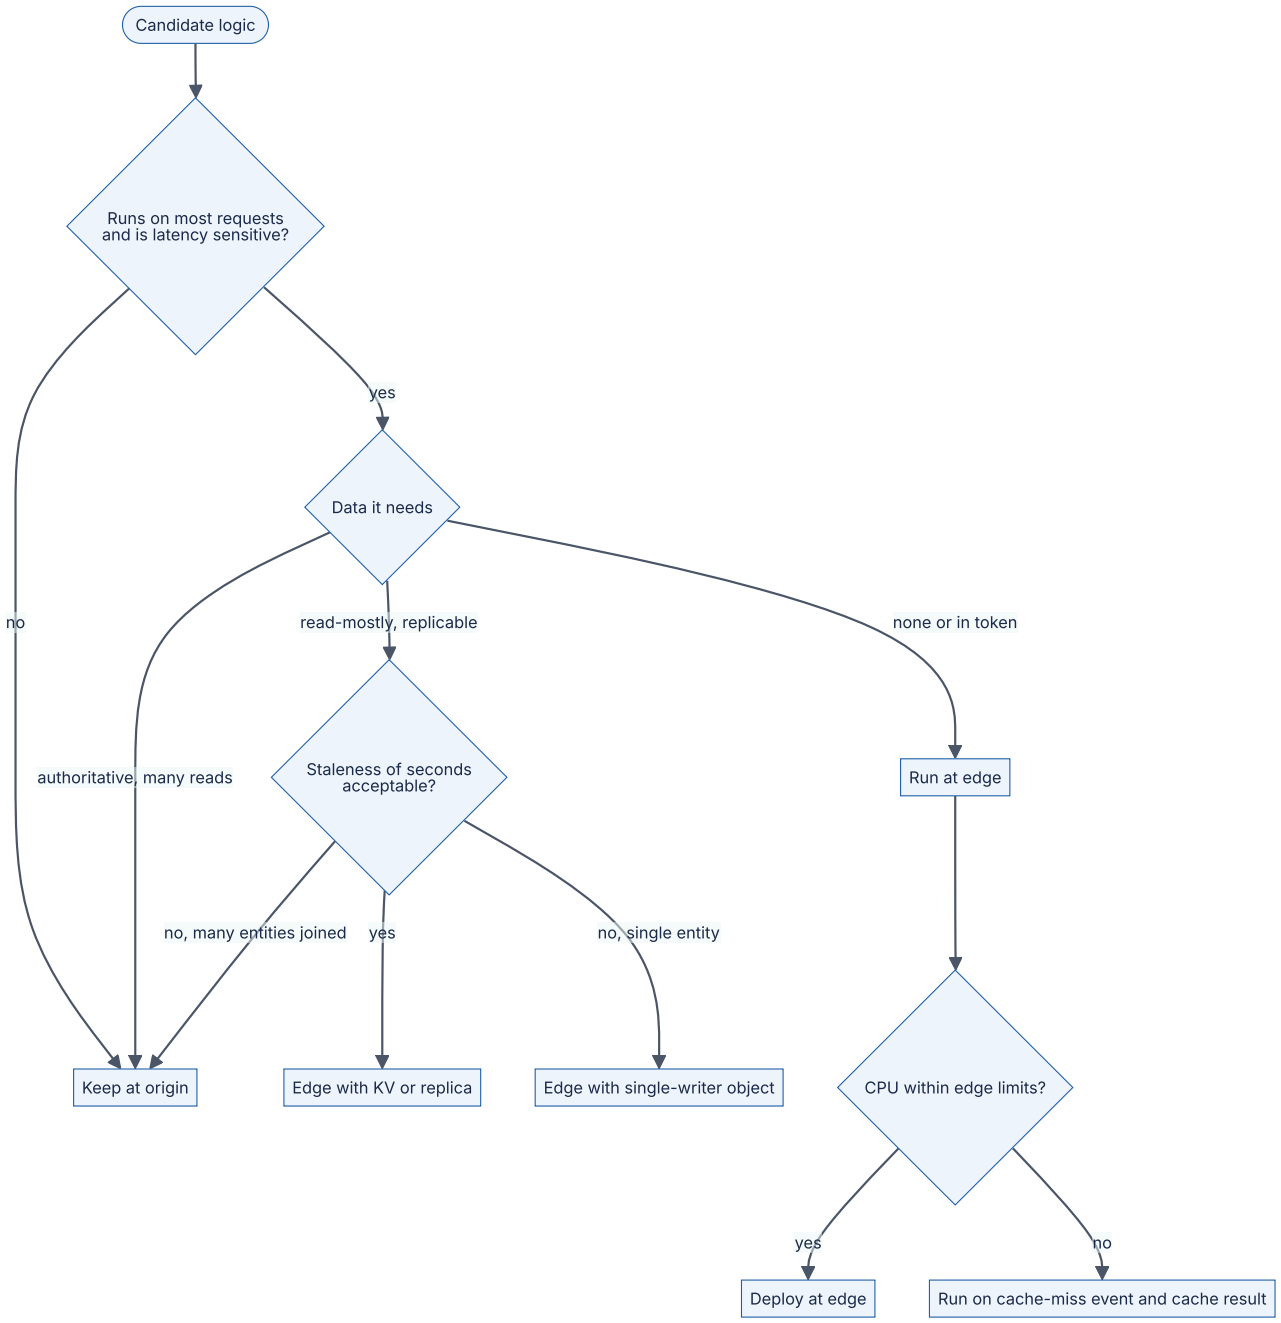
Work that fits the edge needs little data, or data that is read-mostly and replicable, and benefits every request:

- **Authentication and token validation.** Verify a JWT signature against public keys cached at the edge; reject bad tokens and bots before they cost origin capacity. Verify signed URLs for private photos (§21.11).
- **A/B assignment and feature flags.** Hash a user ID into a bucket, read experiment definitions from KV and rewrite the request, so the origin and cache see a stable variant key.
- **Personalization of cached pages.** Fetch a cached generic page and insert a few user-specific fragments (name, locale, currency) from a token or KV.
- **Request routing.** Choose an origin by geography, tenant, canary weight or health; rewrite URLs; normalize cache keys (§21.6).
- **Image transforms.** Resize and re-encode on a cache miss (origin-request event), then cache the variant, so each size is computed once per cache lifetime.
- **Security filtering and rate limiting** with per-client state in single-writer objects.

Work that does not fit: chatty access to an origin database ($m > 1$), long CPU-heavy jobs (CPU limits), large transactional writes, and anything requiring data that cannot legally

leave a Region (residency, §44.9).

Figure 48.14 — Deciding whether a piece of logic belongs at the edge.



Reading the diagram. This is a decision flow, not a data flow. Rare or latency-insensitive logic stays at the origin. For per-request logic, data decides: none (or only the token) means the edge; read-mostly data tolerating staleness means edge plus KV or a replica; consistent state about one entity means a single-writer object; authoritative data joined across entities means the origin ($m > 1$). CPU-heavy work moves to a cache-miss event. At each edge leaf, check behavior when the edge store is stale or unreachable, and whether the origin can serve as fallback.

48.11 Cost at scale

§33.9.3 derived the break-even request rate between functions and a fixed pair of servers. At scale three more terms matter: the front door's per-request charge, the provisioning factor of the always-on alternative (how far above average load it must run), and data transfer, which is the same for every compute choice and often larger than compute.

FORMULA

Monthly cost curves for functions, autoscaled containers and VMs

$$C_{\text{FaaS}} = R\,(c_{\text{req}} + c_{\text{fd}} + M D\, c_{\text{GBs}}) + R\, b\, c_{\text{eg}} \qquad C_{\text{fleet}} = \max\left(n_{\min}, \left\lceil \frac{\phi R}{T r} \right\rceil\right) c_{\text{unit}} + F + R\, c_{\text{lb}} + R\, b\, c_{\text{eg}}$$

Symbol	Meaning	Units
R	Requests per month	requests/month
c_{req}, c_{fd}	Function request charge; HTTP front-door charge per request	$/request
M, D, c_{GBs}	Memory, billed duration, price per GB-second	GB, s, $/GB-s
b	Response bytes leaving the cloud per request	GB/request
c_{eg}	Internet egress price	$/GB
$n_{\min}$	Minimum units for availability	units
ϕ	Provisioning factor: capacity ÷ average load (1.5 autoscaled, 3 sized for peak)	dimensionless
T	Seconds per month (2,592,000)	s
r	Requests per second one unit sustains at target utilization	RPS/unit
c_{unit}	Monthly price of one container task or VM	$/unit-month
F, c_{lb}	Load balancer's fixed monthly charge and per-request charge	$/month, $/request

WORKED EXAMPLE

Worked example — One API at 1 million, 100 million and 10 billion requests per month. Prices are illustrative, loosely based on us-east-1 list prices as of 2026; verify before use. Each request runs 100 ms (10 ms of it CPU) and returns 10 KB.

- **Functions:** $M = 0.5$ GB, $D = 0.1$ s, $c_{\text{GBs}} = \$0.0000166667$, $c_{\text{req}} = \$0.20$ per million, HTTP front door $c_{\text{fd}} = \$1.00$ per million. Per request: $0.05 \times 0.0000166667 + 2 \times 10^{-7} + 10^{-6} = \$2.033 \times 10^{-6}$.
- **Containers:** 1 vCPU and 2 GB tasks at $\$0.04048$ per vCPU-hour + $\$0.004445$ per GB-hour $= \$0.04937$ per hour $\times\ 730 = \$36.04$ per month; each sustains $r = 60$ RPS (10 ms CPU at 60% utilization); autoscaled, $\phi = 1.5$; $n_{\min} = 2$.
- **VMs:** 2 vCPU instances at an illustrative committed $\$0.06$ per hour $= \$43.80$ per month; $r = 120$ RPS; sized for peak, $\phi = 3$, plus 10% spare; $n_{\min} = 2$.
- **Load balancer** (containers and VMs): $F = \$20$ per month plus an illustrative $\$0.25$ per million requests. **Egress:** $c_{\text{eg}} = \$0.09$ per GB.

1. Average rates: $10^6/T = 0.39$ RPS; $10^8/T = 38.6$ RPS; $10^{10}/T = 3,858$ RPS.
2. Units: containers $\lceil 1.5 \times 38.6/60 \rceil = 1 \rightarrow 2$ (minimum) at 100 M; $\lceil 1.5 \times 3,858/60 \rceil = 97$ at 10 B. VMs $\lceil 3 \times 3,858/120 \rceil = 97$, plus 10 spare $= 107$ at 10 B; 2 below that.
3. Egress: 10 KB × requests $= 10$ GB, 1 TB and 100 TB: $0.90, $90 and $9,000.

Table 48.7 — Monthly cost by scale (illustrative prices).

Requests/month	Functions: compute + requests	Functions: front door	Containers: tasks + LB	VMs: instances + LB	Egress (all)	Total: functions / containers / VMs
1 million	$1.03	$1.00	$72.08 + $20.25	$87.60 + $20.25	$0.90	$2.93 / $93.23 / $108.75
100 million	$103.33	$100.00	$72.08 + $45.00	$87.60 + $45.00	$90	$293.33 / $207.08 / $222.60
10 billion	$10,333	$10,000	$3,496 + $2,520	$4,687 + $2,520	$9,000	$29,333 / $15,016 / $16,207

4. Break-even, functions versus the minimum container fleet: $R^* = (2 \times 36.04 + 20)/(2.033 \times 10^{-6} - 0.25 \times 10^{-6}) = 92.08/1.783 \times 10^{-6} \approx 51.6$ million requests per month, about 20 RPS average, consistent with the 23–45 RPS of §33.9.3.

Interpretation. At 1 million requests functions cost 3% of the alternatives; at 100 million they cost 40% more; at 10 billion nearly twice as much, and over half of that gap is the front door's per-request charge, not compute. Egress is identical across the three and, at 10 billion, about twice the fleets' instance cost. **Engineering im-**

> **plication.** Below the break-even, functions win on both cost and operations. Above it, first remove avoidable per-request charges (a function URL or load balancer instead of a full-featured gateway, Arm pricing, right-sized memory), then compare again; and always optimize egress (CDN offload, compression), which no compute choice changes. Engineer time, omitted here, favors functions at every scale below a dedicated platform team's cost.

The curves explain the Prime Video case in §33.9: a fine-grained serverless design is the cheapest way to start and the most expensive way to run a high, steady volume. Spiky traffic shifts the comparison toward functions, because the fleet's ϕ grows with peak-to-average ratio while functions bill only actual work; provisioned concurrency (§48.5.3) shifts it back.

48.12 Operating serverless

Observability. Alert on serverless-specific signals: throttles, init duration and cold-start count, concurrency versus limit, iterator age (stream lag), queue age and dead-letter depth. Log the request ID, version and cold-start flag so latency splits into warm and cold populations (§48.5.2).

Tracing across asynchronous hops. A request that crosses a queue loses its trace unless the producer writes the trace context (W3C `traceparent`, §40.6.2) into message attributes and the consumer restores it. Batches complicate this: one invocation may process ten messages from ten traces, so the consumer's span should carry **span links** to each producer span rather than pretend to have one parent. Managed services propagate context only where the provider integrates them; verify each hop.

Versions, aliases and gradual deployment. A published function **version** is immutable code plus configuration; an **alias** is a named pointer (for example `live`) that triggers and callers use. Shifting an alias's routing weights (say 5% to the new version for ten minutes, with automatic rollback on alarms) is a canary release (§43.6) without load balancers. Provisioned concurrency attaches to a version or alias, so pre-warm the new version before shifting traffic, or the canary measures cold starts rather than code.

Testing. Keep handlers thin around plain functions and unit-test them with recorded events (§48.7.2). Emulators (AWS SAM CLI, LocalStack, Azure Functions Core Tools, Cloudflare's local runtime) catch wiring mistakes; permissions, event-source settings and limits need an ephemeral cloud stack per branch from infrastructure as code (§43.8).

Lock-in. Handler logic is portable; the event formats, triggers, IAM policies, workflow definitions and managed data services around it are not. Keep business logic behind ports and adapters (§33.10), use standard event envelopes such as CloudEvents where possible, and prefer container-based platforms (Cloud Run, Knative) when portability matters more

than the deepest integration. Lock-in to a managed service that removes a whole operational burden is often a good trade; make it deliberately.

48.13 Serverless versus containers: a decision table

Table 48.8 — Functions, serverless containers, containers on a cluster and edge functions (as of 2026).

Row	Functions (Lambda, Azure Functions)	Serverless containers (Cloud Run, Fargate)	Containers on a cluster or VMs	Edge functions (Workers, Compute)
What it is	Code run per event in a managed sandbox	Your image, scaled by the provider	Your image on capacity you manage	Small code at every PoP
How it works	One request per environment (Lambda); scale to zero	Many requests per instance; scale to zero or minimum	Orchestrator schedules pods on nodes	Isolate or Wasm instance per request
Advantages	No servers, per-ms billing, rich event triggers	Any language and binary, container portability	Full control, cheapest at steady high load, long-lived connections	Lowest user latency, global by default
Disadvantages	Cold starts, limits, per-request cost at scale	Fewer knobs; some cold starts	Operations, capacity planning, idle cost	Tight CPU and memory limits, weak data locality
Performance	Warm: ms overhead; cold: 100 ms to seconds	Cold start on scale-out; warm like servers	Predictable; no cold starts	Start in µs to ms; origin round trips dominate
Operational complexity	Low	Low to medium	High	Low
Cost	Linear in requests; zero when idle	Per instance-second; zero or minimum when idle	Per node, used or not	Per request and CPU time
Use cases	Event glue, pipelines, spiky APIs, schedules	Web APIs, workers, migrated services	Large steady fleets, stateful systems, GPUs	Auth, routing, A/B, personalization, transforms
Choose when	Traffic is spiky or below ~20–45 RPS average, work is short	You want containers without a cluster	Load is steady and high, or you need control	Logic needs no origin round trip ($m \le 1$)

Most mature systems use several columns: the edge for authentication and routing, functions for event-driven glue and pipelines, and containers for the steady, high-volume core (§42.16).

48.14 Summary and revision notes

SUMMARY

- Serverless means no resource management, automatic scaling including to zero, and pay-per-use billing. It is FaaS for logic plus managed services for state [Jonas et al. 2019].
- Lambda's published design has four parts: frontend, Worker Manager (sticky slot state), Placement and workers. Each slot is a Firecracker microVM serving one function and one request at a time. Images load on demand as deduplicated, convergently encrypted chunks from tiered caches. SnapStart restores snapshots, and after-restore hooks must fix uniqueness.
- A cold start is placement, sandbox, code loading, runtime init and function init. The last is usually the largest. Mixture arithmetic gives the cliff: if the cold fraction exceeds $1 - q$, the q-th percentile is a cold-start latency.
- Under a fixed keep-alive, $P_{\text{cold}} = e^{-\lambda K}$. Rare functions stay cold and waste memory, which is why prediction-based pre-warming exists. The simulation also shows the cold-start cascade inflating burst concurrency.
- Concurrency $= \lambda D$. Limits apply per account and to the scaling rate. Cap asynchronous consumers, reserve capacity for critical functions, and pool database connections ($N_{\text{pool}} = \lambda_q d_q$).
- Build pipelines from queues, streams and fan-out. Make every handler idempotent, report partial batch failures, and use dead-letter queues. Orchestrate multi-step work with a workflow engine, never with synchronous function chains.
- Edge runtimes use V8 isolates (ms start, shared process plus OS sandbox and Spectre defenses), Wasm instances per request (µs start) or restricted JavaScript. Lambda@Edge runs microVM functions in regional caches.
- Edge data comes in four kinds: per-PoP cache, eventually consistent KV (~60 s), single-writer Durable Objects (strong per object), and SQLite read replicas with session guarantees.
- Edge logic helps only if it makes at most one origin round trip ($m \leq 1$). Auth, A/B assignment, routing, personalization and cached image transforms fit. Chatty database access does not.
- Function cost is linear in requests. Fleets cost a step function of capacity. Break-even is tens of RPS on average. At 10 billion requests a month the front door and egress rival compute.
- Operating serverless means alerting on throttles, init duration and iterator age, linking traces across batches, canarying through weighted aliases, testing in ephemeral cloud stacks, and choosing lock-in deliberately.

48.15 Knowledge checkpoint

1. State the three properties that define serverless in the Berkeley view.
2. What is a slot in Lambda, and how many concurrent invocations does it serve?
3. Why does Lambda use convergent encryption for container image chunks?
4. Name two things that go wrong if initialization state is captured in a snapshot.
5. Cold starts are 1.5% of invocations. Can the p99 be a warm latency? Why?
6. A function is invoked on average every 10 minutes. What fraction is cold with a 10-minute keep-alive?
7. Why did the simulation need up to 25 environments for a burst whose average concurrency was 3.4?
8. A function receives 500 RPS at 300 ms. What concurrency does it need?
9. Why does a slower database increase Lambda concurrency even without more traffic?
10. Give two reasons a synchronous Lambda-to-Lambda call is an anti-pattern.
11. Why should a stream consumer use bisect-on-error and an on-failure destination?
12. What two defenses beyond the V8 sandbox protect isolate tenants from Spectre-style attacks?
13. Why must a counter not live in an edge KV store?
14. Edge code makes three sequential calls to an origin 150 ms away. When could it still beat origin rendering?
15. Which term in the cost model is identical for functions, containers and VMs?

Answers

1. No resource management by the developer, automatic scaling including to zero, and billing in proportion to resources used rather than reserved.
2. A pre-loaded execution environment for one function on a worker, inside its own microVM. It serves one invocation at a time and many in sequence.
3. Identical chunks from different customers encrypt to identical ciphertext, so shared base layers are stored and cached once. Nobody without the plaintext can read them.
4. Any two of: duplicated random seeds or UUIDs, duplicated nonces, stale network connections, expired credentials.
5. No. More than 1% of requests are cold, so at least one cold request falls in the slowest 1%. The p99 is at least the fastest cold latency.
6. $e^{-\lambda K} = e^{-1} \approx 36.8\%$.
7. The cold-start cascade. New environments take 300–700 ms to initialize, so each early burst request holds an environment about seven times longer. More requests then find no idle environment and start yet more cold environments.
8. $500 \times 0.3 = 150$ environments.
9. Duration D rises, and concurrency is λD by Little’s Law.

10. Any two of: the caller is billed while waiting, concurrency multiplies by chain depth, timeouts and retries compound, and no durable record exists of completed steps.
11. A failing record blocks its whole shard. Bisecting isolates the bad record, and the destination removes it so the shard can make progress.
12. Any two of: the process-level OS sandbox, trust-based cordons, no high-resolution timers or shared-memory threads, and dynamic process isolation of suspicious scripts.
13. KV is eventually consistent and last-write-wins, and it allows about one write per second per key. Concurrent increments from different PoPs lose updates.
14. Practically never: the edge path spends $3 \times 150 = 450$ ms on origin round trips, while origin rendering costs one 150 ms trip plus a few 1 ms database calls. It wins only after batching the calls into one ($m = 1$) or moving the data to the edge.
15. Egress (data transfer to the Internet), Rbc_{eg}.

48.16 Interview questions

Basic

Q1. What is a cold start, and how would you reduce its impact on an API? **Answer.** It is the latency of creating an execution environment: placement, sandbox, code loading, runtime and function initialization. Measure init duration first. Trim dependencies and lazy-load what the hot path does not need. Pick a fast-starting runtime or snapshot restore, and add more memory for CPU-bound init. Use provisioned concurrency sized to measured burst concurrency only where the SLO demands it. Move work that need not be synchronous behind a queue.

Q2. When would you choose serverless over containers? **Answer.** When traffic is spiky, low or unpredictable (below roughly 20–45 RPS average for a typical API), work is short and event-driven, and the team wants no capacity planning. Choose containers for steady high volume, long-lived connections, long jobs, special hardware or fine control. Compute the break-even with real duration, memory and front-door charges.

Intermediate

Q3. Your functions exhausted the PostgreSQL connection limit during a traffic spike. What do you do? **Answer.** In the short term, cap the functions' concurrency. Then put a connection pooler (RDS Proxy or PgBouncer in transaction mode) between the functions and the database, sized by Little's Law on query rate and query time. Avoid session state that pins connections, and put a queue in front of write-heavy paths. Alert on connection count and on proxy wait time.

Q4. Design a pipeline that thumbnails 70 uploads per second with bursts to 1,000 per second. **Answer.** Send object-created events through an event bus to a dedicated queue. A function consumes batches with a concurrency cap sized for the burst backlog it can tolerate. Make writes idempotent by object version, report partial batch failures, and add a dead-letter queue with an alarm. Use separate queues for moderation and audit so they fan out independently. Monitor queue age, throttles and DLQ depth, and use tracing with span links.

Advanced

Q5. Design a global per-user rate limiter at the edge. **Answer.** Validate the token in the edge function, then route each user's check to a single-writer object keyed by user ID (a Durable Object). It holds a token bucket in memory and in colocated storage, so the counts are exact. KV would lose concurrent increments. To bound latency for users far from their object's home, allow a small local allowance per PoP, reconciled asynchronously. Fail open or closed by endpoint risk. Shard by user so that no object is a global hot spot.

Q6. A team proposes moving its whole web app to edge functions "for latency". How do you evaluate it? **Answer.** Count origin round trips per request (m) and compare $R_{ue} + c_e + mR_{eo}$ with the origin path. With a regional database and $m > 1$, the edge is slower. Move auth, routing, A/B assignment and cache-assembled personalization to the edge. Replicate read-mostly data to KV or SQLite replicas where staleness is acceptable, and put per-entity coordination in single-writer objects. Keep transactional, joined data at the origin. Check CPU limits, residency rules, observability and cost per request too.

48.17 Practical exercises

1. Run the simulation of §48.5.4 with bursts every 30 minutes. Find the smallest keep-alive that brings p99 under 200 ms, and compare its idle environment-hours with the provisioned level that does the same.
2. Add a predictive pre-warm policy to the simulation: create P environments 10 s before each burst and reclaim them after it. Compare cold starts and idle hours with fixed provisioned concurrency.
3. Measure init and handler duration for one function in two runtimes at three memory sizes. Plot cost per million invocations against latency.
4. Extend the batch handler of §48.7.2 so that it claims the idempotency key before a non-idempotent side effect, and write a test with two concurrent workers.
5. Recompute Table 48.7 with Arm pricing, 256 MB memory and no API gateway. Find the new break-even.

48.18 Design challenges

1. **Global image service.** Serve PhotoShare's 17,400 views per second with on-the-fly resizing to 12 sizes and two formats. Decide what runs on viewer and on cache-miss events, estimate transform invocations from the cache hit ratio, and cost the design.
2. **Serverless checkout.** Build a checkout saga from functions and a workflow engine. Include idempotency keys, compensation, concurrency caps for the payment provider and tracing across every hop.
3. **Multi-tenant webhook platform.** Deliver 50,000 tenants' webhooks with per-tenant rate limits and retries. Choose queues, concurrency caps and isolation (§47.8), and compute concurrency for 2,000 deliveries per second at 800 ms each.

Chapter 49 — Large-Scale Data Infrastructure and High-Performance Computing

> **Level:** 4–5 · **Track:** Shared · **Estimated reading time:** 6 h

This chapter covers two kinds of system that break the book's usual picture of independent machines serving independent requests. **Exabyte data infrastructure** stores so much that, statistically, something is always broken, and the metadata about the data becomes a distributed system in its own right. **High-performance computing (HPC)** couples thousands of nodes so tightly that the slowest message or the slowest node sets the pace for all of them. The two worlds grew up separately and are converging in AI training clusters.

Storage at scale (§49.3–§49.4) quantifies what changes at an exabyte and compares four published systems: Colossus, Tectonic, Amazon S3 and Windows Azure Storage. **Analytics** (§49.5–§49.7) lays out the modern data platform, takes apart Dremel/BigQuery and Snowflake, and works out when to ship disks instead of using the network. **HPC** (§49.8–§49.12) covers scaling laws, MPI and collective cost models, RDMA networking, parallel file systems and schedulers. §49.13 explains why an AI training cluster looks like a supercomputer, which sets up Chapters 61, 65 and 80.

49.1 Learning objectives

After this chapter you should be able to:

- Estimate drive counts, daily drive failures, repair traffic and metadata memory for an exabyte-scale storage cluster.
- Compare the published designs of Colossus, Tectonic, Amazon S3 and Windows Azure Storage.
- Draw the layers of a modern data platform and explain why storage and compute are separated.
- Explain how Dremel encodes nested records into columns with repetition and definition levels, and how its serving tree and shuffle tier execute queries.
- Describe Snowflake's three layers, micro-partitions and pruning.
- Decide between network transfer and physical shipment for a bulk migration, and estimate cross-region replication cost.
- Distinguish tightly coupled from embarrassingly parallel workloads, compute strong- and weak-scaling efficiency, and read a Top500 entry.

- Use MPI's model of ranks, communicators and collectives, and compute α–β costs of ring, tree and Rabenseifner all-reduce, including the crossover message size.
- Explain RDMA verbs, compare InfiniBand with RoCEv2, describe DCQCN and PFC's risks, and compute fat-tree and dragonfly bisection bandwidth.
- Describe Lustre and Spectrum Scale, size a checkpoint, and choose a checkpoint interval with Young's formula.

49.2 Prerequisites

- Object storage, GFS/HDFS, Colossus and Tectonic overviews, erasure coding and metadata services — §15.4–§15.7 (this chapter builds on them and does not repeat the mechanisms).
- Columnar storage and Parquet — §13.13 (Dremel and Snowflake are columnar engines).
- MapReduce, Spark, shuffle and data locality — §29.4–§29.7 (the batch engines on top of the data platform).
- Kafka and change data capture — §31.3, §31.14 (the ingestion path of §49.5).
- Amdahl's and Gustafson's laws — §4.12 (strong and weak scaling).
- Durability and failure-rate arithmetic — §4.15–§4.16.
- Leaf–spine networks, ECMP, oversubscription and incast — §7.17; congestion control — §7.7.7; DMA and kernel bypass — §5.7.
- Gang scheduling and Slurm — §46.10, §46.12 (HPC jobs are gangs).
- Cloud data-transfer pricing — §41.10.3.

49.3 What changes at exabyte scale

49.3.1 Four things that change

DEFINITION

Definition — Exabyte scale. A storage system whose capacity is measured in exabytes (1 EB = 10^{18} bytes = 1,000 PB = 1 million TB), typically spread over thousands of servers and tens to hundreds of thousands of drives in one or a few datacenters, and serving many tenants at once.

First-principles explanation

Picture a city of a million light bulbs. Each bulb lasts years, yet on any evening hundreds are out, and a crew must be replacing them all the time. Nobody calls a dead bulb an "incident"; it is a line item in the maintenance budget. A storage system at an exabyte is that city. Four things change compared with a petabyte system:

1. **Failure is constant.** With tens of thousands of drives or more, several fail every day. Repair is a permanent background workload, not an emergency.
2. **Metadata dominates.** The bytes scale out easily by adding drives. The *catalog* (which file has which blocks on which drives) runs to billions or trillions of entries and receives millions of requests per second. It can no longer live on one machine (§15.5 showed why GFS's single master ran out of room).
3. **Data gravity.** Moving a petabyte across a WAN takes days or weeks, so computation moves to where the data is, and the location of the data shapes the whole architecture. The term "data gravity" was coined by Dave McCrory in 2010 [McCrory 2010].
4. **Cost per petabyte becomes the design objective.** A redundancy overhead of 3× versus 1.5× is a difference of about 75,000 drives per exabyte. Efficiency, not peak performance, is what Tectonic's paper puts in its title [Pan et al. 2021].

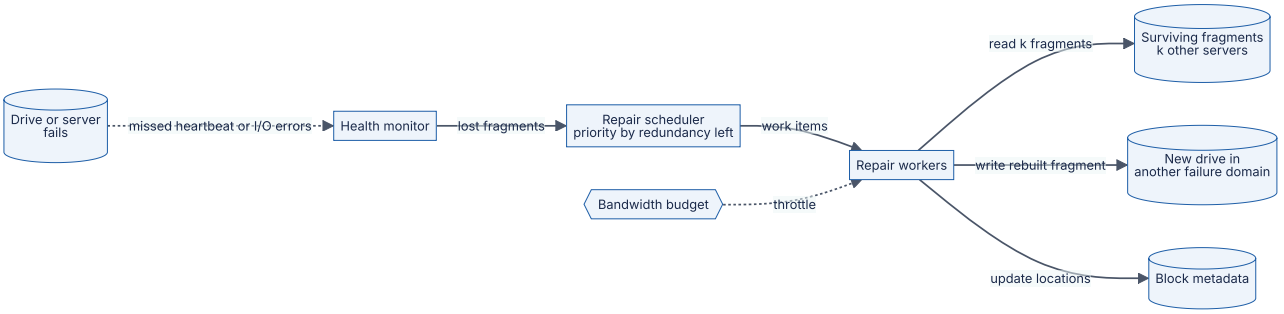
Why does this exist?

Companies consolidated many petabyte clusters into exabyte clusters because many small clusters strand capacity (one is full while another is half empty), duplicate operations work, and force applications to know which cluster their data is on. Facebook reports that before Tectonic its blob and warehouse storage ran on separate, specialized systems whose clusters scaled to tens of petabytes, and that consolidation into exabyte-scale multitenant clusters improved resource efficiency and operational simplicity [Pan et al. 2021; Facebook Engineering 2021].

How it works internally: the permanent repair loop

1. **Detect.** Servers report drive errors, checksum mismatches and scrub results; a central service notices missed heartbeats.
2. **Prioritize.** A repair scheduler lists stripes that lost fragments, most-endangered first.
3. **Reconstruct and place.** For RS(k, m) (§15.6) a worker reads k surviving fragments, recomputes the lost one and writes it in a different failure domain.
4. **Throttle.** Repair bandwidth is capped to protect client latency, but kept high enough that repair finishes long before the next correlated failure.

Figure 49.1 — The permanent repair loop of an exabyte storage cluster.



Reading the diagram. A failed *drive or server* is detected asynchronously (dotted) by the *health monitor*; the *repair scheduler* dispatches *repair workers*, which synchronously read *k* surviving fragments, write the rebuilt one to a *new drive* in another failure domain and update the *block metadata*. A *bandwidth budget* throttles repair. Failure points: a rack or power-domain outage creates thousands of repairs at once (a repair storm); a metadata outage stalls repair entirely. Scaling: repair throughput grows with the number of workers and servers, so bigger clusters repair a given failure faster.

Mathematical foundations

FORMULA

Drives, daily failures and repair traffic

$$N_{\text{drives}} = \frac{C \cdot o}{D} \qquad F_{\text{day}} = \frac{N_{\text{drives}} \cdot \text{AFR}}{365} \qquad R_{\text{day}} = F_{\text{day}} \cdot u \cdot D \cdot k$$

Symbol	Meaning	Units
C	Usable (logical) capacity	bytes
o	Redundancy overhead: raw bytes per usable byte (3 for triple replication, $(k+m)/k$ for RS(k, m))	dimensionless
D	Capacity of one drive	bytes
N_{drives}	Number of drives	count
AFR	Annualized failure rate: fraction of drives that fail per year	1/year
F_{day}	Expected drive failures per day	drives/day
u	Fill fraction of a failed drive	dimensionless
k	Fragments read to rebuild one lost fragment (1 for replication)	count
R_{day}	Bytes read per day for repair	bytes/day

WORKED EXAMPLE

Worked example — Drive failures in a 1 EB cluster. 1 EB usable, RS(6, 3) erasure coding ($o = 9/6 = 1.5$), 20 TB drives, AFR 1.5%, drives 80% full. Field studies report annual failure or replacement rates of roughly 1–4% for large populations, higher than datasheet MTTF figures imply [Schroeder and Gibson 2007; Pinheiro et al. 2007].

1. Raw capacity: $10^{18} \times 1.5 = 1.5 \times 10^{18}$ B.
2. Drives: $1.5 \times 10^{18} / (2 \times 10^{13}) = 75,000$ drives. At 36 drives per server that is about 2,100 servers.
3. Failures per year: $75,000 \times 0.015 = 1,125$; per day: $1,125/365 = 3.1$ drives.
4. At AFR 3%: 6.2 drives a day. With triple replication instead ($o = 3$): 150,000 drives and 6.2 failures a day even at 1.5%.
5. Repair reads per failure: 0.8×20 TB $\times 6 = 96$ TB. Per day: $3.1 \times 96 \approx 296$ TB, a continuous $296 \times 10^{12} / 86,400 \approx 3.4$ GB/s of reads plus the rebuilt writes.
6. Redundancy cost: triple replication would need $75,000$ more drives than RS(6, 3); at about $300 per 20 TB drive (illustrative, as of 2025) that is about $22 million in drives alone, before servers, power and space.

Interpretation. A failed drive every eight hours is routine, and repair is a multi-GB/s background job that never stops. **Engineering implication.** Budget network and disk bandwidth for repair permanently; use codes with lower repair fan-in (local reconstruction codes, §15.6.2) when repair traffic dominates; spread each stripe across failure domains so a rack loss does not take out more than m fragments of any stripe; and automate drive replacement, because humans cannot triage three failures a day per cluster.

Drives are not the only thing that fails. Jeff Dean's often-quoted list for a new cluster's first year includes about a thousand individual machine failures, thousands of disk failures, and several rack-level and network events [Dean 2009]. Correlated failures (a rack's power, a top-of-rack switch, a bad firmware batch) matter more for durability than independent ones, which is why placement across failure domains is as important as the code itself [Ford et al. 2010].

49.3.2 Metadata dominates

At GFS scale, one master held all metadata in RAM (§15.5.1). At an exabyte, the number of objects, not bytes, sets the size of the problem.

FORMULA

Metadata footprint

$$M = r_{\text{meta}}\left(N_{\text{files}}\, b_{\text{file}} + N_{\text{blocks}}\, b_{\text{block}}\right) \qquad N_{\text{files}} = \frac{C}{\bar{s}}$$

Symbol	Meaning	Units
M	Total metadata stored, all replicas	bytes
r_{meta}	Replication factor of the metadata store	count
N_{files}, N_{blocks}	Number of files (objects) and blocks	count
b_{file}, b_{block}	Metadata bytes per file (name entry plus attributes) and per block (fragment locations)	bytes
C	Usable capacity	bytes
$\bar{s}$	Mean file size	bytes

WORKED EXAMPLE

Worked example — Metadata for 1 EB. Assume $b_{\text{file}} = 250$ B, $b_{\text{block}} = 150$ B (nine fragment locations plus checksums and versions), $r_{\text{meta}} = 3$.

1. Warehouse-like data, $\bar{s} = 100$ MB: $N_{\text{files}} = 10^{18}/10^{8} = 10^{10}$; say 1.2×10^{10} blocks.
2. $M = 3 \times (10^{10} \times 250 + 1.2 \times 10^{10} \times 150) = 3 \times (2.5 + 1.8) \times 10^{12} = 12.9$ TB.
3. Blob-like data, $\bar{s} = 100$ KB, one block record per object: $N = 10^{13}$; $M = 3 \times 10^{13} \times 400 = 1.2 \times 10^{16}$ B $= 12$ PB.
4. Request rate: if the cluster serves 10 TB/s of reads in 8 MB requests and clients cache nothing, the metadata layer sees $10^{13}/(8 \times 10^{6}) = 1.25$ million lookups per second.

Interpretation. Even large-file metadata is far beyond one server's RAM, and small-object metadata is itself a petabyte-scale database. **Engineering implication.** Exabyte systems store metadata in a sharded, replicated key-value or table store (Bigtable for Colossus, ZippyDB for Tectonic, §49.4), split it into layers with different access patterns, and let clients cache it aggressively.

49.3.3 Data gravity and cost per petabyte

Data gravity is the observation that large datasets attract applications and services, because moving the data is slower and costlier than moving the code. Two consequences follow. Analytics engines run in the same region as the data and read it in place (§49.5).

And migration between clusters, regions or providers is a project measured in weeks, with its own tooling (§49.7).

Cost per usable petabyte-year has four parts: drives (raw capacity × overhead, amortized over four to six years), servers and networking, power and cooling, and space and operations. Denser drives, erasure coding, tiering (§15.9) and multitenant sharing each cut one of them. For comparison, public cloud object storage list prices (as of 2026) range from about $21,000 per PB-month for frequently accessed classes to about $1,000 per PB-month for deep-archive classes (§15.9).

> COMMON MISTAKE
>
> **"Exabyte systems are just petabyte systems with more servers."** The bytes scale linearly, but failure handling, metadata and data placement change in kind: repair becomes a continuous workload, the namespace becomes a distributed database, and redundancy overhead becomes the biggest line in the budget.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Repair storm after a rack loss	Thousands of fragments lose redundancy at once	Under-replicated stripe count spikes	Prioritize stripes by redundancy left; raise repair budget temporarily	Spread stripes across racks and power domains
Data loss from correlated failures	Bad firmware batch or one power domain	Many drives of one model fail together	Restore from geo-replica	Mix drive batches; failure-domain-aware placement
Metadata hot spot	One directory or table receives most lookups	Per-shard latency and request skew	Split or re-shard the hot range	Hash-partition names; client-side caching

49.4 Exabyte storage systems as published

Four operators have described exabyte-scale storage in public: Google (Colossus, only in blog posts and talks), Meta (Tectonic, a FAST 2021 paper), Amazon (S3, in talks and blog posts) and Microsoft (Windows Azure Storage, an SOSP 2011 paper). They solve the same problems with different emphasis. This section covers only what each has published; §15.5.3 introduced Colossus and Tectonic, and §15.4 the S3-style object store.

49.4.1 Google Colossus

INDUSTRY EXAMPLE

Google Colossus. Colossus succeeded GFS as Google's cluster file system. Google's 2021 overview describes a **client library**; a **control plane** of scale-out **curators** that handle metadata operations such as file creation and store file metadata in **Bigtable**; **D file servers** that hold data and to which clients connect directly; and **custodians**, background workers that maintain durability and availability (reconstruction) and balance disk space. A single cluster scales to exabytes and tens of thousands of machines, and files can be replicated or erasure coded per application [Hildebrand and Serenyi 2021]. A 2025 post describes placing hot data on flash and the rest on disk, and states that many Colossus file systems hold multiple exabytes, with two above 10 EB (as of 2025) [Greenfield and Pollen 2025]. *Evidence: Primary* — [Hildebrand and Serenyi 2021; Greenfield and Pollen 2025]

The key idea is recursion: Bigtable stores Colossus metadata while storing its own data in Colossus, bootstrapped by a smaller metadata system underneath. Moving metadata from one master's RAM into a sharded database lets the catalog grow by orders of magnitude.

49.4.2 Meta Tectonic

DEFINITION

Definition — Multitenant file system. One storage cluster shared by several applications (**tenants**) with different workloads, in which each tenant can tune durability, layout and performance for its own data while sharing drives, servers and operations.

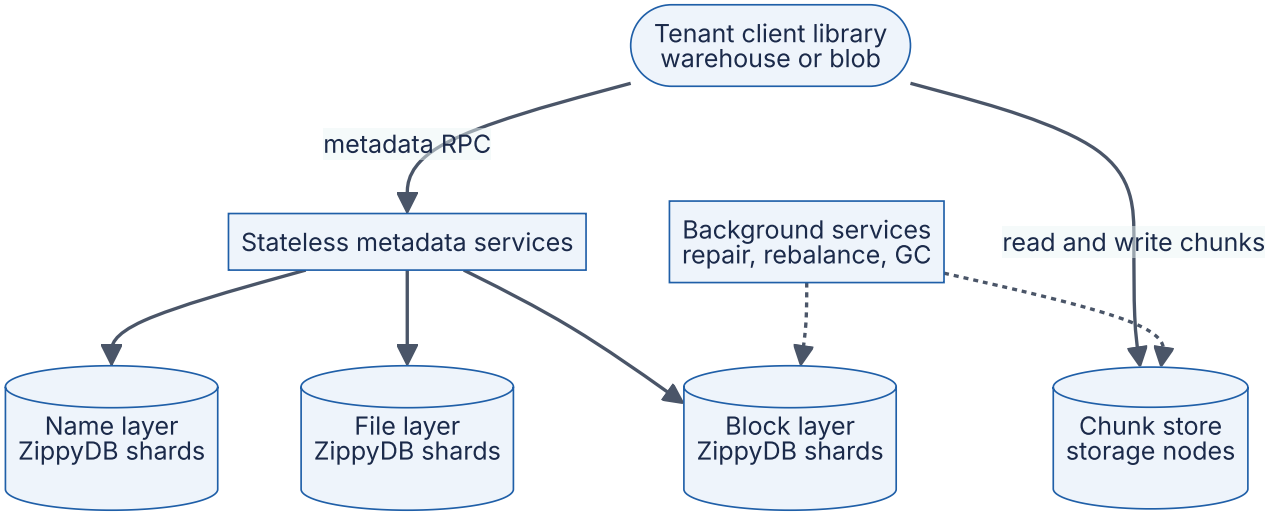
Tectonic replaced Haystack, f4 and the warehouse's HDFS clusters with a single exabyte-scale, datacenter-wide file system [Pan et al. 2021]. Its design has three parts.

1. **Chunk store.** A flat, scalable pool of storage nodes storing chunks, the unit of placement. A **block** is a logical unit made of chunks, either replicated or Reed–Solomon encoded.
2. **Layered metadata.** Metadata is split into a **Name layer** (directory → names), a **File layer** (file → blocks) and a **Block layer** (block → chunk locations), each hash-partitioned and stored in **ZippyDB**, a Paxos-replicated, sharded key-value store, behind stateless metadata services. Splitting by layer separates operations with different access patterns: listing a directory touches one Name shard; reading a file touches File and Block shards.
3. **Tenant-specific client library.** The client library orchestrates reads and writes directly against chunk-store nodes and is configured per tenant: the warehouse writes

large, full blocks and encodes them immediately; blob storage first appends small writes to replicated blocks for low latency and encodes them later.

Tectonic also shares resources among tenants with **TrafficGroups** and priority **TrafficClasses**, so that latency-sensitive blob reads borrow spare disk time from the warehouse without letting either starve the other [Pan et al. 2021]. The cost of the layered key-value design is that ZippyDB offers no cross-shard transactions, so some operations that span shards (for example, some recursive directory operations) are restricted or non-atomic (§15.5.3).

Figure 49.2 — Tectonic's architecture: layered metadata over a flat chunk store.



Reading the diagram. The *tenant client library* resolves a path through the *metadata services*, which read three independently sharded layers in *ZippyDB*: *Name* (directory to file IDs), *File* (file to block IDs) and *Block* (block to chunk locations). All of these are synchronous RPCs. Data then flows directly between client and *chunk store* nodes, never through the metadata services. *Background services* (dotted, asynchronous) repair lost chunks, rebalance and garbage-collect. Storage boundaries: metadata in ZippyDB, bytes in the chunk store. Failure points: a hot ZippyDB shard limits throughput; cross-shard operations are not transactional. Scaling: each layer and the chunk store grow independently.

49.4.3 Amazon S3 at scale

INDUSTRY EXAMPLE

Amazon S3. In a 2023 essay based on his FAST ’23 keynote, S3 engineer Andy Warfield described S3 as storing more than 280 trillion objects and serving more than 100 million requests per second on average (as of 2023), built from hundreds of microservices. He emphasized that individual hard drives have not become faster even as they became larger, so S3 manages “heat” by spreading each customer’s objects over very large numbers of drives so that bursts from different workloads decorrelate; he also described the ShardStore storage-node software and the use of lightweight formal methods to check it [Warfield 2023; Bornholt et al. 2021]. Since December 2020 S3 provides strong read-after-write consistency (§15.4) [Vogels 2021]. *Evidence: Primary* — [Warfield 2023; Bornholt et al. 2021; Vogels 2021]

S3 is a different shape of system from Colossus or Tectonic: a regional, multi-datacenter object service with a flat key namespace, an HTTP API and billing per request and per GB, rather than a file system inside one datacenter. It spreads each object’s data across several Availability Zones, so it survives the loss of a datacenter [AWS S3 User Guide]. Its index is a distributed key-value map from (bucket, key) to object locations (§15.4.2), partitioned by key prefix; that is why S3 documents per-prefix request-rate limits and why the internal partitioning follows load.

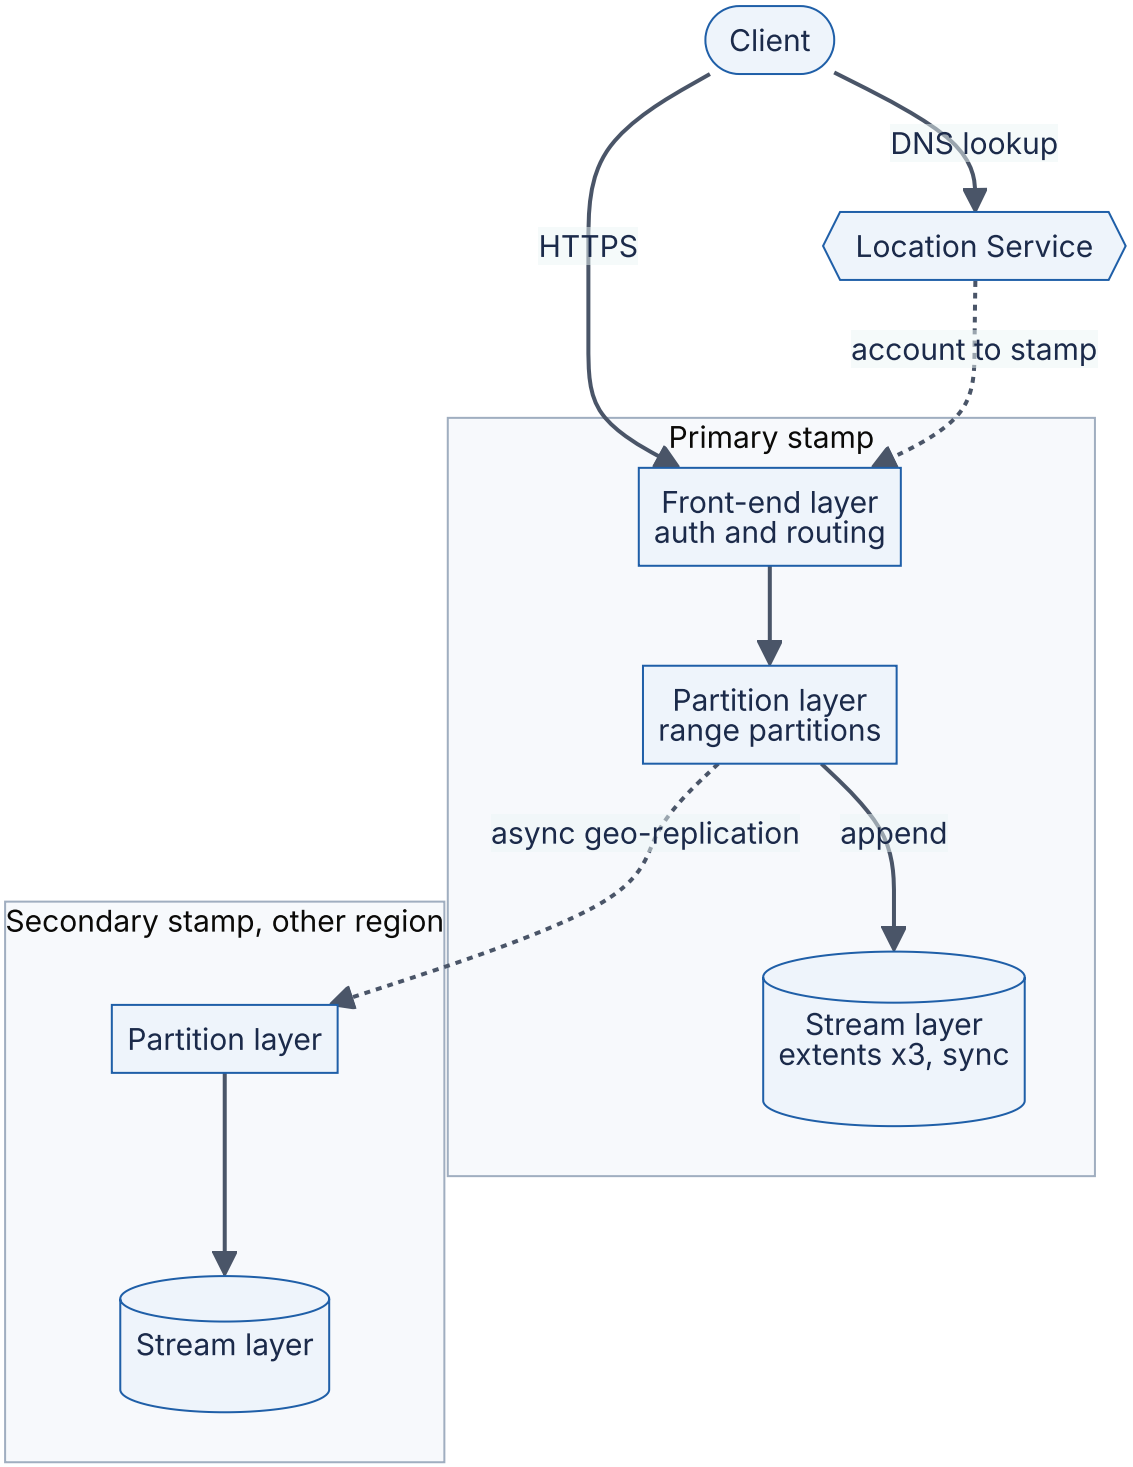
49.4.4 Windows Azure Storage

Windows Azure Storage (WAS), described at SOSP 2011, is the most complete public description of a cloud storage service’s internals [Calder et al. 2011].

1. **Storage stamps.** The unit of deployment is a **stamp** of 10–20 racks of 18 storage nodes (about 2 PB raw in 2011, up to 30 PB planned). A global **Location Service** assigns each account to a stamp and points its DNS name at that stamp.
2. **Stream layer.** A distributed, append-only file system inside the stamp. A **stream** is an ordered list of **extents**; an extent (target size about 1 GB) is the unit of replication, appended until **sealed** and then immutable. A Paxos-replicated **Stream Manager** tracks extents; **Extent Nodes** store them. Appends replicate **synchronously** to three Extent Nodes in different fault and upgrade domains. Sealed extents are later erasure coded (§15.6.2) [Huang et al. 2012].
3. **Partition layer.** Implements Blobs, Tables and Queues on top of streams. Data lives in **Object Tables** split into **RangePartitions** by key; a **Partition Manager** assigns ranges to **Partition Servers** and uses a Paxos **Lock Service** to make sure each range has exactly one server. This layer also performs **asynchronous geo-replication** to a second stamp in another region.
4. **Front-end layer.** Stateless servers that authenticate and route requests.

The paper’s central design argument is the split of replication into two kinds: synchronous intra-stamp replication in the stream layer protects against disk, node and rack failures with strong consistency, while asynchronous inter-stamp replication in the partition layer protects against disasters without putting WAN latency on the write path.

Figure 49.3 — Windows Azure Storage: location service, stamps and layers.



Reading the diagram. The *client* resolves its account name through DNS maintained by the *Location Service,* which maps accounts to stamps. Requests over HTTPS reach a stateless *front end,* which routes by key to the *partition server* owning that range; the partition layer appends to streams, and the *stream layer* synchronously writes each append to three Extent Nodes before acknowledging. Geo-replication to the *secondary stamp* is asynchronous (dotted), so a regional disaster can lose the last seconds of writes. Storage boundaries: durable bytes only in the stream layer. Failure points: a partition server failure moves its ranges to another server in seconds (the data is in the stream layer); losing the primary stamp requires geo-failover. Scaling: add partition servers within a stamp; add stamps under the Location Service.

49.4.5 Comparison

Table 49.1 — Exabyte storage systems as published.

Aspect	Google Colossus	Meta Tectonic	Amazon S3	Windows Azure Storage
Public source	Blog posts (2021, 2025)	FAST 2021 paper	Talks, blogs, SOSP 2021	SOSP 2011 paper
Interface	Cluster file system (internal)	Datacenter file system (internal)	Regional object store (HTTP)	Blobs, Tables, Queues (HTTP)
Scope of one instance	Cluster, multiple EB	Datacenter, EB	Region, multi-AZ	Stamp (tens of PB), many stamps
Metadata	Curators over Bigtable	Name/File/Block layers in ZippyDB	Sharded key-value index	Partition layer range partitions
Data servers	D file servers	Chunk store	Storage nodes (ShardStore)	Stream layer extent nodes
Redundancy	Replication or RS, per file	Replication or RS, per tenant	Across ≥ 3 AZs (details unpublished)	3× sync in stamp; EC of sealed extents
Geo-replication	Above the file system	Above the file system	Optional, async (replication rules)	Async, built into partition layer
Distinctive idea	Metadata recursion; flash/HDD placement	Tenant-specific client library; layered metadata	Heat decorrelation; formal methods	Two-level replication split

The same three lessons recur in all four. Metadata moves into a scalable database; data flows directly between clients and storage servers; and redundancy is tuned per workload because replication buys latency and erasure coding buys cost.

COMMON MISTAKE

“Colossus, Tectonic and S3 are interchangeable.” Colossus and Tectonic are internal file systems used by other systems; S3 and Azure Storage are public HTTP services with per-request billing and regional failure tolerance. Their published numbers are not comparable one for one.

49.5 The modern data platform architecture

49.5.1 Layers of the platform

DEFINITION

Definition — Data platform. The shared infrastructure that collects an organization’s data, stores it durably in open or managed formats, makes it queryable by several compute engines, and serves results to analysts, applications and machine-learning pipelines, with a catalog and access control across all of it.

First-principles explanation

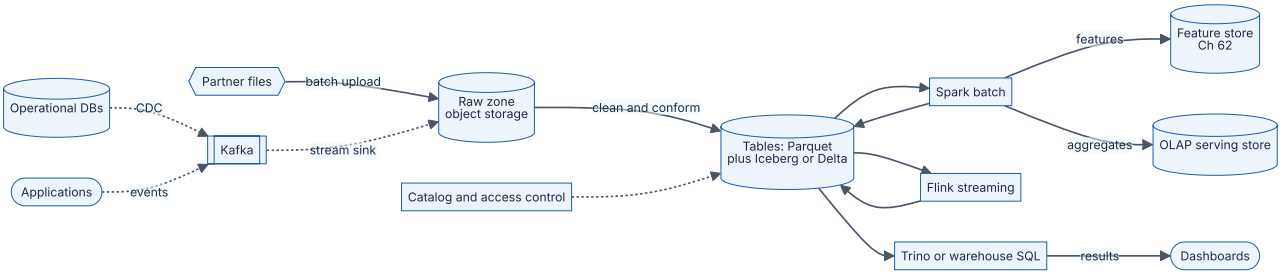
Think of a city’s water system: intake from rivers and wells, a reservoir, treatment plants, and pipes to homes and factories. Nobody builds a reservoir per tap. A data platform has the same shape: many sources flow into one durable store, several processing engines “treat” the data, and many consumers draw from the results.

How it works internally

1. **Ingestion.** Operational databases are copied by **change data capture** (CDC, §31.14.2) into Kafka (Chapter 31) or directly into storage; application events stream through Kafka; partners drop files in batches.
2. **Raw zone in object storage.** Everything lands unchanged in an object store or cluster file system (§15.4, §49.4), partitioned by date and source. This is the system of record, kept for reprocessing.
3. **Table formats.** Cleaned and conformed data is written as columnar files (Parquet, §13.13) managed by a **table format** such as Apache Iceberg, Delta Lake or Apache Hudi, which adds a metadata layer listing a table’s files, so engines get atomic commits, snapshots, schema evolution and file pruning on top of plain objects. Many teams call the successive refinement steps bronze, silver and gold.
4. **Compute engines.** Batch engines (Spark, §29.5), streaming engines (Flink, §29.9), interactive SQL engines (Trino, originally Presto [Sethi et al. 2019]) and warehouses (§49.6) read the same tables.

5. **Serving.** Results feed dashboards, low-latency OLAP stores, feature stores (Chapter 62), application databases (“reverse ETL”) and training pipelines (Chapter 61).
6. **Cross-cutting services.** A catalog (table names, schemas, owners), access control, lineage, data-quality checks and an orchestrator (for example Airflow) run across all layers.

Figure 49.4 — The modern data platform.



Reading the diagram. Left to right is the direction of data flow. *Operational databases* and *applications* feed *Kafka* asynchronously (dotted); *partner files* arrive in batches. A stream sink writes everything to the *raw zone* in object storage. Jobs clean the raw data into *tables* of Parquet files tracked by a table format. *Spark*, *Flink* and SQL engines read the same tables (synchronous scans) and write derived tables back; results flow to *dashboards*, a *feature store* and an *OLAP serving store*. The *catalog* governs every table. Storage boundaries: all durable data is in object storage; engines are stateless apart from caches. Failure points: a bad upstream schema change propagates to every consumer, which is why the catalog enforces schemas and quality checks gate promotions. Scaling: storage and each engine scale independently.

49.5.2 Separation of storage and compute

Hadoop-era clusters co-located data and computation on the same nodes, because networks were slow (§29.7). Modern platforms **separate storage from compute**: data lives in a shared storage service; compute clusters are stateless and sized per workload, started for a job and stopped afterwards. The benefits are elasticity (pay for compute only while it runs), isolation (a heavy batch job and an interactive dashboard use different clusters on the same data), and independent scaling (storage grows with data, compute with queries). The costs are network bandwidth between the tiers, higher first-byte latency, and the need for local SSD caches. Fast datacenter networks (§7.17) made the trade worth it; §29.7 worked out that locality’s advantage shrank from about 8× to about 2×.

The **lakehouse** combines the open files of a data lake with warehouse features (transactions, schema enforcement, indexing, caching) implemented by the table format and engines [Armbrust et al. 2021]. Chapter 61 owns the deep treatment of table formats and lakehouses.

49.6 Warehouses at scale

49.6.1 Dremel and BigQuery

DEFINITION

Definition — Dremel. Google's interactive query engine for read-only nested data, published in 2010, which combines a columnar encoding of nested records with a multi-level **serving tree** that executes aggregation queries over trillions of rows in seconds; it is the engine behind Google BigQuery [Melnik et al. 2010; Melnik et al. 2020].

Why does this exist?

Google's logs and crawl data were nested protocol buffers with repeated fields, too big for MapReduce's minutes-long turnaround when an engineer wanted to ask a quick question. Flattening nested records into relational tables loses structure and multiplies rows. Dremel answered both: store nested data column by column without flattening, and answer queries interactively by fanning out to thousands of servers.

How it works internally: repetition and definition levels

Storing a nested column needs two small integers per value so that records can be reassembled and missing values located:

- The **repetition level** r says at which repeated field in the path this value repeated; $r = 0$ means "a new record starts here".
- The **definition level** d says how many of the optional or repeated fields in the path are actually present; a value below the maximum marks a `NULL` and where it occurred.

The program below stripes the two-record example from the Dremel paper, where `Name` and `Language` are repeated and `Url` optional.

```
        """Striping nested records into columns with repetition and definition lev-
els."""

        R1 = {"DocId": 10,
              "Name": [{"Language": [{"Code": "en-us", "Country": "us"}, {"Code":
"en"}],
                       "Url": "http://A"},
                      {"Url": "http://B"},
                      {"Language": [{"Code": "en-gb", "Country": "gb"}]}]}
        R2 = {"DocId": 20, "Name": [{"Url": "http://C"}]}

        # Labels for every field on the paths we stripe.
        LABEL = {"DocId": "required", "Name": "repeated", "Language": "repeated",
                 "Code": "required", "Url": "optional"}

        def stripe(record, path):
            """Return [(value, repetition_level, definition_level)] for one column
path."""
            out = []

            def walk(node, depth, r, d):
                if depth == len(path):
                    out.append((node, r, d))
                    return
                field = path[depth]
                label = LABEL[field]
                v = node.get(field)
                values = v if label == "repeated" else ([] if v is None else [v])
                if not values:                          # missing: record how deep we got
                    out.append((None, r, d))
                    return
                rep_here = sum(LABEL[f] == "repeated" for f in path[:depth + 1])
                d_here = d + (label != "required")
                for i, child in enumerate(values):
                    walk(child, depth + 1, r if i == 0 else rep_here, d_here)

            walk(record, 0, 0, 0)
            return out

        def count_records(column):
            return sum(1 for _, r, _ in column if r == 0)   # r = 0 starts a new record

        if __name__ == "__main__":
            code = stripe(R1, ["Name", "Language", "Code"]) + stripe(R2, ["Name",
"Language", "Code"])
            url = stripe(R1, ["Name", "Url"]) + stripe(R2, ["Name", "Url"])
            doc = stripe(R1, ["DocId"]) + stripe(R2, ["DocId"])
            for name, col in (("Name.Language.Code", code), ("Name.Url", url), ("DocId",
doc)):
                print(f"{name:<20}", col)
            assert code == [("en-us", 0, 2), ("en", 2, 2), (None, 1, 1), ("en-gb", 1,
2), (None, 0, 1)]
            assert url == [("http://A", 0, 2), ("http://B", 1, 2), (None, 1, 1),
```

```
("http://C", 0, 2)]
            assert doc == [(10, 0, 0), (20, 0, 0)]
            assert count_records(code) == count_records(url) == count_records(doc) == 2
            print("levels match the Dremel paper's example")
```

What to notice:

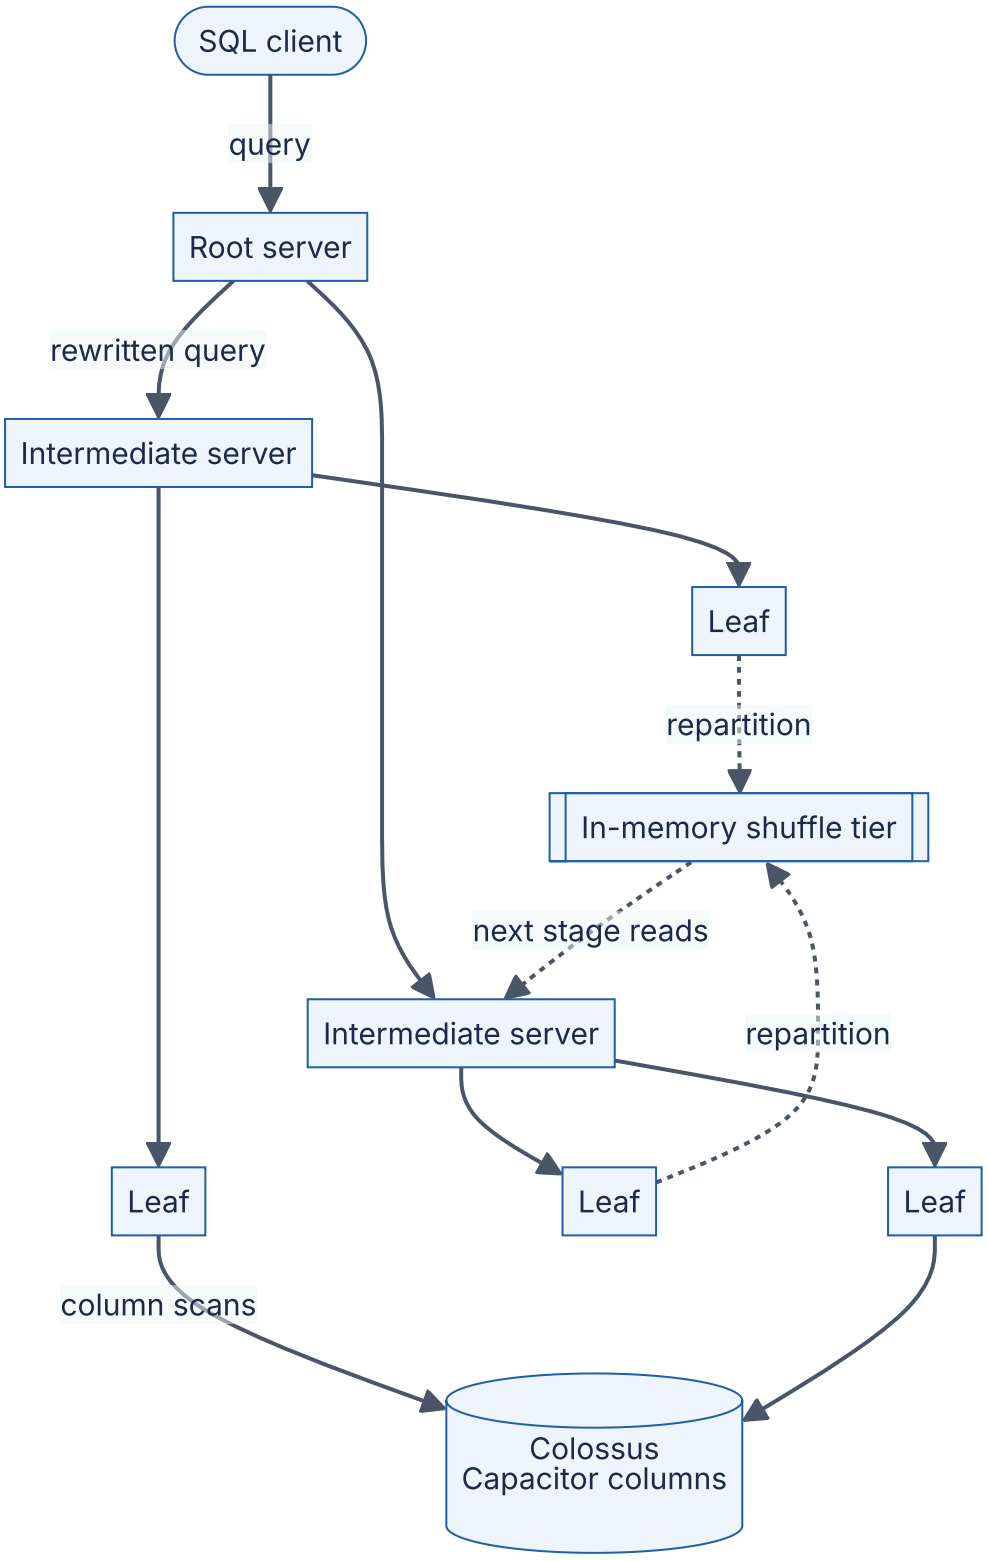
- `"en"` gets $r = 2$ because it repeats at `Language`, the second repeated field; `"en-gb"` gets $r = 1$ because a new `Name` began.
- The second `Name` of R1 has no `Language`, so the column stores `NULL` with $d = 1$: `Name` was present, `Language` was not. Without that entry, a reader could not tell which `Name` the later codes belong to.
- Required fields add nothing to d; levels take a few bits, are run-length encoded, and Parquet adopted the scheme (§13.13.2). Counting $r = 0$ entries aligns columns read independently.

How it works internally: the serving tree and the shuffle tier

1. The **root server** receives a SQL query, reads table metadata, and rewrites the query for the next level: `SELECT country, COUNT(*) ... GROUP BY country` becomes partial aggregations over subsets of the table.
2. **Intermediate servers** rewrite again for their children and merge the partial results coming back up.
3. **Leaf servers** scan **tablets** (horizontal pieces of the table) column by column from the distributed file system and compute partial aggregates.
4. A query dispatcher schedules tablets on available slots, re-dispatches slow ones, and can return results after a chosen fraction of tablets when approximate answers are acceptable [Melnik et al. 2010].

The 2020 retrospective explains how Dremel changed over a decade: storage was disaggregated onto the cluster file system (GFS, then Colossus); joins and large aggregations needed data redistribution, so a disaggregated **in-memory shuffle tier** replaced the fixed tree for those stages; the ColumnIO format gave way to **Capacitor**; and the service became serverless, with compute allocated in **slots** on demand rather than per-customer clusters [Melnik et al. 2020].

Figure 49.5 — Dremel’s serving tree with a disaggregated shuffle tier.



Reading the diagram. A *SQL client* sends a query to the *root*, which rewrites it into partial queries for *intermediate servers*, which do the same for *leaves*. Leaves scan only the needed columns of their tablets from *Colossus*; partial results flow back up the tree (synchronous) and are merged at each level. For joins and high-cardinality group-bys, leaves write repartitioned data to the *shuffle tier* (dotted, because producers and consumers are decoupled), and the next stage reads it. Storage boundaries: tables in the file system, in-

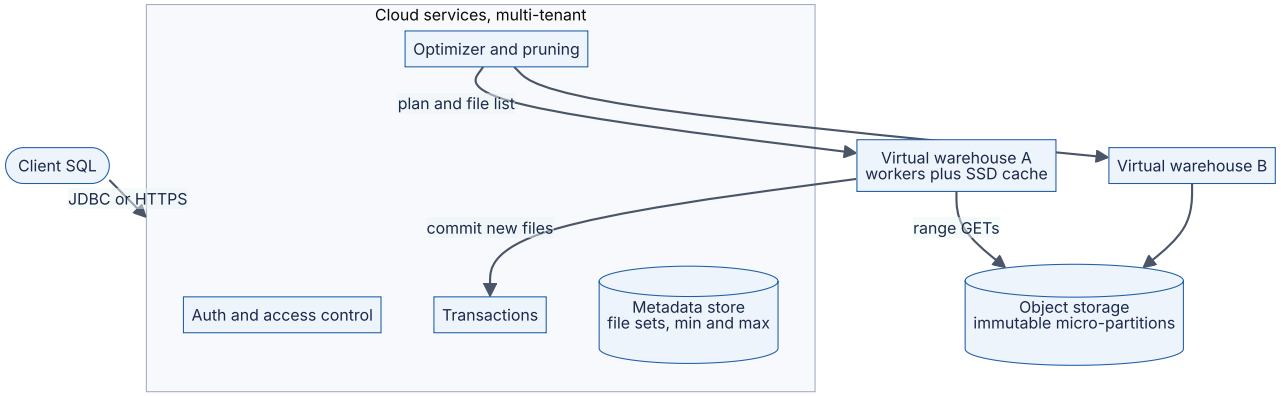
termediate data in shuffle memory. Failure points: a slow leaf (straggler) delays the root, so tablets are re-dispatched; a lost shuffle partition is recomputed. Scaling: wider and deeper trees for larger fan-out; slots are added per query.

49.6.2 Snowflake

Snowflake's SIGMOD 2016 paper describes a warehouse designed for the cloud from the start, with three layers [Dageville et al. 2016]:

1. **Data storage.** Tables are stored in Amazon S3 as large, immutable files, which the documentation calls **micro-partitions** (50–500 MB of uncompressed data each, as of 2026 [Snowflake Docs]). Inside each file, values are grouped by column (a PAX-style hybrid layout) with a header recording column offsets, so a reader fetches only the needed columns with ranged GETs.
2. **Virtual warehouses (VWs).** A VW is a cluster of cloud instances in a "T-shirt" size, created, resized or suspended at will. Each query runs on one VW; VWs never share workers, so one team's workload cannot slow another's. Workers cache table files on local SSD; files are assigned to workers by consistent hashing (§14.8), so a resize moves only some cache assignments, and idle workers can **steal** files from overloaded peers to handle skew.
3. **Cloud services.** A multi-tenant, always-on layer for authentication, query parsing and optimization, transactions and metadata. Every micro-partition's per-column minimum and maximum are kept in metadata, so the optimizer **prunes** files that cannot match a predicate, which replaces indexes. Immutable files plus file-set metadata give snapshot isolation and **time travel** to earlier versions.

Figure 49.6 — Snowflake's three layers.



Reading the diagram. The *client* connects to *cloud services*, which authenticate, optimize and look up file lists and min/max statistics in the *metadata store*. The plan, with pruned file lists, goes to one *virtual warehouse*; its workers read the remaining micro-partitions from *object storage* by ranged GETs (synchronous) through their SSD caches. Writes create new immutable files and commit by updating metadata through *transac-*

tions. Storage boundaries: durable data in object storage, metadata in cloud services, caches on workers. Failure points: a worker failure re-runs its part of the query; a cloud-services outage stops all warehouses. Scaling: more warehouses for concurrency, larger ones for speed.

Table 49.2 — Dremel/BigQuery and Snowflake compared.

Aspect	Dremel / BigQuery	Snowflake
Storage	Colossus, Capacitor columnar files	Object storage, immutable micro-partitions
Compute model	Serverless shared slots	Dedicated virtual warehouses per workload
Data redistribution	In-memory shuffle tier	Worker-to-worker exchange, spill to SSD and storage
Pruning	Partitioning and clustering metadata	Per-file min/max metadata
Isolation	Slot reservations and quotas	Separate warehouses
Choose when	Bursty, ad hoc, hands-off scaling	Predictable isolation and per-workload sizing

COMMON MISTAKE

“Separation of storage and compute means every query reads from object storage.” Both systems cache aggressively: Snowflake keeps table files on worker SSDs, and BigQuery’s storage and shuffle tiers keep hot data in memory and flash. Separation means the durable copy is shared and compute is disposable, not that caching disappears.

49.7 Data movement at scale

Andrew Tanenbaum’s line “never underestimate the bandwidth of a station wagon full of tapes hurtling down the highway” [Tanenbaum and Wetherall 2011] is an engineering rule at petabyte scale. AWS turned it into products: Snowball appliances of tens to hundreds of terabytes, and from 2016 Snowmobile, a 45-foot shipping container that could move up to 100 PB, since retired [AWS 2016].

FORMULA

Network transfer time versus shipment

$$T_{\text{net}} = \frac{8S}{\rho B \eta} \qquad T_{\text{ship}} = \frac{S}{b_{\text{load}}} + T_{\text{transit}} + \frac{S}{b_{\text{unload}}} \qquad B_{\text{ship}} = \frac{8S}{T_{\text{ship}}}$$

Symbol	Meaning	Units
S	Data volume	bytes
B	Link line rate	bits/s
η	Achieved fraction of line rate (protocol overhead, sharing)	dimensionless
ρ	Compression ratio (original/compressed), if compression keeps up with the link	dimensionless
b_{load}, b_{unload}	Aggregate copy rate onto and off the devices	bytes/s
T_{transit}	Time in transport, including handling	s
B_{ship}	Effective bandwidth of shipping	bits/s

WORKED EXAMPLE

Worked example — Migrating 50 PB. Options: a dedicated 10 Gb/s or 100 Gb/s link at $\eta = 0.8$, or a container-sized shipment loaded and unloaded at 125 GB/s (1 Tb/s) with three days in transit. Data is already compressed Parquet, so $\rho = 1$.

1. 10 Gb/s: $T = 8 \times 5 \times 10^{16} / (8 \times 10^{9}) = 5 \times 10^{7}$ s $= 579$ days.
2. 100 Gb/s: 57.9 days.
3. Shipment: load $5 \times 10^{16} / 1.25 \times 10^{11} = 4 \times 10^{5}$ s $= 4.6$ days; transit 3 days; unload 4.6 days; total 12.3 days $= 1.06 \times 10^{6}$ s.
4. Effective shipping bandwidth: $4 \times 10^{17} / 1.06 \times 10^{6} \approx 3.8 \times 10^{11}$ b/s ≈ 380 Gb/s. Matching it over the network needs $380 / 0.8 \approx 470$ Gb/s of line rate.
5. Cross-region alternative inside one cloud at an illustrative \$0.02/GB (§41.10.3): 5×10^{7} GB $\times 0.02 = \$1$ million, in addition to time.

Interpretation. For a one-time bulk move, shipping wins by an order of magnitude in time; the load and unload rates, not the truck, are the bottleneck. **Engineering implication.** Ship the historical bulk, then use the network for the daily delta (a few TB a day fits easily on 10 Gb/s), and run both in parallel with a cutover plan: copy, verify checksums, catch up incrementally, switch writers.

Compression helps only for data not already compressed (raw logs and JSON often shrink 5–10× with zstd; Parquet barely shrinks) and only if the compressor keeps up with the link; **deduplication** (§15.8.3) and filtering to needed partitions also cut volume. **Replication cost**: continuous cross-region replication costs the per-GB transfer price on every byte written, plus storage in the second region; at an illustrative $0.02/GB, replicating 50 TB of new data a day costs $1,000 a day, about $365,000 a year, which is why many platforms replicate only gold tables and keep raw data regional (Chapter 44 covers geo-replication).

49.8 HPC fundamentals

49.8.1 What HPC is

DEFINITION

Definition — High-performance computing (HPC). The use of many tightly interconnected processors working together on a single computational problem (simulating climate, fluid flow, molecules, nuclear physics, or training a large model) to solve it faster or at a larger size than any single machine could. A **supercomputer** is a system built for this, optimized for floating-point throughput and low-latency communication between nodes.

First-principles explanation

A thousand people can paint a thousand separate fences with no coordination: that is **embarrassingly parallel** work, like rendering frames or running independent simulations (parameter sweeps). Now ask a thousand people to solve one giant jigsaw puzzle laid out on a single table: each works on a region but must constantly check edges with neighbors. That is **tightly coupled** work. Weather simulation splits the atmosphere into cubes; every time step, each cube needs the boundary values (“halos”) of its neighbors, and the whole computation waits for the slowest exchange. Web-scale data systems (§29) mostly live in the first world; HPC lives in the second, which is why its networks and software look different.

49.8.2 Strong and weak scaling

Amdahl’s law (§4.12.1) describes **strong scaling**: fixed problem, more processors. Gustafson’s law (§4.12.2) describes **weak scaling**: the problem grows with the processors.

FORMULA

Scaling efficiency and a stencil code's step time

$$E_{\text{strong}}(p) = \frac{T(1)}{p\,T(p)} \qquad E_{\text{weak}}(p) = \frac{T(1)}{T(p)}\Big|_{\text{work}\,\propto\,p} \qquad T_{\text{step}}(p) = \frac{N}{p}t_c + 6(\alpha + 8(\frac{N}{p})^{2/3}\beta) + k\lceil \log_2 p\rceil\alpha$$

Symbol	Meaning	Units
$T(p)$	Run time on p processes	s
N	Grid cells in a 3-D domain, split into p cubes	count
t_c	Compute time per cell per step	s
α	Per-message latency	s
β	Time per byte (inverse bandwidth)	s/B
k	Global reductions (all-reduces of a scalar) per step	count

WORKED EXAMPLE

Worked example — Strong-scaling a 1,024³ stencil. $N = 1,024^3 \approx 1.07 \times 10^9$ cells, $t_c = 10$ ns, 8-byte values, $\alpha = 2$ µs, $\beta = 1/(25\text{ GB/s}) = 4 \times 10^{-11}$ s/B, $k = 2$ (a conjugate-gradient solver's two dot products).

1. $p = 512$: each rank holds $128^3 = 2,097,152$ cells; compute $= 20.97$ ms. Halo: six faces of $128^2 \times 8 = 131,072$ B; $6 \times (2 + 5.24)$ µs $= 43.5$ µs. Reductions: $2 \times 9 \times 2 = 36$ µs. Step ≈ 21.05 ms; efficiency vs pure compute $= 20.97/21.05 = 99.6\%$.
2. $p = 32,768$: $32^3 = 32,768$ cells per rank; compute $= 327.7$ µs. Halo: faces of $32^2 \times 8 = 8,192$ B; $6 \times (2 + 0.33) = 14.0$ µs. Reductions: $2 \times 15 \times 2 = 60$ µs. Step $= 401.7$ µs; efficiency $= 327.7/401.7 = 81.6\%$.
3. Speedup from 512 to 32,768 ranks (64×): $21.05/0.4017 = 52.4\times$.

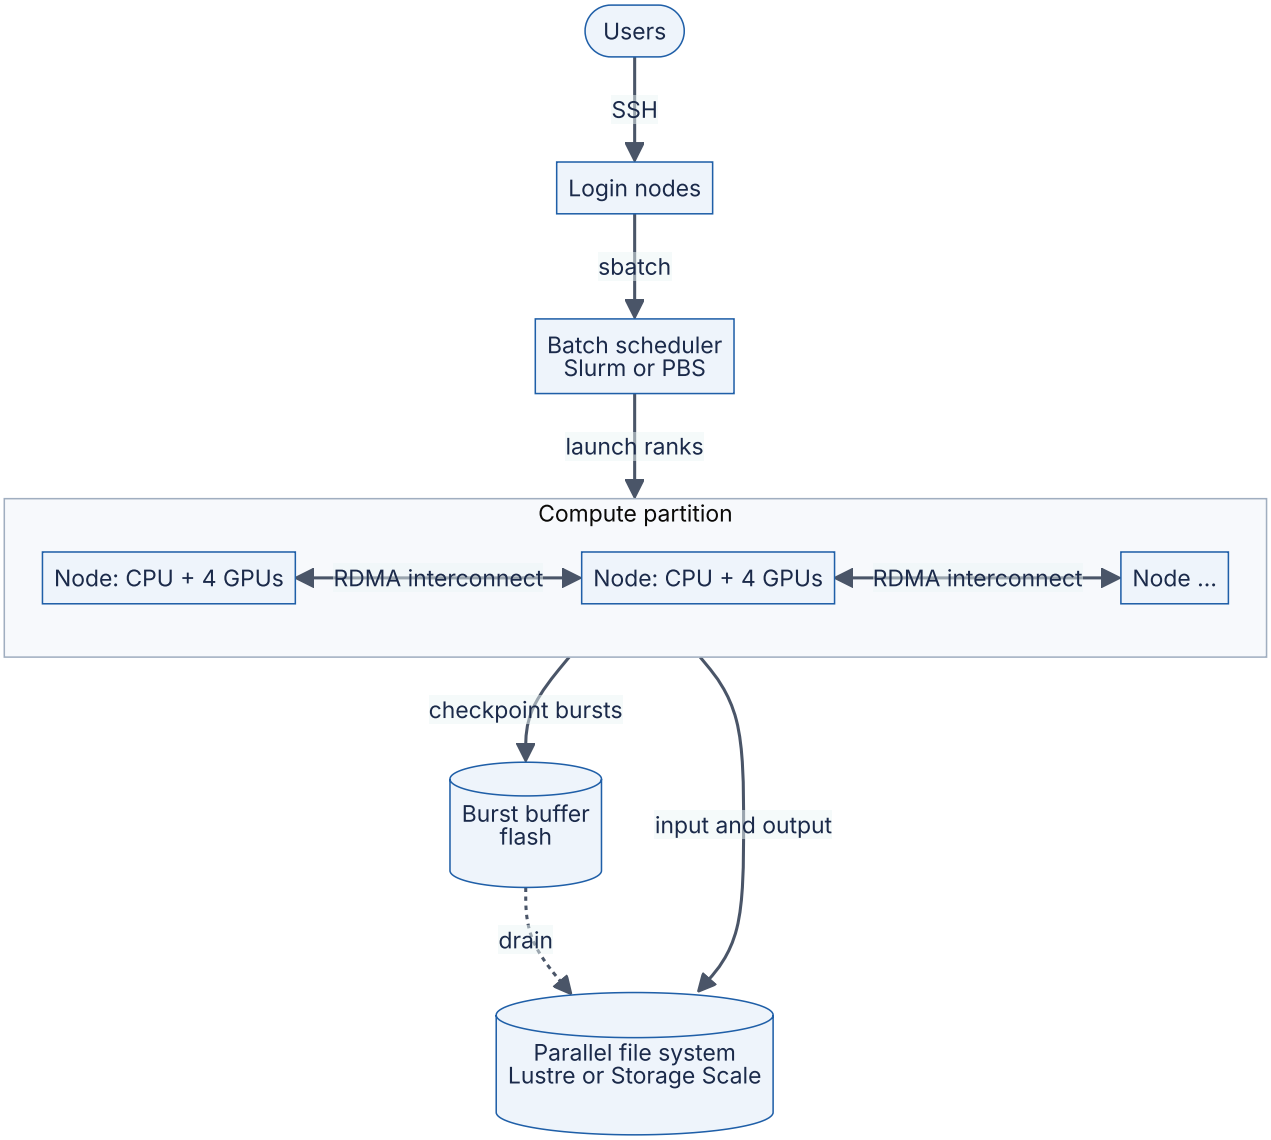
Interpretation. Compute shrinks as $1/p$, halo volume as $p^{-2/3}$, and the reduction latency *grows* as $\log p$; at large scale the 2 µs latency, not bandwidth, is what limits the code. **Engineering implication.** Strongly scaled HPC codes need microsecond-latency networks, fast collectives (§49.9) and few global synchronizations; this is why supercomputers use RDMA interconnects (§49.10) rather than kernel TCP.

49.8.3 Supercomputer architecture and the Top500

A modern supercomputer has **compute nodes** (CPUs plus, now usually, GPUs), a **high-speed interconnect** (InfiniBand or HPE Slingshot), **login nodes** where users compile and submit, a **batch scheduler** (§49.12), a **parallel file system** (§49.11), often a **burst buffer** of flash, and management networks. Frontier at Oak Ridge, the first system to ex-

ceed one exaflop per second on HPL (June 2022), has 9,408 nodes, each with one AMD EPYC CPU and four AMD Instinct MI250X GPUs, on a Slingshot dragonfly network [OLCF Frontier; Top500].

Figure 49.7 — Architecture of a supercomputer.



Reading the diagram. *Users* log in to *login nodes* over SSH and submit jobs to the *batch scheduler*, which allocates whole nodes as a gang (§46.10) and launches MPI ranks on them. *Compute nodes* exchange messages over the *RDMA interconnect* (bidirectional, synchronous within a time step). Checkpoints go first to a flash *burst buffer*, which drains asynchronously (dotted) to the *parallel file system*, where inputs and results also live. Failure points: one node failure kills a tightly coupled job, which restarts from its last checkpoint; a metadata storm stalls all jobs. Scaling: nodes, interconnect and file-system servers grow in balanced proportions.

DEFINITION

Definition — Rmax and Rpeak. The **Top500** list, published twice a year since 1993, ranks systems by **Rmax**, the sustained rate in floating-point operations per second (FLOP/s, 64-bit) achieved on the High-Performance Linpack (HPL) benchmark, which solves a dense linear system $Ax = b$ by LU factorization. **Rpeak** is the theoretical peak: devices × FLOPs per cycle × clock rate. The ratio Rmax/Rpeak is the HPL efficiency [Top500; Dongarra et al. 2003].

WORKED EXAMPLE

Worked example — Reading a Top500 entry. El Capitan led the November 2024 list with Rmax ≈ 1.742 EFlop/s and Rpeak ≈ 2.746 EFlop/s [Top500].

1. HPL efficiency: $1.742/2.746 = 63.4\%$.
2. For a hypothetical cluster of 1,000 nodes, each with 4 GPUs of 50 TFLOP/s FP64 peak: Rpeak $= 1,000 \times 4 \times 50 \times 10^{12} = 2 \times 10^{17}$ = 200 PFlop/s; at a similar efficiency, Rmax ≈ 127 PFlop/s.

Interpretation. HPL is dense, compute-bound and communication-light, so it shows the best case. Benchmarks with sparse, memory-bound kernels, such as HPCG, achieve only a few percent of peak on the same machines. **Engineering implication.** Use Rmax to compare systems, not to predict your application; measure your own kernels' arithmetic intensity (Chapter 64 covers the roofline model).

49.9 MPI

49.9.1 The programming model

DEFINITION

Definition — MPI (Message Passing Interface). A standardized library interface, maintained by the MPI Forum since 1994 (MPI-4.1 published in 2023), through which the processes of a parallel program exchange data by explicit messages. Each process is a **rank** (an integer from 0 to $p-1$) within a **communicator**, a group of processes with its own isolated message context; `MPI_COMM_WORLD` contains all of them [MPI Forum 2023].

How it works internally

1. **Launch.** The scheduler allocates nodes and a launcher (`mpirun` or `srun`) starts p copies of the same program (single program, multiple data); each learns its rank

and p.

2. **Point-to-point.** `MPI_Send` and `MPI_Recv` move a buffer from one rank to another, matched by (communicator, source, tag). Non-blocking variants (`MPI_Isend`, `MPI_Irecv`, completed with `MPI_Wait`) let a rank compute while messages are in flight, which is how halo exchanges overlap with interior computation.
3. **Collectives.** Every rank of a communicator calls the same operation: **broadcast** (root's buffer to all), **reduce** (combine everyone's buffer with an operation such as sum, result at root), **all-reduce** (reduce, with the result at every rank), **all-gather** (every rank's piece concatenated at every rank), **reduce-scatter** (reduce, then each rank keeps one piece), **all-to-all** (each rank sends a distinct piece to every other) and **barrier**. MPI-3 added non-blocking collectives; MPI-4 added persistent collectives and partitioned communication.
4. **Implementations** (Open MPI, MPICH and vendor derivatives) choose an algorithm per call based on message size, process count and topology.

```
        # illustrative: run with  mpirun -n 4 python3 allreduce_demo.py  (needs mpi4py
and numpy)
        from mpi4py import MPI
        import numpy as np

        comm = MPI.COMM_WORLD
        rank, size = comm.Get_rank(), comm.Get_size()
        config = comm.bcast({"steps": 10} if rank == 0 else None, root=0)   # broadcast
an object
        local = np.full(4, float(rank))                                      # this
rank's gradient
        total = np.empty_like(local)
        comm.Allreduce(local, total, op=MPI.SUM)                             # buffer
all-reduce
        if rank == 0:
            print(config["steps"], total)   # with 4 ranks: 10 [6. 6. 6. 6.]
```

What to notice: every rank runs the same code and branches on `rank`; lower-case `bcast` pickles Python objects, while upper-case `Allreduce` sends raw buffers, the form used for large arrays.

49.9.2 Collective cost models

DEFINITION

Definition — α-β (Hockney) model. Sending an n-byte message costs $\alpha + n\beta$, where α is a fixed per-message **latency** (software overhead plus network) and β the time per byte (inverse bandwidth). Reductions add $n\gamma$ for computation; γ is usually small and is ignored below [Thakur et al. 2005].

Three all-reduce algorithms are worth knowing:

- **Binomial tree** reduce to a root, then binomial-tree broadcast: $2\lceil \log_2 p \rceil$ rounds, each sending the whole vector.
- **Ring** (reduce-scatter then all-gather around a ring): $2(p-1)$ steps, each sending n/p bytes. Patarasuk and Yuan proved that $2\frac{p-1}{p}n\beta$ is a lower bound on the bandwidth term for all-reduce, so the ring is **bandwidth-optimal** [Patarasuk and Yuan 2009].
- **Rabenseifner**: recursive-halving reduce-scatter plus recursive-doubling all-gather, achieving the ring's bandwidth term with only $2\log_2 p$ latency terms when p is a power of two [Thakur et al. 2005].

FORMULA

All-reduce costs in the α-β model (computation ignored)

$$T_{\text{ring}} = 2(p-1)\alpha + 2\frac{p-1}{p}n\beta \qquad T_{\text{tree}} = 2\lceil \log_2 p \rceil(\alpha + n\beta) \qquad T_{\text{Rab}} = 2\log_2 p\,\alpha + 2\frac{p-1}{p}n\beta$$

$$n^* = \frac{(p - 1 - \log_2 p)\alpha}{(\log_2 p - \frac{p-1}{p})\beta} \quad \text{(ring beats tree for } n > n^*\text{)}$$

Symbol	Meaning	Units
p	Number of ranks	count
n	Vector size per rank	bytes
α	Per-message latency	s
β	Time per byte	s/B
n^*	Crossover size between ring and tree	bytes

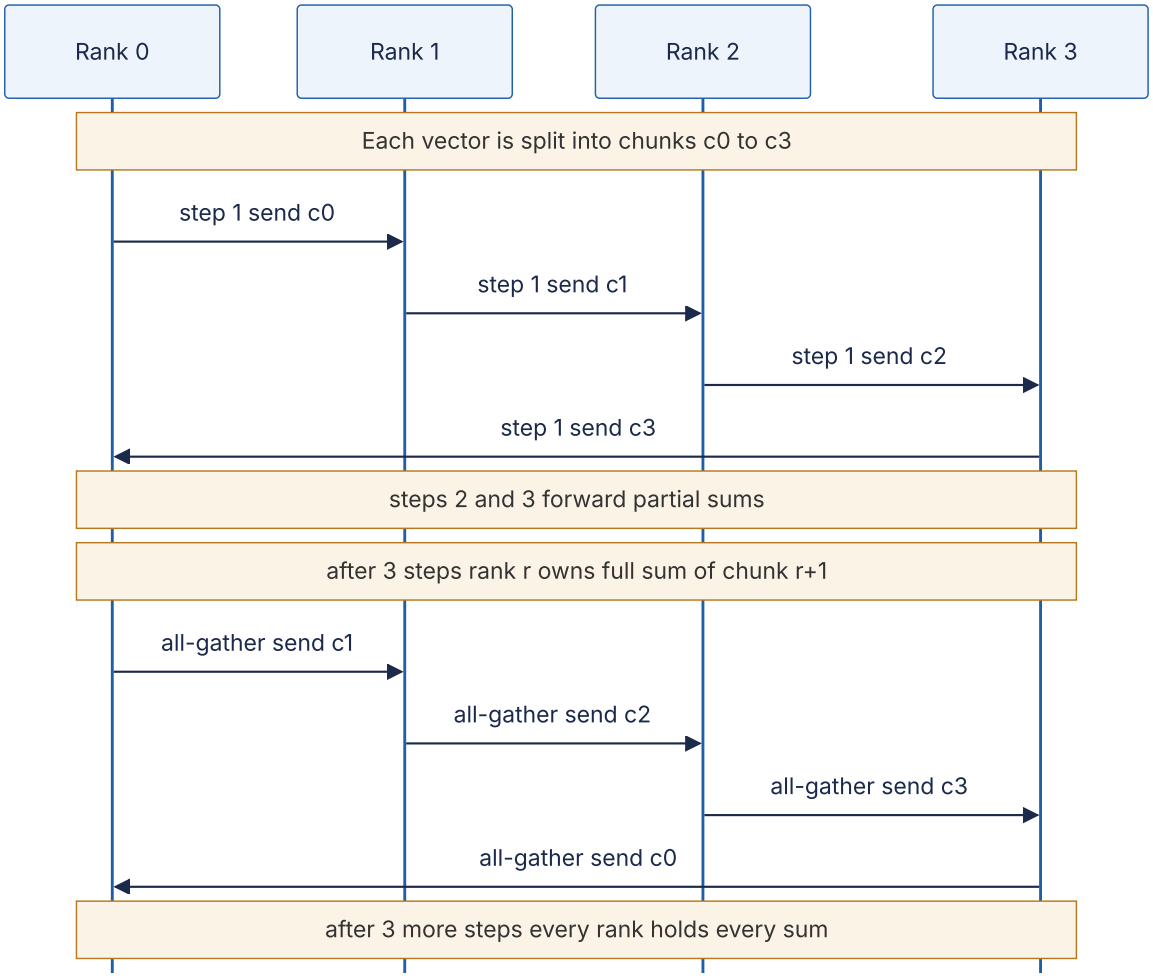
WORKED EXAMPLE

Worked example — Ring versus tree for 64 ranks. $p = 64$, $\alpha = 5$ µs, links of 200 Gb/s so $\beta = 1/(25 \times 10^9) = 4 \times 10^{-11}$ s/B.

1. Large vector, $n = 1$ GB (250 million FP32 gradients). Ring: latency $2 \times 63 \times 5$ µs $= 0.63$ ms; bandwidth $2 \times \frac{63}{64} \times 10^9 \times 4 \times 10^{-11} = 78.75$ ms; total **79.4 ms**. Tree: $12 (5 + 40) = $ **480 ms**. The ring is 6× faster, because the tree sends the full gigabyte $\log_2 p$ times on its critical path.
2. Small vector, $n = 8$ KB. Ring: $0.63 + 0.0006 \approx$ **0.631 ms**, all latency. Tree: $12 \times (5 + 0.33)$ µs $= $ **64 µs**, 10× faster.
3. Crossover: $n^* = 57 \times 5 \times 10^{-6} / ((6 - 0.984) \times 4 \times 10^{-11}) = 2.85 \times 10^{-4} / 2.006 \times 10^{-10} \approx 1.42$ MB.
4. Rabenseifner at 1 GB: $0.06 + 78.75 = 78.8$ ms, best of both.

Interpretation. Latency terms dominate small messages and bandwidth terms dominate large ones; no single algorithm wins everywhere. **Engineering implication.** Libraries switch algorithms by size (MPI implementations use tuned thresholds; NCCL uses rings and double binary trees), and training frameworks **bucket** many small gradient tensors into messages of several megabytes so they land on the bandwidth-optimal side of the crossover (Chapter 65).

Figure 49.8 — Ring all-reduce on four ranks: reduce-scatter, then all-gather.



Reading the diagram. Four *ranks* form a logical ring. In each reduce-scatter step every rank sends one chunk (n/p bytes) to its right neighbor, which adds it to its own copy, and all four sends happen simultaneously, so every link is busy. After $p - 1 = 3$ steps, each rank owns one fully reduced chunk. The all-gather phase circulates those finished chunks for another 3 steps, overwriting instead of adding. Messages are synchronous within a step: each step waits for the slowest link, so one slow node or link slows the whole ring. Storage boundary: everything is in device memory. Scaling: per-rank traffic stays at about $2n$ as p grows, but latency grows linearly, which is why large systems use hierarchical rings (within a node, then across nodes) or trees.

The program below simulates the ring step by step, checks that every rank ends with the exact sum and that each sends exactly $2\frac{p-1}{p}n$ bytes, and evaluates the cost models.

```
        """Ring all-reduce: a step-by-step simulation plus alpha-beta cost models."""
        import math
        import random

        def ring_allreduce(buffers):
            """Sum-all-reduce lists in place using reduce-scatter then all-gather.

            buffers[r] is rank r's vector; its length must be divisible by p.
            Returns (steps, bytes_sent_per_rank) assuming 8-byte elements.
            """
            p, n = len(buffers), len(buffers[0])
            assert n % p == 0, "pad the vector so every rank owns one equal chunk"
            c = n // p                                      # chunk length
            chunk = lambda k: range(k * c, (k + 1) * c)  # indices of chunk k
            steps, sent = 0, [0] * p

            # Phase 1, reduce-scatter: p-1 steps; rank r sends chunk (r - s) mod p.
            for s in range(p - 1):
                msgs = [(r, (r + 1) % p, (r - s) % p) for r in range(p)]
                payload = {(src, k): [buffers[src][i] for i in chunk(k)] for src, _, k
in msgs}
                for src, dst, k in msgs:                # all sends in a step are simul-
taneous
                    for j, i in enumerate(chunk(k)):
                        buffers[dst][i] += payload[(src, k)][j]
                    sent[src] += 8 * c
                steps += 1
            # Now rank r holds the complete sum of chunk (r + 1) mod p.

            # Phase 2, all-gather: p-1 steps; rank r forwards chunk (r + 1 - s) mod p.
            for s in range(p - 1):
                msgs = [(r, (r + 1) % p, (r + 1 - s) % p) for r in range(p)]
                payload = {(src, k): [buffers[src][i] for i in chunk(k)] for src, _, k
in msgs}
                for src, dst, k in msgs:
                    for j, i in enumerate(chunk(k)):
                        buffers[dst][i] = payload[(src, k)][j]
                    sent[src] += 8 * c
                steps += 1
            return steps, sent

        def t_ring(p, n, a, b):          # Patarasuk and Yuan: bandwidth-optimal
            return 2 * (p - 1) * a + 2 * (p - 1) / p * n * b

        def t_tree(p, n, a, b):          # binomial-tree reduce, then binomial broadcast
            return 2 * math.ceil(math.log2(p)) * (a + n * b)

        def t_recursive_doubling(p, n, a, b):
            return math.ceil(math.log2(p)) * (a + n * b)

        def t_rabenseifner(p, n, a, b):  # recursive-halving reduce-scatter + doubling
```

```
all-gather
            return 2 * math.log2(p) * a + 2 * (p - 1) / p * n * b

        def crossover_ring_vs_tree(p, a, b):
            lg = math.log2(p)
            return (p - 1 - lg) * a / ((lg - (p - 1) / p) * b)

        if __name__ == "__main__":
            random.seed(49)
            for p in (2, 3, 4, 8, 12):
                n = p * 5
                data = [[random.randint(-100, 100) for _ in range(n)] for _ in range(p)]
                expected = [sum(col) for col in zip(*data)]
                steps, sent = ring_allreduce(data)
                assert all(buf == expected for buf in data), "every rank must hold the
sum"
                assert steps == 2 * (p - 1)
                assert all(x == 8 * 2 * (p - 1) * n // p for x in sent)  # 2(p-1)/p * n
elements
            print("ring all-reduce correct for p = 2, 3, 4, 8, 12")

            alpha, beta = 5e-6, 1 / 25e9      # 5 us per message; 25 GB/s = 200 Gb/s
link
            p = 64
            for n in (8 * 1024, 1e6, 1e9):
                r, t = t_ring(p, n, alpha, beta), t_tree(p, n, alpha, beta)
                rd, rab = t_recursive_doubling(p, n, alpha, beta), t_rabenseifner(p, n,
alpha, beta)
                print(f"n={n:>12,.0f} B  ring {r*1e3:9.3f} ms  tree {t*1e3:9.3f} ms  "
                      f"rec-doubling {rd*1e3:9.3f} ms  Rabenseifner {rab*1e3:9.3f} ms")
            n_star = crossover_ring_vs_tree(p, alpha, beta)
            print(f"ring beats tree above n* = {n_star/1e6:.2f} MB")
            assert abs(t_ring(p, n_star, alpha, beta) - t_tree(p, n_star, alpha, beta))
< 1e-12
```

Output:

```
ring all-reduce correct for p = 2, 3, 4, 8, 12
n=       8,192 B  ring     0.631 ms  tree     0.064 ms  rec-doubling     0.032 ms
Rabenseifner     0.061 ms
n=   1,000,000 B  ring     0.709 ms  tree     0.540 ms  rec-doubling     0.270 ms
Rabenseifner     0.139 ms
n=1,000,000,000 B  ring    79.380 ms  tree   480.060 ms  rec-doubling   240.030 ms
Rabenseifner    78.810 ms
ring beats tree above n* = 1.42 MB
```

What to notice:

- Each step builds all payloads *before* applying any of them, modeling simultaneous sends; applying them in place one by one would let a chunk travel two hops in one step and give a wrong answer.

- With the chunk index $(r - s) \bmod p$, the chunk a rank receives in step s already carries $s + 1$ contributions and gains its own, so after the last step ($s = p - 2$) it holds all p.
- Recursive doubling ($\log_2 p$ rounds of full-vector exchange) wins for tiny messages, which is why MPI libraries use it for scalars such as the dot products of §49.8.2.

COMMON MISTAKE

"All-reduce gets slower with more ranks because each rank sends more data." With the ring, each rank sends $2\frac{p-1}{p}n < 2n$ bytes whatever p is. What grows is the latency term, $2(p-1)\alpha$, and exposure to the slowest link. That is why hierarchical and tree variants matter at thousands of ranks.

49.10 High-performance networking

49.10.1 RDMA

DEFINITION

Definition — RDMA (remote direct memory access). A network capability in which the network interface card (NIC) moves data directly between the memory of an application on one machine and registered memory on another, without the kernel on the data path (**kernel bypass**), without intermediate copies (**zero-copy**), and, for one-sided operations, without involving the remote CPU at all. Applications use it through the **verbs** interface (libibverbs) [InfiniBand Trade Association; NVIDIA RDMA Programming Manual].

First-principles explanation

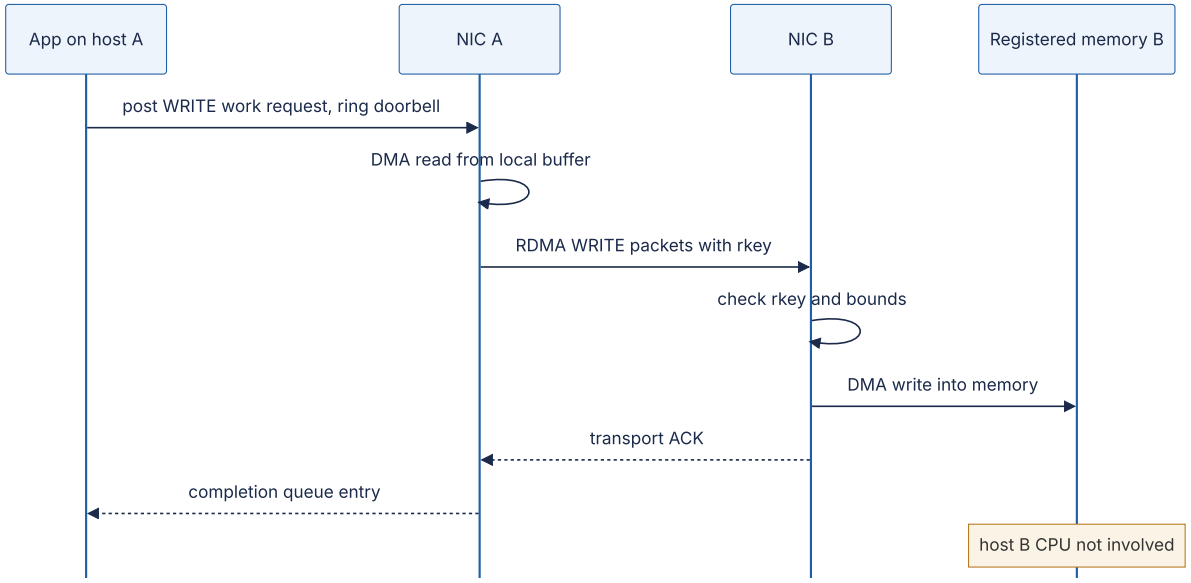
Sending data with TCP is like mailing a letter through two post offices: the sender's kernel copies the data, segments it and computes checksums; the receiver's kernel takes interrupts, reassembles and copies again. Each step costs microseconds of CPU. RDMA is like giving a trusted courier a key to a specific shelf in the recipient's warehouse: the courier (the NIC) puts the parcel on the shelf directly. §5.7.5 introduced kernel bypass; here is the mechanism.

How it works internally

1. **Register memory.** The application registers a buffer; the NIC pins it and returns a local key (`lkey`) and a remote key (`rkey`). The remote side gets the `rkey` and address out of band.

2. **Create queue pairs.** A **queue pair (QP)**, a send queue and a receive queue living in user memory, is connected to a QP on the peer. Transports include reliable connected (RC), unreliable connected and unreliable datagram.
3. **Post work requests.** The application writes a work request (opcode, local buffer, remote address and `rkey`) to the send queue and rings a doorbell register on the NIC, with no system call.
4. **NIC executes.** Two-sided **SEND/RECV** consumes a receive buffer that the peer posted. One-sided **RDMA WRITE** and **RDMA READ** access remote memory directly; atomics (fetch-and-add, compare-and-swap) do so atomically.
5. **Completion.** The NIC writes a completion entry to a **completion queue (CQ)**, which the application polls.

Figure 49.9 — An RDMA WRITE with verbs.



Reading the diagram. The *application* posts a work request and rings the doorbell in user space; *NIC A* reads the buffer from local memory by DMA and sends packets to *NIC B*, which validates the remote key and writes straight into *registered memory*. On a reliable connection NIC B acknowledges in hardware, and NIC A posts a completion that the application polls. Every step is asynchronous with respect to host B's CPU, which never runs. Failure points: an invalid or revoked key fails the operation; a lost packet triggers hardware retransmission, which on lossy networks can collapse throughput (§49.10.3); a QP enters an error state on repeated failure and must be reset. Scaling: each connected QP consumes NIC memory, so very large clusters use shared or datagram transports.

Typical results: one-way latency of one to a few microseconds at full line rate with almost no host CPU, versus tens of microseconds for kernel TCP.

49.10.2 InfiniBand versus RoCEv2

InfiniBand (IB) is a complete network stack designed for RDMA: its own links, switches and addressing, a central **subnet manager** that assigns addresses and computes routes, and **credit-based link-level flow control**, under which a sender transmits only when the receiver has advertised buffer space, so the fabric does not drop packets for congestion. **RoCEv2** (RDMA over Converged Ethernet, version 2) carries the InfiniBand transport inside UDP/IP packets (destination port 4791) over ordinary Ethernet switches, so it is routable across layer 3. Ethernet drops packets when buffers overflow, and early RDMA NICs recovered poorly from loss (go-back-N retransmission), so RoCEv2 deployments usually make the Ethernet lossless with **Priority Flow Control (PFC)**, IEEE 802.1Qbb, which pauses one traffic class on a link when the receiver's buffer passes a threshold.

Table 49.3 — RDMA fabrics compared.

Aspect	InfiniBand	RoCEv2	Provider transports (e.g., AWS SRD)
What it is	RDMA-native network stack	IB transport over UDP/IP Ethernet	Cloud-specific reliable datagram transport
Loss handling	Credit-based, lossless by design	PFC for losslessness plus ECN congestion control	Tolerates loss; multipath spraying, fast retransmit
Advantages	Mature, low latency, in-network reduction (SHARP)	Ethernet economics, tooling, multi-vendor	No lossless fabric needed
Disadvantages	Separate fabric and skills, fewer vendors	PFC risks (below), tuning	Provider-specific
Choose when	Dedicated HPC or AI clusters	Large Ethernet datacenters	Running HPC in that cloud

AWS's Scalable Reliable Datagram, used by its Elastic Fabric Adapter, takes the third approach: it sprays packets of one flow over many paths, delivers out of order and retransmits quickly, so it needs no lossless fabric [Shalev et al. 2020]. The Ultra Ethernet Consortium is standardizing an Ethernet transport with similar goals (as of 2026).

49.10.3 Congestion control: DCQCN and the risks of PFC

PFC keeps packets from being dropped, but it is a blunt instrument. A pause stops *all* traffic of that class on the link, including flows not going to the congested port (**head-of-line blocking**); pauses propagate upstream hop by hop (**congestion spreading**); a cycle of switches each waiting for the next to drain can **deadlock**; and a malfunctioning NIC that sends pauses continuously can freeze a large part of the network (a **pause storm**). Microsoft's account of RoCEv2 at datacenter scale reports deadlocks and a NIC-induced pause storm, and its mitigations: DSCP-based PFC, watchdogs that disable PFC on a port paused too long, and transport fixes for livelock [Guo et al. 2016].

DCQCN (Data Center Quantized Congestion Notification) adds end-to-end, ECN-based rate control so that PFC is a rarely used backstop [Zhu et al. 2015]. Three roles:

1. **Congestion point (switch).** Marks packets with ECN with a probability that rises with queue length between two thresholds, as in RED.
2. **Notification point (receiver NIC).** On marked packets, sends a **congestion notification packet (CNP)** to the sender, at most one per flow per interval (50 µs in the paper).
3. **Reaction point (sender NIC).** Cuts the flow's rate on each CNP, and raises it in stages (fast recovery toward the previous rate, then additive and hyper increase) when CNPs stop.

FORMULA

DCQCN rate reduction and recovery

$$R_T \leftarrow R_C, \quad R_C \leftarrow R_C\left(1 - \frac{\alpha}{2}\right), \quad \alpha \leftarrow (1-g)\alpha + g \qquad \text{fast recovery: } R_C \leftarrow \frac{R_T + R_C}{2}$$

Symbol	Meaning	Units
R_C	Current sending rate of the flow	Gb/s
R_T	Target rate (rate before the last cut)	Gb/s
α	Estimate of congestion severity; decays when no CNP arrives	dimensionless (0–1)
g	Gain of the α update (1/256 in the paper)	dimensionless

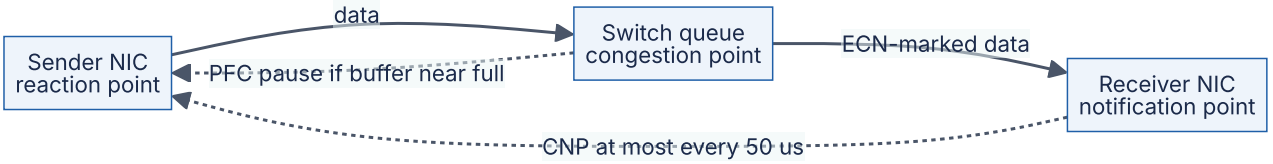
WORKED EXAMPLE

Worked example — A flow hitting congestion. A 100 Gb/s flow with $\alpha = 1$ receives a CNP, then a second one before recovery.

1. First CNP: $R_T = 100$; $R_C = 100 \times (1 - 0.5) = 50$ Gb/s; α stays at 1.
2. Second CNP: $R_T = 50$; $R_C = 25$ Gb/s.
3. Congestion clears. Five fast-recovery steps toward $R_T = 50$: 37.5, 43.75, 46.9, 48.4, 49.2 Gb/s; additive increase then raises R_T step by step back toward 100.
4. If congestion had been mild, α would have decayed (for example to 0.25), and a CNP would cut only $1 - 0.125 = 12.5\%$.

Interpretation. Rate cuts are multiplicative and fast, recovery is staged and slower, and α makes the cut proportional to persistent congestion. **Engineering implication.** ECN thresholds must be set so DCQCN reacts before PFC thresholds are reached; otherwise PFC does the work and brings its risks.

Figure 49.10 — DCQCN's control loop.



Reading the diagram. Data flows left to right from the *reaction point* through a *switch*, which marks packets with ECN as its queue grows, to the *notification point*, which returns CNPs (dotted, asynchronous feedback) to the sender, which cuts its rate. PFC (dotted) is the last-resort hop-by-hop pause when buffers are nearly full. Failure points: thresholds set wrongly let PFC trigger first, causing head-of-line blocking and congestion spreading; a NIC that floods pauses freezes upstream links unless a watchdog intervenes. Scaling: control is per flow and distributed, so it needs no central coordinator.

49.10.4 Topologies and bisection bandwidth

DEFINITION

Definition — Bisection bandwidth. The minimum total link capacity, in one direction, crossing any cut that divides the network's endpoints into two equal halves. **Full bisection bandwidth** means every endpoint in one half can send to the other half at full injection rate simultaneously.

A **fat tree** is the three-tier folded Clos network built from identical k-port switches described by Al-Fares et al. [2008]: k pods, each with $k/2$ edge and $k/2$ aggregation switches,

plus $(k/2)^2$ core switches; it gives full bisection bandwidth (§7.17.1 sized a two-tier leaf–spine). A **dragonfly** groups routers into **groups** with all-to-all local links inside each group and at least one global (optical) link between every pair of groups, so any minimal path takes at most one global hop; it cuts the number of long, expensive cables, and adaptive routing (sending some traffic through an intermediate group) handles adversarial patterns [Kim et al. 2008]. Slingshot systems such as Frontier use dragonfly topologies.

FORMULA

Fat-tree and dragonfly sizes

Fat tree: $H = \frac{k^3}{4}, \quad S = \frac{5k^2}{4}, \quad B_{\text{bis}} = \frac{H}{2} b$ Dragonfly: $g = ah + 1, \quad H = a\,p\,g, \quad B_{\text{bis}} \approx \lfloor \frac{g}{2} \rfloor \lceil \frac{g}{2} \rceil b$

Symbol	Meaning	Units
k	Ports per switch	count
H	Number of hosts (endpoints)	count
S	Number of switches	count
b	Link rate	Gb/s
a, p, h	Routers per group, hosts per router, global links per router	count
g	Number of groups with one global link per pair	count
B_{bis}	Bisection bandwidth, one direction	Gb/s

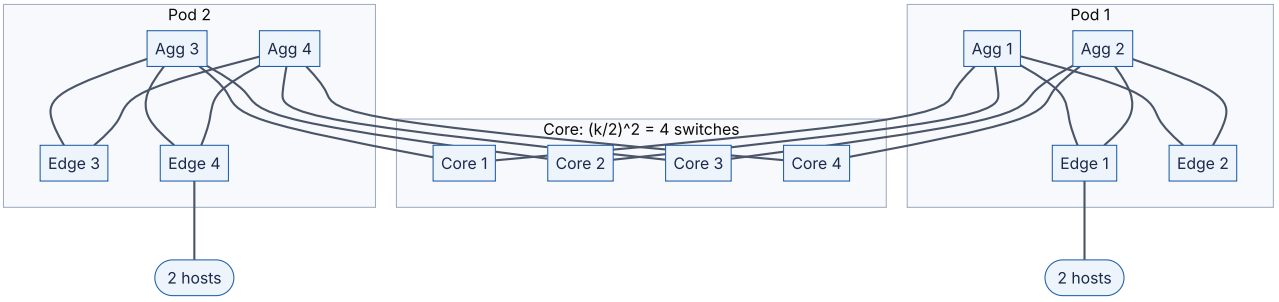
WORKED EXAMPLE

Worked example — Bisection of a fat tree and a dragonfly.

1. Fat tree, $k = 64$, 400 Gb/s links: $H = 64^3/4 = 65,536$ hosts; $S = 5 \times 4,096/4 = 5,120$ switches; $B_{\text{bis}} = 32,768 \times 400$ Gb/s $= 13.1$ Pb/s.
2. With 2:1 oversubscription at the edge (more hosts per edge switch, fewer up-links), bisection halves relative to injection, so an all-to-all exchange runs at 200 Gb/s per host.
3. Dragonfly, $p = h = 8$, $a = 16$, 200 Gb/s links: $g = 16 \times 8 + 1 = 129$ groups; $H = 16 \times 8 \times 129 = 16,512$ hosts. Splitting groups 64/65, $64 \times 65 = 4,160$ global links cross: $4,160 \times 200$ Gb/s $= 832$ Tb/s.
4. Per host in the smaller half ($64 \times 128 = 8,192$ hosts): $832/8,192 \approx 102$ Gb/s, about half the 200 Gb/s injection rate.

Interpretation. The fat tree gives every host full rate across any cut at the price of many switches and cables; the dragonfly gives about half across a worst-case bisection, which suffices for uniform random traffic (only half of it crosses any bisection) but not for adversarial patterns without adaptive routing. **Engineering implication.** Size bisection for your communication pattern: all-to-all (FFTs, mixture-of-experts layers) needs full bisection; nearest-neighbor halos and rings need far less if ranks are placed with topology in mind (§46.11.2).

Figure 49.11 — A fat tree with k = 4 (two of four pods shown).



Reading the diagram. Each *edge* switch connects $k/2 = 2$ hosts and both *aggregation* switches of its pod; each aggregation switch connects to $k/2 = 2$ *core* switches, the first aggregation switch of every pod to cores 1–2 and the second to cores 3–4. Links are bidirectional with equal capacity at every tier, which is what makes the bisection full: traffic between pods has $(k/2)^2 = 4$ equal-cost paths through the core, spread by ECMP or adaptive routing. Failure points: a core switch failure removes a quarter of inter-pod capacity; an edge switch failure isolates its hosts. Scaling: capacity is fixed by k; bigger networks use higher-radix switches or more tiers.

49.11 Parallel file systems

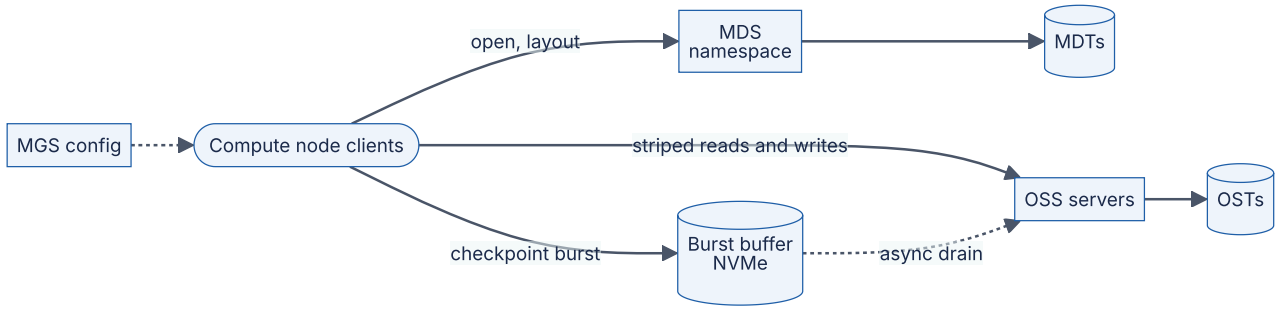
DEFINITION

Definition — Parallel file system. A POSIX file system whose files are striped across many storage servers so that thousands of clients can read and write one file or many files concurrently at aggregate bandwidths of terabytes per second; examples are Lustre and IBM Storage Scale (formerly Spectrum Scale and GPFS).

Lustre separates metadata from data [Lustre Docs]. A **management server (MGS)** holds configuration. **Metadata servers (MDS)** store the namespace, permissions and file layouts on **metadata targets (MDTs)**; the distributed namespace (DNE) spreads directories over several MDTs. **Object storage servers (OSS)** store file data as objects on **object storage targets (OSTs)**. Clients talk to all of them over LNet, Lustre's network layer, which runs over InfiniBand or Ethernet. A file's layout says which OSTs hold it: `lfs setstripe -c 8 -S 4M` stripes a file round-robin in 4 MiB pieces over 8 OSTs, so one file can use 8 servers' bandwidth. A distributed lock manager keeps client caches coherent. **Storage Scale** instead is a shared-disk design: every node can access every disk, metadata is handled by the nodes themselves under distributed byte-range and token locking, and data is striped widely [Schmuck and Haskin 2002].

Burst buffers are a tier of flash, on compute nodes or dedicated servers, that absorbs checkpoint bursts at high speed and drains them to the parallel file system while the computation continues [Liu et al. 2012].

Figure 49.12 — Lustre with a burst buffer.



Reading the diagram. *Clients* contact the *MDS* only to open, create or look up files and obtain layouts (synchronous); data then flows in parallel to many *OSS* servers and their *OSTs*. Checkpoints can land on a *burst buffer*, which drains asynchronously (dotted) to the OSTs. Storage boundaries: namespace on MDTs, file data on OSTs, transient checkpoints on flash. Failure points: the MDS is the classic bottleneck (100,000 ranks each creating a file at once is a metadata storm); an OSS failure stalls files striped over it until failover. Scaling: OSTs add bandwidth; extra MDTs add metadata throughput.

FORMULA

Checkpoint write time and Young’s optimal interval

$$\delta = \frac{Ns}{\min(B_{\text{fs}},\, Nb_{\text{node}})} \qquad M_{\text{sys}} = \frac{M_{\text{node}}}{N} \qquad \tau_{\text{opt}} \approx \sqrt{2\,\delta\, M_{\text{sys}}} \qquad \text{waste} \approx \frac{\delta}{\tau} + \frac{\tau}{2M_{\text{sys}}}$$

Symbol	Meaning	Units
N	Nodes in the job	count
s	Checkpoint bytes per node	bytes
B_{fs}	Aggregate write bandwidth of the storage tier	bytes/s
b_{node}	Per-node write bandwidth (NIC or local flash)	bytes/s
δ	Time to write one checkpoint	s
M_{node}, M_{sys}	Mean time between failures of one node and of the whole job	s
τ, τ_{opt}	Checkpoint interval and its first-order optimum [Young 1974]	s

WORKED EXAMPLE

Worked example — Checkpointing a 4,000-node job. $s = 128$ GB per node; parallel file system 2.5 TB/s; node-local NVMe burst buffer 8 GB/s per node; $M_{\text{node}} = 50,000$ h.

1. Checkpoint size: $4,000 \times 128$ GB $= 512$ TB. To the file system: $\delta = 512 \times 10^{12} / 2.5 \times 10^{12} = 205$ s.
2. Job MTBF: $50,000/4,000 = 12.5$ h $= 45,000$ s.
3. Young: $\tau_{\text{opt}} = \sqrt{2 \times 205 \times 45,000} = \sqrt{1.84 \times 10^{7}} \approx 4,290$ s (72 min). Waste $\approx 205/4,290 + 4,290/90,000 = 4.8\% + 4.8\% = 9.6\%$.
4. Burst buffer: $\delta = 128/8 = 16$ s. $\tau_{\text{opt}} = \sqrt{2 \times 16 \times 45,000} = 1,200$ s; waste $= 1.3\% + 1.3\% = 2.7\%$. The 205 s drain to the file system overlaps the next 20 minutes of computation.

Interpretation. Faster checkpoints allow more frequent ones, cutting both write time and lost work: about 7 percentage points of the machine are recovered.
Engineering implication. At scale, checkpoint bandwidth is sized from the failure rate, not from capacity; write one file per process or use collective MPI-IO to avoid lock contention on a shared file, and stage through flash (Chapter 65 applies this to training).

Table 49.4 — Parallel file systems versus object storage.

Aspect	Lustre	Storage Scale	Object storage
Metadata	Dedicated MDS/MDTs	Distributed among nodes, token locks	Sharded key-value index
Interface	POSIX	POSIX, plus NFS/S3 gateways	HTTP GET/PUT, no in-place update
Strength	Bandwidth for large striped I/O	Mixed workloads, shared disk	Capacity, durability, cost
Weakness	Small files, metadata storms	Licensing, complexity	Latency, no POSIX semantics
Choose when	HPC scratch, checkpoints	Enterprise HPC, mixed analytics	Data lakes, archives, long-term datasets

49.12 Batch schedulers for HPC

HPC schedulers (Slurm, PBS Pro and its open-source variant OpenPBS, IBM LSF) allocate whole nodes to jobs as gangs, order queues by multifactor priority and fair-share, and backfill short jobs into holes before reservations; §46.12 covers Slurm's architecture and works a backfill example. Three HPC-specific points matter here: jobs request **topology** (for example, all nodes under few switches or within one dragonfly group) because collective costs depend on placement; jobs must state **time limits**, which backfill needs and which also bound checkpoint planning (§49.11); and **node health checks** run before and after jobs, because in a tightly coupled job one bad node fails the whole allocation.

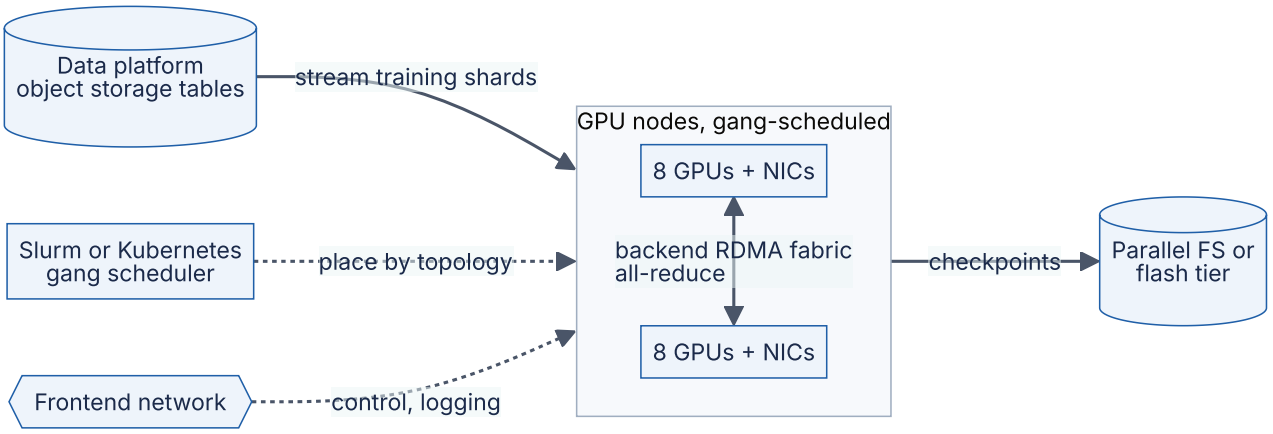
49.13 Convergence of HPC, big data and AI

HPC optimized tightly coupled floating-point work with MPI and parallel file systems; big-data systems optimized throughput on commodity clusters that tolerate failure by re-execution (§29.4.3) [Reed and Dongarra 2015]. Large-model training reunites them. Each training step is a tightly coupled, bulk-synchronous computation whose gradients are combined by all-reduce (§49.9), so it needs a supercomputer's network: RDMA, high bisection bandwidth, topology-aware placement and gang scheduling. Its input is a petabyte-scale dataset prepared on a data platform (§49.5, Chapter 61); its checkpoints are a parallel-file-system problem (§49.11); and its failure rate at tens of thousands of GPUs is an exabyte-storage-style problem of constant failure (§49.3).

INDUSTRY EXAMPLE

Meta's AI training clusters. Meta described two 24,576-GPU clusters built in 2024, one on RoCEv2 Ethernet and one on InfiniBand, each with 400 Gb/s endpoints, to compare the fabrics at scale [Meta Engineering 2024]. Its SIGCOMM 2024 paper on RoCE for distributed training describes a dedicated backend network for collectives, separate from the frontend datacenter network, and congestion-control and routing changes made for collective traffic [Gangidi et al. 2024]. *Evidence: Primary* — [Meta Engineering 2024; Gangidi et al. 2024]

Figure 49.13 — An AI training cluster as a supercomputer.



Reading the diagram. Training data streams from the *data platform* into *GPU nodes*, which a *gang scheduler* places by topology (dotted, control path). Within each step, nodes exchange gradients synchronously over a dedicated *backend RDMA fabric*; a separate *frontend network* carries control and logging. Checkpoints go to a *parallel file system or flash tier*. Failure points: one failed GPU or link stalls every rank; the checkpoint tier bounds how often the job can save. Scaling: add nodes in topology units (racks, groups), together with fabric bisection and checkpoint bandwidth.

Chapter 65 develops the parallelism strategies and communication volumes of distributed training, and Chapter 80 the design of clusters with tens of thousands of GPUs.

49.14 Summary and revision notes

SUMMARY

- At an exabyte, failure is constant (about 3 drives a day for 75,000 drives), repair is a permanent multi-GB/s workload, metadata becomes a sharded database, data gravity pins computation to data, and redundancy overhead dominates cost.
- Colossus (curators over Bigtable), Tectonic (layered metadata in ZippyDB), S3 (regional object service) and Azure Storage (stamps; synchronous stream-layer, asynchronous geo-replication) all move metadata into a scalable store and keep data off the metadata path.
- The data platform: ingestion (CDC, Kafka) → raw zone in object storage → Parquet plus a table format → Spark, Flink, SQL engines → serving; storage and compute are separated and caches recover locality.
- Dremel stores nested data with repetition and definition levels, runs queries on a serving tree and a disaggregated shuffle tier; Snowflake separates storage, virtual warehouses and cloud services, and prunes immutable micro-partitions by min/max metadata.
- Ship data when $8S/(\rho B\eta)$ exceeds load + transit + unload time; 50 PB takes 579 days on 10 Gb/s versus about 12 days by shipment.
- HPC is tightly coupled; strong scaling is limited by latency terms that grow with $\log p$. Top500 ranks by HPL Rmax; Rmax/Rpeak is typically 60–70% for leading GPU systems.
- α–β model: ring all-reduce $2(p-1)\alpha + 2\frac{p-1}{p}n\beta$ is bandwidth-optimal; trees win below a crossover of about 1.4 MB for 64 ranks at 5 µs and 25 GB/s; Rabenseifner combines both.
- RDMA gives microsecond, zero-copy, kernel-bypass transfers via queue pairs and completion queues. InfiniBand is lossless by credits; RoCEv2 relies on PFC plus DCQCN, and PFC brings head-of-line blocking, congestion spreading, deadlock and pause storms.
- Fat trees give full bisection ($k^3/4$ hosts); dragonflies trade about half bisection for fewer long cables.
- Lustre separates MDS/MDT from OSS/OST and stripes files; burst buffers absorb checkpoints; Young's $\tau \approx \sqrt{2\delta M}$ sets the interval.

49.15 Knowledge checkpoint

1. How many 24 TB drives does 2 EB usable need with RS(10, 4), and how many fail per day at AFR 2%?
2. Why does metadata, not capacity, usually limit a single-master file system?

3. Name Tectonic’s three metadata layers and the store that holds them.
4. In Windows Azure Storage, which layer replicates synchronously and which asynchronously, and why split them?
5. What do repetition level 0 and a definition level below the maximum mean in Dremel?
6. How does Snowflake avoid indexes for selective queries?
7. A 10 PB migration over a 40 Gb/s link at 80% efficiency: how long?
8. State the difference between strong and weak scaling.
9. Compute ring and tree all-reduce times for $p = 16$, $n = 100$ MB, $\alpha = 2$ µs, $\beta = 10^{-10}$ s/B.
10. Why does a one-sided RDMA WRITE not involve the remote CPU?
11. Give three risks of PFC.
12. How many hosts does a $k = 48$ fat tree support?
13. With $\delta = 60$ s and $M_{\text{sys}} = 8$ h, what is Young’s checkpoint interval?

Answers

1. Raw $= 2 \times 1.4 = 2.8$ EB; $2.8 \times 10^{18} / 2.4 \times 10^{13} \approx 116,700$ drives; $116,700 \times 0.02/365 \approx 6.4$ per day.
2. Its memory and request rate scale with the number of files and blocks, which grows much faster than any one server’s RAM, especially with small files.
3. Name, File and Block layers, stored in ZippyDB.
4. Stream layer: synchronous, within a stamp (local failures, strong consistency). Partition layer: asynchronous, across stamps (disasters, no WAN latency on writes).
5. $r = 0$ starts a new record; d below the maximum marks a `NULL` and says how much of the path was present.
6. It keeps per-column min/max for every immutable micro-partition in metadata and prunes partitions that cannot match.
7. $8 \times 10^{16} / (3.2 \times 10^{10}) = 2.5 \times 10^{6}$ s, about 29 days.
8. Strong: fixed total problem, more processors (Amdahl). Weak: problem grows with processors, fixed work per processor (Gustafson).
9. Ring: 30×2 µs $+ 2 \times \frac{15}{16} \times 10^{8} \times 10^{-10} = 0.06 + 18.75 = 18.8$ ms. Tree: $8 \times (2\ \mu\text{s} + 10\ \text{ms}) = 80$ ms.
10. The remote NIC validates the key and writes into pre-registered memory by DMA; no interrupt or software runs on the remote host.
11. Head-of-line blocking, congestion spreading, deadlock from cyclic buffer dependencies, and pause storms from faulty NICs (any three).
12. $48^3/4 = 27,648$ hosts.
13. $\sqrt{2 \times 60 \times 28,800} = \sqrt{3.456 \times 10^{6}} \approx 1,860$ s, about 31 minutes.

49.16 Interview questions

Basic

Q1. Why do exabyte storage systems use erasure coding instead of triple replication? Answer. RS(6, 3) stores 1.5 bytes per byte instead of 3 while tolerating three losses, which at an exabyte saves tens of thousands of drives. The costs are repair fan-in (k reads per lost fragment), CPU and higher small-write latency, so systems replicate hot or small writes first and encode later.

Q2. What is the difference between embarrassingly parallel and tightly coupled workloads? Answer. Embarrassingly parallel tasks need no communication and tolerate failures by re-running a task; tightly coupled ranks exchange data every step, so latency, collectives and a single failure affect the whole job.

Intermediate

Q3. Design the storage and compute layers of an analytics platform for 20 PB. Answer. Object storage as the system of record, raw and curated zones, Parquet tables under Iceberg or Delta with a catalog; Spark for batch, Flink for streaming, a SQL engine or warehouse for interactive use, each on its own elastic cluster with SSD caches; CDC and Kafka for ingestion; replicate only curated tables cross-region; lifecycle cold partitions to cheaper tiers.

Q4. Gradient all-reduce takes 40% of each training step. What do you check? Answer. Message sizes (bucket small tensors past the α–β crossover); algorithm choice (ring or tree by size and scale, hierarchical within and across nodes); overlap of communication with backward computation; topology of the placement; link utilization and congestion signals (ECN marks, PFC pauses); and stragglers, since one slow rank delays every step.

Advanced

Q5. You run RoCEv2 for a 4,000-GPU cluster. How do you keep PFC from hurting you? Answer. Use PFC only for the RDMA class with DSCP-based classification; tune DCQCN so ECN marking starts well below PFC thresholds; size switch headroom; enable PFC watchdogs on switches and NICs; avoid routing loops and cyclic buffer dependencies by topology (up-down routing in a Clos); monitor pause counters and CNP rates per port; and consider transports that tolerate loss.

Q6. Size checkpointing for a 10,000-node job with node MTBF of 5 years. Answer. Job MTBF $= 43,800/10,000 = 4.4$ h. If each node writes 100 GB to a 5 TB/s file system, $\delta = 200$ s and $\tau \approx \sqrt{2 \times 200 \times 15,800} \approx 2,500$ s, with waste near 16%. A burst buffer at 10 GB/s per node

gives $\delta = 10$ s, $\tau \approx 560$ s and waste near 4%, so the flash tier pays for itself in recovered machine time.

49.17 Practical exercises

1. Extend the ring simulation with a hierarchical all-reduce (reduce within groups of 8, ring across group leaders, broadcast within groups) and compare its α–β cost with the flat ring for $p = 1,024$.
2. Modify the striping program to reassemble records from the three columns and assert that you get R1 and R2 back.
3. Write a calculator for drive count, daily failures and repair bandwidth, and plot repair traffic against AFR for RS(6, 3), RS(10, 4) and 3× replication.
4. On a Lustre system, write a 64 GB file with stripe counts of 1, 4 and 16 and compare the bandwidth you achieve.

49.18 Design challenges

1. **Exabyte archive.** Design a 3 EB scientific-data archive for a consortium with 2 PB of new data a week from instruments in another country: redundancy scheme, failure-domain layout, metadata store, ingest path (network or shipment) and cost per PB-year.
2. **Shared research cluster.** Design a 2,048-GPU cluster for both MPI simulations and model training: fabric (InfiniBand or RoCEv2), topology and bisection, parallel file system and burst buffer sizing, scheduler policy and checkpoint guidance.

Chapter 50 — Security Architecture and Privacy Engineering

> **Level:** 4 · **Track:** Shared · **Estimated reading time:** 6 h

Chapter 10 gave you the building blocks of security: threat models, cryptographic primitives, certificates, password storage, secrets, envelope encryption, a first look at zero trust, DDoS defense and tamper-evident audit logs. This chapter is about putting those blocks together into an architecture that still protects people when individual blocks fail, and about a second discipline that sits beside security: **privacy engineering**, the work of making sure a system collects, uses and keeps personal data only in ways its owners would expect and the law allows.

Security asks “can an unauthorized party get at this data?” Privacy asks “should *anyone*, including us, be doing this with it?” A perfectly secure system can still violate privacy, for example by reusing delivery addresses to build advertising profiles.

The running example is **QuickBite**, the hypothetical food-delivery platform of Chapter 2, now running in the United States, the European Union and Asia-Pacific (Chapter 44). For this chapter we assume QuickBite has 3,000 employees, 250 services running as about 20,000 workloads, 40 million customers and 600,000 couriers whose phones report location while they work. Every QuickBite number is a teaching assumption, not a measurement of a real company.

Chapter 71 goes deeper into differential privacy for machine learning; Chapters 77 and 79 apply these ideas to AI systems.

50.1 Learning objectives

After this chapter you should be able to:

- Map layered security controls onto a reference architecture, estimate how independent they are, and reduce blast radius under an assume-breach model.
- Describe BeyondCorp and the NIST SP 800-207 components, and design workload identity with SPIFFE and SPIRE.
- Separate workforce from customer identity, design federation with SAML or OpenID Connect, and choose token lifetimes from an exposure-window calculation.

- Place a policy engine such as OPA or Cedar in an architecture and find privilege-escalation paths in an access graph.
- Explain the SolarWinds and xz-utils compromises, the SLSA build levels, SBOMs, Sigstore signing, dependency confusion and reproducible builds.
- Design a detection pipeline, reason about alert precision from base rates, deploy honeytokens and compute MTTD and MTTR.
- Apply Cavoukian's privacy-by-design principles, build a data inventory and enforce purpose limitation.
- Model lawful basis and consent as data and design a deletion pipeline that reaches backups.
- Distinguish pseudonymization from anonymization, test k-anonymity and explain linkage attacks.
- Define ε-differential privacy, calibrate the Laplace mechanism and track a privacy budget under composition.
- Compare secure multi-party computation, homomorphic encryption and trusted execution environments.

50.2 Prerequisites

- Threat modeling, cryptography and PKI — §10.3–§10.5 (signing, attestation and SPIFFE certificates reuse them).
- Secrets, envelope encryption, zero trust and audit logs — §10.8–§10.10, §10.12 (this chapter continues from there).
- Sessions, JWT, OAuth 2.0, OpenID Connect and Zanzibar — §8.10–§8.14 (identity architecture assumes them).
- Cloud IAM principals, policies and roles — §41.12 (escalation paths live there).
- Pipeline identity and the supply-chain introduction — §43.11 (this chapter treats the topic in depth).
- Multi-tenant isolation and confused deputies — §47.12 (blast radius between customers).
- Data residency — §44.9 (where personal data may live).
- Log pipelines — §40.4 (the SIEM is a log pipeline).

50.3 Defense in depth as an architecture

50.3.1 Layers that fail independently

DEFINITION

Definition — Defense in depth. An architecture in which an asset is protected by several layers of controls, each of which can stop or reveal an attack on its own, chosen so that the layers fail for *different* reasons. An attacker must defeat every layer on the path to the asset; a defender needs only one layer to hold or to raise an alarm.

First-principles explanation

Picture a bank vault. There is a guard at the door, a locked gate, a time-locked vault door, a camera and an alarm that calls the police. None of them is perfect. The design works because they are *different*: the guard can be bribed but the time lock cannot; the lock can be picked but the camera records it. If all five used the same key, stealing that key would defeat all five at once, and you would really have one layer dressed up as five.

Software is the same. A phished password is stopped by phishing-resistant MFA; failing that, by a missing device certificate; failing that, by an authorization policy; failing that, a detection rule pages someone. The safety comes from layers that rely on different secrets, administrators and code.

Why does this exist?

Every control fails sometimes, and architectures that depend on one control (a firewall, a VPN, one admin password) fail completely with it. The goal is that the inevitable compromise of one component does not become the compromise of the system [Adkins et al. 2020].

Mathematical foundations

FORMULA

Probability that an attack passes every layer

$$P_{\text{breach}} = \prod_{i=1}^{n} p_i \quad \text{(independent layers)}$$

Symbol	Meaning	Units
P_{breach}	Probability that one attack attempt reaches the asset undetected	probability
n	Number of layers on the attack path	count
p_i	Probability that layer i fails to stop or detect the attempt	probability

WORKED EXAMPLE

Worked example — QuickBite's admin console. An attacker phishes a support agent. Assume (teaching numbers) the layers fail with $p_1 = 0.05$ (MFA bypass), $p_2 = 0.2$ (device-posture check passes on an attacker machine), $p_3 = 0.3$ (authorization allows the bulk export) and $p_4 = 0.5$ (detection misses the export).

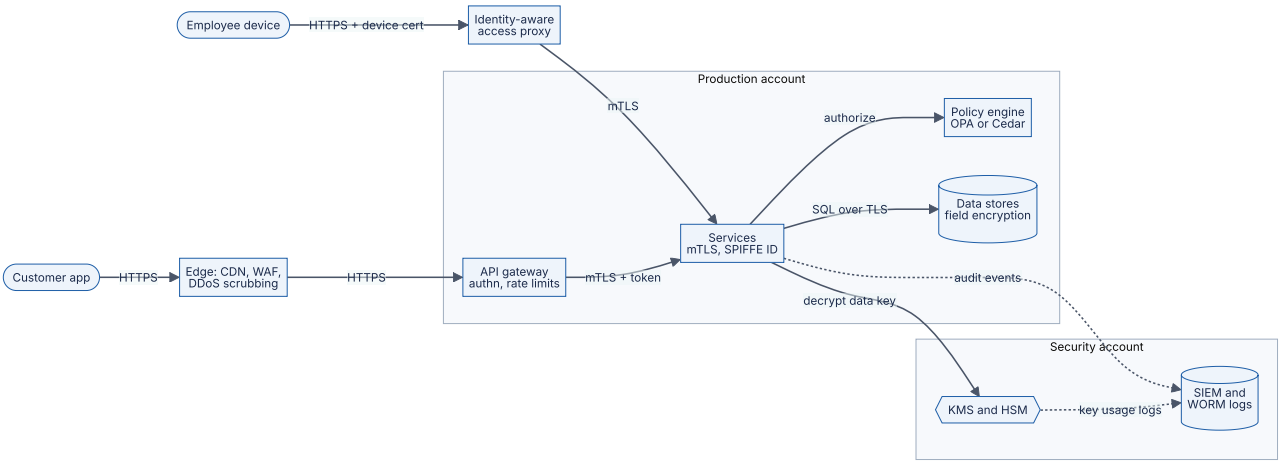
1. Independent layers: $P = 0.05 \times 0.2 \times 0.3 \times 0.5 = 0.0015$, about 1 in 670 attempts.
2. Now suppose the attacker instead phishes an identity-provider administrator, who can both enroll a new MFA device and add herself to the export group. Layers 1 and 3 now fail *together*: the effective path is $0.05 \times 0.2 \times 0.5 = 0.005$, about 1 in 200, a 3.3× increase, and in practice worse, because an IdP administrator can often also change device trust.

Interpretation. The product rule rewards independence. Layers that share an administrator, a credential or a code base multiply as if they were one. **Engineering implication:** for every pair of layers, ask "what single compromise defeats both?" and separate those duties (different admins, separate accounts, separate signing keys). The numbers are illustrative; what matters is comparing designs, not the absolute probability.

50.3.2 A reference architecture with controls mapped

A useful way to review a design is to draw it once and then place controls at each boundary, from the internet edge to the data and its keys. Figure 50.1 does this for QuickBite.

Figure 50.1 — Defense-in-depth reference architecture for QuickBite.



Reading the diagram. Customers enter through the edge tier (CDN, web application firewall and DDoS scrubbing, §10.11) and then the API gateway, which authenticates tokens and rate-limits (Chapter 22). Employees never use a VPN: they reach internal tools through an identity-aware access proxy that checks user, device certificate and posture (§50.4). Inside production, every service-to-service call is mTLS with a workload identity, and every sensitive action is authorized by a policy engine (§50.5.4). Data stores encrypt sensitive fields with data keys that only the KMS can unwrap (§10.9). Solid arrows are synchronous calls; dotted arrows are asynchronous audit and key-usage events flowing to a SIEM and write-once log store in a *separate* security account, so a production administrator cannot erase evidence. Failure points: the gateway, proxy, policy engine and KMS become critical dependencies (cache decisions and data keys briefly; fail closed for writes). Scaling: control tiers are stateless and scale horizontally; KMS quotas are managed with data-key caching.

Table 50.1 — Layers, controls and the threats they address.

Layer	Control	Main threat stopped	Section
Edge	CDN, WAF, DDoS scrubbing	Floods, common injection	§10.11, Ch 21
Human identity	Phishing-resistant MFA, SSO	Stolen passwords	§50.5
Device	Device certificates, posture checks	Attacker-owned machines	§50.4.1
Workload identity	SPIFFE IDs, mTLS	Spoofed internal callers	§50.4.3
Authorization	Policy engine, ReBAC, deny by default	Excess privilege, IDOR	§50.5.4, §8.12
Network	Segmentation, egress proxy	Lateral movement, exfiltration	§10.10.3
Data	Field encryption, tokenization	Database theft, backup leaks	§10.9, §50.10
Supply chain	Signed builds, provenance, admission	Malicious artifacts	§50.6
Detection	SIEM, detections as code, honeytokens	What the other layers missed	§50.7

50.3.3 Assume breach and blast radius

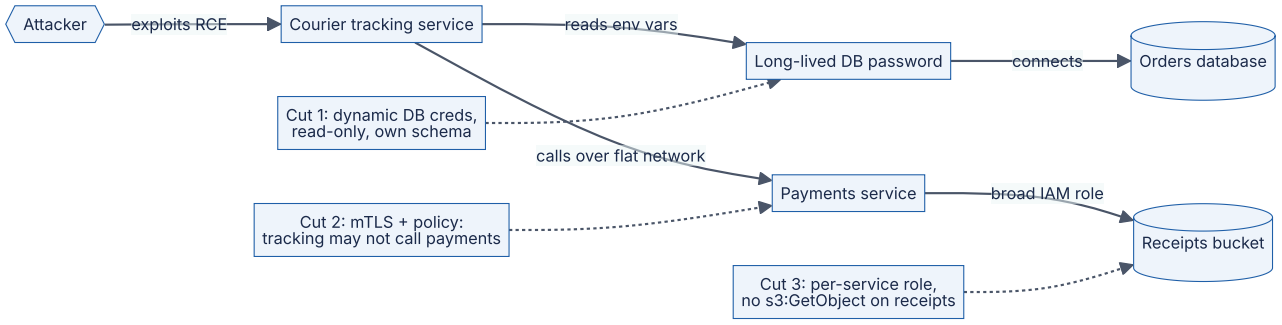
DEFINITION

Definition — Assume breach. A design stance that treats the compromise of any single component, credential or person as a given and asks how far the attacker gets next. **Blast radius** is the set of assets an attacker can reach from one compromised principal; architecture reduces it by limiting what each principal may do and where it may connect.

The question shifts from “how do we keep attackers out?” to “if the courier-tracking service is owned tonight, what can its credentials read, which other services will accept its calls, and how soon will we know?” Three tools reduce the answer:

1. **Least privilege per principal.** One identity and one role per service; permissions scoped to specific resources, not wildcards; no standing human administrator access (time-boxed, approved elevation instead) [Adkins et al. 2020].
2. **Partitioning.** Separate cloud accounts per environment and per sensitive domain (payments, identity, logging), cells per region (§44.10) and per-tenant keys (§47.5.4), so that one compromised account sees one partition.
3. **Credential lifetime.** A credential that lives one hour is worth far less to an attacker than one that lives a year (§50.5.3).

Figure 50.2 — Attack path from a compromised service, with the controls that cut it.



Reading the diagram. An attacker gains code execution in the courier-tracking service. Without further controls, its long-lived database password opens the orders database, and the flat network lets it call payments, whose broad role reads every receipt. The dotted "cut" nodes remove each edge: short-lived database credentials scoped to the tracking schema (§10.8); a workload-identity policy denying tracking-to-payments calls (§50.4.3); and per-service IAM roles (§41.12). After the cuts, the blast radius is the tracking service's own data. Failure point: cuts are configuration and drift, so test them continuously with a job that attempts forbidden calls and expects denial.

RECOMMENDATION

Recommendation — Measure blast radius. For each service, compute from IAM policies and network and mesh policies the set of data stores and services it can reach, and track the totals as metrics. A reachability graph that shrinks quarter over quarter is a more honest security metric than a count of controls deployed.

Failure scenarios

What goes wrong	Why	Detection	Recovery	Prevention
Two layers fall to one credential	Shared administrator or signing key	Access-graph analysis	Rotate, split duties	Separate accounts and admins per layer
A layer silently disabled	Debug change left in production	Config drift alerts; control health checks	Re-enable; investigate window	Policy as code with review
Control becomes an outage	Policy engine or KMS unavailable	SLO alerts	Cached decisions, failover	Treat controls as tier-0 services
Defense only at the edge	Internal calls trusted by default	Internal pen test	Add mTLS and authz	Zero trust (§50.4)

> COMMON MISTAKE
>
> **“We have five security products, so we have defense in depth.”** Depth comes from independent failure, not from the number of products. Five tools administered from one SSO group with one shared break-glass password are one layer.

50.4 Zero trust architecture in depth

Section 10.10 introduced zero trust: network location confers no trust, and every request is authenticated and authorized from the identity of user, device and workload. Here we look at how it is actually built, first in Google’s published BeyondCorp design, then in the vendor-neutral vocabulary of NIST SP 800-207, then for service-to-service traffic.

50.4.1 BeyondCorp as published

First-principles explanation

Think of an office where the front door no longer matters: every room has a receptionist who checks your badge, whether your laptop is a company laptop in good repair, and whether you may enter *this* room *now*. How you got into the building is irrelevant.

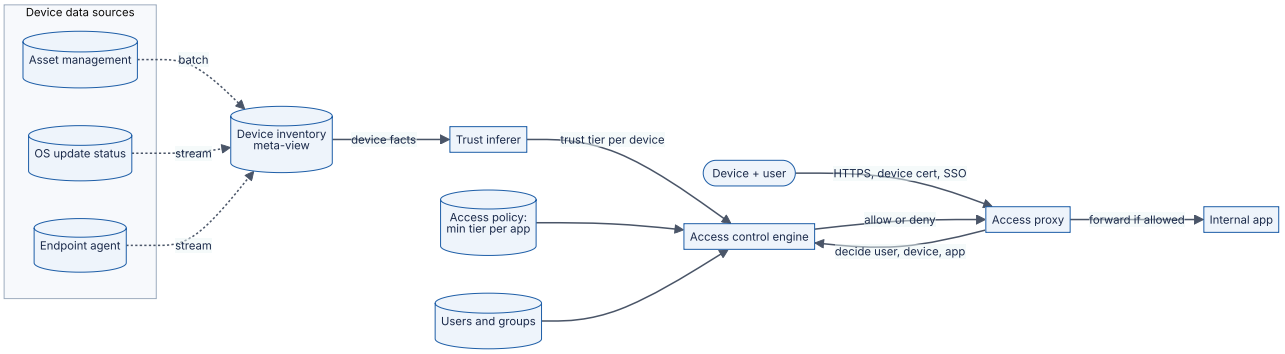
How it works internally

Ward and Beyer described the design in four parts [Ward & Beyer 2014]; Osborn et al. and Cittadini et al. later described the deployment and the access proxy [Osborn et al. 2016; Cittadini et al. 2016]:

1. **Securely identify the device.** A **device inventory** records every managed device. Each device carries a certificate that identifies it (stored in a hardware or OS certificate store); the certificate proves *which* inventory record the device is, and the inventory says what is known about it.
2. **Securely identify the user.** A user and group database feeds a single sign-on system that issues short-lived credentials after strong authentication.
3. **Remove trust from the network.** Office networks become **unprivileged networks**, treated like the internet; being plugged in at headquarters grants nothing.
4. **Externalize applications.** Internal applications are reachable only through an internet-facing **access proxy**, which terminates TLS, authenticates user and device, and asks the **access control engine** for a per-request decision.
5. **Infer trust.** A pipeline aggregates device data from many sources (asset management, OS update status, endpoint agents) into a single view; a **trust inferer** assigns each device a **trust tier**; access policies require a minimum tier per application (for

example, the code-review tool requires a fully patched, managed device; the cafeteria menu requires much less) [Osborn et al. 2016].

Figure 50.3 — BeyondCorp trust inference and access decision.



Reading the diagram. Device facts arrive asynchronously (dotted arrows) from several systems and are merged into one inventory view, because no single source is trustworthy or complete. When a laptop misses a critical patch its tier drops and the next request is denied, with no network change. At request time (solid arrows) the proxy authenticates device certificate and SSO session and asks the engine for a decision. Failure points: stale inventory data, and the proxy and engine as critical infrastructure. Scaling: the proxy is a stateless L7 tier; decisions are cheap lookups against precomputed tiers.

INDUSTRY EXAMPLE

Google BeyondCorp. Google moved employee access off its privileged corporate network onto per-request decisions from user identity, device inventory and inferred trust, over several years. The papers stress that most effort went into inventory data quality and gradual migration (simulating policy against logged traffic before enforcing), not the proxy. *Evidence: Primary* — [Ward & Beyer 2014]; [Osborn et al. 2016]; [Cittadini et al. 2016]

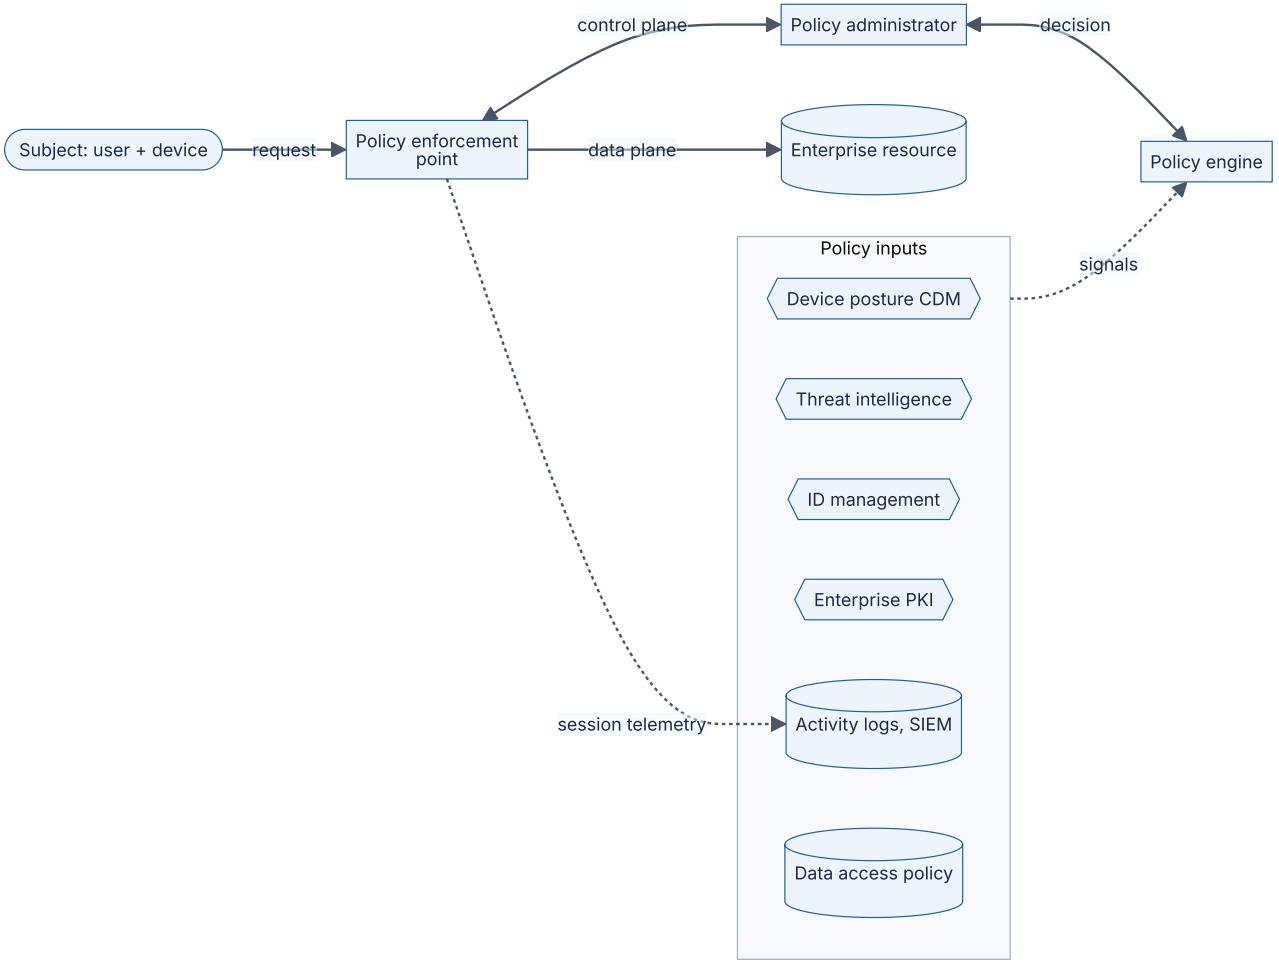
50.4.2 NIST SP 800-207 logical components

NIST SP 800-207 gives zero trust a vendor-neutral vocabulary [Rose et al. 2020]. Its tenets include: all communication is secured regardless of network location; access is granted per session by dynamic policy that includes the observable state of client and resource; authentication and authorization are strictly enforced before access; and the enterprise monitors asset posture and collects state to improve decisions.

DEFINITION

Definition — PE, PA, PDP and PEP. The **policy engine (PE)** makes the grant or deny decision using enterprise policy and external inputs. The **policy administrator (PA)** carries out that decision by establishing or tearing down the session path (for example, issuing a session token or configuring a gateway). Together the PE and PA form the **policy decision point (PDP)**. The **policy enforcement point (PEP)** sits in the data path between subject and resource and enables, monitors and terminates connections on the PA's instructions [Rose et al. 2020].

Figure 50.4 — NIST SP 800-207 logical components.



Reading the diagram. The subject's request reaches the PEP, which forwards data-plane traffic to the resource only after the control plane approves. The PEP asks the PA, which asks the PE; the PE evaluates policy using asynchronous inputs such as device posture (continuous diagnostics and mitigation, CDM), threat intelligence, identity, PKI, logs and data-access policy. Session telemetry flows back into the logs, so behavior can change the next decision. BeyondCorp maps cleanly: access proxy = PEP; access control engine = PE; the SSO and proxy configuration = PA; device inventory and trust inferer =

inputs. Failure points: the PDP is on every request path, so replicate it and cache decisions briefly; a PEP that fails open defeats the model.

The standard describes deployment variants (device agent with gateway, enclave gateway in front of legacy systems, resource portal, application sandboxing) and distinguishes **criteria-based** trust algorithms (all conditions must hold) from **score-based** ones (a confidence score must exceed a threshold).

50.4.3 Service-to-service identity with SPIFFE, SPIRE and mTLS

QuickBite's 20,000 workloads call each other millions of times per second, and each callee needs to know cryptographically which workload is calling. IP addresses fail: pods move constantly and addresses are reused.

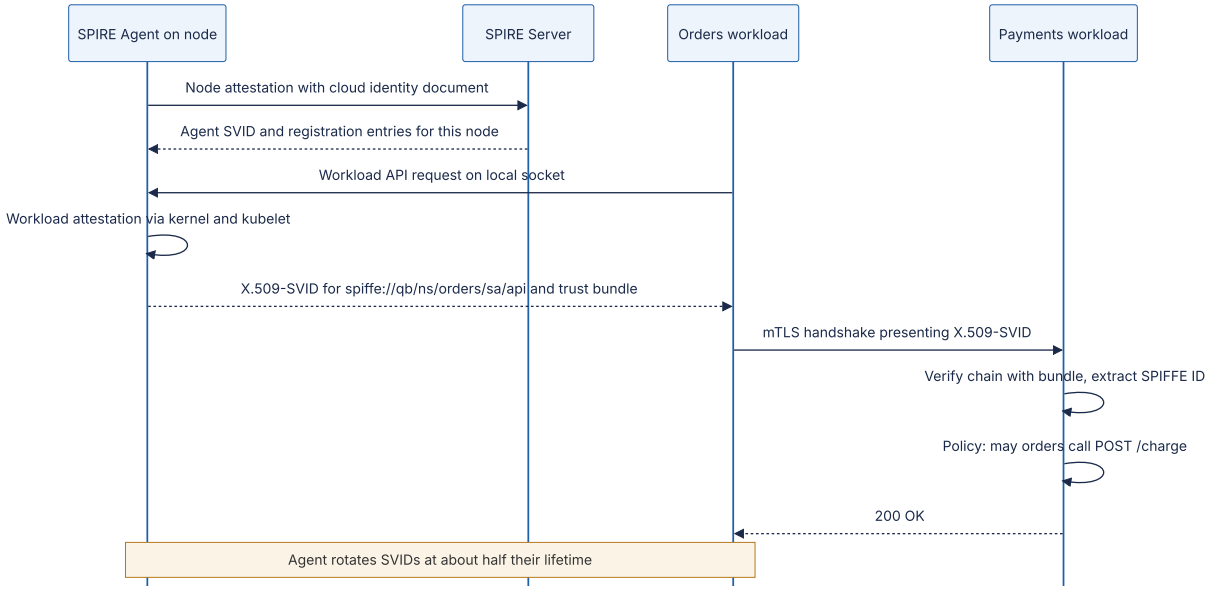
> DEFINITION
>
> **Definition — SPIFFE ID and SVID. SPIFFE** (Secure Production Identity Framework for Everyone) is an open specification for workload identity. A **SPIFFE ID** is a URI of the form `spiffe://<trust-domain>/<path>`, for example `spiffe://quickbite.example/ns/payments/sa/charge-api`. A **SPIFFE Verifiable Identity Document (SVID)** is a short-lived credential carrying that ID: an **X.509-SVID** (a certificate whose URI subject alternative name is the SPIFFE ID, used for mTLS) or a **JWT-SVID** (a signed token, used where TLS cannot be end to end). A **trust bundle** holds the CA certificates that verify a trust domain's SVIDs [SPIFFE Spec].

The design problem is "secret zero": how does a freshly started workload get its first credential without someone baking a secret into the image? SPIFFE's answer is **attestation**: a local agent identifies the workload from facts the platform vouches for (which node it runs on, which Kubernetes service account, which Unix user), and hands it an SVID over the **Workload API**, a local socket that requires no credential from the caller.

SPIRE, the reference implementation, has two parts:

1. **SPIRE Server** acts as the signing authority for a trust domain and holds **registration entries** mapping selectors (for example `k8s:ns:payments`, `k8s:sa:charge-api`) to SPIFFE IDs.
2. **SPIRE Agent** runs on every node. It first performs **node attestation**: it proves the node's identity to the server using platform evidence such as a cloud instance identity document or a Kubernetes projected service-account token. It then performs **workload attestation** for each local process that connects to the Workload API, inspecting the caller through the kernel and the kubelet, and fetches and caches SVIDs for the matching entries.

Figure 50.5 — SPIRE attestation, SVID issuance and an mTLS call.



Reading the diagram. The agent proves which node it is, receiving its own SVID and the registration entries it may serve. The orders workload calls the local Workload API; the agent attests the process and returns an X.509-SVID plus trust bundle, with no secret in the image. The workload then opens an mTLS connection to payments; payments verifies the certificate chain against the bundle, extracts the SPIFFE ID and evaluates an authorization policy keyed on that ID, not on an IP address. All calls are synchronous; rotation happens in the background. Failure points: if the SPIRE Server is down, agents serve cached SVIDs until they expire, so SVID lifetime sets the outage budget; a compromised node obtains only the SVIDs of workloads registered to it. Scaling: one agent per node, replicated servers; trust domains **federate** by exchanging bundles.

Mathematical foundations

FORMULA

Certificate issuance rate

$$R = \frac{N}{f\,T} + \frac{N_{\text{new}}}{\Delta t}$$

Symbol	Meaning	Units
R	Signing requests per second at the issuer	signatures/s
N	Workloads holding an SVID	count
T	SVID lifetime	s
f	Fraction of lifetime after which a renewal occurs	dimensionless
$N_{\text{new}}/\Delta t$	Rate of newly started workloads	workloads/s

WORKED EXAMPLE

Worked example — QuickBite's SPIRE load. $N = 20,000$ workloads; $T = 1$ h $= 3,600$ s (SPIRE's default X.509-SVID lifetime, as of 2026); renewal at half-life, $f = 0.5$; deployments start 5,000 new pods per hour (1.39/s).

1. Renewals: $20,000/(0.5 \times 3,600) = 20,000/1,800 = 11.1$ signatures/s.
2. New workloads: 1.39/s. Total $R \approx 12.5$ signatures/s.
3. An ECDSA P-256 signature costs well under a millisecond of CPU, so a single server core handles this many times over.
4. Outage budget: a workload renews at 30 min and its certificate expires at 60 min, so the issuer can be down for up to about 30 minutes before the first certificates expire.

Interpretation. Signing throughput is not the constraint; availability is. Halving T to 30 min doubles the renewal rate to 22 signatures/s (still trivial) but halves the outage budget to 15 min. **Engineering implication:** choose T from the outage you must survive and the exposure you accept for a stolen key, then run the issuer with the redundancy that outage budget implies.

INDUSTRY EXAMPLE

Google ALTS and Istio. Google's Application Layer Transport Security (ALTS) mutually authenticates production workloads by service identity rather than host or IP [Google ALTS]. Istio issues each pod a certificate whose identity is a SPIFFE ID derived from its Kubernetes service account, and writes authorization policies over those principals [Istio Docs: Security]. *Evidence: Primary* — [Google ALTS]; [Istio Docs: Security]

COMMON MISTAKE

"mTLS means every service is authorized." mTLS proves *who* is calling; it says nothing about *what* the caller may do. Without a per-route authorization policy, an mTLS mesh is a flat network with encryption: any compromised workload can still call any other.

50.5 Identity architecture

50.5.1 Workforce identity versus customer identity

Identity is now the main perimeter. The first decision is to recognize two different problems.

Table 50.2 — Workforce identity versus customer identity.

	Workforce identity (IAM)	Customer identity (CIAM)
Who	Employees, contractors, partner staff	Customers, couriers, restaurant staff
Scale	Thousands to hundreds of thousands	Millions to billions
Lifecycle	Driven by HR: joiner, mover, leaver	Self-service sign-up and deletion
Authentication	Managed devices, phishing-resistant MFA (security keys, passkeys)	Passwords or passkeys, social login, risk-based step-up
Authorization	Groups, roles, just-in-time elevation	Ownership and sharing (ReBAC), consent
Federation	Inbound from partners (SAML, OIDC); outbound to SaaS	Inbound social and enterprise login
Primary risk	Insider and phished administrator	Account takeover, credential stuffing, privacy
Regulation	Employment and audit rules	Privacy law (§50.9), consumer protection

Keep the two in separate identity systems. A customer database with 40 million rows and a public sign-up form should never be one group membership away from production administration.

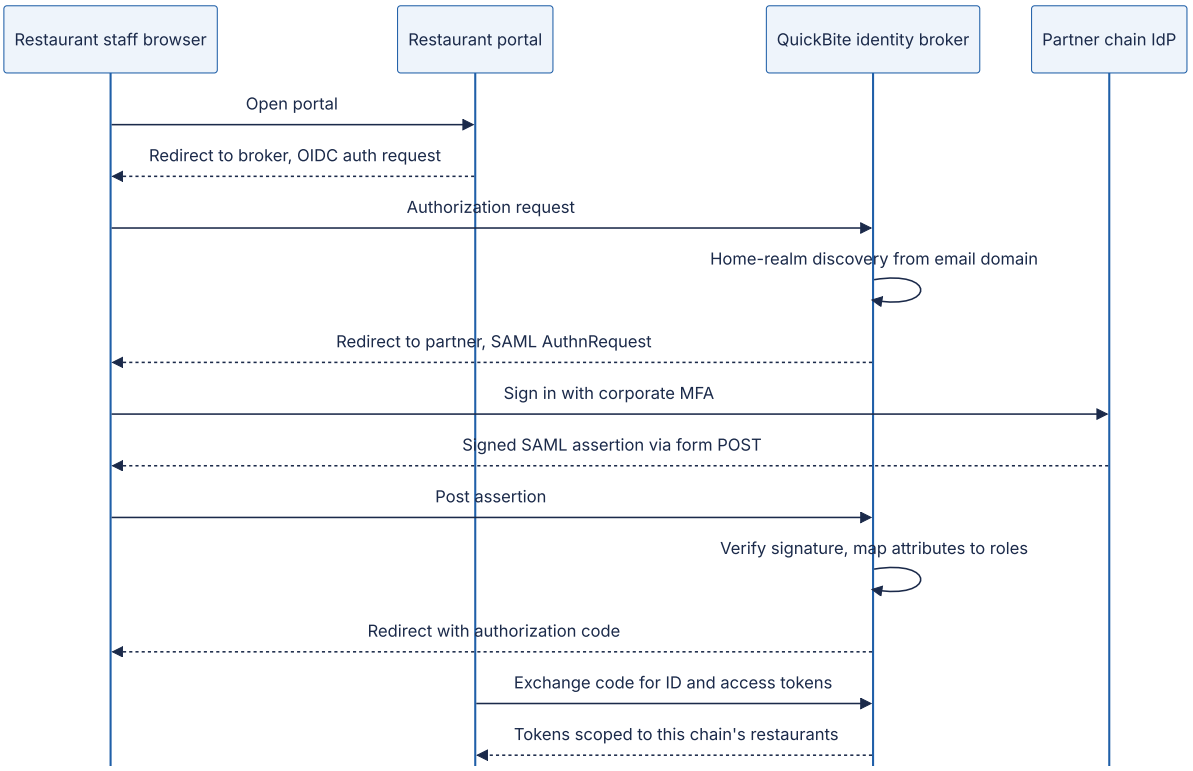
50.5.2 Federation with SAML and OpenID Connect

Federation lets one organization's identity provider (IdP) vouch for a user to another organization's service provider (SP) or relying party, so the user has one credential and the SP never sees the password. Two protocols dominate:

- **SAML 2.0** exchanges signed XML **assertions**, usually through browser redirects and form POSTs. It is the incumbent for enterprise SSO into SaaS.
- **OpenID Connect (OIDC)**, a layer on OAuth 2.0 (§8.14.6), returns a signed JWT **ID token** describing the authentication. It is simpler for mobile and API clients and is the default for new designs.

QuickBite's large restaurant chains want their staff to log in to the restaurant portal with their own corporate accounts. Rather than integrate each partner into every service, QuickBite runs an **identity broker**: partners federate into the broker (SAML or OIDC), and the broker issues QuickBite's own tokens.

Figure 50.6 — Brokered federation for partner staff.



Reading the diagram. The portal speaks only OIDC, to one broker. The broker discovers the user's home organization from the email domain, sends the browser to the partner

IdP with a SAML request, verifies the returned assertion, maps partner attributes to QuickBite roles, and completes a standard OIDC code flow (§8.14.3). All steps are synchronous redirects except the back-channel code exchange. Failure points: signature validation (XML signature wrapping attacks have broken naive SAML parsers; use a maintained library), attribute mapping that lets a partner claim other chains' restaurants, and the broker as a tier-0 dependency. Scaling: the broker is nearly stateless.

50.5.3 Sessions, token lifetimes and revocation at scale

A single user "session" is really several stacked credentials, each with its own lifetime:

1. **IdP session** (hours to days): lets the user get new tokens without re-entering credentials.
2. **Refresh token** (days to weeks): exchanged at the authorization server for new access tokens. Because it is checked against server-side state on every use, it can be revoked immediately.
3. **Access token** (minutes): verified locally by resource servers and therefore hard to revoke before it expires (§8.13.4).

Three techniques keep this safe. **Refresh token rotation** issues a new refresh token on every use; if an old one reappears, two parties hold it, so the server revokes the token family. **Sender-constrained tokens** bind a token to a client key (mTLS-bound tokens or DPoP), so a stolen token is useless alone [RFC 8705; RFC 9449]. **Push revocation** signals, such as the OpenID Continuous Access Evaluation Profile (CAEP), tell resource servers that a session was revoked instead of waiting for expiry [OpenID SSF]. The IETF's OAuth 2.0 Security Best Current Practice recommends rotation or sender-constraining for refresh tokens issued to public clients [RFC 9700].

FORMULA

Token exposure window and refresh load

$$W_{\max} = T_a, \qquad \mathbb{E}[W] = \frac{T_a}{2}, \qquad L = \frac{N_s}{T_a}$$

Symbol	Meaning	Units
T_a	Access-token lifetime	s
$W_{\max}$	Worst-case time a stolen access token stays usable after its session is revoked, with no deny-list or push signal	s
$\mathbb{E}[W]$	Expected remaining usable time if revocation is uniformly distributed over the token's life	s
N_s	Concurrently active sessions that refresh continuously	sessions
L	Refresh requests per second at the authorization server	requests/s

WORKED EXAMPLE

Worked example — Choosing QuickBite's access-token lifetime. QuickBite has $N_s = 2,000,000$ active app sessions at peak.

1. $T_a = 60$ min $= 3,600$ s: $W_{\max} = 60$ min, $\mathbb{E}[W] = 30$ min; $L = 2,000,000/3,600 = 556$ refreshes/s.
2. $T_a = 5$ min $= 300$ s: $W_{\max} = 5$ min, $\mathbb{E}[W] = 2.5$ min; $L = 2,000,000/300 = 6,667$ refreshes/s, 12× the load.
3. Middle option: $T_a = 15$ min plus a push-revocation deny-list propagated within $t_p = 10$ s: $W_{\max} \approx 10$ s for revoked sessions, $L = 2,000,000/900 = 2,222$ refreshes/s.

Interpretation. Shortening tokens buys exposure reduction linearly with authorization-server load. A revocation signal decouples the two: tokens can stay moderately long while revocation is near-immediate. **Engineering implication:** size the token service for L with headroom (refreshes are bursty after an outage, when every client refreshes at once), and use short lifetimes or push revocation for privileged sessions, where 30 minutes of exposure is unacceptable.

50.5.4 Authorization services and policy engines

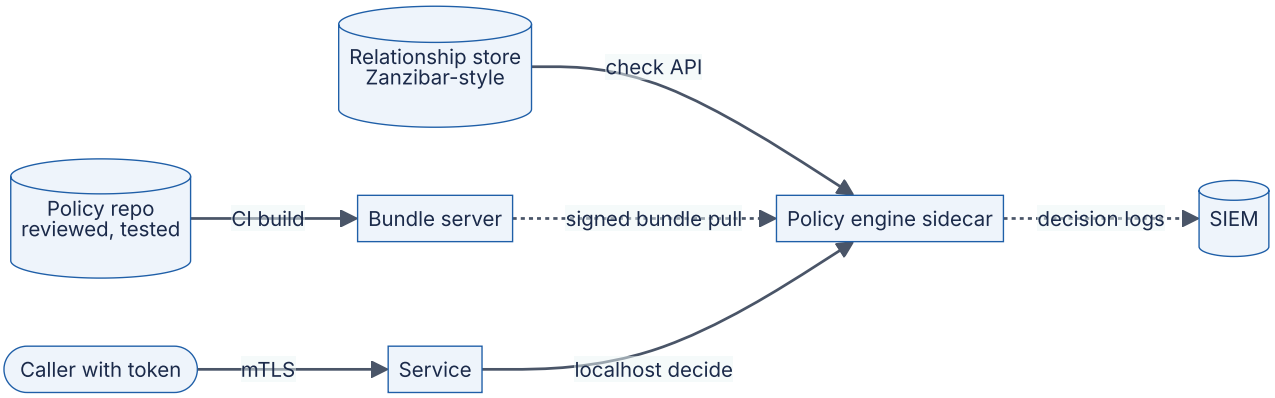
Authentication answers “who”; authorization answers “may they”. In a microservice system, authorization logic scattered through 250 code bases is impossible to audit. The architecture answer is to **externalize** it: services ask a policy decision point, and policy lives as reviewed code.

- **Open Policy Agent (OPA)**, a CNCF graduated project, evaluates policies written in Rego over JSON input; it serves API authorization, Kubernetes admission and infrastructure-as-code checks [OPA Docs].
- **Cedar**, from AWS (open-sourced 2023, used by Amazon Verified Permissions), expresses `permit` and `forbid` statements over principal, action, resource and context, and is designed for automated analysis, such as proving one policy set never permits more than another [Cedar Docs; Cutler et al. 2024].
- **Relationship-based access control (ReBAC)**, as in Google Zanzibar, decides access from a graph of relationships (“user is editor of folder, folder is parent of document”); see §8.12.2. Policy engines and ReBAC combine well: Zanzibar-style tuples answer “is this user related to this object?”, and a policy engine adds conditions such as device tier or time of day.

```
// illustrative Cedar policy for QuickBite's support console
permit (
  principal in Group::"support-tier2",
  action == Action::"viewOrder",
  resource
) when {
  context.device_trust == "high" &&
  resource.region == principal.region
};
forbid (principal, action == Action::"exportOrders", resource)
  unless { context.approved_ticket != "" };
```

What to notice: the `forbid` rule overrides any `permit`, so a bulk export always needs an approved ticket however generous the group grants become; the region condition enforces data residency (§44.9) in the authorization layer as well as in placement.

Figure 50.7 — Policy-engine deployment with central authoring and local decisions.



Reading the diagram. Policies are reviewed and tested in a repository, and CI compiles them into a signed bundle. Each service runs the engine beside it, pulling bundles asynchronously, so a decision is a sub-millisecond localhost call that survives a bundle-server outage. Relationship checks that need fresh shared data go synchronously to a relationship store. Every decision is logged asynchronously for audit and for detecting anomalous denials. Failure points: stale bundles (alert on bundle age), and the choice between failing open or closed when the engine is unreachable (fail closed for writes and sensitive reads).

50.5.5 Privilege escalation paths

Attackers rarely need administrator credentials; they need a chain of ordinary permissions that leads to them. Common chains in cloud and cluster environments:

- **Role passing.** A principal that can create a compute resource (a function or VM) *and* pass a more powerful role to it can run code as that role.
- **Policy self-editing.** Permission to create a new version of a policy attached to oneself is permission to become anything.
- **Workload creation.** In Kubernetes, permission to create pods in a namespace lets you mount any service account in that namespace, or a host path if admission control allows it.
- **Pipeline write access.** Anyone who can edit a CI workflow that deploys to production with a privileged identity has production access (§43.11).

Figure 50.8 — An escalation path through ordinary permissions.

Reading the diagram. The developer role has no direct permission on customer data (dotted edge), yet the graph has a path: edit the workflow, which runs as the CI deploy role, which may create a function and pass it the administrator role. Each edge looks harmless in isolation. Failure points: any one of these edges is enough to close the gap, which is why escalation analysis must be done on the *graph*, not on individual policies.

Prevention: protected branches and required review on workflow files, deploy roles that can pass only an allow-listed set of roles, and periodic graph analysis (attack-path tools such as BloodHound do this for Active Directory; cloud providers and open-source tools offer equivalents for IAM).

50.6 Software supply-chain security

Section 43.11.2 introduced provenance, SBOMs and signing from the pipeline's view. Here we take the attacker's: every artifact is produced by a chain of people, repositories, builders, dependencies and registries, and whoever controls a link controls what you run, with your signature on it.

50.6.1 Two published case studies

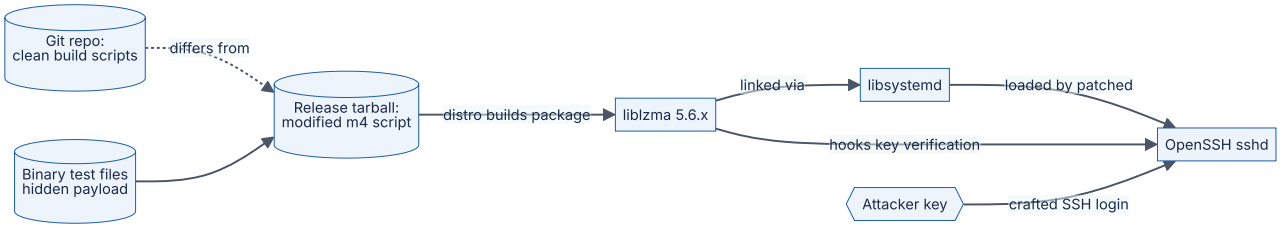
INDUSTRY EXAMPLE

SolarWinds Orion (2020). In December 2020 FireEye (now Mandiant) disclosed that trojanized updates of SolarWinds Orion network-management software carried a backdoor it named SUNBURST; CISA issued Emergency Directive 21-01 ordering US federal agencies to disconnect affected Orion versions [FireEye 2020; CISA 2020]. The malicious code was not in SolarWinds' source repository: a separate implant on the build system, which CrowdStrike named SUNSPOT, watched for Orion builds and swapped a source file during compilation, so the output was compiled and signed by SolarWinds' own legitimate process [CrowdStrike 2021]. SolarWinds reported that fewer than 18,000 customers installed affected versions [SolarWinds 2020]. Lesson: code review and code signing do not help if the build machine is compromised; the build itself must be hardened and verifiable. *Evidence: Primary* — [FireEye 2020]; [CISA 2020]; [CrowdStrike 2021]; [SolarWinds 2020]

INDUSTRY EXAMPLE

xz-utils backdoor, CVE-2024-3094 (2024). On 29 March 2024 Andres Freund reported a backdoor in versions 5.6.0 and 5.6.1 of xz-utils, a compression library, after noticing that SSH logins on a test system used unusually high CPU and took about half a second longer [Freund 2024]. A contributor had spent roughly two years earning maintainer trust. The malicious build logic was present in the release tarballs but not in the visible Git source, and its payload was hidden in binary test files; on distributions that linked OpenSSH's server to liblzma through libsystemd, it hooked a function used during SSH key verification. CISA advised downgrading to an uncompromised version; the CVE was rated CVSS 10.0, and it was caught mostly before reaching stable distribution releases [CISA 2024; NVD CVE-2024-3094]. *Evidence: Primary* — [Freund 2024]; [CISA 2024]; [NVD CVE-2024-3094]

Figure 50.9 — How the xz-utils backdoor reached sshd.



Reading the diagram. Distributions built from the release tarball, not the Git tree; the tarball's modified build script extracted a payload from test files and linked it into liblzma. Distribution patches linking sshd to libsystemd pulled liblzma into the SSH server, where the payload intercepted key verification so a holder of the attacker's key could execute commands. Failure points exploited: unreviewed differences between source and release artifacts, binary blobs in the repository, and a single overloaded maintainer. Controls that would have helped: building from the source repository rather than maintainer-made tarballs, reproducible builds that compare the two, and minimizing what a privileged daemon loads.

50.6.2 SLSA levels, provenance and SBOMs

SLSA v1.0 organizes build integrity into a **Build track** [SLSA 2023]:

Table 50.3 — SLSA v1.0 Build levels.

Level	Requirement	Threat addressed	Effort
Build L0	None	—	—
Build L1	Provenance exists, describing how the artifact was built	Mistakes; unknown build origin	Low: generate provenance
Build L2	Hosted build platform generates and signs provenance	Tampering after the build	Medium: move to hosted CI
Build L3	Hardened platform: builds isolated from each other; signing material inaccessible to user-defined build steps	Compromise of one build affecting others; forged provenance	High: hardened builders

Provenance is commonly expressed as an **in-toto attestation**: a signed statement binding an artifact digest to the builder identity, source repository and commit, and build parameters. An **SBOM** (software bill of materials, in SPDX or CycloneDX format) lists the artifact's components and versions. Provenance answers "who built this from what"; an SBOM answers "what is inside". US Executive Order 14028 (2021) pushed SBOMs into federal procurement, and NTIA published minimum elements for them [NTIA 2021].

Mathematical foundations

FORMULA

Probability that at least one dependency is compromised

$$P_{\text{any}} = 1 - (1 - p)^{n}$$

Symbol	Meaning	Units
P_{any}	Probability that at least one dependency in the tree is malicious during a period	probability
p	Probability that a single dependency is compromised during that period	probability
n	Number of distinct direct and transitive dependencies	count

WORKED EXAMPLE

Worked example — QuickBite's dependency tree. A typical QuickBite service image contains $n = 1,500$ transitive packages. Assume (illustratively) $p = 10^{-4}$ per package per year.

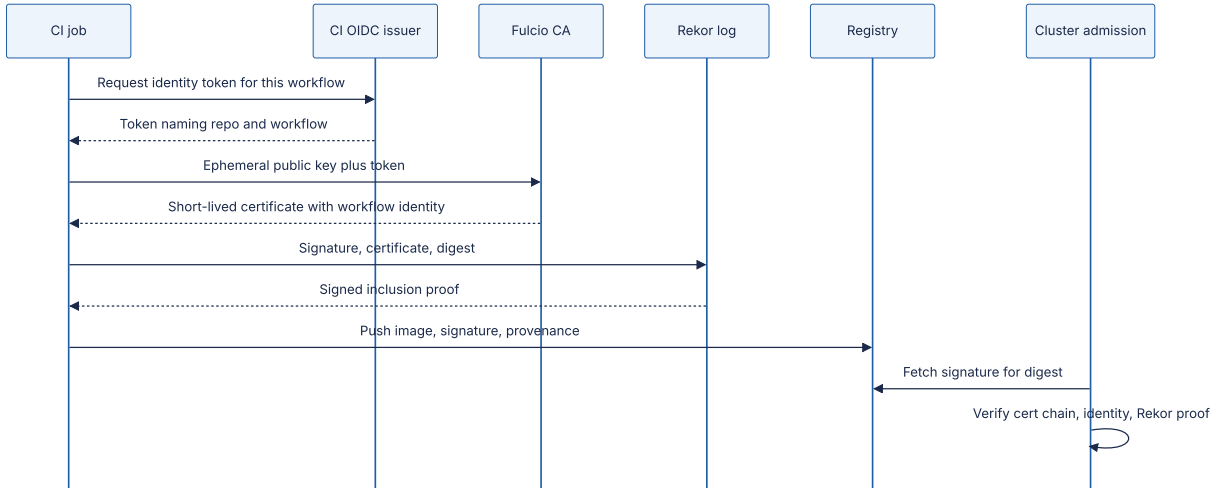
1. $(1 - 10^{-4})^{1500} = e^{1500 \ln(0.9999)} \approx e^{-0.150} = 0.861$.
2. $P_{\text{any}} = 1 - 0.861 = 0.139$: about a 14% chance per year per service.
3. Halving the tree to 750 packages: $1 - e^{-0.075} = 0.072$.

Interpretation. Risk grows almost linearly with dependency count while $np \ll 1$. **Engineering implication:** dependency count is a security metric; prune unused packages, prefer well-maintained libraries with several maintainers, and pin by hash so that a compromised *new* version is not pulled automatically.

50.6.3 Signing and verification with Sigstore

Traditional code signing fails in practice because long-lived private keys are lost, shared or stolen. **Sigstore** replaces them with identity-based, keyless signing: the signer authenticates with OIDC, the **Fulcio** certificate authority issues a certificate valid for about ten minutes that binds an ephemeral key to that identity, and the signature is recorded in **Rekor**, a public append-only transparency log, so verification can later prove the signature was made while the certificate was valid [Sigstore Docs].

Figure 50.10 — Keyless signing in CI and verification at admission.



Reading the diagram. The CI job proves *which repository and workflow* it is with the CI platform's OIDC token; Fulcio embeds that identity in a short-lived certificate, and the private key lives only in memory. Rekor's inclusion proof lets anyone check the signing event later. At deploy time admission verifies not just "is this signed?" but "signed by `repo:quickbite/payments, workflow: release` from our CI issuer?" Failure points: accepting

any valid Sigstore signature (anyone can get one for their own identity), and audit-only admission. Verification is cached per digest.

50.6.4 Dependency confusion and reproducible builds

Dependency confusion exploits package managers that consult both a private and a public registry. If an internal package name such as `quickbite-geo` leaks (in a manifest or error message) and an attacker publishes `quickbite-geo` version 99.0 on the public registry, a resolver that prefers the highest version installs the attacker's package. Birsan demonstrated this in 2021 against dozens of large companies [Birsan 2021]. Defenses: scoped or namespaced package names that you own on the public registry, a single internal proxy registry that resolves internal names only internally, and lockfiles with hashes.

Reproducible builds make a build deterministic, so independent parties building the same source get bit-for-bit identical output [Reproducible Builds]. That turns "trust the builder" into "check the builder": a second, independent builder (or a downstream distribution) rebuilds and compares digests. Reproducibility would have flagged both SolarWinds (output differs from a clean rebuild of the source) and xz (tarball differs from the Git tree). It is the practical answer to Thompson's warning that you cannot trust code you did not totally create yourself, compilers included [Thompson 1984].

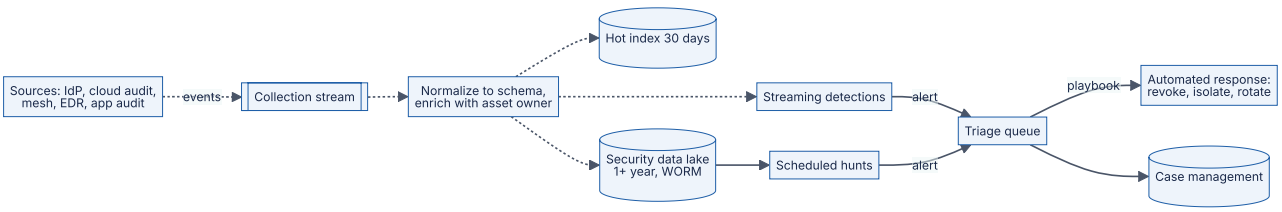
50.7 Detection and response architecture

Prevention fails eventually; detection decides whether a failure costs an afternoon or a year. SolarWinds victims were compromised for months before discovery.

50.7.1 Centralized logging and the SIEM

A **security information and event management (SIEM)** system collects security-relevant events from every layer, normalizes them to a common schema, stores them for search and runs detections over them.

Figure 50.11 — Detection and response pipeline.



Reading the diagram. Sources include identity-provider sign-ins, cloud audit logs (§10.12), service-mesh connection logs, endpoint detection and response (EDR) agents and application audit events. They flow asynchronously through a durable stream, are

normalized (for example to the Open Cybersecurity Schema Framework, OCSF) and enriched with asset owner and data classification. A hot index supports investigation; a write-once data lake keeps a year or more for retrospective hunts, because intrusions are often found long after they start. Streaming detections fire within seconds, scheduled hunts cover longer windows, and triage triggers playbooks. Failure points: dropped sources (monitor ingestion volume per source; a silent source is an incident), and cost, which grows with volume (§40.4.4).

50.7.2 Detection engineering and base rates

Detection engineering treats detections as code: each rule is version-controlled, mapped to an attacker technique (commonly using the MITRE ATT&CK knowledge base), tested against recorded or simulated attack data, and measured for precision. Precision matters because attacks are rare.

FORMULA

Alert precision from base rate

$$\text{Precision} = \frac{\text{TPR} \cdot \pi}{\text{TPR} \cdot \pi + \text{FPR} \cdot (1 - \pi)}$$

Symbol	Meaning	Units
π	Fraction of evaluated events that are malicious (base rate)	probability
TPR	True-positive rate: fraction of malicious events that alert	probability
FPR	False-positive rate: fraction of benign events that alert	probability

WORKED EXAMPLE

Worked example — A "good" rule that drowns analysts. QuickBite evaluates 10^9 sign-in and API events per day, of which 100 are malicious ($\pi = 10^{-7}$). A rule has TPR $= 0.99$ and FPR $= 10^{-5}$.

1. True positives: $0.99 \times 100 = 99$ per day.
2. False positives: $10^{-5} \times 10^9 = 10,000$ per day.
3. Precision $= 99/(99 + 10,000) = 0.0098$: under 1% of alerts are real.

Interpretation. A 99.999%-specific rule still produces 100 false alarms per true one. **Engineering implication:** run broad rules as low-severity *signals*, then alert on correlations (an impossible-travel sign-in *and* a new MFA device *and* a bulk export by the same identity), and prefer detectors with near-zero false-positive rates, such as honeytokens.

50.7.3 Honeytokens

A **honeytoken** is a credential, record or file that no legitimate process ever uses, so any use is an alarm. Examples: a fake cloud access key in a developer configuration file, a fake "admin" row in the customer table, a document named `passwords.xlsx` on a file share, a never-routed DNS name embedded in an internal wiki. Products such as Thinkst Canarytokens generate them and alert on use [Thinkst Canary]. Their FPR is close to zero, which makes them the antidote to the base-rate problem; the cost is placement discipline (they must be where attackers look and nowhere legitimate automation touches).

50.7.4 Incident response playbooks and time to detect

NIST SP 800-61 Rev. 3 (2025) organizes incident response around the NIST Cybersecurity Framework 2.0 functions, with preparation and lessons learned feeding detection, response and recovery [NIST SP 800-61r3]. A **playbook** is a pre-agreed, partly automated procedure for one incident type. QuickBite's leaked-credential playbook: identify the principal; revoke its sessions and keys (§50.5.3); query the data lake for everything it did since the credential was created; rotate secrets it could read; notify the data owner if personal data was accessed (§50.9). Incident roles are covered in §39.12.

FORMULA

Dwell time and exposure

$$\text{MTTD} = \frac{1}{m}\sum_{j=1}^{m}\left(t_j^{\text{detect}} - t_j^{\text{start}}\right), \qquad \text{MTTR} = \frac{1}{m}\sum_{j=1}^{m}\left(t_j^{\text{contain}} - t_j^{\text{detect}}\right), \qquad E = r\,(\text{MTTD} + \text{MTTR})$$

Symbol	Meaning	Units
m	Number of incidents in the sample	count
$t^{\text{start}}, t^{\text{detect}}, t^{\text{contain}}$	Time of compromise, of detection, of containment	timestamp
MTTD	Mean time to detect	h
MTTR	Mean time to respond (here: detection to containment)	h
r	Rate at which an active attacker can access records	records/h
E	Expected records exposed per incident	records

WORKED EXAMPLE

Worked example — Where to invest. QuickBite's last four credential incidents had start-to-detect times of 30, 6, 72 and 12 h, and detect-to-contain times of 2, 1, 5 and 4 h. Assume an attacker with a stolen support credential can read $r = 2,000$ customer records per hour (throttled by rate limits).

1. MTTD $= (30 + 6 + 72 + 12)/4 = 120/4 = 30$ h. MTTR $= (2 + 1 + 5 + 4)/4 = 12/4 = 3$ h.
2. $E = 2,000 \times (30 + 3) = 66,000$ records per incident.
3. Halving MTTR to 1.5 h: $E = 2,000 \times 31.5 = 63,000$ (-4.5%). Halving MTTD to 15 h: $E = 2,000 \times 18 = 36,000$ (-45%).
4. Lowering r to 200 records/h with a per-identity export limit: $E = 200 \times 33 = 6,600$ (-90%).

Interpretation. Detection time dominates, and the one 72-hour incident dominates the mean, so look at the distribution, not just the average. Industry reports put the median *dwell time* in the days to weeks: Mandiant reported a global median of 11 days for incidents it investigated in 2024 [Mandiant 2025]. **Engineering implication:** rate limits on data access (a blast-radius control) and faster detection both beat faster cleanup; measure all three.

50.8 Privacy by design

50.8.1 Cavoukian's seven principles

Ann Cavoukian, then Information and Privacy Commissioner of Ontario, set out seven foundational principles of **privacy by design** [Cavoukian 2009]. GDPR later made "data protection by design and by default" a legal obligation (Article 25) [EU 2016]. Table 50.4 translates each principle into an engineering practice.

Table 50.4 — Privacy-by-design principles as engineering practices.

Principle	What it means	Engineering practice
1. Proactive not reactive; preventative not remedial	Anticipate privacy harms before launch	Privacy review in the design doc, alongside the threat model
2. Privacy as the default setting	The user does nothing to be protected	Opt-in sharing; minimal default retention; coarse location by default
3. Privacy embedded into design	Part of the architecture, not a bolt-on	Classification tags in schemas; purpose checks in the data-access layer
4. Full functionality: positive-sum, not zero-sum	Privacy and features together	Aggregates and differential privacy for analytics (§50.11)
5. End-to-end security: full lifecycle protection	From collection to destruction	Encryption, retention TTLs, verified deletion (§50.9.3)
6. Visibility and transparency	Practices can be verified	Data inventory, processing records, user-facing data download
7. Respect for user privacy: keep it user-centric	Users control their data	Consent management, granular settings, easy deletion

50.8.2 Data inventory and classification

You cannot protect or delete data you cannot find. A **data inventory** records, for every dataset, its owner, personal-data categories, locations and replicas, retention and purposes. Generate it from the systems: schema annotations checked in CI (a column must declare its classification before a migration merges), scanners that sample stores for emails and card numbers, and lineage (Chapter 61) showing which derived tables inherit personal data.

Table 50.5 — A classification scheme for QuickBite.

Class	Examples	Default controls
Public	Restaurant menus, prices	Integrity only
Internal	Service metrics, aggregate order counts	Access by employees
Confidential personal	Names, emails, delivery addresses, order history	Field encryption, purpose checks, retention 3 years after last order
Restricted	Payment tokens, precise courier location history, health-related dietary notes, government IDs	Tokenization, separate account, short retention, access approval and logging

50.8.3 Purpose limitation

GDPR requires personal data to be collected for specified, explicit and legitimate purposes and not processed further in an incompatible way (Article 5(1)(b)) [EU 2016]. Engineering it means making **purpose** a first-class field: every dataset carries the purposes it was collected for; every access request (a service call, an analytics job, a training pipeline) declares its purpose; and the data-access layer or policy engine (§50.5.4) allows the read only when the two match. For example, courier location collected for “delivery tracking” may be read by the dispatch service, but a marketing job declaring “advertising” is denied, and an analytics job declaring “service improvement” gets only aggregates. The declared purpose is logged with every access, which turns an audit question (“who used location data for what?”) into a query.

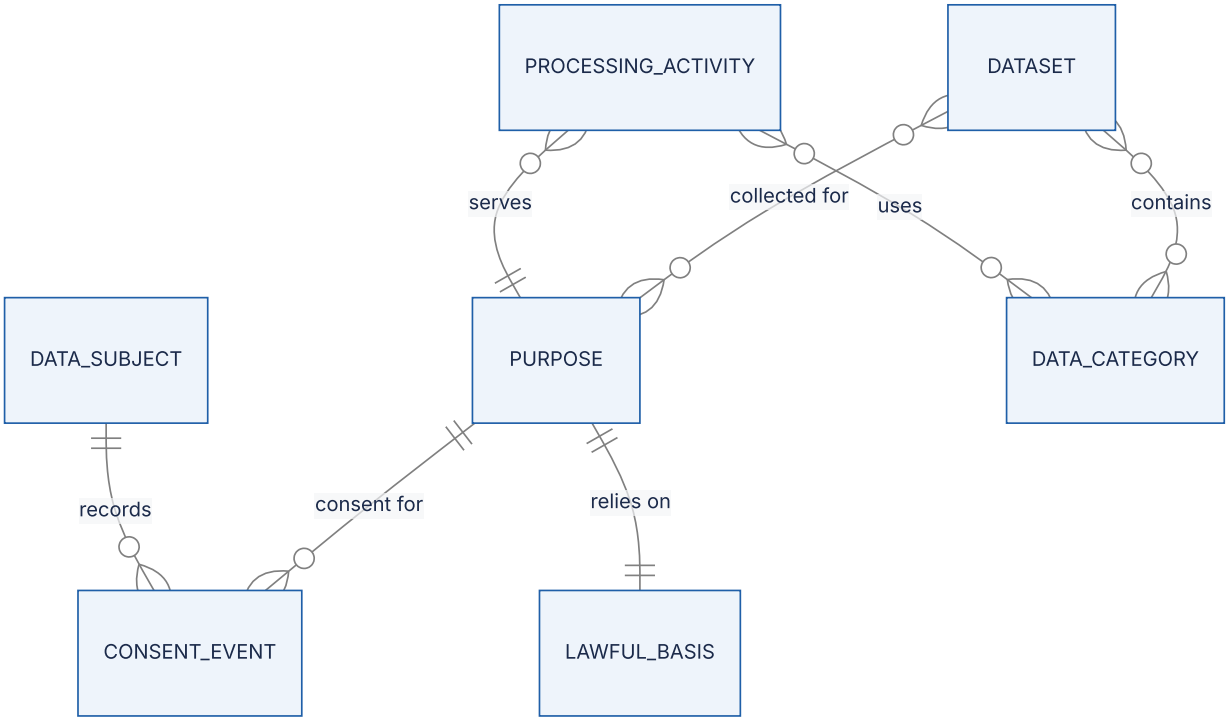
50.9 GDPR and CCPA engineering

> NOTE
>
> **Note — Architecture, not legal advice.** This section describes how engineers build systems that can meet obligations under the EU General Data Protection Regulation (GDPR, Regulation (EU) 2016/679) and the California Consumer Privacy Act as amended (CCPA). What a specific product must do depends on jurisdiction, facts and counsel’s interpretation, and the rules change.

50.9.1 Lawful basis tracked as data

GDPR Article 6 permits processing only on one of six lawful bases: consent, performance of a contract, legal obligation, vital interests, public task, and legitimate interests [EU 2016]. Article 30 requires a record of processing activities. Engineers implement both as data rather than as documents, so that systems can check them.

Figure 50.12 — Data model for purposes, lawful bases and consent.



Reading the diagram. Each **purpose** (such as “delivery”, “fraud prevention”, “marketing email”) is tied to exactly one lawful basis: delivery relies on contract, fraud prevention on legitimate interests, marketing on consent. **Processing activities** (services and jobs) declare the purposes they serve and the data categories they use, which is the machine-readable Article 30 record. **Consent events** are append-only: each grant or withdrawal is a new row with timestamp, version of the consent text shown, and source, so the current state is the latest event per subject and purpose, and history is provable. Datasets carry their collection purposes, which is what the purpose check in §50.8.3 compares against.

50.9.2 Consent management

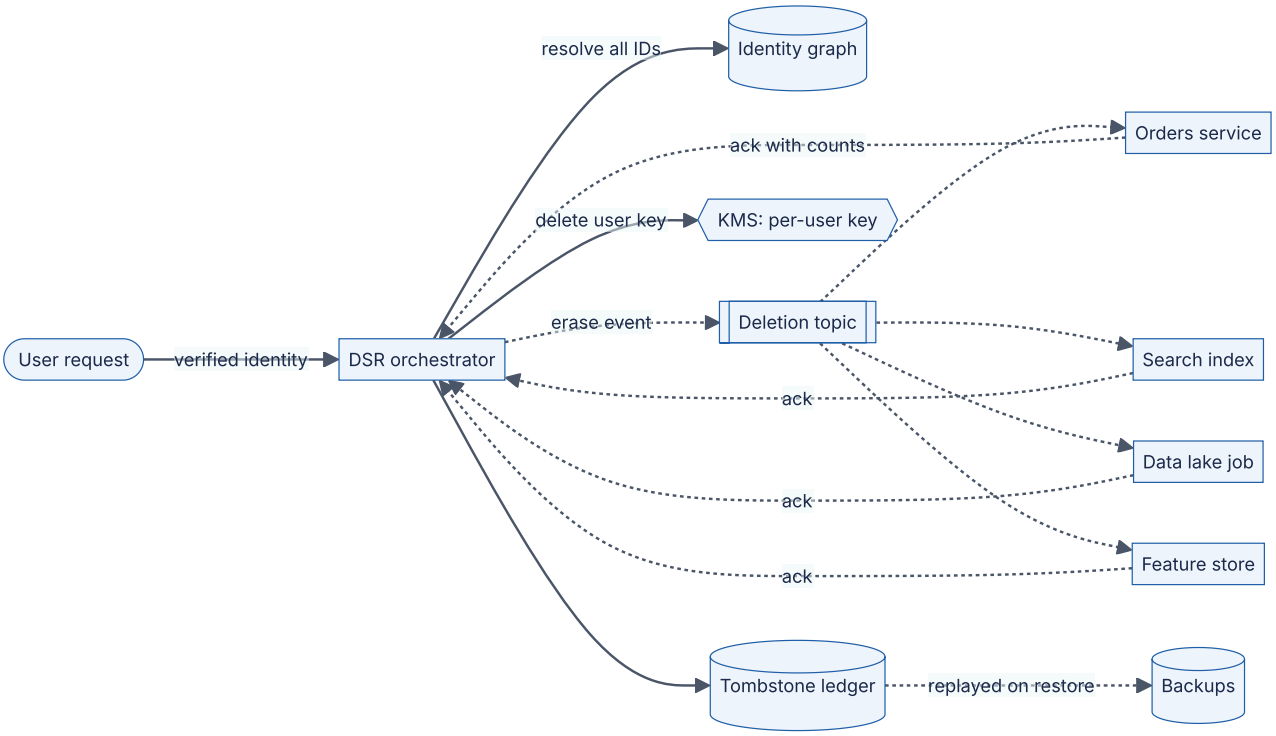
Consent must be freely given, specific, informed and unambiguous, and as easy to withdraw as to give (GDPR Articles 4(11) and 7) [EU 2016]. A **consent service** owns the ledger, serves low-latency reads (“may I email user 42?”) from a replicated cache, and publishes every change as an event so downstream systems stop processing within a bounded time. The CCPA centers instead on notice and the right to opt out of sale or sharing; California’s regulations require honoring opt-out preference signals such as Global Privacy Control [CPPA Regulations]. One service can represent both regimes: “purpose × subject → allowed, as of time t, because of event e”.

50.9.3 Data-subject requests and the deletion pipeline

Data subjects have rights of access (Article 15), erasure (Article 17) and portability (Article 20), among others; controllers must respond without undue delay and in any

event within one month, extendable by two further months for complex requests (Article 12(3)) [EU 2016]. The CCPA gives consumers rights to know, delete and correct, with a 45-day response period extendable once by another 45 days [CCPA]. With 250 services, the hard problem is reach: personal data is in primary databases, caches, search indexes, Kafka topics, the data lake, ML feature stores, logs and backups.

Figure 50.13 — Deletion pipeline across services and backups.



Reading the diagram. The orchestrator verifies the requester's identity (a deletion request is also an attack vector), resolves every identifier for the user (account ID, emails, device IDs, payment tokens) and publishes an erase event to a durable topic. Every system holding personal data, as listed in the data inventory, subscribes, deletes or anonymizes, and acknowledges asynchronously with counts; the orchestrator tracks completion and escalates on missing acks. Two mechanisms handle backups, which are immutable by design: **crypto-shredding**, where personal fields are encrypted under a per-user key and deleting the key makes every backup copy unreadable (§10.9, §47.5.4); and a **tombstone ledger** of deleted IDs that is replayed after any restore, so restored data is re-deleted before it serves traffic. Failure points: a new service that never subscribes (require a deletion handler for any dataset tagged personal), and legal holds, which must be explicit exemptions.

FORMULA

Deletion completion time

$$T_{\text{done}} = \max\left(\max_i t_i,\ T_{\text{backup}}\right)$$

Symbol	Meaning	Units
t_i	Time for online system i to delete and acknowledge	days
T_{backup}	Time until no readable backup contains the data: backup retention, or key-deletion delay with crypto-shredding	days
T_{done}	Time until the data is gone everywhere	days

WORKED EXAMPLE

Worked example — Meeting a one-month deadline. QuickBite's online systems finish within $t_i \le 2$ days (the data-lake compaction job runs weekly, so it takes up to 7 days; $\max_i t_i = 7$). Backups are retained 35 days.

1. Without crypto-shredding: $T_{\text{done}} = \max(7, 35) = 35$ days, beyond one month, unless the backups are excluded by the tombstone-replay argument, which counsel must accept.
2. With per-user keys and a KMS key-deletion waiting period of 7 days: $T_{\text{backup}} = 7$, so $T_{\text{done}} = \max(7, 7) = 7$ days.

Interpretation. The slowest system sets the deadline, and backups are usually the slowest. **Engineering implication:** put personal data in backups only in encrypted form under keys you can destroy, and make batch systems process deletions on a cadence shorter than the legal deadline.

INDUSTRY EXAMPLE

Meta's DELF. Cohn-Gordon et al. describe DELF, Facebook's framework for deletion correctness: developers annotate how each object type relates to others (whether deleting a user should cascade to their posts, for example), static and dynamic checks catch missing annotations, and deletions run as restartable, logged graph traversals that can be undone for a period if run in error [Cohn-Gordon et al. 2020]. *Evidence: Primary* — [Cohn-Gordon et al. 2020]

Data residency (where personal data may be stored and processed) is a placement constraint covered in §44.9; the deletion pipeline must run in each region, against that region's stores.

50.10 Data minimization and de-identification

The safest personal data is data you never collected. **Data minimization** (GDPR Article 5(1)(c)) means collecting only what a purpose needs, coarsening it (city instead of GPS fix, birth year instead of birth date), aggregating early, and deleting on a schedule with TTLs. When data must be shared or analyzed, de-identification reduces what it reveals.

50.10.1 Pseudonymization versus anonymization

> DEFINITION
>
> **Definition — Pseudonymization and anonymization. Pseudonymization** replaces direct identifiers with pseudonyms such that the data can no longer be attributed to a person *without additional information kept separately* (GDPR Article 4(5)); pseudonymized data is still personal data. **Anonymization** makes re-identification not reasonably likely by any means, taking into account the means reasonably likely to be used (GDPR Recital 26); truly anonymous data falls outside GDPR [EU 2016].

A keyed pseudonym, $\mathrm{HMAC}_K(\text{user_id})$ with K in a KMS (§10.4.6), lets analysts join datasets on a stable ID without seeing the real one; destroying or rotating K breaks linkability. An unkeyed hash of an email address is *not* adequate pseudonymization: anyone can hash a list of known emails and match them.

Tokenization replaces a sensitive value (a card number, a national ID) with a random token; the mapping lives only in a hardened **token vault**. Systems that handle only tokens fall out of the most demanding compliance scope (the PCI DSS cardholder-data environment shrinks to the vault and the payment path). Vaultless variants use format-preserving encryption (NIST SP 800-38G) so a token fits existing 16-digit columns [NIST SP 800-38G].

50.10.2 k-anonymity

Removing names is not enough. Sweeney estimated that 87% of the US population was likely uniquely identified by just 5-digit ZIP code, gender and date of birth, and demonstrated the risk by re-identifying a governor's record in "anonymized" hospital data using a voter list [Sweeney 2000; Sweeney 2002]. Attributes that are harmless alone but identifying in combination are **quasi-identifiers**.

FORMULA

k-anonymity

$$k = \min_{E \in \mathcal{E}} |E|, \qquad P_{\text{re-id}} \le \frac{1}{k}$$

Symbol	Meaning	Units
$\mathcal{E}$	Equivalence classes: groups of rows with identical quasi-identifier values	set of groups
$\lvert E\rvert$	Number of rows in class E	rows
k	Size of the smallest class; the table is k-anonymous	rows
$P_{\text{re-id}}$	Probability of picking out one person's row by linking on quasi-identifiers alone	probability

WORKED EXAMPLE

Worked example — QuickBite's dietary-preference research extract. A 10-row extract has quasi-identifiers ZIP, age and gender and a sensitive attribute, dietary note (health-related). Raw, every row is unique: $k = 1$.

1. Generalize ZIP to 3 digits (`021**` , `024**`) and age to decades (`30-39` , `50-59`), keeping gender: classes are (021, 30s, F) = 3, (021, 30s, M) = 3, (024, 50s, F) = 2, (024, 50s, M) = 2 rows. $k = \min(3, 3, 2, 2) = 2$, so $P_{\text{re-id}} \le 1/2$.
2. Also suppress gender: classes (021, 30s) = 6 and (024, 50s) = 4. $k = 4$, $P_{\text{re-id}} \le 0.25$.
3. But all four rows in (024, 50s) have the dietary note "diabetic". Anyone who knows a neighbor in ZIP 024xx in her fifties is in the extract learns her condition with certainty, despite $k = 4$.

Interpretation. k-anonymity bounds *row* identification, not *attribute* disclosure. **Engineering implication:** check diversity of the sensitive attribute within each class as well (l-diversity), and treat k-anonymity as a necessary sanity check, not a guarantee.

```
    """k-anonymity and distinct l-diversity checks on a small released table."""
    from collections import defaultdict

    ROWS = [  # (zip, age, gender, diet) -- diet is the sensitive attribute
        ("02139", 34, "F", "gluten-free"), ("02138", 36, "F", "diabetic"),
        ("02141", 31, "F", "none"),        ("02139", 38, "M", "none"),
        ("02142", 33, "M", "diabetic"),    ("02138", 35, "M", "gluten-free"),
        ("02445", 52, "F", "diabetic"),    ("02446", 57, "F", "diabetic"),
        ("02445", 55, "M", "diabetic"),    ("02446", 51, "M", "diabetic"),
    ]
    COLS = ("zip", "age", "gender", "diet")

    def generalize(row, zip_digits=3, age_band=10, keep_gender=True):
        z, age, g, diet = row
        lo = age // age_band * age_band
        return (z[:zip_digits] + "*" * (5 - zip_digits),
                f"{lo}-{lo + age_band - 1}",
                g if keep_gender else "*",
                diet)

    def classes(rows, qi=("zip", "age", "gender")):
        """Group rows into equivalence classes over the quasi-identifiers."""
        idx = [COLS.index(c) for c in qi]
        groups = defaultdict(list)
        for r in rows:
            groups[tuple(r[i] for i in idx)].append(r)
        return groups

    def k_anonymity(rows, qi=("zip", "age", "gender")) -> int:
        return min(len(g) for g in classes(rows, qi).values())

    def l_diversity(rows, qi=("zip", "age", "gender"), sensitive="diet") -> int:
        s = COLS.index(sensitive)
        return min(len({r[s] for r in g}) for g in classes(rows, qi).values())

    def report(name, rows):
        sizes = sorted(len(g) for g in classes(rows).values())
        print(f"{name:<28} classes={len(sizes):>2} sizes={sizes} "
              f"k={k_anonymity(rows)} l={l_diversity(rows)}")

    if __name__ == "__main__":
        raw = ROWS
        gen = [generalize(r) for r in ROWS]
        gen_nog = [generalize(r, keep_gender=False) for r in ROWS]
        report("raw", raw)
        report("zip3 + decade", gen)
        report("zip3 + decade, no gender", gen_nog)

        assert k_anonymity(raw) == 1                 # every raw row is unique
        assert k_anonymity(gen) == 2 and l_diversity(gen) == 1
```

```
            assert k_anonymity(gen_nog) == 4              # better k ...
            assert l_diversity(gen_nog) == 1              # ... but one class is all
"diabetic"
            homog = [g for g in classes(gen_nog).values() if len({r[3] for r in g}) ==
1]
            assert len(homog) == 1 and homog[0][0][0] == "024**"
            print("all tests passed")
```

Output (tested with Python 3.13):

```
raw                          classes=10 sizes=[1, 1, 1, 1, 1, 1, 1, 1, 1, 1] k=1 l=1
zip3 + decade                classes= 4 sizes=[2, 2, 3, 3] k=2 l=1
zip3 + decade, no gender     classes= 2 sizes=[4, 6] k=4 l=1
all tests passed
```

What to notice:

- `classes` is the whole idea: group by the quasi-identifier tuple; *k* is the smallest group.
- Generalization raises *k* (1 → 2 → 4) but `l_diversity` stays 1 because one class is homogeneous, which is the **homogeneity attack**.
- The quasi-identifier list is an *input*: if an attacker knows an attribute you did not list, the computed *k* is meaningless.

50.10.3 Failure modes: linkage and high-dimensional data

Beyond homogeneity, k-anonymity fails against **background knowledge** (an attacker who knows the target is not gluten-free narrows a class) and **linkage across releases** (two k-anonymous releases of overlapping data can be intersected). Refinements such as l-diversity and t-closeness address some attribute-disclosure risks [Machanavajjhala et al. 2007; Li et al. 2007], but the deeper problem is dimensionality. In sparse, high-dimensional data, such as purchase histories, ratings or location traces, almost every record is unique, and every attribute is a quasi-identifier.

> INDUSTRY EXAMPLE
>
> **Netflix Prize de-anonymization.** Netflix released 100 million movie ratings with subscriber names removed for a recommendation contest. Narayanan and Shmatikov showed that an adversary who knows a little about a subscriber can find their record: with 8 movie ratings (of which 2 may be completely wrong) and dates with up to a 14-day error, 99% of records could be uniquely identified; 2 ratings with dates within 3 days sufficed for 68%. Cross-referencing with public reviews on IMDb identified some subscribers and their full rating histories [Narayanan & Shmatikov 2008].
> *Evidence: Primary* — [Narayanan & Shmatikov 2008]

For QuickBite, order histories and courier location traces are exactly this kind of data. Releasing them "anonymized" by dropping names is releasing them identified. The robust alternative for statistics is differential privacy.

50.11 Differential privacy: an introduction

50.11.1 The definition

First-principles explanation

Imagine a survey that asks "have you ever ordered from the diabetic menu?" Each person secretly flips a coin: heads, they answer truthfully; tails, they flip again and answer "yes" on heads and "no" on tails. Any individual "yes" is deniable, since it may have come from the coin, yet across 10,000 people the coin's contribution is known and can be subtracted out. That is **randomized response**, and it captures the idea of differential privacy: the output should be almost the same whether or not any one person's data is included, so the output cannot reveal much about any one person.

FORMULA

ε-differential privacy

$$\Pr[M(D) \in S] \le e^{\varepsilon} \Pr[M(D') \in S]$$

for all pairs of datasets D, D' differing in one person's data, and all sets of outputs S.

Symbol	Meaning	Units
M	Randomized mechanism (the query plus its noise)	—
D, D'	Neighboring datasets differing in one individual	datasets
S	Any set of possible outputs	—
ε	Privacy-loss parameter; smaller is more private	dimensionless (nats)

WORKED EXAMPLE

Worked example — Reading ε. At $\varepsilon = 0.1$, $e^{0.1} = 1.105$: including you changes the probability of any output by at most 10.5%. At $\varepsilon = 1$, $e^{1} = 2.72$. At $\varepsilon = 10$, $e^{10} \approx 22,000$, a weak worst-case bound. **Implication:** single-digit or smaller ε gives a meaningful per-person guarantee.

The guarantee holds whatever the attacker knows and whatever other data they link with, which is exactly what k-anonymity lacks [Dwork & Roth 2014]. A relaxed form, (ε, δ)-DP, allows the bound to fail with small probability δ.

50.11.2 The Laplace mechanism

For a numeric query f, the **sensitivity** $\Delta f = \max_{D, D'} |f(D) - f(D')|$ is the most one person can change the answer. A count has $\Delta f = 1$ if each person contributes at most one row. The **Laplace mechanism** releases $f(D) + Y$ with Y drawn from a Laplace distribution centered on zero, and is ε-DP [Dwork & Roth 2014].

FORMULA

Laplace noise scale and error tail

$$b = \frac{\Delta f}{\varepsilon}, \qquad \Pr[|Y| > t] = e^{-t/b}, \qquad \mathbb{E}|Y| = b, \qquad t_{95} = b \ln 20$$

Symbol	Meaning	Units
Δf	Sensitivity of the query	query units (here: people)
ε	Privacy budget spent on this query	dimensionless
b	Scale of the Laplace distribution	query units
Y	Noise added	query units
t	Error threshold	query units
t_{95}	Error exceeded with probability 5%	query units

WORKED EXAMPLE

Worked example — A private count. QuickBite's analytics team wants the number of distinct customers in a district who ordered from the diabetic menu last month. True count: 1,240. Each customer counts once, so $\Delta f = 1$. Budget $\varepsilon = 0.5$.

1. $b = 1/0.5 = 2$.
2. Probability the error exceeds 5: $e^{-5/2} = e^{-2.5} = 0.082$.
3. 95% error bound: $t_{95} = 2 \ln 20 = 2 \times 2.996 = 5.99$, so 95% of releases fall within ±6, a relative error of $6/1,240 = 0.48\%$.
4. For a district with a true count of 12, the same ±6 is a 50% relative error.
5. At $\varepsilon = 0.1$: $b = 10$, $t_{95} = 30$, which swamps the small district completely.

Interpretation. Noise is fixed in absolute size, so DP is cheap for large aggregates and expensive for small groups. **Engineering implication:** design releases around large groups (coarser geography, longer windows), bound each person's contribution so that Δf stays small, and never release the raw value alongside the noisy one.

```
        """Laplace mechanism for a counting query, with empirical error versus ep-
silon."""
        import math
        import random

        def laplace_noise(scale: float, rng: random.Random) -> float:
            """Sample Lap(0, scale) by inverse-CDF: u ~ U(-1/2, 1/2)."""
            u = rng.random() - 0.5
            while u == -0.5:                        # avoid log(0) at the boundary
                u = rng.random() - 0.5
            return -scale * math.copysign(1.0, u) * math.log(1 - 2 * abs(u))

        def private_count(true_count: int, epsilon: float, rng: random.Random,
                          sensitivity: float = 1.0) -> float:
            """Release a count with epsilon-DP: add Laplace noise with b = sensitivity /
epsilon."""
            if epsilon <= 0:
                raise ValueError("epsilon must be positive")
            return true_count + laplace_noise(sensitivity / epsilon, rng)

        def error_profile(true_count: int, epsilon: float, trials: int = 200_000,
                          t: float = 5.0, seed: int = 7) -> dict:
            """Empirical mean |error| and P(|error| > t), next to their closed forms."""
            rng = random.Random(seed)
            errors = [abs(private_count(true_count, epsilon, rng) - true_count)
                      for _ in range(trials)]
            b = 1.0 / epsilon
            return {
                "epsilon": epsilon,
                "b": b,
                "mean_abs_err": sum(errors) / trials,          # theory: b
                "p_err_gt_t": sum(e > t for e in errors) / trials,  # theory: exp(-t/b)
                "p_theory": math.exp(-t / b),
                "err95": sorted(errors)[int(0.95 * trials)],   # theory: b * ln(20)
            }

        if __name__ == "__main__":
            print(f"{'eps':>5} {'b':>6} {'mean|err|':>10} {'P(>5) emp':>10} "
                  f"{'P(>5) th':>9} {'95% err':>8}")
            for eps in (0.1, 0.5, 1.0, 2.0):
                r = error_profile(true_count=1_240, epsilon=eps)
                print(f"{r['epsilon']:>5} {r['b']:>6.2f} {r['mean_abs_err']:>10.3f} "
                      f"{r['p_err_gt_t']:>10.4f} {r['p_theory']:>9.4f}
{r['err95']:>8.2f}")
                # Tests: empirical values agree with the closed forms.
                assert abs(r["mean_abs_err"] - r["b"]) / r["b"] < 0.02
                assert abs(r["p_err_gt_t"] - r["p_theory"]) < 0.005
                assert abs(r["err95"] - r["b"] * math.log(20)) / (r["b"] * math.log(20))
< 0.03
            print("all tests passed")
```

Output (tested with Python 3.13):

```
  eps      b  mean|err|  P(>5) emp  P(>5) th  95% err
  0.1  10.00     10.012     0.6068    0.6065    29.95
  0.5   2.00      2.002     0.0822    0.0821     5.99
  1.0   1.00      1.001     0.0069    0.0067     3.00
  2.0   0.50      0.501     0.0001    0.0000     1.50
all tests passed
```

What to notice:

- The empirical columns match the closed forms: mean absolute error equals b, the tail equals $e^{-t/b}$, and the 95th percentile equals $b \ln 20$.
- Error scales as $1/\varepsilon$: every halving of ε doubles the noise.
- This is a teaching implementation; production libraries also defend against floating-point attacks on naive sampling. Use a vetted DP library.

50.11.3 Composition and the privacy budget

FORMULA

Sequential and parallel composition

$$\varepsilon_{\text{total}} = \sum_{i=1}^{q} \varepsilon_i \quad \text{(same data)}, \qquad \varepsilon_{\text{total}} = \max_{j} \varepsilon_j \quad \text{(disjoint partitions)}$$

Symbol	Meaning	Units
q	Number of queries answered on overlapping data	count
ε_i	Budget spent by query i	dimensionless
ε_j	Budget spent on disjoint partition j	dimensionless

WORKED EXAMPLE

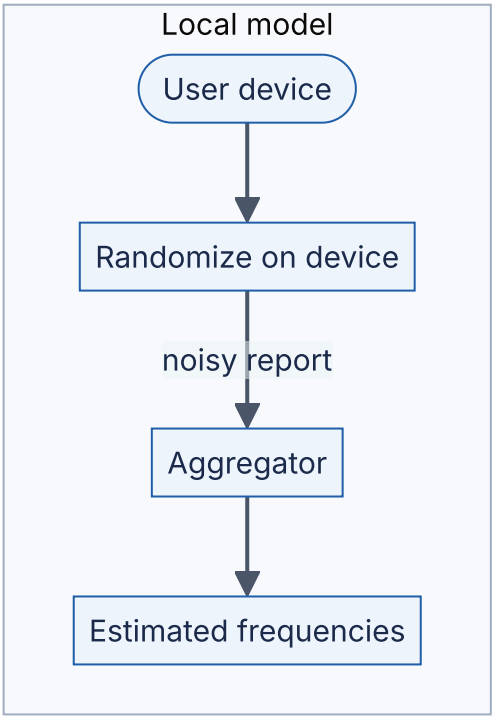
Worked example — A dashboard that leaks over time. A dashboard refreshes 4 statistics daily over the same customers, each at $\varepsilon = 0.25$.

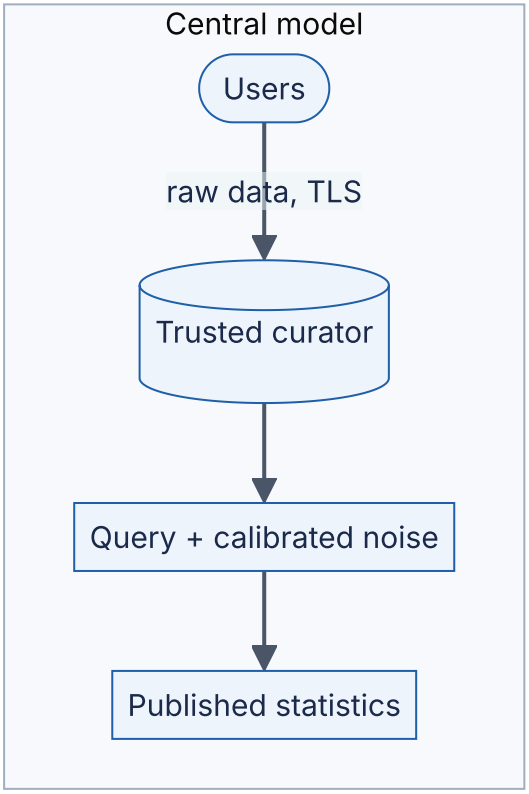
1. Per day: $4 \times 0.25 = 1.0$. Per year: $365 \times 1.0 = 365$, a meaningless guarantee (e^{365}).
2. Releasing one count per district, where each customer lives in one district, costs $\max = 0.25$ per release, not $0.25 \times$ (number of districts).
3. Instead: publish weekly, 4 statistics at $\varepsilon = 0.1$ each: $52 \times 0.4 = 20.8$ per year, and track it in a **privacy-budget ledger** per dataset.

Interpretation. Privacy loss accumulates with every answer. Tighter accounting methods (advanced composition, Rényi DP, zero-concentrated DP) grow more slowly than the simple sum, which is why deployed systems use them. **Engineering implication:** the budget is a finite resource owned by the dataset, not the query author; route all releases through a service that debits it.

50.11.4 Central and local models, and deployments

Figure 50.14 — Central versus local differential privacy.





Reading the diagram. In the central model, users trust the curator with raw data and noise is added once at release, so accuracy is high for a given ε. In the local model each device randomizes before sending, so the collector never holds raw values, at the price of far more noise: useful estimates need millions of reports. Failure points: the curator's raw store (central), and cumulative budget across repeated reports (local).

INDUSTRY EXAMPLE

Deployed differential privacy. The **US Census Bureau** protected 2020 Census results with a differentially private disclosure-avoidance system (the TopDown Algorithm), after its own reconstruction experiments on 2010 data showed traditional methods were inadequate [Abowd 2018]; for the redistricting data it set a total privacy-loss budget of ε = 19.61 (17.14 for persons, 2.47 for housing units) [US Census Bureau 2021]. **Google's RAPPOR** collected statistics from Chrome with local DP, using Bloom-filter encoding and two rounds of randomized response, a permanent one per value and a fresh one per report, to limit privacy loss across repeated reports [Erlingsson et al. 2014]. **Apple** describes local DP with per-use-case privacy budgets for features such as emoji and QuickType suggestions [Apple 2017].
Evidence: Primary — [Abowd 2018]; [US Census Bureau 2021]; [Erlingsson et al. 2014]; [Apple 2017]

Chapter 71 covers DP for machine learning (DP-SGD), accounting and practical libraries in depth.

50.12 Computing on protected data: MPC, homomorphic encryption and confidential computing

Encryption at rest and in transit (§10.9) leaves a gap: data must be decrypted to be *used*, and whoever runs the computation sees it. Three families of techniques narrow that gap.

- **Secure multi-party computation (MPC)** lets parties compute a function of their combined inputs while each learns only the output. In **additive secret sharing**, a value x is split into random shares with $x = (s_1 + s_2 + s_3) \bmod q$. Three restaurants want their average order value without revealing their own: restaurant A's 30 is split as (17, 52, −39), one share per party; each party sums the shares it holds and publishes only that sum, and the three sums add to the total. Multiplications need interaction, so cost grows with circuit depth and round trips.
- **Homomorphic encryption (HE)** allows computation on ciphertexts: the result, decrypted, equals the computation on plaintexts. Partially homomorphic schemes support one operation (Paillier supports addition); **fully homomorphic encryption**, first constructed by Gentry in 2009, supports arbitrary circuits at large slowdowns, commonly orders of magnitude over plaintext [Gentry 2009].
- **Trusted execution environments (TEEs)** use hardware to isolate code and data from the host operating system, hypervisor and cloud operator. **Intel SGX** protects *enclaves* inside a process; **AMD SEV-SNP** and **Intel TDX** protect *whole virtual machines* with memory encryption and integrity; **AWS Nitro Enclaves** carve an isolated VM out of an EC2 instance with no persistent storage, no external network and only a local vsock channel to its parent [AWS Docs: Nitro Enclaves]. All rely on

remote attestation: the hardware signs a measurement (hash) of the loaded code, and a relying party, such as a KMS key policy that releases a decryption key only to an enclave whose measurement matches an approved build, verifies it before trusting the TEE with secrets.

Table 50.6 — Comparing techniques for computing on protected data.

	MPC	Homomorphic encryption	TEE
Who is trusted	No single party (a threshold must not collude)	Key holder only	Hardware vendor and attested code
Performance	Network-bound; often 10–1,000× plaintext	Often 10^3–10^6× plaintext for FHE (as of 2026)	Near native; some overhead on memory and I/O
Functionality	Any function, best for simple ones	Limited depth or slow	Arbitrary code
Main weakness	Collusion, complexity	Cost, limited operations	Side channels, firmware bugs, vendor trust
Operational complexity	High: several organizations operate parties	Medium: libraries, parameter choice	Medium: attestation pipeline, reproducible enclave builds
Choose when	Mutually distrusting organizations	Outsourced simple analytics on encrypted data	Protecting data from the operator at near-native speed

INDUSTRY EXAMPLE

Signal private contact discovery. Signal described running contact discovery inside SGX enclaves so that the service could match a user's address book against registered users without the operator seeing the address book; clients verify the enclave by remote attestation before sending data [Signal 2017]. *Evidence: Primary* — [Signal 2017]

WARNING / TRADE-OFF

TEEs move trust; they do not remove it. Published side-channel attacks against SGX (for example Foreshadow in 2018) and periodic firmware vulnerabilities mean a TEE should be one layer of defense in depth, combined with attestation of *reproducibly built* code, patch tracking of microcode versions in the attestation policy, and minimization of what the enclave holds [Van Bulck et al. 2018].

50.13 Security architecture review checklist

Table 10.13 is the per-design checklist for fundamentals. Use Table 50.7 when reviewing an architecture as a whole, or in an interview when asked “how would you secure this?”

Table 50.7 — Security and privacy architecture review checklist.

Area	Review question	Good answer looks like	Section
Layer independence	Which single compromise defeats two layers?	Separate admins, accounts and keys per layer	§50.3.1
Blast radius	What can each service and admin reach?	Reachability graph measured and shrinking	§50.3.3
Zero trust	Where are PEP and PDP? What do they fail to?	Access proxy and mesh; replicated PDP; fail closed	§50.4
Workload identity	How does a new workload get its first credential?	Attestation, SPIFFE SVIDs, hour-scale lifetimes	§50.4.3
Human identity	Workforce and customer identity separate? MFA type?	Separate systems; phishing-resistant MFA for staff	§50.5.1
Sessions	Exposure window of a stolen token?	Short tokens or push revocation; rotated refresh tokens	§50.5.3
Authorization	Where does policy live and who reviews it?	Policy as code, tested; decision logs	§50.5.4
Escalation	Any path from developer to admin?	Graph analysis in CI; protected pipelines	§50.5.5
Supply chain	Can we prove what built each artifact?	SLSA Build L3 provenance; signed; verified at admission	§50.6
Detection	Time to detect a stolen credential?	Correlated detections; honeytokens; MTTD tracked	§50.7
Inventory	Where is every personal-data field?	Generated inventory with classification	§50.8.2
Purpose	Can a job read data outside its purpose?	Purpose checks in access layer; logged	§50.8.3
Data rights	How long until a deletion reaches backups?	Deletion pipeline, crypto-shredding, T_{done} below deadline	§50.9.3
Releases	Are shared datasets anonymous or just pseudonymous?	DP or aggregates for statistics; no “anonymized” microdata	§50.10, §50.11
Data in use	Does the operator need to see plaintext?	TEE, MPC or HE where justified	§50.12

50.14 Summary and revision notes

SUMMARY

- Defense in depth needs independent layers; $\prod p_i$ collapses when one credential spans two layers. Assume breach; measure blast radius as reachability.
- BeyondCorp: access proxy, device inventory, trust inference. NIST SP 800-207: PE and PA (the PDP) and the PEP.
- SPIFFE gives workloads attested, short-lived X.509 or JWT identities; SVID lifetime trades stolen-key exposure against issuer outage budget.
- Keep workforce and customer identity separate; broker federation; choose token lifetimes from $W_{\max} = T_a$ and refresh load N_s/T_a, or decouple them with push revocation.
- Externalize authorization into tested policy (OPA, Cedar, ReBAC) and analyze escalation paths as a graph.
- SolarWinds and xz-utils show attacks on builds and releases; SLSA provenance, Sigstore signing, admission verification, hash pinning and reproducible builds answer them.
- Base rates make most rules imprecise; correlate signals and use honeytokens. Detection time usually dominates exposure.
- Privacy by design: inventory, classification and purpose checks in the data-access path; lawful basis and consent as data; deletion as a pipeline reaching backups via crypto-shredding.
- Pseudonymized data is still personal data. k-anonymity fails to homogeneity, background knowledge and high-dimensional linkage (Netflix Prize).
- ε-DP bounds what any output reveals about one person; Laplace noise has scale $\Delta f/\varepsilon$; budgets add under composition and must be tracked.
- MPC, HE and TEEs protect data in use with different trust and performance trade-offs.

50.15 Knowledge checkpoint

1. Why does a shared identity-provider administrator weaken defense in depth?
2. Map BeyondCorp's components to NIST SP 800-207's PE, PA and PEP.
3. With SVID lifetime 2 h and renewal at half-life, how long can the issuer be down?
4. Why is refresh token rotation able to detect theft?
5. An access token lives 10 minutes with no deny-list. What are the worst-case and expected exposure after revocation?
6. Why did code signing not stop SUNBURST?
7. A rule has FPR 10^{-4} over 10^{8} benign events per day and catches all 10 real attacks. What is its precision?

8. Is HMAC-pseudonymized data anonymous under GDPR?
9. A table is 5-anonymous. Why might it still disclose a sensitive attribute?
10. For a count with $\Delta f = 1$ and $\varepsilon = 0.2$, what is b and $\Pr[|Y| > 10]$?
11. Ten queries each at $\varepsilon = 0.3$ on the same data: what is the total budget by basic composition?
12. Why does crypto-shredding help deletion from backups?

Answers

1. One compromise defeats several layers at once (MFA enrollment, group membership, device trust), so their failure probabilities no longer multiply.
2. Access control engine = PE; SSO and proxy configuration = PA; access proxy = PEP; device inventory and trust inferer feed the PE.
3. About 1 h: renewal at 1 h, expiry at 2 h.
4. Each refresh token is single-use; a second presentation means two parties hold it, so the server revokes the token family.
5. Worst case 10 minutes; expected 5 minutes.
6. The backdoor was inserted during the build on SolarWinds' own build system, so the legitimate process signed it.
7. False positives $= 10^{-4} \times 10^{8} = 10,000$; precision $= 10/10,010 \approx 0.1\%$.
8. No. It is pseudonymous: re-identification is possible with the key, so it remains personal data.
9. A class can be homogeneous in the sensitive attribute, or background knowledge can narrow it.
10. $b = 1/0.2 = 5$; $\Pr = e^{-10/5} = e^{-2} = 0.135$.
11. $10 \times 0.3 = 3.0$.
12. Data encrypted under a per-user key becomes unreadable everywhere, including immutable backups, once the key is destroyed.

50.16 Interview questions

Basic

Q1. What is zero trust, in one minute? Answer. Network location grants nothing. Every request is authenticated (user, device, workload), authorized per request by a policy decision point using current context, and encrypted, with enforcement points in front of each resource. BeyondCorp is the canonical deployment; NIST SP 800-207 is the reference vocabulary. It complements, rather than removes, segmentation.

Q2. Pseudonymization versus anonymization? Answer. Pseudonymization replaces identifiers but remains reversible or linkable with extra information (a key, a lookup table), so it is still personal data. Anonymization makes re-identification not reasonably

likely by any means; for rich data that usually requires aggregation with differential privacy rather than removing columns.

Intermediate

Q3. Design service-to-service authentication and authorization for 20,000 Kubernetes workloads. Answer. SPIRE (or a mesh using SPIFFE IDs) with node attestation via cloud identity documents and workload attestation via Kubernetes selectors; X.509-SVIDs of about an hour, renewed at half-life; mTLS everywhere in strict mode. Authorization by per-route policy keyed on SPIFFE ID, enforced by sidecars or a policy engine with locally cached bundles. Size the issuer for availability, not throughput.

Q4. How would you implement GDPR erasure across 250 microservices? Answer. An inventory lists every personal dataset and its deletion handler; an orchestrator verifies the requester, resolves identifiers, publishes an erase event and tracks acknowledgements; batch systems delete on a cadence under the deadline; backups rely on per-user-key crypto-shredding plus a tombstone ledger replayed on restore; legal holds are explicit exemptions. Check T_{done} against one month.

Advanced

Q5. Your CI system was compromised for an unknown period. What do you do, and what would you change? Answer. Assume every artifact built in the window is untrusted: freeze deploys, revoke CI credentials and OIDC trust, rotate every secret CI could read, rebuild from reviewed source on a clean, hardened builder and compare against reproducible rebuilds, and query logs for what the CI identity did. Afterwards: SLSA Build L3 builders, keyless signing bound to workflow identity, admission policies verifying provenance, and protected workflow files.

Q6. Product wants per-neighborhood demand statistics shared with restaurants weekly. How do you protect customers? Answer. Release aggregates with central differential privacy, never microdata. Bound each customer's contribution per cell, compute sensitivity, allocate a yearly ε per dataset in a budget ledger, coarsen cells so true counts are large relative to $b \ln 20$, merge small cells, and publish the methodology.

50.17 Practical exercises

1. **Laplace error table.** Extend the code in §50.11.2 to sensitivity 5 (a customer may contribute up to 5 orders) and verify that b and the empirical errors scale by 5.
2. **Randomized response.** Implement the coin-flip survey of §50.11.1 for 10,000 people with a true rate of 20%, estimate the rate, and show the estimator is $2\hat{p} - 0.5$. What ε does it provide? (Hint: $\ln 3$.)

3. **l-diversity.** Modify the k-anonymity code to search over generalization levels for the least generalization achieving $k \geq 3$ and $l \geq 2$.
4. **Exposure calculator.** Write a function that takes T_a, N_s and revocation propagation time and prints $W_{\max}$, $\mathbb{E}[W]$ and refresh load; reproduce the §50.5.3 example.

50.18 Design challenges

1. **Zero trust for couriers.** 600,000 couriers use personal phones. Design device trust, token lifetimes and authorization for the courier app and its location stream without a managed-device fleet.
2. **Privacy-preserving analytics platform.** Design a platform where analysts query order data only through a DP service with budget accounting, purpose checks and audit, and state what queries it refuses.
3. **Confidential payments processing.** Move card tokenization into TEEs so the cloud operator never sees card numbers. Specify attestation, key release policy, reproducible enclave builds and what happens when a microcode vulnerability is announced.

50.20 Open verification items

- SPIRE default X.509-SVID TTL (1 h) and JWT-SVID TTL confirmed only for v1.9.x documentation; check the current release.
- Fulcio certificate validity of about ten minutes (as of 2026).

- Census 2020 redistricting budget (ε = 19.61; 17.14 persons, 2.47 housing units) taken from the June 2021 press release as reported; confirm against the Bureau's technical documentation.
- Mandiant M-Trends 2025 median dwell time of 11 days confirmed only via secondary summaries.
- Exact title, issue and author list of Cittadini et al. 2016 (BeyondCorp access proxy) and the full author list of Cedar (OOPSLA 2024) and DELF (USENIX Security 2020).
- CCPA response periods (45 + 45 days) and opt-out preference signal requirements; regulations change.
- Performance ranges in Table 50.6 for MPC and FHE are order-of-magnitude, workload-dependent estimates.

Chapter 51 — Cost-Aware and Sustainable Architecture

> **Level:** 4 · **Track:** Shared · **Estimated reading time:** 5 h

Every architecture has a price, a carbon footprint and a curve that says how both grow with load. Engineers usually hear about the price as a surprise bill, and about the carbon not at all. This chapter treats both as designed properties, like latency or availability: unit economics (§51.4), FinOps practice (§51.5), capacity purchasing (§51.6), engineering levers (§51.7), forecasting (§51.8) and build-versus-buy (§51.9), then energy and carbon metrics (§51.10), carbon-aware design (§51.11), measurement (§51.12) and trade-offs (§51.13).

The running example is again **QuickBite**, the hypothetical food-delivery platform of Chapter 2, at its 2-million-daily-user design point: 500,000 orders a day, or 15 million in a 30-day month (§2.11). Every QuickBite price and quantity is a teaching assumption, not a measurement of a real company or a vendor’s price list.

This chapter builds on earlier ones and does not repeat them: capacity planning and peak-to-average ratios (§18.11), the serverless cost curve (§33.9.3 and §48.11), purchase options and a three-tier cost estimate (§41.13), per-tenant metering, showback and margin (§47.11), and the cost of logs, metrics and traces (§40.4.4, §40.5.3).

51.1 Learning objectives

After this chapter you should be able to:

- Treat cost as a non-functional requirement, sketch the cost curve of a design choice and name published cases where architecture changed cost by an order of magnitude.
- Build a cost-per-order model from compute, storage, network and third-party API costs, and compute contribution margin.
- Describe the FinOps lifecycle (inform, optimize, operate), its personas, showback versus chargeback, tagging and anomaly detection.
- Choose a commitment level against a fluctuating usage curve, compute coverage, utilization and savings, and verify the choice in code.
- Select the right engineering lever for compute, storage, network, databases and observability, and estimate its effect.

- Write a cost forecast with a sensitivity analysis for a design document.
- Compare build, buy and managed options by total cost of ownership, including engineering time.
- Compute PUE, WUE, operational carbon and embodied carbon, and classify emissions into Scopes 1, 2 and 3.
- Design temporal and spatial carbon-aware scheduling, and compute a Software Carbon Intensity (SCI) score.
- Explain what carbon footprint tools measure and where their estimates are weak.
- Make explicit trade-offs among cost, reliability, latency and carbon.

51.2 Prerequisites

- Back-of-the-envelope estimation and QuickBite's load — §2.11 (all unit costs are divided by these volumes).
- Capacity planning, headroom and peak-to-average ratio — §18.11 (commitments are bought against the same curves).
- The serverless break-even model — §33.9.3 (the first cost curve of this chapter).
- Cloud purchase options, data-transfer pricing and the three-tier estimate — §41.10.3, §41.13 (the price vocabulary).
- Storage classes and lifecycle rules — §15.9 (storage tiering).
- Log volume and metric cardinality — §40.4.4, §40.5.3 (observability cost).
- Metering and cost allocation per tenant — §47.11 (showback and chargeback mechanics).
- Bin packing and resource reclamation — §46.7, §46.5.4 (utilization, the largest efficiency lever).
- Kafka replication — Chapter 31 (the build-versus-buy example).

Units: KB, MB, GB, TB are powers of ten. A month is 30 days (720 hours) unless a price is quoted per 730-hour month, as in §41.13. kWh is kilowatt-hours; gCO_2e is grams of carbon dioxide equivalent. All prices are illustrative and dated "as of 2026".

51.3 Why cost is an architectural property

51.3.1 Cost as a non-functional requirement

DEFINITION

Definition — Cost as a non-functional requirement. A **cost requirement** is a measurable bound on what a system may spend to deliver its function, stated per unit of business value (for example, “infrastructure cost at most $0.01 per order at 15 million orders a month”) rather than as a total. Like a latency or availability objective, it is set during requirements, checked in design review and monitored in production.

First-principles explanation

Think of two restaurants with the same menu. One cooks every dish to order on a separate stove; the other preps sauces in bulk each morning. Both serve the same food, but their costs respond differently to a busy Saturday: the first needs more stoves and cooks, the second mostly more plates. The menu (the function) does not tell you which kitchen is cheaper. The *kitchen design* does.

Software works the same way. Two designs that pass the same tests can differ tenfold in cost, because structure sets cost: network hops per request, data copied, idle capacity and per-call fees. Changing a deployed structure takes months, so cost belongs in the design.

Why does this exist?

On premises, cost was a yearly capital decision made by people who bought servers. In the cloud, every engineer who merges code makes a spending decision billed by the second; spending authority moved to engineering, but cost feedback did not move with it [Storment and Fuller 2023]. The major cloud architecture frameworks made cost optimization, and later sustainability, pillars alongside reliability and security [AWS Well-Architected: Cost Optimization Pillar; Google Cloud Architecture Framework; Azure Well-Architected Framework].

How it works internally

1. **State the cost requirement per unit** (§51.4), derived from what the product earns per order, user or GB.
2. **Model each alternative’s cost curve** against the main load driver, separating fixed from variable parts.

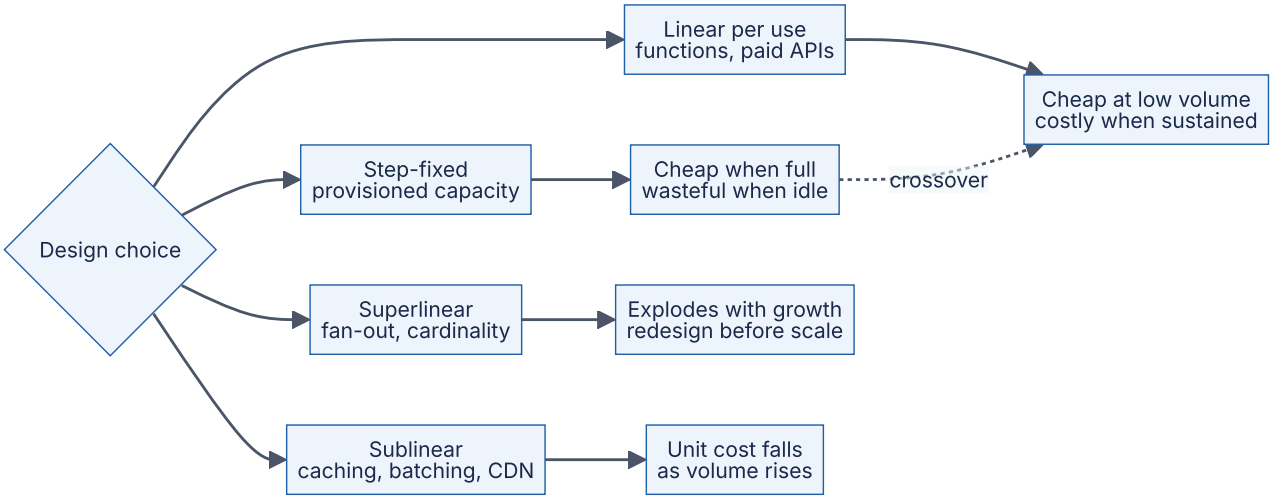
3. **Compare on the curve, not at one point**: the cheaper design at launch may be the expensive one at ten times the load (§33.9.3).
4. **Record the model and forecast in the design document** (§51.8); monitor unit cost in production and revisit the design at each crossover.

51.3.2 Cost curves of design choices

Every design choice has a characteristic **cost curve**, monthly cost as a function of load. Four shapes recur:

1. **Step-fixed.** Provisioned servers, reserved databases and dedicated clusters cost the same at 10% and at 90% load, then jump when you add a node. Cheap per unit when full, expensive when idle.
2. **Linear per use.** Functions, per-request managed services and third-party APIs cost nearly zero at zero load and grow in proportion to it. Cheap when idle, expensive at sustained high volume.
3. **Superlinear.** Designs whose per-request work grows with load: all-to-all communication, fan-out per follower, cross-zone chatter that grows with replica count, or metric series that multiply with labels (§40.5.3).
4. **Sublinear.** Designs that amortize work: caches whose hit ratio rises with traffic, batch pipelines, CDNs, and the volume discounts in tiered price sheets.

Figure 51.1 — Cost curve shapes and the design choices that produce them.



Reading the diagram. The diamond is the design decision; the middle column holds the four curve shapes and the right column their consequences. The dotted arrow is the step-fixed versus linear crossover that §33.9.3 computed for serverless. The failure point is superlinear growth, which no purchasing discount rescues; scaling safely means knowing each component’s shape and crossovers.

Mathematical foundations

The simplest useful model splits cost into a fixed part and a variable part.

FORMULA

Fixed-plus-variable cost and unit cost

$$C(N) = F + vN \qquad u(N) = \frac{C(N)}{N} = \frac{F}{N} + v \qquad N^* = \frac{F_A - F_B}{v_B - v_A}$$

Symbol	Meaning	Units
$C(N)$	Total cost for the period at volume N	$/month
F	Fixed cost that does not change with volume over the period	$/month
v	Variable cost per unit of volume	$/unit
N	Volume (requests, orders, GB) in the period	units/month
$u(N)$	Unit cost	$/unit
N^*	Crossover volume at which designs A and B cost the same ($F_A > F_B, v_A < v_B$)	units/month

WORKED EXAMPLE

Worked example — Where does pay-per-use stop paying? QuickBite's tablet notifications can run on (A) two always-on containers and a broker, F_A = $400/month, v_A = $0.10 per million messages, or (B) a managed push service, F_B = 0, v_B = $1.00 per million (illustrative prices).

1. Crossover: N^* = 400/(1.00 − 0.10) = 444 million messages a month.
2. Today, 60 million: A costs 400 + 6 = $406; B costs $60.
3. After a live-status feature, 2 billion: A costs 400 + 200 = $600 ($u$ = $0.30 per million); B costs $2,000.

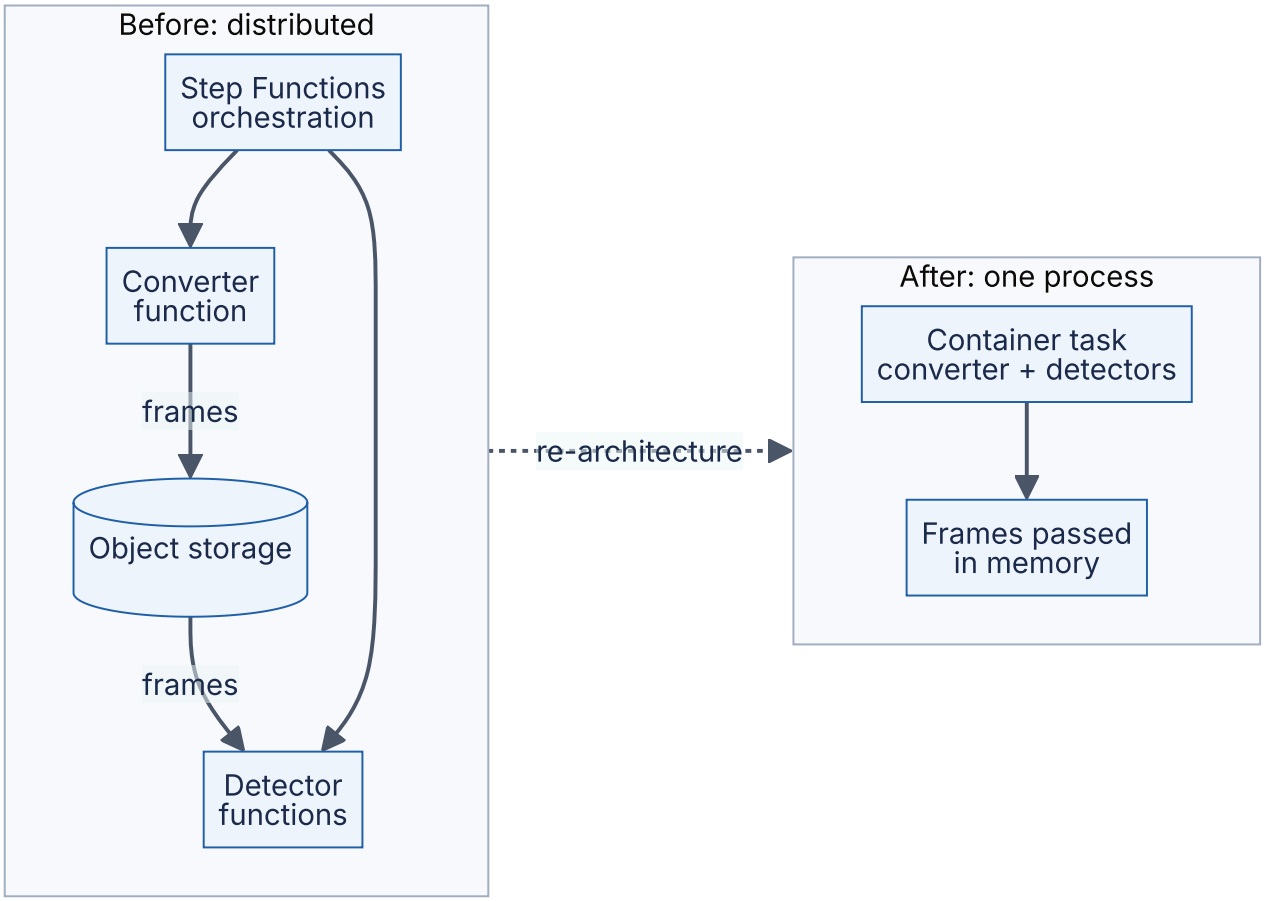
Interpretation. Each design is cheaper on one side of 444 million. **Engineering implication.** Record the crossover in the design document; when the forecast (§51.8) reaches it within a year, prepare the migration while it is still a two-way door (§2.8.2).

51.3.3 Published examples where architecture changed cost

Table 51.1 — Published cases where an architectural change moved cost by a large factor.

Case	Change	Reported effect	Evidence
Prime Video stream monitoring	Distributed functions and orchestration consolidated into one process on containers	Infrastructure cost reduced by about 90% (≈10×)	Primary [Kolny 2023]; see §33.9.3
Dropbox storage	Most user data moved from a third-party cloud to its own custom storage infrastructure	About $74.6 million lower operating cost over 2016–2017	Primary [Dropbox 2018]
Google datacenter fleet	Facility design for low overhead (cooling, power distribution)	Fleet trailing-twelve-month PUE about 1.09 in 2024, against an industry survey average near 1.56–1.58	Primary [Google: Data Center Efficiency]; [Uptime Institute 2024]

Figure 51.2 — The Prime Video monitoring service before and after consolidation, as described by the team.



Reading the diagram. Originally (left), an orchestrator invoked converter and detector functions, and frames traveled between them through object storage, so every transition and storage request carried a per-use charge and a round trip. After consolidation (right), one container task holds all components and frames stay in memory: the storage boundary leaves the hot path, and with it the dominant cost, which fell by about 90% [Kolny 2023]. The trade-off: scaling means running more tasks, and a detector fault now shares a process with the others. The cost curve of §33.9.3 predicts this crossover at sustained volume.

INDUSTRY EXAMPLE

Dropbox's move to its own storage infrastructure. Dropbox's 2018 registration statement described an "infrastructure optimization" that migrated the large majority of user data from a third-party provider to its own custom-built infrastructure in colocation facilities, reporting reductions in operating cost of about $39.5 million in 2016 and $35.1 million in 2017. At Dropbox's scale, storage was a large share of the cost of revenue, and a specialized system beat a general-purpose service once a dedicated team was affordable. §51.9 turns this into a build-versus-buy calculation. *Evidence: Primary* — [Dropbox 2018]; figures as reported, not independently audited here.

Common misconceptions

COMMON MISTAKE

"Cost is an operations problem; we will optimize later." Purchasing discounts and rightsizing (§51.6, §51.7) typically remove tens of percent. Architectural choices, such as how many hops a request takes or whether an API is called per listing or per order, move cost by factors of ten. Only design review can catch those, and only before the design is built.

COMMON MISTAKE

"The cheapest design is the one with the lowest bill today." A design is cheap only relative to a load. Compare cost curves across the forecast range and note the crossovers; otherwise you lock in the design that is cheapest at launch and most expensive at success.

51.4 Unit economics

51.4.1 Cost per unit of value

DEFINITION

Definition — Unit cost and unit economics. A **unit cost** is the cost of delivering one unit of business value: one request, one active user, one order, one GB stored or one model inference. **Unit economics** compares that cost with the revenue the same unit earns. The **contribution margin** of a unit is its revenue minus every cost that varies with it; it is what the unit contributes toward fixed costs and profit.

First-principles explanation

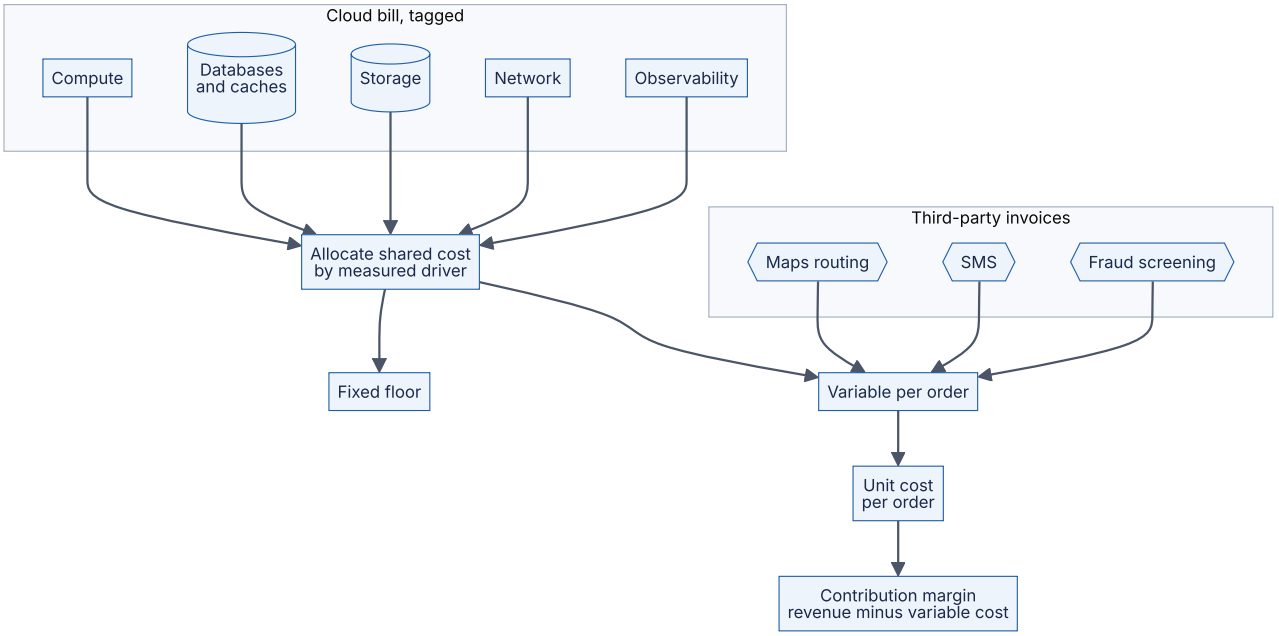
A bill that doubles is good news if orders tripled and bad news if they stayed flat. Dividing by a business driver turns a bill into a rate you can compare across months, teams and designs, as dividing distance by time gives speed. The denominator should be something the business sells and that drives cost: orders for QuickBite, seats for SaaS, GB-months for storage, minutes for video. Engineers cannot act on “the cloud bill is $485,000”; they can act on “routing costs two cents per order, 62% of technology cost”. The FinOps Foundation framework treats unit economics as the bridge between cost data and business value [FinOps Foundation: Framework].

How it works internally

1. **Choose the unit** (orders and active users for QuickBite).
2. **Collect all costs**: tagged cloud bill, third-party invoices, licences and, for a full picture, engineering time.
3. **Allocate shared costs** by a measured driver (CPU-seconds, bytes) with the formula of §47.11.2.
4. **Split fixed from variable** (§51.3.2): the always-on floor, control planes and non-production environments are fixed.
5. **Report variable cost per unit and fixed cost separately**, and alert on the trend, so growth alone does not hide a regression.

51.4.2 Worked model: QuickBite’s cost per order

Figure 51.3 — QuickBite cost-per-order model: from cost lines to unit cost and contribution margin.



Reading the diagram. The tagged cloud bill and third-party invoices (hexagons) feed the model. Cloud lines pass through allocation, which splits shared resources by a measured driver into a fixed floor and per-order cost; per-call third-party costs go straight to the variable bucket. Variable cost per order gives unit cost; revenue minus variable cost gives contribution margin. The weak link is allocation of untagged and shared resources (§51.5.3).

WORKED EXAMPLE

Worked example — QuickBite's monthly technology cost per order. Volume: 15 million orders a month (§2.11). Cloud costs are illustrative totals for the 2-million-user design point; third-party prices are QuickBite assumptions, including the $0.005 routing call of §2.4.

Table 51.2 — QuickBite monthly technology cost model (illustrative).

Line	Driver	Monthly cost	Per order
Compute (Kubernetes nodes for all services)	vCPU-hours	$46,000	$0.00307
Databases and caches	instance-hours, IOPS	$24,000	$0.00160
Storage (images, back-ups, cold logs)	GB-months	$5,000	$0.00033
Network (CDN, egress, cross-zone, NAT)	GB transferred	$11,000	$0.00073
Observability (logs, met-rics, traces)	GB ingested, series	$9,000	$0.00060
Cloud subtotal		**$95,000**	**$0.00633**
Maps routing: 4 calls per order × $0.005	calls	$300,000	$0.02000
SMS: 0.3 messages per order × $0.008	messages	$36,000	$0.00240
Fraud screening: 90% card orders × $0.004	checks	$54,000	$0.00360
Third-party subtotal		**$390,000**	**$0.02600**
Total technology cost		**$485,000**	**$0.03233**

Step by step:

1. Cloud per order: $95,000/15,000,000 = \$0.00633$.
2. Maps: $4 \times 0.005 = \$0.020$ per order; $0.020 \times 15 \times 10^6 = \$300,000$.
3. SMS: $0.3 \times 0.008 = \$0.0024$; fraud: $0.9 \times 0.004 = \$0.0036$. Third-party total: $0.020 + 0.0024 + 0.0036 = \$0.026$ per order.
4. Total: $0.00633 + 0.026 = \$0.0323$ per order, or $485,000 a month.

Interpretation. Third-party APIs are 80% of technology cost; the entire cloud bill is less than a third of the routing invoice. **Engineering implication.** The best cost lever is not instance purchasing but routing-call discipline: caching route estimates per zone pair, or calling once per order instead of four times, saves more than elimi-nating the cloud bill entirely.

Now suppose $38,000 of the cloud subtotal is a fixed floor (zone-safe minimum fleet, control planes, non-production, baseline observability). The variable part is $(95,000 - 38,000)/15 \times 10^6 = \$0.0038$ per order. With the formula of §51.3.2, unit technology cost is $u(N) = 38,000/N + 0.0038 + 0.026$:

- At 1.5 million orders a month (the pilot): $0.0253 + 0.0038 + 0.026 = \$0.0551$.
- At 15 million: $\$0.0323$.
- At 60 million: $0.00063 + 0.0038 + 0.026 = \$0.0304$.

Unit cost falls as fixed cost is amortized, then flattens at a variable floor of about three cents that only design changes can lower.

51.4.3 Contribution margin

FORMULA

Contribution margin per unit

$$CM = P - \sum_k V_k \qquad CMR = \frac{CM}{P} \qquad \text{Break-even units} = \frac{F_{\text{total}}}{CM}$$

Symbol	Meaning	Units
P	Revenue the company keeps per unit (net of pass-through amounts)	$/unit
V_k	Each cost that varies per unit (labor, payment fees, technology, support)	$/unit
CM	Contribution margin per unit	$/unit
CMR	Contribution margin ratio	fraction
F_{total}	Total fixed costs of the business for the period	$/month

WORKED EXAMPLE

Worked example — QuickBite's margin per order, and an architecture that destroys it. Illustrative assumptions: average basket $30, QuickBite commission 20% ($6.00) plus a $2.50 delivery fee, so $P = \$8.50$. Variable costs: courier pay $5.20; card processing 2.5% of the $32.50 charged plus $0.15, which is $0.96; support and refunds $0.45; technology $0.032 (Table 51.2).

Table 51.3 — QuickBite contribution margin per order (illustrative).

Item	Good design	Per-listing routing design
Revenue kept, *P*	$8.50	$8.50
Courier pay	−$5.20	−$5.20
Payment processing	−$0.96	−$0.96
Support and refunds	−$0.45	−$0.45
Technology	−$0.032	−$12.01
Contribution margin	**$1.86**	**−$10.12**

1. Good design: $8.50 - 5.20 - 0.96 - 0.45 - 0.032 = \$1.858 \approx \$1.86$; $CMR = 1.858/8.50 = 21.9\%$.
2. The design rejected in §2.4 asked the maps provider for a live route time for each of 20 restaurants on every browse page. QuickBite serves 30 browse reads per user per day and 0.25 orders, so 120 browse reads per order. Routing calls per order: $120 \times 20 = 2,400$, costing $2,400 \times 0.005 = \$12.00$.
3. Technology then becomes $0.032 - 0.020 + 12.00 = \$12.01$ per order, and the margin $1.858 + 0.020 - 12.00 = -\$10.12$.
4. If QuickBite's fixed costs (staff, offices, marketing) were $2 million a month, the good design breaks even at $2,000,000/1.858 \approx 1.08$ million orders a month; the bad design never does.

Interpretation. With a sensible design, technology is under 2% of the variable cost of an order, and labor dominates. One unbounded per-call dependency turned that 2% into a loss larger than the revenue. **Engineering implication.** Put per-unit third-party calls in the design review checklist, and compute cost per business unit for each design alternative, not cost per request.

COMMON MISTAKE

"Cost per request is the unit cost." Requests are an implementation detail. A client redesign that sends three requests where it used to send one improves cost per request and worsens cost per order. Measure per business unit and use per-request cost only for engineering diagnosis.

51.5 FinOps practice

51.5.1 What FinOps is

DEFINITION

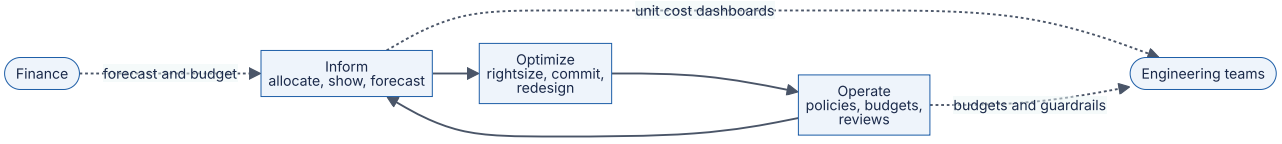
Definition — FinOps. FinOps (cloud financial operations) is an operational practice in which engineering, finance, product and leadership collaborate to make data-driven spending decisions on variable, usage-based technology costs, so that the organization gets the most business value per unit spent. The FinOps Foundation organizes the practice into a repeating lifecycle of three phases (**inform**, **optimize** and **operate**), a set of personas, and capabilities grouped into domains [FinOps Foundation: Framework; Storment and Fuller 2023].

First-principles explanation

In a shared house with one electricity meter and one person paying, nobody turns off the heater. Put a live meter in each room, agree who pays for what, and review the bill monthly, and consumption falls without orders. FinOps does this for the cloud. Its goal is value per dollar, not cutting: spending more on a feature that earns more is a FinOps success.

How it works internally

Figure 51.4 — The FinOps lifecycle: inform, optimize, operate.



Reading the diagram. The phases form an endless loop, and different services may be at different phases. **Inform** turns billing data into allocated cost and forecasts; **optimize** acts on it (rightsizing, commitments, redesign); **operate** embeds results in budgets, policies and review cadences. Dotted arrows are asynchronous information flows to engineering and from finance. The failure point is a loop that stops at inform, with dashboards nobody acts on. Maturity grows per capability as **crawl, walk, run** [Storment and Fuller 2023].

Table 51.4 — FinOps personas and what each needs (after the FinOps Foundation framework).

Persona	Main question	Needs from the practice
FinOps practitioner	Is spend allocated, understood and improving?	Clean billing data, tagging coverage, a cadence
Engineering	What does my service cost and how do I lower it?	Near-real-time cost per service, levers, anomaly alerts
Finance	Will we hit the budget?	Accurate forecasts, accruals, chargeback data
Product	What does a unit cost, and is the feature worth it?	Unit economics, margin by feature or tenant
Procurement	What should we commit to and negotiate?	Usage trends, commitment coverage and utilization
Leadership	Is cloud spend creating value?	Unit-cost trends, efficiency targets, accountability

51.5.2 Showback and chargeback

Chapter 47 defined **showback** (reporting attributed cost to a team or tenant) and **chargeback** (billing it to their budget) and gave the allocation formula (§47.11.2). The organizational choice between them is a FinOps decision.

Table 51.5 — Showback versus chargeback.

Aspect	Showback	Chargeback
What it is	Cost reported to the consuming team	Cost debited from the consuming team's budget
Behavioral effect	Awareness; peer comparison	Direct accountability; strong incentive
Data accuracy needed	Approximate allocation is acceptable	Must be auditable and defensible
Shared-cost handling	Can show "unallocated" openly	Needs agreed rules for every shared dollar
Risk	Ignored if no one owns action	Gaming, disputes, teams avoiding shared platforms
Choose when	Early maturity, platform adoption phase	Mature allocation, teams own budgets

Start with showback; charging back before allocation is trusted produces arguments about rules instead of engineering changes.

51.5.3 Tagging and allocation strategy

A **tag** (a label in Google Cloud and Kubernetes) is a key–value pair on a resource that billing exports carry; tags turn a bill into per-team and per-service cost.

Table 51.6 — A minimal tagging scheme for QuickBite.

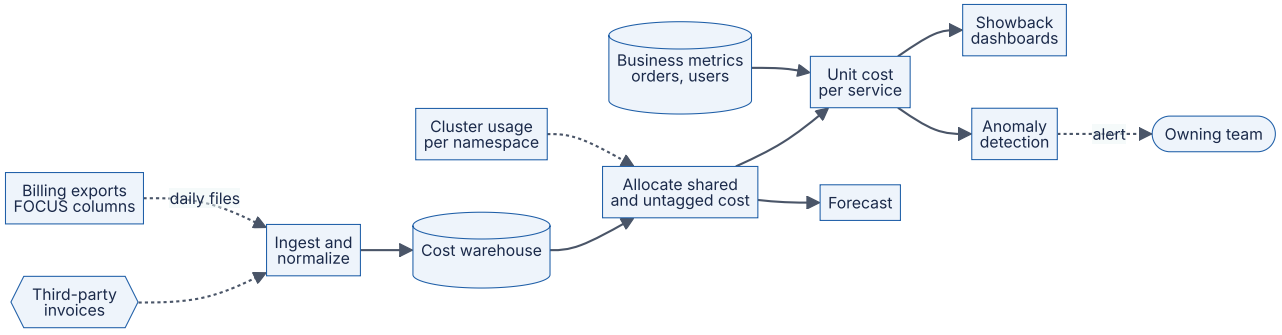
Key	Example value	Used for
`cost-center`	`cc-4120`	Finance mapping, chargeback
`team`	`dispatch`	Showback, ownership, anomaly routing
`service`	`order-api`	Unit cost per service
`env`	`prod`, `staging`, `dev`	Non-production waste, scheduling off-hours
`product`	`consumer-app`	Unit economics per product
`data-class`	`pii`, `public`	Retention and security policy (not cost, but enforced together)

Four rules make tagging work:

1. **Enforce at creation**: infrastructure-as-code modules set tags (§43.8), and policies deny untagged production resources.
2. **Use account and project structure first**: one account per team and environment allocates even untaggable resources.
3. **Allocate what cannot be tagged** (shared clusters, support, commitment discounts) by measured usage, such as namespace CPU and memory requests (§47.11.2).
4. **Measure coverage**: the share of spend allocated each month, with 90% or more a common mature target.

The FinOps Foundation's **FOCUS** specification (FinOps Open Cost and Usage Specification) standardizes billing-export columns across providers, so one pipeline can read several clouds and SaaS vendors [FinOps Foundation: FOCUS].

Figure 51.5 — A cost data pipeline: billing export to showback, forecasts and anomaly alerts.



Reading the diagram. Billing exports and invoices arrive asynchronously (dotted), typically daily with hours of lag, and are normalized into a cost warehouse, the storage

boundary. Allocation adds per-namespace cluster usage; joining business metrics gives unit cost per service, which feeds dashboards, forecasts and anomaly alerts routed by the `team` tag. Failure points: billing lag delays detection by up to a day, and missing tags send cost to “unallocated”. Large estates produce billions of line items a month, so the warehouse must scale.

51.5.4 Anomaly detection

A **cost anomaly** is spending that departs from the expected pattern: a recursive trigger, a forgotten load test, DEBUG logging left on. It is cheap to catch in a day and expensive in a month.

FORMULA

A simple cost anomaly score

$$z_t = \frac{c_t - \hat{c}_t}{\sigma_t} \qquad \text{alert if } z_t > k \text{ and } c_t - \hat{c}_t > A_{\min}$$

Symbol	Meaning	Units
c_t	Observed cost of a service on day t	$/day
$\hat{c}_t$	Expected cost: same weekday’s median over recent weeks, scaled by business volume	$/day
σ_t	Robust spread of recent residuals (for example 1.4826 × median absolute deviation)	$/day
k	Threshold in standard deviations	dimensionless
$A_{\min}$	Minimum absolute excess worth an alert	$/day

WORKED EXAMPLE

Worked example — Catching a DEBUG log level. QuickBite's observability spend for the `dispatch` team is normally $300/day on a Tuesday, with a robust spread of $25. A deployment leaves DEBUG logging on, and Tuesday's cost is $520. Threshold $k = 4$, $A_{\min} = \$100$.

1. $z = (520 - 300)/25 = 8.8 > 4$.
2. Excess $= \$220 > \$100$, so the alert fires.
3. If unnoticed for a 30-day month: $220 \times 30 = \$6,600$, which is 73% of the whole monthly observability line of Table 51.2.

Interpretation. The two-part test ignores large relative jumps in tiny services and noise in huge ones. **Engineering implication.** Scale $\hat{c}_t$ by business volume so a promotion is not an anomaly, and alert the owning team, not a central inbox.

Failure scenarios

Table 51.7 — FinOps practice failure scenarios.

What goes wrong	Why	Detection	Recovery	Prevention
Dashboards nobody reads	No owner or cadence	Flat unit cost, no tickets	Monthly cost review per team	Make unit cost part of service reviews
30% of spend "unallocated"	Untagged resources, shared clusters	Coverage metric	Allocate by usage; fix modules	Deny untagged creation
Runaway bill over a weekend	Recursive trigger, loop, test left running	Anomaly alert, budget alarm	Disable trigger; set quota	Hard quotas in non-production
Optimization harms reliability	Cuts removed redundancy	SLO burn after cost change	Restore capacity	Review cost changes against SLOs (§51.13)

COMMON MISTAKE

"FinOps is a finance team's job." Finance can see the bill but cannot change it; only engineers can. FinOps succeeds when the people who write and deploy code see the cost of what they run, in their own tools, within a day.

51.6 Capacity purchasing strategy

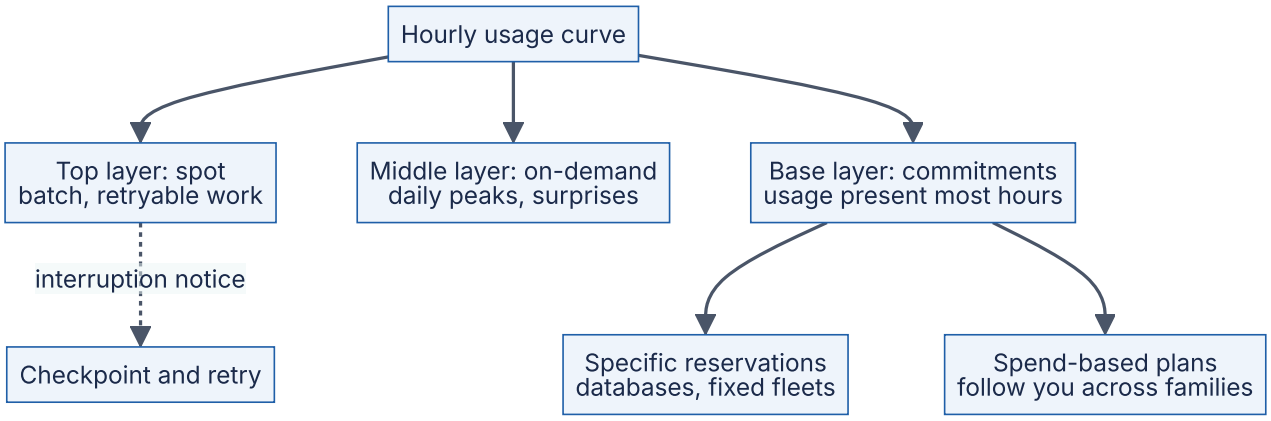
51.6.1 The commitment portfolio

DEFINITION

Definition — Commitment portfolio, coverage and utilization. A **commitment portfolio** is the mix of purchase options that serves a workload: commitments (reserved instances, savings plans, committed-use discounts) for the steady base, on-demand for the variable middle, and spot for interruptible work. **Coverage** is the share of eligible usage billed at committed rates. **Commitment utilization** is the share of purchased commitment actually consumed. The **effective savings rate** is the total discount achieved against what the same usage would have cost on demand.

§41.13.1 gave the purchase options and the single-instance break-even $u^* = 1 - d$. Real fleets have a usage curve that rises at lunch and dinner and falls at night, so the question is "how much?" Think of a company buying monthly train passes for a hundred commuters: buy passes for those who ride on most days and single tickets for the rest. Commitments are passes for compute-hours, paid every hour of the term at a discount.

Figure 51.6 — Layers of a commitment portfolio against a daily usage curve.



Reading the diagram. Usage is layered by how reliably each slice is present. The base layer becomes commitments: specific reservations for stable resources such as databases, and spend-based plans that follow you across instance families. On-demand covers peaks and growth; spot serves interruptible work, and the dotted arrow is the asynchronous interruption notice that triggers checkpoint and retry. Failure points: over-commitment locks in waste for one to three years, and spot can vanish in a regional shortage. Rebalance monthly.

Mathematical foundations

FORMULA

Coverage, utilization, effective savings and the optimal commitment level

$$\text{Coverage} = \frac{\sum_t \min(x_t, c)}{\sum_t x_t} \qquad \text{Utilization} = \frac{\sum_t \min(x_t, c)}{cH}$$

$$C(c) = c\,p_c\,H + p_{od} \sum_t \max(x_t - c, 0) \qquad \text{ESR} = 1 - \frac{C(c)}{p_{od} \sum_t x_t} \qquad c^* = Q_x(d)$$

Symbol	Meaning	Units
x_t	Usage in hour t (instance-equivalents)	instances
c	Committed level, paid every hour	instances
H	Hours in the term considered	hours
p_{od}	On-demand price per instance-hour	$/instance-hour
p_c	Committed effective price, $p_{od}(1-d)$	$/instance-hour
d	Commitment discount	fraction
$C(c)$	Total cost at commitment level c	$
ESR	Effective savings rate against all-on-demand	fraction
$Q_x(d)$	The d-quantile of hourly usage: the level exceeded in a fraction $1-d$ of hours	instances

Why the quantile rule? One more committed instance costs $p_c H$ and saves p_{od} in every hour where usage exceeds c, so it pays while such hours number more than $H(1-d)$. Commit until the level is exceeded in only a fraction $1-d$ of hours: the d-quantile. A 40% discount means the 40th percentile. This is the newsvendor result of operations research.

Code example

The program below builds a 30-day hourly usage curve for QuickBite's order-processing fleet (a nightly floor, a daytime wave, a weekday lift and noise), evaluates every commitment level, and checks the quantile rule against brute force.

```
        """Choose a compute commitment level against an hourly usage curve (Section
51.6)."""
        import math
        import random

        H = 720             # hours in a 30-day month
        P_OD = 0.10         # on-demand price per instance-hour, $ (illustrative)
        DISCOUNT = 0.40     # commitment discount d (illustrative 1-year plan)
        P_C = P_OD * (1 - DISCOUNT)

        def usage_curve(seed=7):
            """Hourly instance demand: floor + diurnal wave + weekday lift + noise."""
            rng = random.Random(seed)
            out = []
            for t in range(H):
                hour, day = t % 24, t // 24
                diurnal = 60 * max(0.0, math.sin(math.pi * (hour - 7) / 15)) if 7 <=
hour <= 22 else 0.0
                weekday = 15 if day % 7 < 5 else 0
                out.append(max(0.0, 40 + diurnal + weekday + rng.gauss(0, 5)))
            return out

        def month_cost(usage, c):
            """Commit c instances for every hour; overflow runs on demand."""
            committed = c * P_C * H
            overflow = sum(max(u - c, 0.0) for u in usage) * P_OD
            used = sum(min(u, c) for u in usage)
            coverage = used / sum(usage)               # share of usage on commitment
            utilization = used / (c * H) if c else float('nan')  # share of commitment
used
            return committed + overflow, coverage, utilization

        def quantile(xs, q):
            s = sorted(xs)
            return s[min(len(s) - 1, int(q * len(s)))]

        usage = usage_curve()
        on_demand_only = sum(usage) * P_OD
        grid = [c / 2 for c in range(0, 2 * int(max(usage)) + 2)]
        best_c = min(grid, key=lambda c: month_cost(usage, c)[0])
        rule_c = quantile(usage, DISCOUNT)   # commit up to the d-quantile of hourly de-
mand

        print(f"Usage: min {min(usage):.1f}, mean {sum(usage)/H:.1f}, max
{max(usage):.1f} instances")
        print(f"On-demand only: ${on_demand_only:,.0f}")
        print(f"{'commit':>7} {'cost $':>8} {'saving':>7} {'coverage':>9} {'util':>6}")
        for c in (0, min(usage), 45, rule_c, 75, 100, max(usage)):
            cost, cov, util = month_cost(usage, c)
            print(f"{c:7.1f} {cost:8,.0f} {1 - cost/on_demand_only:7.1%} {cov:9.1%}
{util:6.1%}".replace("nan%", "  n/a"))
        print(f"Grid optimum {best_c:.1f}; quantile rule {rule_c:.1f}")
```

```
        # Tests
        assert abs(month_cost(usage, 0)[0] - on_demand_only) < 1e-6       # no commit-
ment = all on demand
        assert abs(best_c - rule_c) <= 1.0                                  # rule
matches brute force
        assert month_cost(usage, best_c)[0] <= month_cost(usage, max(usage))[0]
        assert month_cost(usage, min(usage))[2] == 1.0                      # floor
commitment fully used
        print("all tests passed")
```

Output:

```
Usage: min 27.2, mean 74.9, max 126.1 instances
On-demand only: $5,394
 commit   cost $  saving  coverage   util
    0.0    5,394    0.0%      0.0%     n/a
   27.2    4,611   14.5%     36.3% 100.0%
   45.0    4,146   23.1%     59.2%  98.5%
   60.1    3,961   26.6%     74.7%  93.1%
   75.0    4,050   24.9%     85.0%  84.9%
  100.0    4,489   16.8%     96.9%  72.6%
  126.1    5,447   -1.0%    100.0%  59.4%
Grid optimum 60.0; quantile rule 60.1
all tests passed
```

What to notice:

- `month_cost` is the formula $C(c)$ term by term: commitment paid for all H hours, overflow at on-demand price.
- `quantile(usage, DISCOUNT)` implements $c^* = Q_x(0.4)$, and the test confirms it lands within one instance of the brute-force optimum.
- The fixed seed makes the curve reproducible, so the tests are deterministic; change the seed to see the rule hold on other curves.

WORKED EXAMPLE

Worked example — Reading the commitment table. Take the rows of the output above.

1. **Commit to the floor (27.2 instances).** Utilization is 100%, but coverage is only 36.3%, and the effective savings rate is 14.5%. Check one figure: commitment $27.2 \times 0.06 \times 720 = \$1,175$; overflow $(53,940 - 27.2 \times 720) \times 0.10 = (53,940 - 19,584) \times 0.10 = \$3,436$; total $4,611. (Total usage is $5,394/0.10 = 53,940$ instance-hours.)
2. **Commit to the 40th percentile (60.1).** Utilization drops to 93.1%, but coverage rises to 74.7%, and savings reach the maximum, 26.6% or $1,433 a month.
3. **Commit to the mean (75).** Utilization 84.9%, savings 24.9%: committing to average usage is close to, but worse than, optimal.
4. **Commit to the peak (126.1).** Coverage 100%, utilization 59.4%, and the cost exceeds all-on-demand by 1%: below the break-even utilization $1 - d = 60\%$ of §41.13.1.

Interpretation. The best commitment is neither the floor (too timid) nor the peak (wasteful). It sits where some commitment goes unused in quiet hours, about 7% here, because the discount on busy hours pays for it. **Engineering implication.** Do not target 100% utilization; it means you are under-committed. Target the quantile, re-run monthly on the latest 30 days, and buy in tranches (for example a quarter of the target every quarter) so commitments expire on a staggered schedule and can follow the curve down.

51.6.2 Spot capacity in the portfolio

Spot capacity is unused provider capacity sold at a large discount that the provider can reclaim with short notice, typically two minutes on AWS and about 30 seconds on Google Cloud and Azure, as of 2026 (§41.8.5). The effective price must include the work lost to interruptions.

WORKED EXAMPLE

Worked example — QuickBite's nightly settlement batch on spot. 2,000 instance-hours a month at $0.10 on demand; spot is 70% cheaper ($0.03). With 30-minute checkpoints, interruptions cause about 10% rework and checkpointing adds 5%.

1. Effective price: $0.03 \times (1 + 0.10 + 0.05) = \$0.0345$ per useful instance-hour.
2. Monthly: $2,000 \times 0.0345 = \$69$ against $200, a 65.5% saving.

Interpretation. Without checkpoints, an interrupted 4-hour job restarts from zero and the deadline becomes uncertain. **Engineering implication.** Checkpoint, diversify across instance types and zones, and fall back to on-demand automatically.

51.7 Engineering levers by resource

Purchasing changes the price of a unit. Engineering changes how many units you need, and it compounds with purchasing. This section summarizes the levers per resource; Table 51.8 collects them with typical savings ranges, which are **illustrative** and depend entirely on the starting point.

51.7.1 Compute

1. **Rightsizing.** Size to p95 CPU and memory measured over weeks. In Kubernetes, set requests from observed usage, because the scheduler packs on requests, not use (§42.12, §46.7).
2. **Autoscaling.** Follow the load curve (§18.8, §18.11.3). QuickBite's browse fleet at a peak-to-average ratio of 9.6 averages about 8 nodes under autoscaling instead of 18 static nodes.
3. **Processor architecture.** Arm-based server processors are often cheaper per unit of throughput. AWS states that Graviton3 instances use up to 60% less energy for the same performance than comparable EC2 instances, and markets better price-performance against x86; these are **vendor claims** whose baseline and workloads are not fully disclosed [AWS: Graviton]. Benchmark your own workload before migrating.
4. **Bin packing and overcommit.** Fill gaps left by latency-sensitive services with batch work and reclaim allocated but unused resources (§46.5.4, §46.5.6).
5. **Efficient code.** Profiling (§40.12) finds the hot functions worth optimizing.

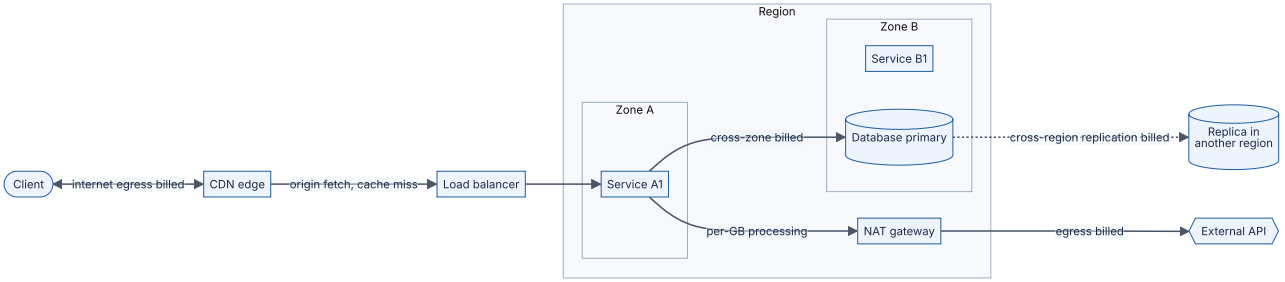
51.7.2 Storage

1. **Tiering and lifecycle rules** (§15.9): archive classes cost roughly an order of magnitude less per GB-month, with retrieval fees and delays.
2. **Retention policies**: decide how long each data class must exist and delete the rest automatically.
3. **Compression and columnar formats**: text logs and JSON often compress 5–10×.
4. **Deduplication**: content-addressed images, backups and artifacts are stored once.
5. **Hygiene**: unattached volumes, old snapshots and incomplete uploads are pure waste (§41.13.2).

51.7.3 Network

Network charges are the most frequent surprise on cloud bills, because they are invisible in architecture diagrams.

Figure 51.7 — Where data transfer is billed in a typical cloud deployment.



Reading the diagram. Each labeled edge is a separately priced transfer. CDN egress is usually cheaper than origin egress, and cache hits avoid origin transfer. Cross-zone traffic is billed in each direction (§41.10.3), so a zone-A service querying a zone-B primary pays on every query. NAT adds a per-GB processing fee, and asynchronous cross-region replication (dotted) is billed per GB. All grow linearly with traffic, so the levers are structural.

The network levers are:

1. **CDN offload** (Chapter 21): every point of hit ratio removes origin egress and compute.
2. **Zone-aware routing**: same-zone replicas, Kubernetes topology-aware routing, and rack-aware follower fetching for Kafka consumers [Apache Kafka: KIP-392]. Keep redundancy across zones but the hot path within one.
3. **Private endpoints** instead of NAT for provider services (§41.10.3).
4. **Compression and binary encodings** such as Protobuf.
5. **Data locality**: process data where it is stored.

WORKED EXAMPLE

Worked example — QuickBite's cross-zone chatter. The order service makes 5 database and cache calls per order request, each returning 8 KB. With replicas spread evenly across three zones and no zone awareness, two thirds of calls cross a zone. Peak-hour traffic is 3,000 requests per second for 4 hours a day; the rest averages 600 requests per second. Price: $0.01 per GB in each direction, so $0.02 per GB crossing (illustrative, as of 2026).

1. Requests per day: $3,000 \times 4 \times 3,600 + 600 \times 20 \times 3,600 = 43.2 + 43.2 = 86.4$ million.
2. Bytes crossing zones per day: $86.4 \times 10^6 \times 5 \times 8 \text{ KB} \times \frac{2}{3} = 2,304$ GB.
3. Monthly cost: $2,304 \times 30 \times 0.02 = \$1,382$.
4. With zone-local read replicas and cache nodes, crossing falls to the 10% of calls that must reach the primary: $\$1,382 \times 0.10/(2/3) = \$207$, saving about $1,175 a month.

Interpretation. Modest at this scale, the saving grows linearly with traffic and also removes cross-zone latency. **Engineering implication.** Make zone locality the default in service discovery and chart cross-zone bytes per service.

51.7.4 Databases

1. **Caching versus read replicas.** A replica copies the whole database at full node price; a cache holds only the hot set. QuickBite's 5 GB of menus, read about 117 times per order (§2.11), fit a small cache. Replicas win for large, unpredictable read sets or SQL queries (§20.3, §18.9).
2. **Serverless databases** suit spiky or development workloads and usually cost more at sustained load (§51.3.2).
3. **Index and query fixes** often beat moving up an instance class; unused provisioned IOPS are fixed waste.

51.7.5 Observability

Chapter 40 gave the levers: sample routine successes but never errors, keep hot retention short (§40.4.4) and budget cardinality (§40.5.3). For QuickBite this cut the log bill from $11,664 to $2,528 a month. Observability grows faster than traffic, so give each team a volume budget.

Table 51.8 — Engineering levers and typical savings ranges (illustrative; actual savings depend on the starting point).

Resource	Lever	Typical saving on the affected line	Main risk
Compute	Rightsizing requests and instances	20–50%	Throttling at peaks if sized on averages
Compute	Autoscaling a high-PAR service	30–60%	Slow scale-up during sudden peaks
Compute	Arm instances (benchmark first)	10–40% price-performance (vendor claims vary)	Porting effort, native dependencies
Compute	Spot for batch	50–80%	Interruptions, deadline misses
Compute	Scheduling non-production off-hours	50–70% of non-production	Developer friction
Storage	Lifecycle tiering and retention	30–80%	Retrieval fees, deleting needed data
Storage	Compression, columnar formats	50–90% of bytes	CPU cost to compress
Network	CDN offload	30–80% of origin egress	Stale content
Network	Zone-aware routing	50–90% of cross-zone transfer	Uneven load per zone
Network	Private endpoints instead of NAT	Most NAT processing	Configuration effort
Database	Cache instead of extra replicas	30–70% of read capacity cost	Invalidation bugs, stale reads
Observability	Sampling, short hot retention, cardinality budgets	50–80%	Losing the trace you needed

RECOMMENDATION

Order of operations. Delete waste first, then rightsize, then redesign hot paths, and only then buy commitments for what remains. Committing first locks in waste for the commitment term (§41.13.2).

51.8 Cost modeling and forecasting

51.8.1 Cost models in design documents

A design document (§2.12.3) should contain a **cost section** with four parts: the unit cost model (§51.4) for each alternative, a forecast over the planning horizon, a sensitivity analysis showing which assumptions matter, and the crossover volumes at which the deci-

sion would flip. Reviewers then argue about assumptions, which can be checked, rather than conclusions.

FORMULA

Driver-based forecast and elasticity

$$C(t) = F + \sum_k v_k D_k(t) \qquad D_k(t) = D_k(0)(1+g)^t \qquad \varepsilon_x = \frac{\Delta C/C}{\Delta x/x}$$

Symbol	Meaning	Units
$C(t)$	Forecast cost in month t	$/month
F	Fixed monthly cost	$/month
v_k	Unit cost of driver k	$/unit
$D_k(t)$	Volume of driver k in month t	units/month
g	Compound monthly growth rate	fraction/month
ε_x	Elasticity of total cost with respect to input x	dimensionless

The program below forecasts QuickBite's technology cost for 12 months at 8% monthly order growth (the rate used in §18.11.4), then varies each input by ±20% one at a time and ranks the inputs by the swing they cause, the data for a **tornado chart**.

```
        """QuickBite 12-month cost forecast with one-at-a-time sensitivity (Section
51.8)."""
        BASE = {
            "orders0": 15e6,        # orders in month 0
            "growth": 0.08,         # compound monthly order growth
            "fixed": 38_000,        # $/month that does not scale with orders
            "infra_var": 0.0038,    # $ of cloud infrastructure per order
            "maps_calls": 4.0,      # routing API calls per order
            "maps_price": 0.005,    # $ per routing call
            "other_3p": 0.006,      # SMS + fraud screening, $ per order
        }

        def monthly_cost(p, t):
            orders = p["orders0"] * (1 + p["growth"]) ** t
            per_order = p["infra_var"] + p["maps_calls"] * p["maps_price"] +
p["other_3p"]
            return p["fixed"] + orders * per_order, orders

        def forecast(p, months=12):
            return sum(monthly_cost(p, t)[0] for t in range(1, months + 1))

        base_total = forecast(BASE)
        c12, n12 = monthly_cost(BASE, 12)
        print(f"Month 12: {n12/1e6:.1f} M orders, ${c12:,.0f}/month,
${c12/n12:.4f}/order")
        print(f"12-month total: ${base_total:,.0f}")
        print(f"{'input (+/-20%)':<12} {'low $M':>8} {'high $M':>8} {'swing $M':>9}
{'elasticity':>10}")
        rows = []
        for k in BASE:
            lo, hi = dict(BASE), dict(BASE)
            lo[k], hi[k] = BASE[k] * 0.8, BASE[k] * 1.2
            a, b = forecast(lo), forecast(hi)
            rows.append((abs(b - a), k, a, b, ((b - a) / base_total) / 0.4))
        for swing, k, a, b, e in sorted(rows, reverse=True):
            print(f"{k:<12} {a/1e6:8.2f} {b/1e6:8.2f} {swing/1e6:9.2f} {e:10.2f}")

        assert abs(forecast(dict(BASE, growth=0.0)) - 12 * monthly_cost(BASE, 0)[0]) <
1e-6
        assert sorted(rows, reverse=True)[0][1] in ("orders0", "growth", "maps_calls",
"maps_price")
        print("all tests passed")
```

Output:

```
Month 12: 37.8 M orders, $1,163,622/month, $0.0308/order
12-month total: $9,617,398
input (+/-20%)   low $M  high $M  swing $M elasticity
orders0          7.79    11.45      3.66       0.95
maps_price       8.39    10.85      2.46       0.64
maps_calls       8.39    10.85      2.46       0.64
growth           8.67    10.68      2.01       0.52
other_3p         9.25     9.99      0.74       0.19
infra_var        9.38     9.85      0.47       0.12
fixed            9.53     9.71      0.18       0.05
all tests passed
```

What to notice:

- Growth compounds: month-12 orders are $15 \times 1.08^{12} = 15 \times 2.518 = 37.8$ million, and the monthly bill grows from $485,000 to $1.16 million.
- Elasticity is the swing divided by the 40% input range: an elasticity of 0.64 means a 10% change in the maps price changes the total by 6.4%.
- The asserts test two invariants: with zero growth the forecast is twelve identical months, and the top-ranked input is a volume or routing driver.

WORKED EXAMPLE

Worked example — What the tornado chart tells the design review.

1. Base forecast: $9.62 million over 12 months.
2. Volume inputs (starting orders, growth) have the largest swings, $3.66 million and $2.01 million, but they are business outcomes, not design choices. They belong in the budget conversation with finance.
3. The largest *design-controllable* inputs are routing calls per order and routing price, each with elasticity 0.64 and a swing of $2.46 million. Cutting calls from 4 to 2 per order (estimate the delivery-time quote from a precomputed zone grid and call the provider only at dispatch) saves half of the routing line: about $0.5 \times 0.020 \times 15 \times 10^6 \times 1.08 \approx \$162,000$ in month 1, and $3.1 million over the year.
4. Cloud variable cost per order has elasticity 0.12: a heroic 20% infrastructure optimization moves the total by less than 5%.

Interpretation. Sensitivity analysis decides where engineering effort pays. Here it points to the routing integration, not the Kubernetes fleet. **Engineering implication.** Put the tornado ranking in the design document; re-run it when prices or volumes change, because the ranking, not the point forecast, is what drives the roadmap.

WARNING / TRADE-OFF

Warning — Forecasts are ranges. One-at-a-time sensitivity ignores interactions, such as faster growth raising the routing contract's tier. Report a low, base and high scenario, and compare actuals with the forecast monthly; a forecast that is never checked teaches nothing.

51.9 Build versus buy versus managed

51.9.1 Total cost of ownership

DEFINITION

Definition — Total cost of ownership (TCO). The **total cost of ownership** of an option is every cost it causes over a stated horizon: infrastructure, licences and service fees, the engineering time to build, operate, upgrade and be on call for it, migration in and out, and the expected cost of its failures. **Build** means writing and running your own; **self-host** means running open-source software yourself; **managed** means paying a provider to run it; **buy** means purchasing a finished product or SaaS.

Engineering time is the line most often left out, because it is not on the cloud bill. A senior engineer's loaded cost (salary, benefits, overhead) is commonly a six-figure annual amount; one full-time equivalent (FTE) spent operating a system can outweigh its infrastructure.

FORMULA

Monthly TCO and the build-versus-managed crossover

$$TCO = I + L + E \cdot w + \frac{M_{\text{in}}}{T} + R \qquad k^{*} = \frac{(E_s - E_m)\,w + (L_s - L_m)}{i_m - i_s}$$

Symbol	Meaning	Units
I	Infrastructure cost (compute, storage, network)	$/month
L	Licences, support and provider fees not in I	$/month
E	Engineering effort to operate, upgrade and be on call	FTE
w	Loaded cost per FTE	$/FTE-month
M_{in}	One-off migration and build cost, amortized over horizon T	$
T	Horizon	months
R	Expected monthly cost of incidents (probability × impact)	$/month
i_s, i_m	Variable infrastructure cost per unit of scale, self-hosted and managed	$/month per unit
k^{*}	Scale (multiple of today) above which self-hosting is cheaper, if $i_m > i_s$	dimensionless

WORKED EXAMPLE

Worked example — Self-hosted Kafka versus a managed Kafka service for QuickBite's event stream. Workload: 50 MB/s produced, replication factor 3, 7-day retention, consumers using rack-aware follower fetching. Prices are illustrative (as of 2026), not any vendor's price list. The managed offering is assumed not to bill replication traffic between its brokers (some do not; check yours). Loaded engineering cost $w = \$20,000$ per FTE-month. Month = 730 hours = 2.628 million s.

Storage, both options: $50\ \text{MB/s} \times 604,800\ \text{s} = 30.24$ TB per copy; × 3 copies = 90.72 TB; provisioned at 70% fill = 129.6 TB.

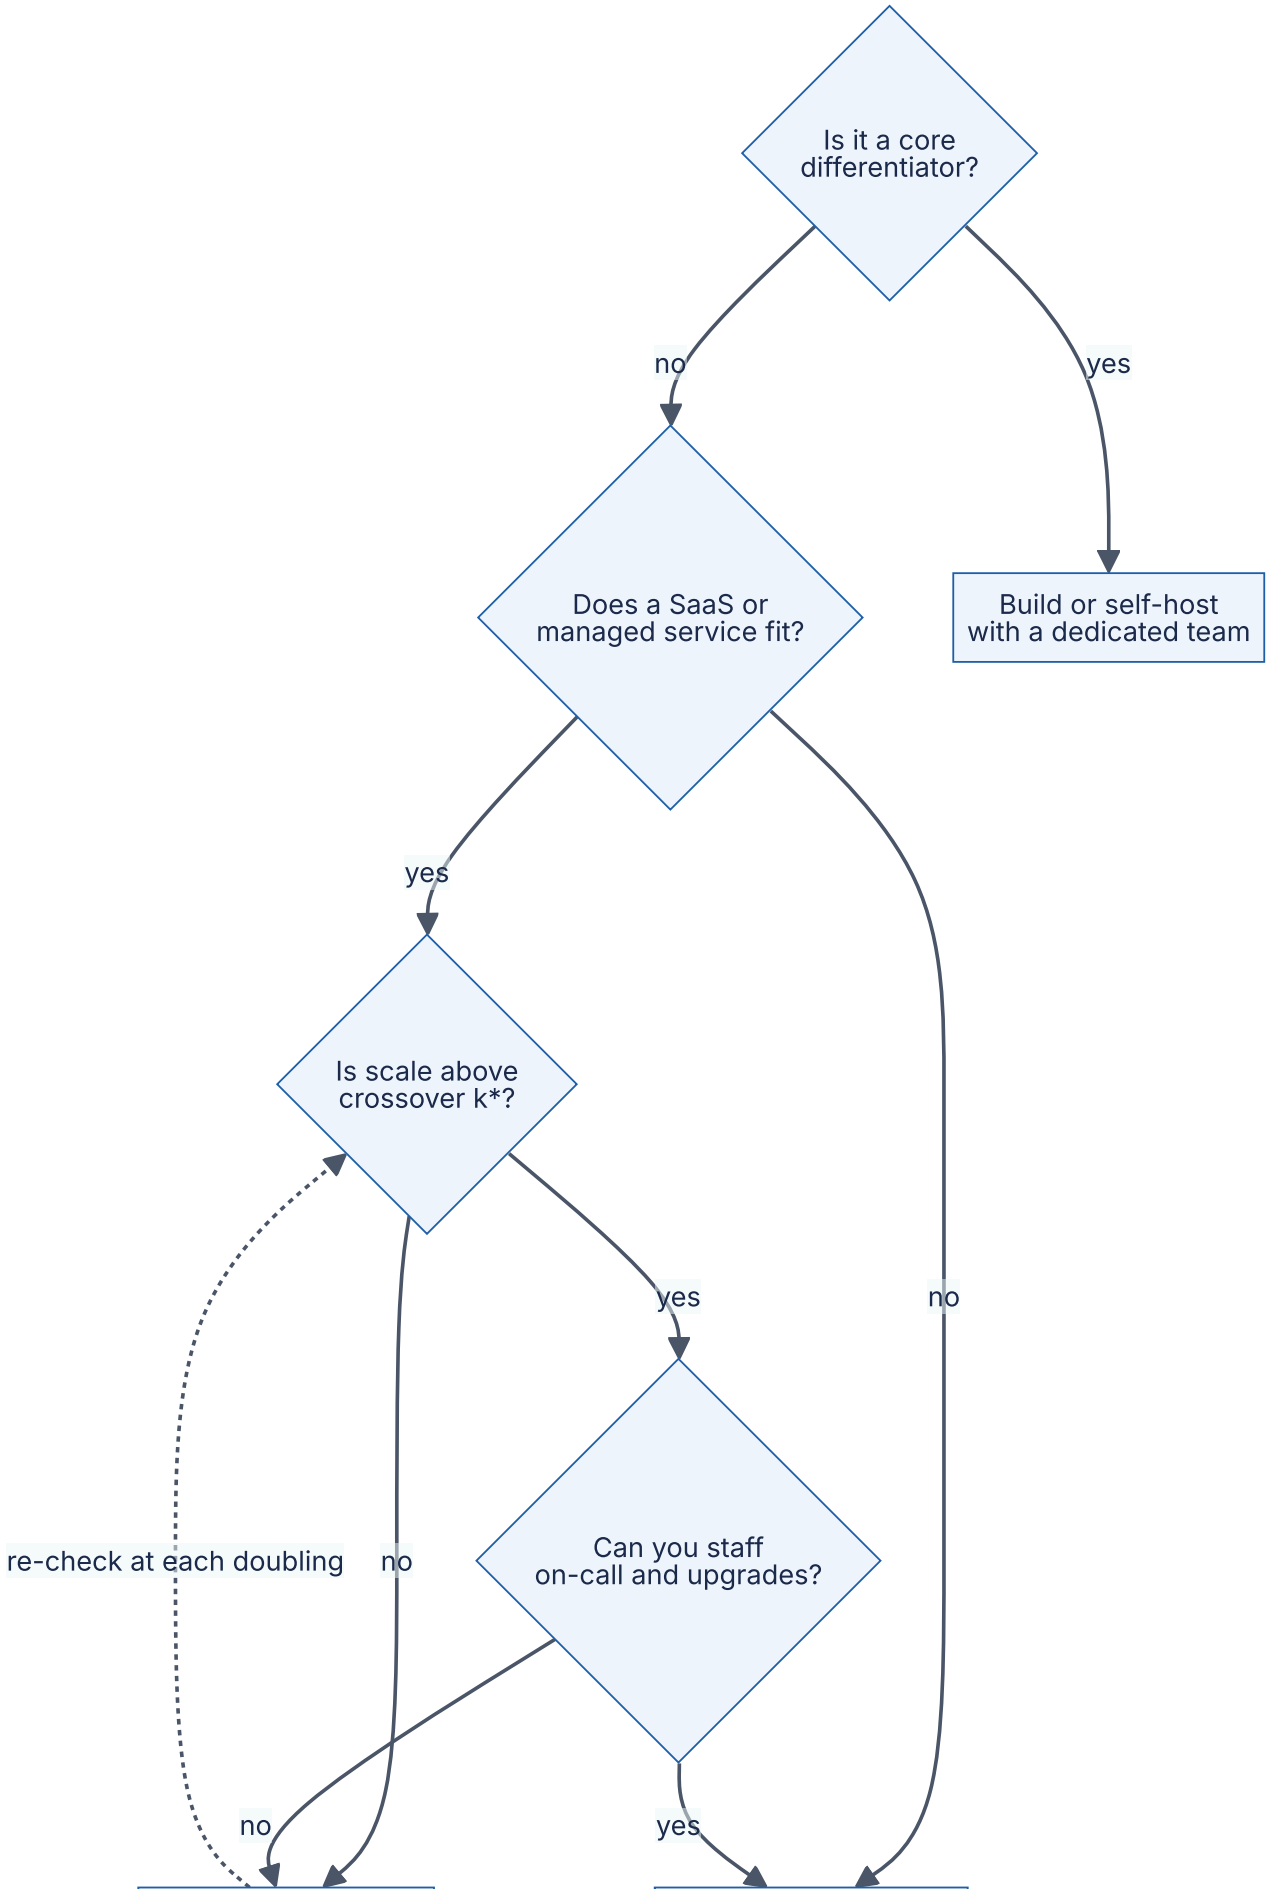
Table 51.9 — Monthly TCO, self-hosted versus managed Kafka (illustrative).

Line	Self-hosted, 50 MB/s	Managed, 50 MB/s	Self-hosted, 500 MB/s	Managed, 500 MB/s
Brokers (6 or 60 at $0.40/h self, $0.84/h managed)	$1,752	$3,679	$17,520	$36,792
Storage (129.6 or 1,296 TB at $0.08 or $0.15/GB-month)	$10,368	$19,440	$103,680	$194,400
Cross-zone transfer at $0.02/GB	$7,008	$1,752	$70,080	$17,520
Engineering (1.0 or 1.5 FTE self; 0.25 FTE managed)	$20,000	$5,000	$30,000	$5,000
Tooling	$500	$0	$1,000	$0
Total	**$39,628**	**$29,871**	**$222,280**	**$253,712**

1. Brokers: $6 \times 0.40 \times 730 = \$1,752$ self-hosted; $6 \times 0.84 \times 730 = \$3,679$ managed. Storage: $129,600\ \text{GB} \times 0.08 = \$10,368$; $\times 0.15 = \$19,440$.
2. Cross-zone, self-hosted: replication to two other-zone followers is 100 MB/s, plus two thirds of producer traffic, 33.3 MB/s; $133.3\ \text{MB/s} \times 2.628 \times 10^6\ \text{s} = 350.4$ TB; $\times \$0.02 = \$7,008$. Managed bills only the producer share: 87.6 TB, $1,752.
3. At 50 MB/s managed is cheaper by $9,757 a month (25%), because of engineering time and unbilled replication.
4. Variable infrastructure per unit of scale: $i_s = 1,752 + 10,368 + 7,008 = \$19,128$; $i_m = 3,679 + 19,440 + 1,752 = \$24,871$. Crossover with today's staffing: $k^* = [(1.0 - 0.25) \times 20,000 + 500]/(24,871 - 19,128) = 15,500/5,743 = 2.7$, about 135 MB/s.
5. At 500 MB/s, self-hosting is cheaper by $31,432 a month (12%) even with 1.5 FTE.

> **Interpretation.** Managed wins while people dominate; self-hosting wins once the provider's markup on infrastructure exceeds the team's cost, here at less than three times today's volume. **Engineering implication.** Compute k^* before choosing, include migration cost (M_{in}) and incident risk (R), which favor whichever option you already run, and revisit the decision at each doubling. The Dropbox case (§51.3.3) is this crossover at very large scale.

Figure 51.8 — A build, self-host, managed or buy decision path.



Is it a core differentiator?
no
yes
Build or self-host with a dedicated team
Does a SaaS or managed service fit?
yes
no
Is scale above crossover k*?
yes
no
re-check at each doubling
no
Can you staff on-call and upgrades?
no
yes

Reading the diagram. Diamonds are decisions, rectangles outcomes. Differentiators justify building; commodity capabilities go to managed services unless scale passes the crossover and operations can be staffed. The dotted edge is the periodic review. Failure points: building commodity infrastructure because it is interesting, and keeping a managed service long after its markup exceeds a team's cost.

51.10 Sustainable computing: energy and carbon basics

51.10.1 Power usage effectiveness and water usage effectiveness

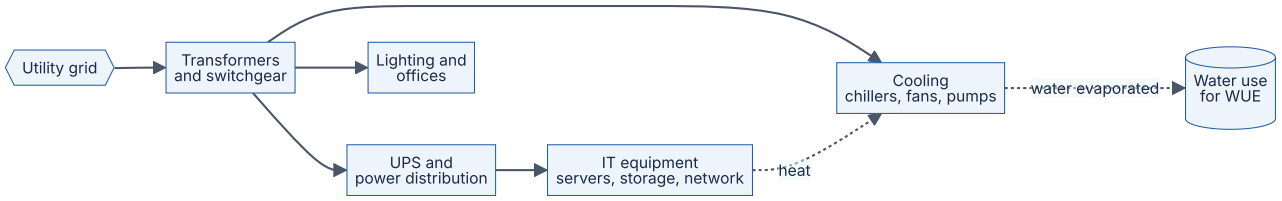
DEFINITION

Definition — PUE and WUE. Power usage effectiveness (PUE) is the ratio of total energy entering a datacenter facility to the energy delivered to its IT equipment (servers, storage, network) over a period, normally a year. An ideal facility has PUE 1.0. **Water usage effectiveness (WUE)** is the annual site water used for cooling and humidification divided by IT equipment energy, in liters per kWh. Both metrics were defined by The Green Grid [Avelar et al. 2012; The Green Grid 2011]; PUE is also standardized as ISO/IEC 30134-2.

First-principles explanation

A datacenter is a building that turns electricity into computation and heat. Some electricity never reaches a server: it is lost converting voltages in transformers and uninterruptible power supplies (UPSs), or spent on cooling the heat the servers make. PUE asks how much the building charges on top of the IT load. A PUE of 1.5 means every kWh of computing costs an extra half kWh of overhead.

Figure 51.9 — Energy flow in a datacenter and the PUE boundary.



Reading the diagram. Grid electricity (hexagon) splits into the path through UPS and distribution to IT equipment, the PUE denominator, and parallel paths to cooling and building loads; everything entering is the numerator. Dotted arrows are physical side effects: IT heat that cooling removes, and evaporated water, the WUE numerator. Every conversion loses energy, and cooling capacity caps the IT power a hall can host.

Efficiency comes from fewer conversions, free-air cooling and warmer allowed inlet temperatures.

FORMULA

PUE, WUE and operational carbon

$$PUE = \frac{E_{\text{facility}}}{E_{\text{IT}}} \qquad WUE = \frac{V_{\text{water}}}{E_{\text{IT}}} \qquad C_{\text{op}} = E_{\text{IT}} \times PUE \times I$$

Symbol	Meaning	Units
E_{facility}	Total facility energy over the period	kWh
E_{IT}	Energy consumed by IT equipment	kWh
V_{water}	Site water used for cooling and humidification	liters
I	Carbon intensity of the electricity used	gCO_2e/kWh
C_{op}	Operational carbon emissions	gCO_2e

WORKED EXAMPLE

Worked example — PUE, WUE and what overhead costs. A facility draws 13.0 GWh in a year; its IT equipment uses 10.0 GWh; cooling evaporates 18,000 m^3 of water. Electricity: $0.10/kWh and 400 gCO_2e/kWh (illustrative).

1. $PUE = 13.0/10.0 = 1.30$. Overhead energy: 3.0 GWh, costing $300,000 and emitting $3.0 \times 10^6 \times 400\ \text{g} = 1,200\ tCO_2e$ a year.
2. $WUE = 18,000,000\ \text{L}/10,000,000\ \text{kWh} = 1.8\ \text{L/kWh}$.
3. At PUE 1.58 (near an industry survey average), overhead would be $0.58 \times 10 = 5.8$ GWh; at 1.10 (a hyperscale fleet level), 1.0 GWh. The difference, 4.8 GWh, is $480,000 and 1,920 tCO_2e a year for the same computing.

Interpretation. Facility efficiency multiplies everything above it. **Engineering implication.** When you choose a region or colocation provider, ask for annual PUE and WUE (not a design-point or best-month figure). A cooling technique that improves PUE by evaporating water may worsen WUE, a real trade-off in water-stressed regions.

INDUSTRY EXAMPLE

Reported datacenter PUE. Google reports a fleet-wide trailing-twelve-month PUE of about 1.09 for 2024 and publishes quarterly figures with its measurement boundaries. Uptime Institute's annual surveys reported average PUE of about 1.58 in 2023 and about 1.56 for respondents' largest facility in 2024, a figure that has been roughly flat for several years. Self-reported, operator-defined boundaries mean the figures are indicative rather than strictly comparable. *Evidence: Primary* — [Google: Data Center Efficiency; Uptime Institute 2024]

PUE measures building overhead, not useful work: an idle server at PUE 1.1 wastes more than a busy one at 1.4 Barroso et al. 2018.

51.10.2 Operational and embodied carbon, and the three scopes

Operational carbon comes from the electricity a system uses while running. **Embodied carbon** is emitted manufacturing, transporting and disposing of the hardware: chips, servers, storage, network gear and the building. As grids get cleaner, embodied carbon becomes a larger share of the total, which makes keeping hardware busy and in service longer more important.

The **GHG Protocol** classifies an organization's emissions into three scopes [GHG Protocol 2004; GHG Protocol 2011; GHG Protocol 2015]:

Table 51.10 — Scopes 1, 2 and 3 for a company running on its own datacenters versus the public cloud.

Scope	Definition	Own datacenter	Cloud customer
Scope 1	Direct emissions from owned sources	Diesel backup generators, refrigerant leaks	Usually none for IT
Scope 2	Indirect emissions from purchased electricity, heat, cooling	Datacenter electricity	Office electricity only
Scope 3	All other value-chain emissions, upstream and downstream	Server manufacturing, construction, travel	Cloud usage (the provider's Scopes 1 and 2 plus its share of embodied), purchased hardware

Scope 2 can be reported two ways. **Location-based** accounting uses the average intensity of the grid where the electricity was consumed. **Market-based** accounting uses the contractual instruments a company buys, such as renewable energy certificates and power purchase agreements [GHG Protocol 2015]. The two can differ greatly for the same datacenter, so always say which one a number uses.

51.10.3 Grid carbon intensity varies by place and hour

Carbon intensity *I* is the gCO_2e emitted per kWh generated, and it varies by an order of magnitude. Grids dominated by hydro, nuclear or wind can average under about 100 gCO_2e/kWh; grids dominated by coal can exceed 600 (illustrative ranges, as of 2026). Within one grid, intensity also varies by hour: on a sunny afternoon solar can cut it substantially, and it rises again in the evening peak when gas plants ramp up. **Average** intensity describes the generation mix; **marginal** intensity describes the plant that responds to one more kWh of demand, which is what a load shift actually changes. The two can differ, and marginal estimates are model outputs with real uncertainty.

51.11 Carbon-aware architecture

51.11.1 Utilization is the biggest lever

Barroso and Hölzle observed that servers spend most of their time at 10–50% utilization, where they are least energy-efficient, because an idle server still drew a large fraction of its peak power; they called for **energy-proportional** hardware whose power scales with work [Barroso and Hölzle 2007; Barroso et al. 2018]. Hardware has improved, but idle power is still far from zero, so energy per unit of work falls steeply as utilization rises.

FORMULA

Linear server power model and energy per unit of work

$$P(u) = P_{\text{idle}} + (P_{\text{peak}} - P_{\text{idle}})\,u \qquad e(u) = \frac{P(u)}{u\,X_{\max}}$$

Symbol	Meaning	Units
$P(u)$	Server power at utilization u	W
$P_{\text{idle}}, P_{\text{peak}}$	Power at idle and at full load	W
u	CPU utilization	fraction
$X_{\max}$	Throughput at full load	requests/s
$e(u)$	Energy per request	J/request

WORKED EXAMPLE

Worked example — Consolidating a fleet. 100 servers run at 10% utilization; P_{idle} = 200 W, P_{peak} = 400 W (illustrative).

1. Today: $P(0.1) = 200 + 200 \times 0.1 = 220$ W each, 22.0 kW in total.
2. The work is $100 \times 0.1 = 10$ server-equivalents. On 13 servers, $u = 10/13 = 0.77$ and $P = 200 + 200 \times 0.77 = 354$ W, so 4.6 kW in total.
3. Energy falls by $1 - 4.6/22.0 = 79\%$; energy per request falls in the same ratio. Embodied carbon falls too, because 87 servers need not be bought.

Interpretation. Packing work onto fewer, busier machines saves more energy than almost any code optimization. **Engineering implication.** Autoscaling, bin packing (§46.7), batch work filling the troughs (§46.5.4) and multi-tenancy (§47.3.2) are sustainability measures as much as cost measures. Keep the utilization ceiling that latency needs (§18.11.2), but no lower.

Efficient code and hardware come next: fewer cycles and bytes per unit of work, processors with better measured performance per watt, and longer hardware lifetimes that spread embodied carbon [AWS Well-Architected: Sustainability Pillar].

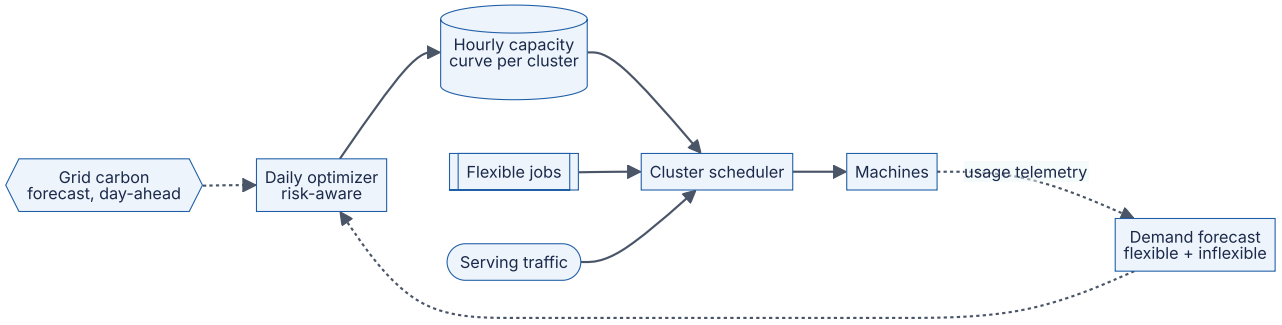
51.11.2 Temporal and spatial load shifting

Carbon-aware computing runs flexible work when and where electricity is cleaner. **Temporal shifting** delays work to lower-carbon hours in the same place; **spatial shifting** moves work to a cleaner region. Only flexible work qualifies: batch processing, model training, backups, video transcoding, report generation. User-facing requests, latency-critical work and data bound to a jurisdiction stay put.

INDUSTRY EXAMPLE

Google's carbon-intelligent computing. Google described a system that uses day-ahead forecasts of grid carbon intensity and of its own flexible and inflexible demand to compute, for each datacenter cluster, a **virtual capacity curve (VCC)**: an hourly limit on the resources available to temporally flexible workloads that preserves the total daily capacity they need. The cluster scheduler then admits flexible work against the curve, so it runs preferentially in cleaner hours; operational data showed the curves restricting capacity in carbon-intensive hours [Radovanović et al. 2022; Radovanović 2020]. In 2021 Google extended the approach to move flexible work between datacenters toward locations with more carbon-free energy [Koningstein 2021]. *Evidence: Primary* — [Radovanović et al. 2022; Koningstein 2021]

Figure 51.10 — Carbon-intelligent scheduling with virtual capacity curves, after the published design.



Reading the diagram. Daily forecasts arrive asynchronously (dotted) from an external carbon source and internal demand prediction. A risk-aware optimizer turns them into an hourly capacity curve per cluster, which the scheduler reads. Serving traffic is never limited; flexible jobs are admitted up to the curve, so they drain in cleaner hours, and telemetry feeds the next forecast. Failure point: a poor forecast can delay jobs, so the curve preserves daily capacity. The design scales because it changes one input to an existing scheduler.

FORMULA

Carbon saved by shifting a job

$$\Delta C = E\,(I_{\text{now}} - I_{\text{shift}}) - E_{\text{move}}\,I_{\text{now}}$$

Symbol	Meaning	Units
E	Facility energy of the job (IT energy × PUE)	kWh
$I_{\text{now}}, I_{\text{shift}}$	Carbon intensity at the original and the shifted time or place	gCO_2e/kWh
E_{move}	Extra energy to move data to another region (zero for temporal shifting)	kWh
ΔC	Emissions avoided per run	gCO_2e

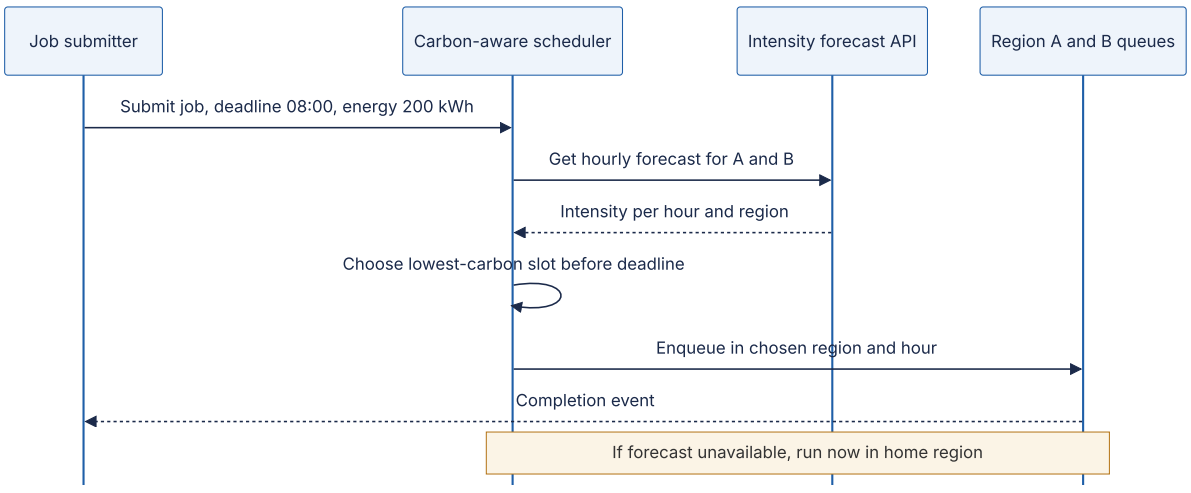
WORKED EXAMPLE

Worked example — Shifting QuickBite's nightly analytics job. The job uses $E = 200$ kWh per run and today starts at 18:00 in region A, where intensity is 450 gCO_2e/kWh. At 13:00 solar lowers it to 250. Region B, on a hydro-dominated grid, averages 50, but the job must copy 5 TB there; assume network energy of 0.005 kWh/GB, a deliberately rough assumption (published estimates vary widely). Intensities are illustrative.

1. Today: $200 \times 450 = 90,000$ g $= 90$ kg per run; $90 \times 365 = 32.9$ tCO_2e a year.
2. Temporal shift to 13:00: $200 \times 250 = 50$ kg; $\Delta C = 40$ kg per run (44%); 18.3 t a year instead of 32.9 t.
3. Spatial shift to region B: computing $200 \times 50 = 10$ kg; moving data $5,000 \times 0.005 = 25$ kWh, $25 \times 450 = 11.25$ kg; total 21.25 kg per run, saving 68.75 kg (76%); 7.8 t a year instead of 32.9 t.
4. Cost check: copying 5 TB at an illustrative $0.02/GB inter-region rate costs $100 per run, $36,500 a year, unless the data is already replicated to region B.

Interpretation. Moving to a clean region saves the most carbon here, but the data movement is half its remaining footprint and adds real cost; the temporal shift is free. **Engineering implication.** Shift in time first; shift in space when the data already lives in both places or the job is compute-heavy relative to its data. Use marginal intensity forecasts where available, and treat results as estimates.

Figure 51.11 — A carbon-aware batch scheduler for QuickBite.



Reading the diagram. The submitter synchronously sends a job with deadline and energy estimate. The scheduler queries the external forecast per region, picks the lowest-emission slot that meets the deadline and residency rules, and enqueues it; completion is reported asynchronously. The note is the failure rule: without a forecast, run now in the home region, because carbon optimization must never break a deadline.

51.11.3 The Software Carbon Intensity score

The Green Software Foundation's **Software Carbon Intensity (SCI)** specification, published as ISO/IEC 21031:2024, defines a *rate* of emissions per functional unit, so that teams can track improvements as the product grows [GSF SCI 2024]. Market-based instruments (offsets, renewable certificates) cannot reduce an SCI score; only using less energy, cleaner energy or less hardware can.

FORMULA

Software Carbon Intensity

$$SCI = \frac{(E \times I) + M}{R} \qquad M = TE \times \frac{TR}{EL} \times \frac{RR}{ToR}$$

Symbol	Meaning	Units
E	Energy consumed by the software system, including datacenter overhead	kWh
I	Location-based carbon intensity of that electricity	gCO_2e/kWh
M	Embodied emissions share of the hardware used	gCO_2e
TE	Total embodied emissions of the hardware	gCO_2e
TR	Time the hardware is reserved for the software	hours
EL	Expected lifespan of the hardware	hours
RR, ToR	Resources reserved, total resources (for example vCPUs)	vCPUs
R	Functional unit (per order, per user, per API call)	units

WORKED EXAMPLE

Worked example — SCI of QuickBite's order API, per order. One month: 30 VMs of 8 vCPUs (240 vCPUs) average 6 W per vCPU; PUE 1.15; $I = 380$ gCO_2e/kWh; each 64-vCPU host has $TE = 1,500$ $kgCO_2e$ embodied over a 4-year life (35,040 h); 15 million orders. All inputs illustrative.

1. $E = 240 \times 6\ W \times 720\ h = 1,036.8$ kWh; with PUE: $1,036.8 \times 1.15 = 1,192.3$ kWh.
2. Operational: $1,192.3 \times 380 = 453,082$ g ≈ 453 kg.
3. Embodied per VM: $1.5 \times 10^6 \times (720/35,040) \times (8/64) = 3,853$ g; for 30 VMs, $M = 115,582$ g ≈ 116 kg.
4. $SCI = (453,082 + 115,582)/15 \times 10^6 = 0.0379$ gCO_2e, about 38 mg per order. Embodied is 20% of it.

Interpretation. The score is per order, so it falls when efficiency rises and stays flat when the business simply grows. **Engineering implication.** Report SCI per functional unit next to cost per unit; raising average utilization from 30% to 60% would cut both E per order and M per order.

51.12 Measuring and reporting

Cloud customers cannot meter the electricity of a shared server, so carbon figures for cloud workloads are estimates. Provider tools (the AWS Customer Carbon Footprint Tool, Google Cloud Carbon Footprint, and Microsoft's Emissions Impact Dashboard for Azure) report emissions per account, service and region from the provider's own energy and hardware data. The open-source **Cloud Carbon Footprint** tool estimates from billing data, multiplying usage by per-service energy coefficients, PUE and grid intensity, and adds embodied emissions with the SCI method [Cloud Carbon Footprint].

Table 51.11 — What carbon estimates can and cannot tell you.

Limitation	Why it matters	Mitigation
Methodologies differ (location- vs market-based, scopes included, embodied or not)	Numbers from two tools are not comparable	State the method next to every number
Coarse granularity (monthly, per service, per region)	Cannot see the effect of one deployment	Use energy proxies (vCPU-hours, GB) for engineering feedback
Reporting lag of weeks to months	Too slow for operational alerts	Track proxies daily, carbon monthly
Average, not marginal, intensity	May misjudge the effect of shifting	Use marginal forecasts for scheduling decisions
Embodied data from few life-cycle assessments	Large uncertainty	Report ranges; prefer relative trends

51.13 Trade-offs: cost versus reliability versus latency versus carbon

Most decisions in this chapter move several properties at once.

Table 51.12 — Decision table for common cost and carbon levers.

Lever	Cost	Reliability	Latency	Carbon	Choose when
Higher utilization targets	Lower	Less headroom for failures	Higher queueing near saturation	Lower	Load is predictable; latency SLO has slack
Multi-region active–active	Higher (2× capacity, replication)	Higher	Lower for distant users	Higher	Availability or locality requires it (Chapter 44)
Spot for batch	Much lower	Interruptions	Unpredictable completion	Lower (uses idle capacity)	Work is checkpointed and deadline-tolerant
Temporal carbon shifting	Neutral or lower	Neutral	Delayed completion	Lower	Jobs have hours of slack
Spatial carbon shifting	Higher if data must move	Neutral	Higher for moved work	Lower	Data already replicated; compute-heavy jobs
Aggressive log sampling	Lower	Harder diagnosis	Neutral	Lower	Errors are always kept (§40.4.4)
Arm or accelerator migration	Usually lower	Migration risk	Workload-dependent	Usually lower	Benchmarks confirm the gain
Managed service over self-host	Lower at small scale	Usually higher	Neutral	Provider's efficiency	Below the TCO crossover (§51.9)
Longer hardware life	Lower capital	Higher failure rate late in life	Older, slower hardware	Lower embodied	Performance per watt not much worse

Three principles sit behind the table. **Reliability is bought with redundancy, which is idle capacity**: set availability targets from user need (§39.6), not habit. **Latency is bought with headroom**: choose the highest utilization that still meets the SLO. **Cost and carbon usually agree**, because waste costs both, so FinOps and sustainability can share one pipeline; where they diverge (spatial shifting, cheap but dirty regions), set explicit weights.

51.14 Summary and revision notes

SUMMARY

- Cost is an architectural property: structure (hops, copies, idle capacity, per-call fees) sets it. State cost requirements per business unit and compare designs across their cost curves, noting crossovers (§51.3).
- Unit cost $u = F/N + v$ falls toward the variable floor as volume grows. For QuickBite, third-party routing calls dominate technology cost, and one per-listing dependency would turn a \$1.86 margin into −\$10.12 (§51.4).
- FinOps runs a continuous inform–optimize–operate loop across engineering, finance, product, procurement and leadership. Start with showback, enforce tags at creation, allocate shared cost by usage, and alert on anomalies scaled by business volume (§51.5).
- Commit up to the d-quantile of hourly usage, not the floor and not the peak. Utilization below 100% at the optimum is expected. Price spot including rework (§51.6).
- Engineering levers reduce the units you need: rightsizing, autoscaling, Arm (benchmark the vendor claims), tiering and retention, CDN and zone-local traffic, caches before replicas, and sampled observability. Delete and rightsize before committing (§51.7).
- Put a driver-based forecast and a sensitivity ranking in every design document. The ranking shows where engineering effort pays (§51.8).
- TCO includes engineering time, migration and risk. Managed services win while people dominate; self-hosting wins beyond the crossover scale k^* (§51.9).
- PUE = facility energy ÷ IT energy; WUE = water ÷ IT energy; operational carbon = IT energy × PUE × intensity. Embodied carbon and Scope 3 matter more as grids decarbonize. Always state location- or market-based (§51.10).
- Utilization is the largest carbon lever. Shift flexible work in time first, and in space when data movement is small. SCI = $((E \times I) + M)/R$ tracks carbon per functional unit (§51.11).
- Cloud carbon figures are estimates with stated methods. Use them for trends and engineering proxies for daily feedback (§51.12).
- Cost and carbon usually agree; reliability and latency cost headroom. Make the weights explicit (§51.13).

51.15 Knowledge checkpoint

1. Why is cost per request a poor unit cost for QuickBite?
2. Two designs: $F_A = \$1,000$, $v_A = \$0.001$; $F_B = \$0$, $v_B = \$0.003$ per unit. Find the crossover.
3. Name the three FinOps phases and one activity in each.

4. When should an organization prefer showback to chargeback?
5. Why should anomaly detection scale expected cost by business volume?
6. With a 55% discount, at which percentile of hourly usage should you commit?
7. Why is 100% commitment utilization usually a sign of under-commitment?
8. Spot is 75% cheaper; interruptions cause 20% rework. What is the effective discount?
9. A facility uses 6.6 GWh with 5.5 GWh of IT load. What is its PUE?
10. Distinguish location-based from market-based Scope 2 accounting.
11. Why does consolidating work onto fewer servers save energy?
12. Why can renewable certificates not lower an SCI score?

Answers

1. Requests are an implementation detail: a client change can raise requests per order and lower cost per request while cost per order rises.
2. $N^* = 1,000/(0.003 - 0.001) = 500,000$ units per period.
3. Inform (allocation, showback, forecasting); optimize (rightsizing, commitments, re-design); operate (budgets, policies, review cadence).
4. When allocation is not yet trusted or the platform is being adopted; chargeback on disputed data produces arguments instead of change.
5. So that legitimate growth, such as a promotion, does not trigger alerts, while real waste at constant volume does.
6. The 55th percentile ($c^* = Q_x(0.55)$).
7. A marginal extra commitment would still be used in most hours, and so would still pay for itself; the optimum leaves some commitment idle in quiet hours.
8. Effective price $0.25 \times 1.2 = 0.30$ of on-demand, a 70% discount.
9. $6.6/5.5 = 1.20$.
10. Location-based uses the average intensity of the local grid; market-based uses contractual instruments the company purchases.
11. Idle power is a large share of peak, so energy per unit of work falls steeply as utilization rises, and fewer servers also mean less embodied carbon.
12. SCI measures emissions from the energy and hardware the software actually uses, at location-based intensity; market-based neutralizations are excluded by design.

51.16 Interview questions

Basic

Q1. How would you include cost in a system design interview? **Answer.** State a unit-cost target (for example, per order). Estimate the main cost lines from the capacity estimate and identify the dominant one, often a paid API, storage or egress. Compare alternatives

by cost curve, and name the crossover where the design would change. Mention purchasing (commit to the base, spot for batch) only after the design levers.

Q2. What is the difference between coverage and utilization of commitments? **Answer.** Coverage is the share of usage billed at committed rates; utilization is the share of purchased commitment used. Raising commitment raises coverage and lowers utilization. The cost-minimizing level is the discount quantile of hourly usage, where utilization is below 100%.

Intermediate

Q3. Your monthly bill rose 40% while traffic rose 10%. How do you investigate? **Answer.** Compare unit cost per service and line item month over month. Check untagged new resources, cross-zone and egress growth, observability volume, expired commitments (falling coverage) and third-party charges; correlate the start date with deployments. Then add volume-scaled anomaly alerts.

Q4. Should a 20-engineer startup run Kafka itself or use a managed service? **Answer.** Compute TCO with engineering time. At modest throughput, a managed service's markup is smaller than even one FTE of operations, and managed reliability is usually better. Recompute the crossover at each doubling, and watch for cross-zone replication charges and storage markup, which decide the comparison at scale.

Advanced

Q5. Design carbon-aware scheduling for a company's batch platform across three regions. **Answer.** Tag jobs with deadline, energy estimate, data location and residency. Use day-ahead marginal intensity forecasts per region; pick the lowest-emission slot meeting the deadline, counting data-movement energy and cost. Cap flexible capacity per cluster-hour, as virtual capacity curves do, instead of scheduling jobs one by one. Run immediately when forecasts fail, and report avoided emissions with the method stated.

Q6. Leadership wants a 30% cut in cloud cost within two quarters without harming SLOs. What is your plan? **Answer.** Quarter one: visibility (tag coverage, unit cost per service), waste removal (idle and non-production resources, storage hygiene, log sampling) and rightsizing from p95 data. Quarter two: fix the top unit-cost drivers (zone-local traffic, caching, paid-API calls), then commit at the discount quantile and move batch to spot. Check every change against SLO burn rates and leave failure headroom alone.

51.17 Practical exercises

1. Run the commitment program of §51.6 with discounts of 30%, 50% and 70%. Plot the optimal commitment level against the discount and explain the shape.

2. Export one month of a cloud bill (or a public sample) and compute tagging coverage and the top five line items. Build a unit cost for one service.
3. Extend the forecast program of §51.8 with a routing price that falls 20% when monthly calls exceed 100 million. Re-run the sensitivity ranking.
4. Compute the SCI per request of a service you operate, stating every assumption, then recompute after raising its CPU utilization target.

51.18 Design challenges

1. **Cost-capped video platform.** Design a video-on-demand service with a cost requirement of $0.002 per minute streamed. Allocate the budget among CDN, origin storage, transcoding and observability, and identify the crossover at which you would build your own CDN caches (§21.10).
2. **Carbon-aware ML training.** A team trains models for 2,000 GPU-hours a week with a 72-hour deadline. Design temporal and spatial shifting across two regions, compute the emissions and cost of each option, and set the rules for data movement.
3. **FinOps for a 300-team platform.** Design tagging, allocation of shared Kubernetes clusters, showback dashboards, anomaly routing and the commitment purchasing process. Define the metrics that show the practice works.

51.20 Open verification items

- Radovanović et al.: confirm the journal volume, issue, pages and year (2022 online versus a 2023 issue) and the full author list; IEEE Xplore and arXiv were unreachable from the build environment.
- SCI: confirm whether ISO/IEC 21031:2024 specifies marginal or average location-based intensity, and the exact symbols in the embodied term. Secondary sources reuse “TR” for two quantities.
- Uptime Institute: the 1.58 (2023) and 1.56 (2024, largest facility) average PUE figures come from secondary summaries.
- Google 1.09 PUE: a 2024 trailing-twelve-month figure; confirm against the current efficiency page.
- Dropbox S-1: the $39.5 million and $35.1 million figures are confirmed only through press reports of the filing.
- AWS Graviton3 “up to 60% less energy”: the baseline (comparable x86 instances or Graviton2) is reported inconsistently.
- FinOps Foundation persona list and FOCUS version and release date (1.0 in 2024 assumed).
- The Green Grid WP#35 publication year (2011 assumed) and the URL of the 2020 Google blog post.

Part X — Traditional System Design Case Studies

Chapter 52 — Case Studies I: Foundational Services

> **Level:** 2–4 · **Track:** A (Traditional) · **Estimated reading time:** 10 h

The previous fifty-one chapters gave you parts: caches, queues, quorums, rate-limiting algorithms, consistent hashing, leader election. This chapter shows you how to put them together. Each of the seven designs here is small enough to sketch in an hour and appears often in interviews, yet each hides one genuinely hard problem. For the URL shortener it is generating short, unique, unguessable codes. For the rate limiter it is counting correctly across hundreds of nodes and several regions without adding latency. For the key-value store it is staying writable while machines fail. You will work each case through the same sixteen sections, with numbers, so the method becomes habit. Chapters 53–56 reuse the method on larger systems and refer back to §52.3.

The cases run roughly from easier to harder: two storage-and-lookup services (§52.4 URL shortener, §52.5 Pastebin), two control-plane services that other systems depend on (§52.6 rate limiter, §52.7 notification system), and three distributed-systems classics (§52.8 key-value store, §52.9 job scheduler, §52.10 web crawler).

52.1 Learning objectives

After this chapter you should be able to:

- Apply the sixteen-section case-study method (§52.3) to an unfamiliar design problem and pace it within a 45-minute interview.
- Turn a one-line product request into functional and numeric non-functional requirements, and derive peak request rates, storage, bandwidth, cache size and node counts with every assumption stated.
- Choose and defend a short-code generation scheme (counter ranges, hashing, random codes, Snowflake-style IDs) and size its keyspace.
- Separate blob storage from metadata, and design expiration (TTL) cleanup that keeps up with millions of deletions per day.
- Design a rate limiter as a shared service, deciding between centralized and local-plus-sync counting, atomic Redis scripts, multi-region budgets and fail-open or fail-closed behavior.
- Design a multi-channel notification pipeline with preferences, priorities, deduplication, provider failover and delivery tracking.

- Assemble a Dynamo-style key-value store end to end and explain how partitioning, quorums, version vectors, hinted handoff, anti-entropy and gossip fit together.
- Design a distributed job scheduler that fires millions of timers on time, executes each job effectively once, and runs dependency graphs.
- Design a polite, distributed web crawler with a prioritized URL frontier, robots.txt compliance and exact and near-duplicate detection.
- Identify the bottleneck, the dominant failure mode and what changes at 10× and 100× growth for each design.

52.2 Prerequisites

This chapter applies earlier material; it does not re-teach it. Review the sections listed for a case before you read it.

- **All cases:** capacity estimation, §2.11 (the average/peak and node-count formulas used throughout); availability arithmetic, §4.14; API design, §8.6 (REST) and §8.8 (gRPC); caching patterns and TTLs, §20.7–§20.8; SLOs, §39.6.
- **URL shortener (§52.4):** unique ID generation, §17.10; the birthday bound, §17.10.2; HTTP redirects and caching headers, §21.6; cache stampede and hot keys, §20.11, §20.15; Kafka partitions, §31.5.
- **Pastebin (§52.5):** object storage, §15.4; storage tiers and lifecycle policies, §15.9; presigned URLs, §15.8.2; authorization, §8.12; CDNs, §21.3.
- **Rate limiter (§52.6):** the algorithms in §22.4–§22.7; distributed rate limiting, §22.8; load shedding, §22.9; Redis internals, §20.6; multi-region systems, §44.3–§44.7.
- **Notification system (§52.7):** mobile push through APNs and FCM, §9.8; message queues and dead-letter queues, §30.4, §30.11; retries with backoff, §22.12; idempotency keys, §22.15.
- **Key-value store (§52.8):** LSM trees, §13.8; consistent hashing, §14.8; leaderless replication and quorums, §27.7–§27.9; failure detection, §27.10; anti-entropy, §27.13; version vectors, §24.11, §27.14; Merkle trees, §17.8.
- **Job scheduler (§52.9):** leader election, leases and fencing tokens, §26.5, §26.11, §26.13; delivery guarantees, §30.8; idempotency, §22.15; cluster scheduling (for contrast), §46.3.
- **Web crawler (§52.10):** DNS, §7.6; Bloom filters, §17.4; hash functions, §17.3; partitioning, §14.6.

52.3 How to use these case studies

Every case in Chapters 52–56 follows the same sixteen sections in the same order. The fixed order is deliberate: it is the order in which uncertainty is removed. You cannot

choose a database before you know the access pattern, and you cannot know the access pattern before you know the requirements and the numbers.

Table 52.1 — The sixteen-section method.

Phase	Sections	Question each phase answers	Interview minutes (of 45)
Scope	1 Problem statement · 2 Functional requirements · 3 Non-functional requirements	What exactly are we building, and how good must it be, in numbers?	5–7
Size	4 Capacity estimation	How big is it: requests per second at peak, bytes per year, bytes per second, memory, nodes?	4–5
Contract	5 API design · 6 Data model	What do clients call, and what is stored under which key?	5–6
Shape	7 High-level architecture	Which components exist and how do requests flow between them?	5–7
Depth	8 Detailed component design · 9 Data flow	How do the two or three hardest parts actually work?	12–15
Stress	10 Bottlenecks · 11 Failure scenarios · 12 Scaling strategy	What saturates first, what breaks, and what changes at 10× and 100×?	5–7
Judgment	13 Trade-offs · 14 Alternative designs · 15 Interview discussion · 16 Production considerations	What did we give up, what else could work, and how is it run?	2–3 plus follow-ups

How to read a case. Read the problem statement and requirements, then close the book and spend 30–45 minutes producing your own design on paper. Only then read the rest. You learn far more from comparing your attempt with a worked answer than from reading the answer first (§3.4 on active recall). Each case emphasizes one distinctive hard problem, named in its problem statement; section 8 spends most of its words there. Treat the other components as standard parts and spend one sentence on each, as you would in an interview.

Conventions used in every case.

1. **Units.** Capacity estimates use decimal units: 1 KB = 10^3 bytes, 1 GB = 10^9 bytes, 1 TB = 10^{12} bytes. Network rates are in bits per second (1 Gbps = 125 MB/s).
2. **Peak rate.** We apply the peak formula of §2.11, $R_{peak} = \frac{D \times h}{3,600} \times b$, where D is the daily volume. Unless a case states otherwise, the busiest hour carries $h = 0.10$ of daily traf-

fic and the burst factor is $b = 2$, so peak $\approx 4.8\times$ the daily average. Cases with sharper peaks (scheduled jobs at the top of the hour, notification campaigns) derive their own.

3. **Node counts.** We use $N = \lceil R_{peak} / (c \times u) \rceil + N_{spare}$ from §2.11, with per-node capacity c stated as an assumption and target utilization $u = 0.6$ unless stated.
4. **Every number is recomputed.** Each `example` callout shows its arithmetic step by step; check it yourself, and change one assumption to see which conclusions move.
5. **Evidence labels.** The designs are teaching designs (*Evidence: Illustrative*). Where a company has *published* how its system works, the fact carries *Evidence: Primary* or *Secondary* with a citation. Never present a case's design as "how X does it".
6. **Cross-references instead of re-derivation.** When a case needs consistent hashing or the Bloom filter formula, it gives one or two sentences and points to the owning section.

How to practice. Use the 45-minute plan in section 15 of each case with a timer. Say requirements and numbers out loud before drawing anything; interviewers judge the reasoning as much as the boxes. After each attempt, list which failure scenarios from section 11 you missed, and repeat the case a week later (§3.4 on spaced repetition). Chapter 91 collects further practice questions with rubrics, and Chapter 89 is the full capacity-estimation handbook. For the data-system principles behind these designs, Kleppmann remains the standard companion [Kleppmann 2017]; Xu's interview guide walks through several of the same problems at a shallower depth and is useful as a second perspective [Xu 2020].

> INTERVIEW TIP
>
> **Interview tip — Name the hard problem early.** Within the first ten minutes, say which component is genuinely difficult and that you intend to spend most of the time there. "The interesting part of a URL shortener is generating codes that are short, unique and not enumerable; the redirect path is a cache lookup." Interviewers reward candidates who allocate time to where the risk is.

52.4 URL shortener

52.4.1 Problem statement

Design a public URL-shortening service. A user submits a long URL such as `https://example.com/articles/2026/11/a-very-long-path?utm_source=newsletter` and receives a short link such as `https://sho.rt/Ab3xK9q`. Anyone who opens the short link is redirected to the long URL. The owner of the link can see how many times it was clicked, when, and from where.

The service looks trivial: a hash map from short code to long URL. Four things make it a real design problem.

1. **ID generation (the distinctive hard problem).** Codes must be short (7 characters), unique across billions of links created on many servers at once, and not enumerable, so that nobody can walk the keyspace and harvest every link.
2. **Redirect latency.** Redirects outnumber creations about 100 to 1 and sit in front of somebody else's page load, so every millisecond is felt.
3. **Analytics write path.** Every redirect is also a write (a click event), which must never slow the redirect.
4. **Abuse.** Short links hide their destination, which makes them attractive for phishing and malware. A shortener that does not fight abuse gets its domain blocked by browsers and mail filters.

52.4.2 Functional requirements

- **Create.** `POST` a long URL; receive a 7-character code. Optional: a custom alias (`sho.rt/spring-sale`), an expiry time, and a title.
- **Redirect.** `GET /{code}` returns an HTTP redirect to the long URL, or 404 if the code does not exist, has expired or has been disabled.
- **Analytics.** Per link: total clicks, clicks per day, top referrers, top countries, and approximate unique visitors.
- **Manage.** List, disable and delete your links. Links are immutable: the destination cannot be edited (this keeps caching simple; §52.4.13 discusses relaxing it).
- **Abuse handling.** Reject known-malicious destinations at creation, re-check links later, and disable reported links quickly.

Out of scope: user sign-up and billing (assume an identity service, §8.11), QR codes and link-in-bio pages.

52.4.3 Non-functional requirements

Property	Target	Why this number
Redirect availability	99.99% per month (4.3 min of downtime)	A broken redirect breaks every page, email and printed poster that uses the link
Create availability	99.9% per month	Creation can retry; users tolerate a rare failure
Redirect latency	p99 ≤ 20 ms server-side within a region; p50 ≤ 5 ms	Redirects add a full round trip before the real page starts to load
Create latency	p99 ≤ 300 ms, including the malicious-URL check	Interactive, but not on anybody's critical path
Durability	Zero loss of acknowledged links (RPO = 0 within a region)	A lost mapping is a permanently broken link
Consistency	Read-your-writes: a link redirects everywhere within 1 s of creation; analytics may lag up to 5 min	Users test their new link immediately; dashboards can be slightly stale
Unpredictability	Knowing some codes must not reveal others	Prevents enumeration of private links

The 99.99% redirect target allows 4.3 minutes of downtime per month (§4.14), which already rules out any design in which a single database primary sits on the redirect path without a cache in front of it.

52.4.4 Capacity estimation

WORKED EXAMPLE

Worked example — URL shortener request rates.

Assumptions. 50 million links created per day; 100 redirects per link created (read:write = 100:1); busiest-hour share $h = 0.10$; burst factor $b = 2$ (§52.3).

1. Creates, average: $50 \times 10^6 / 86,400 = 579$ per second.
2. Creates, peak: $50 \times 10^6 \times 0.10 / 3,600 \times 2 = 2,778$ per second.
3. Redirects per day: $50 \times 10^6 \times 100 = 5 \times 10^9$.
4. Redirects, average: $5 \times 10^9 / 86,400 = 57,870$ RPS.
5. Redirects, peak: $5 \times 10^9 \times 0.10 / 3,600 \times 2 = 277,778$ RPS, about 280,000 RPS.

Interpretation. The system is a read-dominated lookup service with a moderate write rate. *Engineering implication.* Design the redirect path around caches; the create path is small enough that its main difficulty is correctness, not throughput.

WORKED EXAMPLE

Worked example — Storage, keyspace and bandwidth.

Assumptions. Links are kept 10 years. One stored link is 500 bytes: a 7-byte code, a long URL averaging 150 bytes, owner ID, timestamps, flags, plus index and storage-engine overhead. Three replicas. A redirect response (status line, `Location` header, other headers) is about 500 bytes. A click event is 200 bytes.

1. Links per year: $50 \times 10^6 \times 365 = 1.825 \times 10^{10}$ (18.25 billion). Over 10 years: 1.825×10^{11} (182.5 billion).
2. Storage per year: $1.825 \times 10^{10} \times 500\ \text{B} = 9.1\ \text{TB}$. Ten years with three replicas: $9.125 \times 10 \times 3 = 274\ \text{TB}$.
3. Keyspace for 7 base62 characters: $62^7 = 3.52 \times 10^{12}$. Ten years of links fill $1.825 \times 10^{11} / 3.52 \times 10^{12} = 5.2\%$ of it.
4. Redirect egress at peak: $277,778 \times 500\ \text{B} = 139\ \text{MB/s} = 1.11\ \text{Gbps}$.
5. Click events: $5 \times 10^9 \times 200\ \text{B} = 1.0\ \text{TB/day}$ raw; at peak $277,778 \times 200\ \text{B} = 56\ \text{MB/s}$ into the event log.

Interpretation. 274 TB is too large for one database node but modest for a partitioned key-value store. Analytics generates more bytes per day (1 TB) than links do (25 GB), so it needs its own storage path. *Engineering implication.* Partition the link store by code (§14.6), and keep raw clicks only briefly before rolling them up.

WORKED EXAMPLE

Worked example — Cache and redirect fleet.

Assumptions. 200 million distinct links are clicked on a given day; caching all of them at 500 bytes with a 2× overhead factor for the cache's own structures is affordable. One redirect node, serving from an in-process cache or Redis, handles $c = 10,000$ RPS; $u = 0.6$; three spare nodes. Target cache hit ratio 95%.

1. Daily working set: $200 \times 10^6 \times 500\ \text{B} \times 2 = 200\ \text{GB}$, which fits on a handful of cache nodes with 64 GB of memory each (§20.14).
2. Cache misses at peak: $277,778 \times 0.05 = 13,889$ reads/s reach the link store.
3. Redirect nodes: $\lceil 277,778 / (10,000 \times 0.6) \rceil + 3 = \lceil 46.3 \rceil + 3 = 50$ nodes.

Interpretation. With a 95% hit ratio the database sees fewer than 14,000 reads per second, comfortable for a partitioned store. *Engineering implication.* Hit ratio is the single most important number: at 80% the store would see 55,556 reads/s, four times as many.

Table 52.2 — URL shortener capacity summary.

Quantity	Value	Consequence
Peak creates	≈ 2,800/s	Code generation must not need a global lock per create
Peak redirects	≈ 280,000 RPS	Cache-first redirect path; about 50 stateless nodes
Links after 10 years	182.5 billion	7 base62 characters suffice (5.2% of the keyspace)
Link storage, 10 years, 3 replicas	≈ 274 TB	Partitioned key-value or wide-column store
Cache working set	≈ 200 GB	A small Redis cluster plus in-process caches
Click events	1 TB/day; 56 MB/s at peak	Asynchronous log, then roll-ups in an analytics store

The keyspace calculation generalizes into a formula you can reuse for any code length or alphabet.

FORMULA

Code length for a target keyspace fill

$$L = \lceil \log_A \left(\frac{K}{\rho}\right) \rceil$$

Symbol	Meaning	Units
L	Number of characters in the code	characters
A	Alphabet size (62 for `0–9A–Za–z`)	symbols
K	Total codes that will ever be issued over the design lifetime	codes
ρ	Maximum fraction of the keyspace you are willing to fill	fraction

WORKED EXAMPLE

Worked example — How many characters? $K = 1.825 \times 10^{11}$ links over 10 years.

1. With $\rho = 0.10$ (random codes, so that a fresh random code collides with an existing one at most 10% of the time): $K/\rho = 1.825 \times 10^{12}$.
   $\log_{62}(1.825 \times 10^{12}) = \ln(1.825 \times 10^{12}) / \ln 62 = 28.23/4.127 = 6.84$, so $L = 7$.
2. At the 100× growth point, $K = 1.825 \times 10^{13}$: $\log_{62}(1.825 \times 10^{14}) = 32.84/4.127 = 7.96$, so $L = 8$.
3. With a counter (no collisions), ρ can approach 1:
   $\log_{62}(1.825 \times 10^{11}) = 25.93/4.127 = 6.28$, still $L = 7$.

Interpretation. Seven characters cover the design point with a wide margin; 100× growth needs an eighth character. *Engineering implication.* Make code length a parameter, not an assumption baked into validation regexes and database column widths, so you can move to 8 characters without a migration.

52.4.5 API design

```
POST /v1/links                                  (authenticated; Idempotency-Key header,
§22.15)
  request:  { "long_url": "https://example.com/a/very/long/path",
              "custom_alias": "spring-sale",   // optional
              "expires_at": "2027-06-01T00:00:00Z",   // optional
              "title": "Spring sale" }          // optional
  201:      { "code": "Ab3xK9q", "short_url": "https://sho.rt/Ab3xK9q",
              "long_url": "...", "created_at": "2026-11-05T10:15:02Z", "expires_at":
null }
  400 invalid URL · 409 alias taken · 422 destination blocked · 429 creation rate limit

GET /{code}                                     (public; the redirect itself)
  302 Found, Location: <long_url>, Cache-Control: private, max-age=90
  404 unknown or expired · 410 Gone for links disabled for abuse (with an interstitial
page)

GET /v1/links/{code}/stats?from=2026-11-01&to=2026-11-05&granularity=day   (owner only)
  200:      { "code": "Ab3xK9q", "total_clicks": 18234,
              "series": [ { "date": "2026-11-01", "clicks": 4012, "unique_visitors_est":
3550 } ],
              "top_referrers": [ ["news.example.org", 6020] ], "top_countries": [ ["DE",
7211] ],
              "data_freshness_seconds": 140 }

GET    /v1/links?cursor=...&limit=50           (owner's links, cursor pagination)
DELETE /v1/links/{code}                        (owner; disables, does not free the code)
POST   /v1/reports  { "code": "Ab3xK9q", "reason": "phishing" }   (public abuse report)
```

Three API decisions carry design weight. The redirect is a bare path at the root of a short domain, because every character in the short URL counts. Creation accepts an **idempo-**

tency key (§22.15) so a client retrying after a timeout does not mint two codes. Deleting a link *disables* it and never returns the code to the free pool: a recycled code would send old printed links to a stranger's destination.

52.4.6 Data model and database schema

The redirect path needs exactly one access pattern: given a code, return the long URL and its flags. The owner dashboard needs a second: list one owner's links, newest first. Analytics needs a third: aggregate clicks per link per time bucket.

```
        -- Link store: partitioned key-value or wide-column table, partition key = code.
        CREATE TABLE links (
          code         VARCHAR(16) PRIMARY KEY,      -- 7 chars generated; custom
aliases up to 16
          long_url     VARCHAR(2048) NOT NULL,
          owner_id     BIGINT        NOT NULL,
          created_at   TIMESTAMP     NOT NULL,
          expires_at   TIMESTAMP,                    -- NULL = never
          status       SMALLINT      NOT NULL,       -- 0 active, 1 disabled by owner,
2 blocked for abuse
          is_custom    BOOLEAN       NOT NULL
        );

        -- Owner index: a separate table partitioned by owner, clustered by time (a
global secondary index, §14.11).
        CREATE TABLE links_by_owner (
          owner_id     BIGINT,
          created_at   TIMESTAMP,
          code         VARCHAR(16),
          PRIMARY KEY (owner_id, created_at, code)
        );

        -- Analytics roll-up in a columnar store (§13.13): one row per link per hour per
dimension value.
        CREATE TABLE clicks_hourly (
          code         VARCHAR(16),
          hour         TIMESTAMP,
          country      CHAR(2),
          referrer     VARCHAR(255),
          clicks       BIGINT,
          visitors_hll BYTEA                         -- HyperLogLog sketch, mergeable
across hours (§17.5)
        );
```

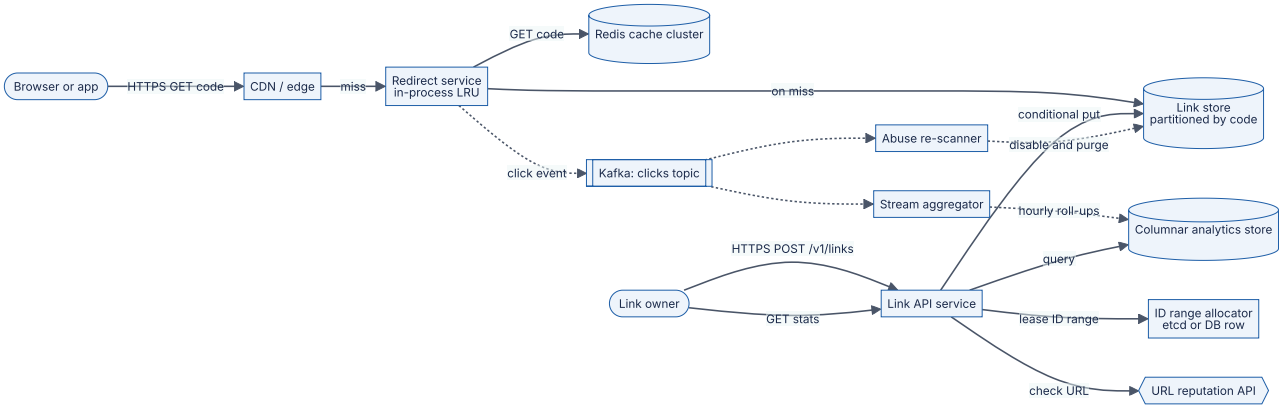
Choice of store. The link table is a pure key lookup with 182.5 billion rows and no joins, so a partitioned key-value or wide-column store (DynamoDB, Cassandra, or sharded MySQL used as a key-value store) fits well (§12.4, §12.6). Partition by `code`: generated codes are uniformly distributed (§52.4.8 makes sure of that), so there are no hot partitions from creation, only from popular links, which the cache absorbs. The owner index is written in the same request; if the store cannot write both atomically, write `links` first

(the source of truth) and repair `links_by_owner` from a change stream (§32.6). Clicks go to a columnar analytics store, because the queries are scans and group-bys over time ranges, the opposite of the link table's point lookups.

Custom aliases share the `links` table, so uniqueness is enforced by a **conditional insert** (insert only if the key does not exist), which every serious key-value store supports. To stop custom aliases from colliding with codes the generator will issue later, aliases must be at least 8 characters or contain a hyphen; generated codes are always exactly 7 alphanumeric characters. The two namespaces can then never overlap.

52.4.7 High-level architecture

Figure 52.1 — URL shortener high-level architecture.



Reading the diagram. Two independent paths share one store. The **read path** (top) runs left to right and is entirely synchronous: the CDN or edge answers repeated redirects for popular codes; misses reach the stateless redirect service, which checks its in-process LRU cache, then the Redis cluster, then the partitioned link store. The **write path** (lower left) is also synchronous: the link API leases a block of counter values from the range allocator (rarely, once per 10,000 creates), checks the destination against a reputation service, and writes the link with a conditional put. Everything dotted is asynchronous: each redirect publishes a click event to Kafka without waiting for the outcome; a stream aggregator rolls events into hourly rows in the columnar store; an abuse re-scanner consumes the same stream (new and newly popular links) and disables bad links, purging caches. Storage boundaries: the link store is the source of truth; Redis and the CDN are disposable copies; Kafka retains raw clicks for a few days. Failure points: Redis loss shifts load to the link store (§52.4.11); Kafka unavailability must drop or buffer click events rather than block redirects; the range allocator is needed only when a node's block runs out. Scaling: redirect nodes and API nodes scale horizontally; the link store scales by adding partitions; Kafka by adding partitions keyed by code.

52.4.8 Detailed component design

Component 1: short-code generation

Five families of scheme are worth comparing. §17.10 covers the underlying ID generators; here we judge them against the shortener's specific needs: 7 characters, uniqueness, no coordination per create, and no enumeration.

Table 52.3 — Short-code generation schemes compared.

Scheme	How it works	Length	Uniqueness	Coordination	Enumerable?	Main weakness
Hash and truncate	Base62 of the first 42 bits of SHA-256(long URL)	7	Collides; must detect and retry with a salt	None	No	Same URL from two users gets the same code; collision handling is a read-before-write
Random code	7 random base62 characters, conditional insert, retry on conflict	7	Retry on conflict (5% chance at 10-year fill)	None	No	Retries grow as the keyspace fills
Global counter	One sequence, base62-encoded	7	Guaranteed	Round trip per create	Yes: `…0001`, `…0002`	Bottleneck and enumeration
Counter ranges, scrambled	Nodes lease blocks of counters; a keyed permutation maps counter → code	7	Guaranteed	One lease per block	No (without the key)	Needs a durable allocator and a secret key
Snowflake-style 64-bit ID	Timestamp + machine + sequence (§17.10.3), base62-encoded	11	Guaranteed	Assign machine IDs once	Partly: time-ordered	Too long: $62^{10} < 2^{63} < 62^{11}$

Hashing the long URL is the classic first answer, and it has a real benefit: the same long URL always yields the same code, which deduplicates. But the benefit is often unwanted (two marketers shortening the same page want separate click counts), and truncation to 42 bits makes collisions certain at scale. By the birthday bound (§17.10.2), with $N = 62^7 = 3.52 \times 10^{12}$ codes and $n = 1.825 \times 10^{10}$ links in the first year, the expected number of colliding pairs is $n^2/(2N) = 4.7 \times 10^7$. Every create therefore needs "insert if absent; on con-

flict, check whether it is the same URL; if not, re-hash with a salt", which is the random-code scheme with extra steps.

Random codes are honestly fine at this scale: at 5.2% fill after ten years, one insert in 19 needs a retry, and a conditional insert detects the conflict in the same round trip. Their cost is that the collision rate rises with fill and that every create is a conditional write, which some stores make more expensive.

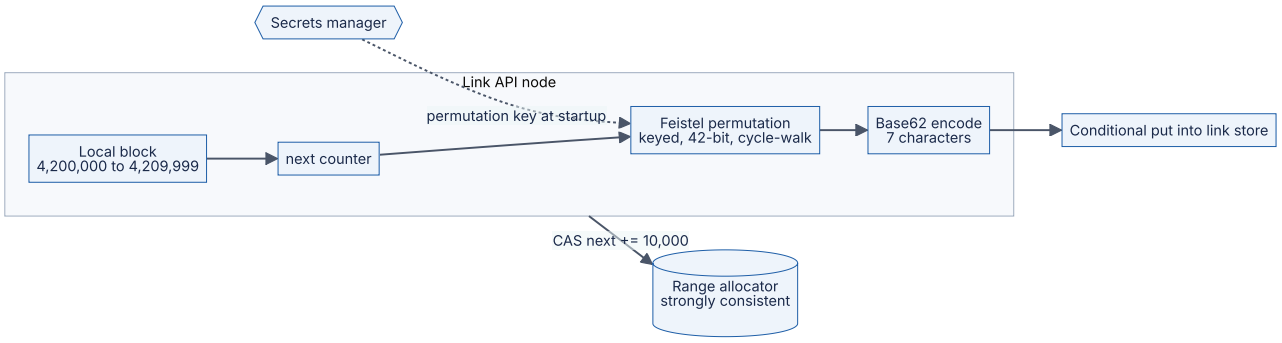
Snowflake IDs are excellent database keys but poor short codes. A 64-bit value needs 11 base62 characters, and the embedded timestamp leaks creation time and lets an attacker guess neighbors.

> INDUSTRY EXAMPLE
>
> **Twitter Snowflake.** Twitter built Snowflake in 2010 to generate roughly time-ordered 64-bit IDs without coordination when it moved storage away from MySQL; IDs combine a millisecond timestamp, a machine number and a per-machine sequence [Twitter: Snowflake 2010]. The design targets database keys, where 64 bits and time order are virtues. For a shortener the same properties are drawbacks: 11 characters instead of 7, and codes that reveal when they were created. Section 17.10.3 covers the layout.
>
> *Evidence: Primary* — [Twitter: Snowflake 2010]

The chosen design: leased counter ranges plus a keyed permutation. Each link API node leases a block of, say, 10,000 consecutive counter values from a range allocator, the same idea as Flickr's ticket servers fetching blocks (§17.10.5). The allocator is a single row updated with compare-and-set in a strongly consistent store (etcd, ZooKeeper, or a relational table): "if `next = 4,200,000`, set `next = 4,210,000`". At 2,778 creates per second at peak and 10,000 per block, the allocator sees one request every 3.6 seconds, so its availability matters but its throughput does not. A node that crashes loses the unused part of its block, which wastes at most 10,000 codes per crash out of 3.52 trillion.

A counter alone is enumerable, so the node passes each counter value through a **keyed pseudorandom permutation** of $[0, 62^7)$ before base62-encoding it. A permutation is a one-to-one mapping, so distinct counters give distinct codes, and without the key consecutive counters map to unrelated codes. A four-round Feistel network over 42 bits with an HMAC round function is a small block cipher; because $2^{42} = 4.40 \times 10^{12}$ exceeds 62^7 by a factor of only 1.25, **cycle-walking** (re-encrypting until the result falls inside the range) takes 1.25 encryptions on average.

Figure 52.2 — Code generation with leased ranges and a keyed permutation.



Reading the diagram. Inside each API node (the subgraph), a create takes the next counter from the node’s local block, permutes it with a secret key, and encodes it as seven base62 characters, all in memory with no network call. Only when the block is exhausted does the node make one synchronous compare-and-set call to the range allocator, a strongly consistent single-row store. The permutation key comes from a secrets manager once at startup (dotted, asynchronous with respect to requests). The final conditional put is a safety net: it should never conflict, and a conflict signals a bug such as two nodes holding the same block. Failure points: an unavailable allocator stops creation only after the local block runs out (with ten API nodes sharing 2,778 creates/s, a 10,000-code block lasts each node 36 s at peak; nodes prefetch the next block at 50% use, and larger blocks buy longer outages); a leaked key makes codes predictable again but not colliding. Scaling: larger blocks reduce allocator traffic linearly.

```
        import hashlib
        import hmac

        ALPHABET = "0123456789ABCDEFGHIJKLMNOPQRSTUVWXYZabcdefghijklmnopqrstuvwxyz"
        LENGTH = 7
        SPACE = 62 ** LENGTH                      # 3,521,614,606,208 possible codes
        HALF_BITS = 21                            # Feistel works on 2 x 21 = 42 bits >=
SPACE

        def base62(n: int, length: int = LENGTH) -> str:
            """Fixed-width base62: 0 -> '0000000'."""
            chars = []
            for _ in range(length):
                n, r = divmod(n, 62)
                chars.append(ALPHABET[r])
            assert n == 0, "value does not fit"
            return "".join(reversed(chars))

        def _round(key: bytes, i: int, half: int) -> int:
            mac = hmac.new(key, f"{i}:{half}".encode(), hashlib.sha256).digest()
            return int.from_bytes(mac[:4], "big") & ((1 << HALF_BITS) - 1)

        def feistel42(x: int, key: bytes, rounds: int = 4) -> int:
            """Keyed permutation of the 42-bit integers (a tiny block cipher)."""
            mask = (1 << HALF_BITS) - 1
            left, right = x >> HALF_BITS, x & mask
            for i in range(rounds):
                left, right = right, left ^ _round(key, i, right)
            return (left << HALF_BITS) | right

        def scramble(counter: int, key: bytes) -> int:
            """Permute [0, SPACE) onto itself by cycle-walking: re-encrypt until in
range."""
            assert 0 <= counter < SPACE
            x = feistel42(counter, key)
            while x >= SPACE:                     # 2^42 / 62^7 = 1.25, so ~1.25 rounds
on average
                x = feistel42(x, key)
            return x

        def short_code(counter: int, key: bytes) -> str:
            return base62(scramble(counter, key))

        KEY = b"rotate-me-via-your-secret-manager"
        codes = [short_code(c, KEY) for c in range(1, 200_001)]
        assert len(set(codes)) == len(codes)          # a permutation never collides
        print([short_code(c, KEY) for c in range(1, 6)])
        print("max code:", base62(SPACE - 1), "| sequential base62 of 1..3:", [base62(c)
for c in (1, 2, 3)])
```

Output:

```
['IBvB4nl', 'tD3NOix', 'ZVpe8s5', 'Pz8JF2G', 'gzwMZQ7']
max code: zzzzzzz | sequential base62 of 1..3: ['0000001', '0000002', '0000003']
```

What to notice:

- Counters 1 to 5 produce unrelated codes, while plain base62 of the same counters is `0000001`, `0000002`, `0000003`: the permutation is what defeats enumeration.
- The assertion checks 200,000 consecutive counters for collisions. A Feistel network is invertible for any round function, so it is a permutation by construction, and cycle-walking preserves that property on the smaller range.
- The key cannot be rotated without changing future codes' mapping, which is harmless (existing codes are stored, not recomputed), but two nodes must never use different keys over the *same* counter range, or two counters could map to one code. Version the key together with the range allocator's state.
- This is obfuscation against enumeration, not authorization. A link that must stay private needs an access check, not just an unguessable code (§17.10, "Sequential IDs in URLs are harmless" misconception).

Component 2: the redirect path and caching

The redirect has a budget of 20 ms at p99 inside the region, and most of it should be unused. The lookup goes through four layers, each absorbing most of the traffic that reaches it: the CDN or edge (for very popular links), the redirect node's in-process LRU cache (a few gigabytes per node, sub-microsecond hits), the shared Redis cluster (about 0.5 ms within the datacenter), and the link store (a few milliseconds).

The most consequential decision is the **HTTP status code**, because it decides who else caches the redirect.

Table 52.4 — Redirect status codes for a shortener.

Status	Meaning (RFC 9110)	Browser caching	Analytics accuracy	Choose when
301 Moved Permanently	Permanent; method may change to GET	Cacheable by default; browsers may reuse it indefinitely without asking you again	Poor: repeat clicks from one browser never reach you	No analytics; you want to minimize load
302 Found	Temporary; method may change to GET	Not cached unless `Cache-Control` allows it	Good	Default for a shortener with analytics
307 Temporary Redirect	Temporary; method preserved	As 302	Good	Redirecting non-GET requests (rare here)
308 Permanent Redirect	Permanent; method preserved	As 301	Poor	APIs that move permanently

This design returns **302 with `Cache-Control: private, max-age=90`**. The `private` directive keeps shared caches from storing a response that the analytics pipeline needs to see, while still letting one browser reuse the redirect for 90 seconds (a double-click or a back-and-forward does not count twice). For the hottest links, the CDN runs a small edge function that serves the redirect from edge cache *and* emits the click event itself, so analytics stays correct without the request reaching the origin (§21.9).

Three cache problems from Chapter 20 show up here in specific forms:

- **Cache penetration (§20.12).** Attackers and broken crawlers request random codes that do not exist; each miss reaches the link store. Cache negative results ("code not found") for 60 seconds, and reject malformed codes (wrong length or alphabet) before any lookup.
- **Hot keys (§20.15).** A link in a viral post can draw 50,000 RPS by itself, all hashing to one Redis shard. The in-process LRU absorbs this, because every redirect node caches the hot code locally; the shard sees at most one request per node per TTL.
- **Invalidation after takedown (§20.10).** Because links are immutable, the only invalidation is disabling a link for abuse. The disable flow writes `status = 2` to the link store, deletes the Redis key, broadcasts an invalidation message that redirect nodes subscribe to, and purges the CDN. The 90-second browser cache is the residual exposure, which is why the `max-age` stays short.

Component 3: the analytics write path

At 280,000 redirects per second, the click stream is the system's largest write load, so it must stay completely off the redirect's critical path. The redirect node appends the event (code, timestamp, hashed IP, user agent class, referrer domain, country from a GeoIP lookup) to an in-memory buffer and returns the redirect immediately. A background thread batches events and produces them to a Kafka topic partitioned by code (§31.5, §31.6). If Kafka is unreachable, the buffer fills to a bound (say 100 MB per node) and then

drops events and counts the drops. Losing some analytics during an outage is acceptable; slowing redirects is not.

Downstream, a stream processor (§29.8) filters bots (known user agents, data-center IP ranges, inhumanly fast repeats), then aggregates per code per hour: a click count, a HyperLogLog sketch of hashed visitor identifiers for approximate unique visitors (§17.5), and per-dimension counters for referrers and countries. Writing roll-ups, not raw events, shrinks 1 TB per day of raw clicks to a few gigabytes of hourly rows. Raw events stay in Kafka for 7 days and in cheap object storage for 30 days, for reprocessing when the bot filter improves. If you need exact counts despite at-least-once delivery from Kafka, make the aggregator's writes idempotent per (partition, offset range) (§32.10); most shorteners accept counts that are accurate to well within 1%.

Component 4: abuse and spam

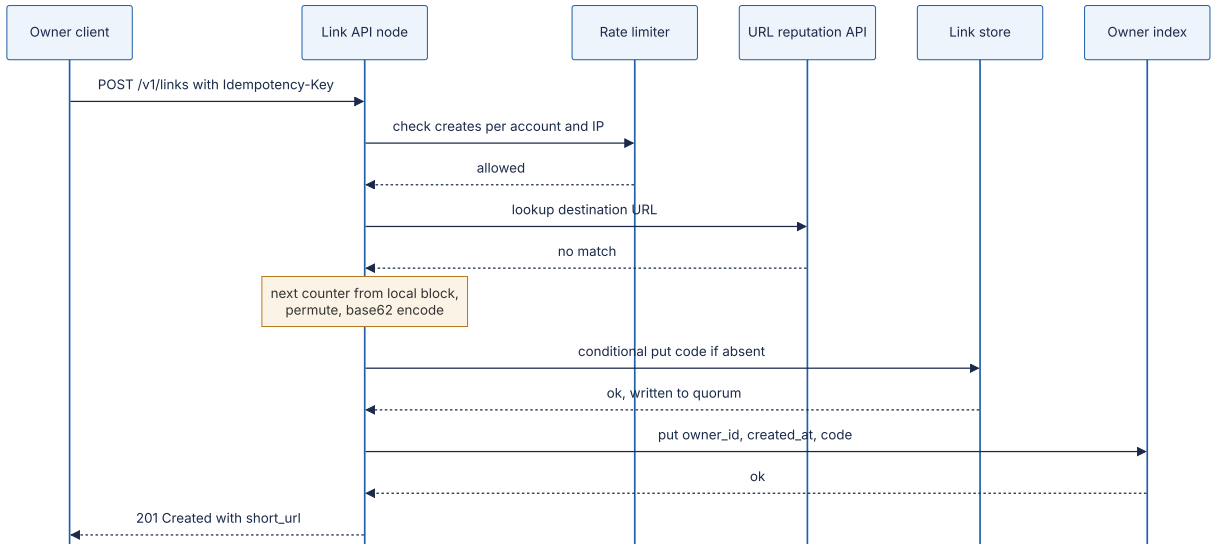
The abuse pipeline has three stages:

1. **At creation (synchronous).** Validate the URL syntax and scheme (`http` and `https` only; reject `javascript:` and `data:` URLs). Look the destination up in a URL reputation service and in your own blocklist of domains. Reject destinations that are themselves short links from your own domain, to prevent redirect loops and chains that hide the final target. Rate-limit creation per account and per IP with the service of §52.6, because abuse arrives in bulk.
2. **After creation (asynchronous).** Destinations change after the link is created: a harmless page can turn into a phishing page a week later. Re-scan links when they are created, when they first become popular (a sudden click spike is itself a signal), and periodically.
3. **On report or detection.** Disable the link (`status = 2`), serve an interstitial warning page with 410 Gone instead of the redirect, and purge caches as described above.

> INDUSTRY EXAMPLE
>
> **Google Safe Browsing.** Google offers the Safe Browsing APIs, which let applications check URLs against Google's continuously updated lists of unsafe web resources (social engineering, malware, unwanted software). The Lookup API sends URLs to Google for a verdict; the Update API keeps a local database of hashed URL prefixes so that most checks happen locally and only potential matches are confirmed with the server, which also limits what the client reveals [Google: Safe Browsing APIs]. A shortener can call such a service synchronously at creation and re-check asynchronously later. Check the current terms of use and versions before relying on a specific API for commercial use.
>
> *Evidence: Primary* — [Google: Safe Browsing APIs]

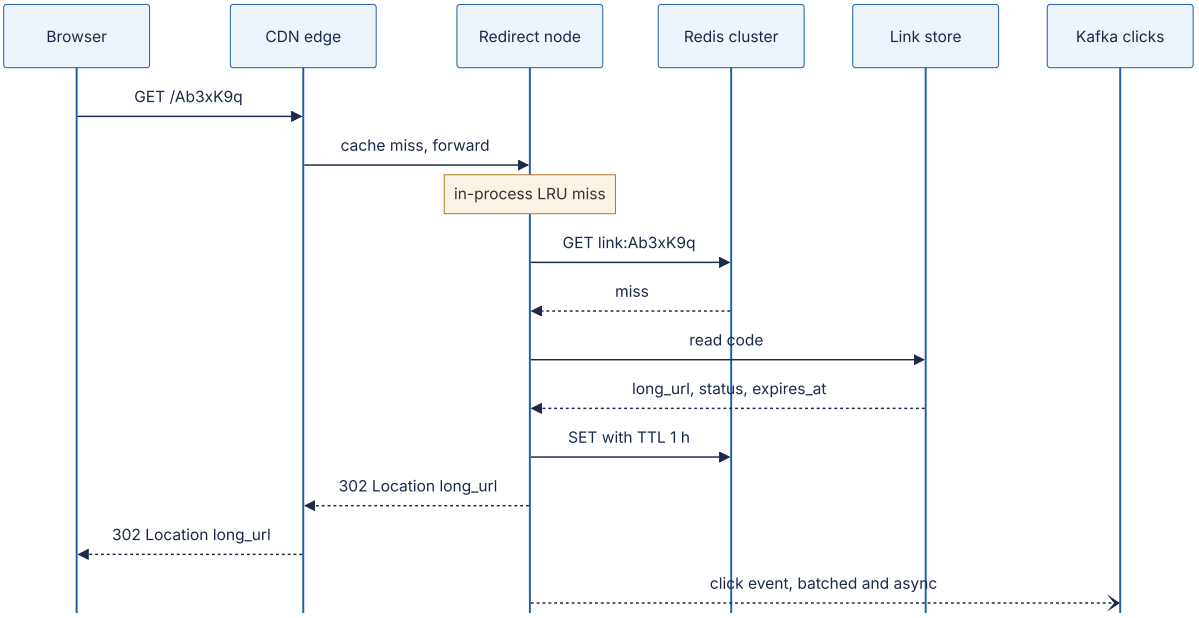
52.4.9 Data flow

Figure 52.3 — Write path: creating a short link.



Reading the diagram. All calls are synchronous. The API node first consults the rate limiter (§52.6) and the reputation service; a timeout from the reputation service falls back to an asynchronous re-scan rather than failing the create, a deliberate fail-open choice for a check that is repeated later. Code generation happens in memory. The conditional put is the commit point: once the link store acknowledges a quorum write, the link exists and is durable. The owner-index write follows; if it fails, the client still gets 201 and a change-stream consumer repairs the index. The idempotency key (stored with the response for 24 hours, §22.15) makes a retried request return the same code. Failure points: link store unavailable (return 503; the client retries with the same key); allocator unavailable (invisible until the local block runs out). Scaling: API nodes are stateless apart from their counter block.

Figure 52.4 — Read path: following a short link.



Reading the diagram. This is the worst case, a miss at every layer; in steady state about 95% of requests stop at the edge, the in-process cache or Redis. The redirect node checks `status` and `expires_at` before answering, so expired and disabled links return 404 or 410 even if the cache still holds them. The click event (half-arrow) is fire-and-forget: it leaves the node in a batch after the response is sent. Concurrent misses for the same code are collapsed into one link-store read by single-flight (§20.11.1). Failure points: Redis down (the node falls through to the store; latency rises to a few milliseconds), link store partition unavailable (cached links keep working; uncached ones fail). Scaling: add redirect nodes and Redis shards; the edge absorbs the hottest links.

52.4.10 Bottlenecks

1. **Link store reads on cache misses.** The read rate the store sees is $R_{peak} \times (1 - \text{hit ratio})$; a cold cache after a Redis failure can multiply it by 20 (§20.13 on cache avalanche). Warm replacement nodes before they take traffic, and keep in-process caches as a second line.
2. **Hot links.** A single code at 50,000 RPS overloads one Redis shard; in-process caching and edge caching are the fix, not more shards.
3. **The click pipeline.** At 56 MB/s at peak it is the largest data flow. Size Kafka partitions for it (§31.13) and make sure backpressure drops events rather than blocking redirects.
4. **Creation-time reputation checks.** An external dependency with its own latency and quotas; cache verdicts per domain for a few minutes.

52.4.11 Failure scenarios

Table 52.5 — URL shortener failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Redis cluster or a shard	Miss rate jumps; store read rate up to 20×	Hit-ratio and store-RPS alerts	Fall through to store; refill gradually	In-process LRU; replicas per shard; request coalescing
One link-store partition	Uncached codes on it fail (~5% of their traffic)	Error rate per partition	Replica takes over (§27.11)	Replication factor 3 across zones
Range allocator	No new blocks; creates fail once local blocks run out	Allocator health; block-refill errors	Restore quorum; nodes retry with backoff	Prefetch at 50%; strongly consistent replicated store
Two nodes hold the same block (bug or restored backup)	Code collisions; second write rejected	Conditional-put conflicts (should be zero)	Abandon the block, lease a new one	Never restore the allocator from backup without jumping `next` forward by a safety margin
Kafka unavailable	Analytics gap	Producer error and drop counters	Buffer, then drop; replay from edge logs if needed	Multi-zone Kafka; bounded buffers
Permutation key leaked	New codes predictable	Security incident	Rotate key with a new allocator epoch	Key in a secrets manager; short access list
Malicious link goes viral	Users phished; domain blocklisted by browsers	Click spike plus reputation re-scan	Disable, purge caches, interstitial	Creation checks, re-scans on spikes, report flow
Region outage	Redirects fail for users routed there	Health checks, synthetic probes	DNS or anycast failover to another region (§44.11)	Link data replicated to every serving region

52.4.12 Scaling strategy

At 10× (500 million creates/day, 2.8 million redirect RPS at peak). The design holds in shape. Redirect nodes grow to about 470 at 10,000 RPS each, and serving from the edge becomes the main lever: moving the redirect logic and a replicated read-only copy of hot links into CDN edge functions removes most origin traffic. Ten-year storage grows to about 2.7 PB with three replicas; tier links not clicked for a year to cheaper storage (§15.9). The allocator still sees fewer than three requests per second at 10,000 codes per block.

At 100× (5 billion creates/day). Ten years now means 18.25 trillion links, which overflows 62^7; move to 8-character codes ($62^8 = 2.18 \times 10^{14}$, 8.4% fill) and widen the permutation to 48 bits. Serve redirects from every region with a fully replicated link store (asynchronous cross-region replication is acceptable because links are immutable and read-your-writes is only needed in the creator's region, where the read goes to the local replica that took the write). The analytics path becomes the dominant cost; sample raw events for low-value links and keep exact counts only for paid accounts.

52.4.13 Trade-offs

- **302 versus 301:** correct analytics and the ability to disable links, in exchange for more requests reaching you.
- **Counter ranges versus random codes:** no collisions and no retries, in exchange for an allocator to operate and a key to protect. Random codes are a perfectly defensible choice at this scale; say so in an interview.
- **Immutable links:** trivial caching and no invalidation storms, in exchange for a product feature (editing the destination). If you add editing, the redirect cache needs versioned keys or event-driven invalidation (§20.10).
- **Dropping click events under pressure:** redirect availability, in exchange for occasional analytics gaps.
- **No deduplication of long URLs:** separate statistics per link, in exchange for more rows.

52.4.14 Alternative designs

- **Relational database with a sequence (small scale).** At 1 million links a day, one PostgreSQL primary with a `BIGSERIAL` key, base62-encoded and permuted, plus a read replica and Redis, is simpler and entirely adequate. Move to a partitioned store when the table approaches a few billion rows.
- **Pre-generated key service.** A batch job generates random unused codes in advance and stores them in a “free codes” table; API nodes claim batches. It avoids collisions at write time, but it is a second stateful store with the same failure modes as the range allocator and more data.
- **Edge-native shortener.** Store links in a globally replicated edge key-value store and run the redirect entirely in CDN edge functions (§48). Latency is excellent; consistency after creation depends on the edge store’s replication delay, often seconds, which conflicts with “redirects everywhere within 1 s”.

52.4.15 Interview discussion

Table 52.6 — 45-minute plan for the URL shortener.

Minutes	Focus	What to produce
0–5	Requirements	Create, redirect, analytics, expiry, custom alias; 100:1 read ratio; 99.99% redirects
5–10	Estimates	280,000 redirect RPS at peak, 2,800 creates/s, 182.5 billion links, 7 characters
10–15	API and data model	`POST /v1/links`, `GET /{code}` with 302; table keyed by code
15–22	Architecture	Figure 52.1: cache layers, link store, async click stream
22–35	Deep dive: code generation	Hash vs random vs counter ranges vs Snowflake; permutation against enumeration
35–42	Redirect caching, hot keys, analytics, abuse	301 vs 302; negative caching; Kafka roll-ups; takedown flow
42–45	Failures and scaling	Redis loss, allocator loss, 8-character codes at 100×

Likely follow-ups.

- *"Why not just hash the URL?"* Truncated hashes collide at billions of links (tens of millions of colliding pairs in the first year), so you still need conflict detection; and identical URLs from different users share a code and its statistics.
- *"How do you stop someone enumerating all links?"* Permute the counter with a keyed permutation or use random codes; rate-limit 404s per client; and never rely on obscurity for private content.
- *"What if a user wants the same short link every time for the same URL?"* Add a `(owner_id, sha256(long_url)) → code` index and check it before creating.
- *"How do you expire links?"* Check `expires_at` on every redirect (correctness), and delete expired rows lazily or with a background sweep (cost); §52.5.8 covers TTL cleanup at scale.

What distinguishes senior and staff answers. A senior candidate quantifies the read path, picks 302 with a reason, and handles hot keys and cache penetration. A staff candidate also notices that the click stream is the largest write load, treats abuse as a first-class subsystem that protects the domain's reputation, discusses the allocator as a durable-state hazard (backups that rewind `next`), and frames code length as an evolvable parameter.

52.4.16 Production considerations

- **Observability.** Track redirect p50/p99 per layer, cache hit ratio per layer, 404 rate (a rising rate signals enumeration or broken campaigns), click-event drop counts, al-

locator lease latency, and the age of the newest roll-up (analytics freshness SLO, §39.6).

- **Security.** Serve only HTTPS with HSTS on the short domain; never redirect to non-HTTP schemes; sign the abuse-takedown API; and keep hashed, not raw, IPs in click events to limit personal data (§50).
- **Cost.** Redirect compute and egress are small; analytics storage and stream processing dominate. Roll-ups, short raw retention and sampling keep the bill proportional to value.
- **Operations.** Run synthetic probes that create a link and follow it from every region every minute; that single check exercises the allocator, the store, replication and the redirect path. Keep the short domain on a separate registrar account with locked DNS: losing the domain loses every link ever issued.

52.5 Pastebin

52.5.1 Problem statement

Design a service where users paste text (code, logs, configuration) and get back a link to share it. Pastes can be public, unlisted or private, can expire after a chosen time, and can be “burn after reading” (deleted after the first view).

At first glance this is a URL shortener whose value is a document instead of a URL, and the code generation of §52.4.8 carries over unchanged. Three things are different and form the hard problems of this case:

1. **The blob/metadata split (the distinctive hard problem).** Values range from a few bytes to 10 MB. Large values do not belong in the same store as the small, frequently updated records that describe them.
2. **Expiration at scale.** Most pastes expire. Making an expired paste *invisible* is easy; *deleting* millions of objects and rows per day, on time and cheaply, from two different stores without leaving orphans, is not.
3. **Access control.** Private pastes must not leak through caches, CDNs or guessable URLs, and the content path must enforce the same rules as the metadata path.

52.5.2 Functional requirements

- **Create** a paste: content up to 10 MB, optional title, syntax-highlighting language, visibility (`public`, `unlisted`, `private`), expiry (10 minutes, 1 hour, 1 day, 1 week, 30 days, never) and a burn-after-read flag.
- **Read** a paste by its code: rendered page (`/p/{code}`) and raw text (`/raw/{code}`).
- **Private pastes** are readable only by the owner and users the owner shares with; optional password protection.

- **Delete** a paste (owner) and report abusive pastes (anyone).
- **List** an owner's pastes, and a public "recent pastes" feed of public pastes only.

Out of scope: real-time collaborative editing, full-text search across pastes (§16 would supply it), comments.

52.5.3 Non-functional requirements

Property	Target
Read availability	99.95% per month
Create availability	99.9% per month
Read latency	p99 ≤ 100 ms for pastes ≤ 100 KB, server-side; p99 ≤ 50 ms for public pastes served from the CDN
Create latency	p99 ≤ 500 ms for pastes ≤ 1 MB
Durability	Acknowledged pastes survive until they expire: ≥ 99.999999999% annual object durability (the class object stores are designed for, §15.6)
Expiry correctness	An expired paste is never served (0 s grace); its bytes are physically deleted within 24 h for pastes with expiry ≥ 1 day, within 1 h otherwise
Access control	A private paste is never served to an unauthorized user from any cache layer
Burn after reading	Served at most once, even under concurrent reads

Two of these are unusual. The *expiry* target separates logical deletion (immediate, a correctness rule) from physical deletion (bounded lag, a cost and privacy rule). The *burn-after-read* target is a concurrency requirement: two simultaneous readers must not both see the content.

52.5.4 Capacity estimation

WORKED EXAMPLE

Worked example — Pastebin request rates and bandwidth.

Assumptions. 10 million pastes created per day; 5 reads per paste (read:write = 5:1); mean paste size 20 KB (the median is about 2 KB, but a few large log dumps pull the mean up); $h = 0.10$, $b = 2$.

1. Creates, peak: $10^7 \times 0.10 / 3,600 \times 2 = 556$ per second.
2. Reads per day: 5×10^7; peak: $5 \times 10^7 \times 0.10 / 3,600 \times 2 = 2,778$ RPS.
3. Ingress at peak: 556×20 KB = 11 MB/s.
4. Egress at peak: $2,778 \times 20$ KB = 55.6 MB/s = 444 Mbps.

Interpretation. Request rates are modest; one region with a CDN in front handles them easily. *Engineering implication.* The design is driven by storage shape and life-cycle, not by throughput.

WORKED EXAMPLE

Worked example — Storage, with expiry.

Assumptions. Expiry mix: 10 minutes 5%, 1 hour 15%, 1 day 20%, 1 week 15%, 30 days 15%, never 30%. Metadata 400 bytes per paste. Creation rate $\lambda = 10^7/86,400 = 115.7$ pastes/s.

1. Live expiring pastes at steady state, by Little's Law $L = \lambda W$ (§4.11), summed over expiry classes:
   - 10 min: $115.7 \times 0.05 \times 600 = 3,472$
   - 1 h: $115.7 \times 0.15 \times 3,600 = 62,500$
   - 1 day: $115.7 \times 0.20 \times 86,400 = 2,000,000$
   - 1 week: $115.7 \times 0.15 \times 604,800 = 10,500,000$
   - 30 days: $115.7 \times 0.15 \times 2,592,000 = 45,000,000$
   - Total ≈ 57.6 million pastes × 20 KB ≈ **1.15 TB**, constant over time.
2. Never-expiring pastes accumulate: $10^7 \times 0.30 \times 365 = 1.095 \times 10^9$ per year × 20 KB = **21.9 TB per year**.
3. Metadata: $10^7 \times 400\,\text{B} \times 365 = 1.46\,\text{TB}$ per year written; about 0.44 TB per year of it remains (the 30% that never expire).
4. Physical deletions: 70% of pastes expire, so 7×10^6 per day at steady state: 81/s on average, $7 \times 10^6 \times 0.10/3,600 \times 2 = 389$/s at peak, because expirations follow the creation curve shifted by the TTL.

Interpretation. Although 70% of pastes expire, the 30% that never expire hold 95% of the stored bytes after one year (21.9 TB versus 1.15 TB). *Engineering implication.* The biggest storage lever is product policy (for example, "never" pastes on the free tier expire after a year without reads), not the deletion machinery. The deletion machinery matters for correctness, privacy and keeping the metadata store small, at roughly 400 deletes per second at peak.

Table 52.7 — Pastebin capacity summary.

Quantity	Value	Consequence
Peak creates / reads	556/s / 2,778 RPS	Small stateless fleet; CDN for public pastes
Peak egress	≈ 444 Mbps	Serve public content from the CDN
Live expiring content	≈ 1.15 TB (steady)	Lifecycle machinery, not capacity, is the challenge
Permanent content growth	≈ 21.9 TB/yr	Object storage with lifecycle tiering (§15.9)
Metadata	≈ 1.46 TB/yr written	A partitioned key-value store or sharded relational store
Physical deletes	7 million/day; ≈ 389/s at peak	A dedicated expiry pipeline

52.5.5 API design

```
POST /v1/pastes                                (anonymous or authenticated; Idempotency-
Key)
  request:  { "title": "nginx.conf", "language": "nginx", "visibility": "private",
              "expires_in": "1d", "burn_after_read": false, "size_bytes": 4096,
              "content": "<inline if <= 1 MB>" }
  201:      { "code": "Qk7Lm2x", "url": "https://paste.example/p/Qk7Lm2x",
              "expires_at": "2026-11-06T10:15:02Z",
              "upload_url": null }                 // presigned PUT URL when size > 1
MB
POST /v1/pastes/{code}/complete                    (after a direct upload; verifies
size and checksum)

GET  /p/{code}       HTML page                     public: CDN-cacheable; private: no-
store
GET  /raw/{code}     text/plain                    same visibility rules
  404 not found or expired · 403 forbidden (private) · 410 gone (burned or removed)

PUT    /v1/pastes/{code}/acl   { "readers": ["user:123", "group:ops"] }   (owner)
DELETE /v1/pastes/{code}                                                  (owner)
GET    /v1/pastes?owner=me&cursor=...                                     (owner)
```

Large pastes do not stream through the API servers. Above 1 MB the API returns a short-lived **presigned upload URL** (§15.8.2) scoped to one object key, one method and the declared size; the client uploads directly to object storage and then calls `complete`, which verifies the object's size and checksum and flips the paste to `active`. The same pattern serves large private pastes for reading: the API checks authorization and returns a 302 to a presigned GET URL valid for 60 seconds.

52.5.6 Data model and database schema

```
        CREATE TABLE pastes (
          code            VARCHAR(16) PRIMARY KEY,     -- generated as in §52.4.8
          owner_id        BIGINT,                      -- NULL for anonymous pastes
          title           VARCHAR(200),
          language        VARCHAR(32),
          visibility      SMALLINT NOT NULL,           -- 0 public, 1 unlisted, 2 pri-
vate
          password_hash   VARCHAR(100),                -- Argon2id, optional (§10.6)
          size_bytes      INT      NOT NULL,
          storage         SMALLINT NOT NULL,           -- 0 inline, 1 object store
          inline_content  BYTEA,                       -- present when storage = 0 (<= 8
KB compressed)
          object_key      VARCHAR(100),                -- e.g. 'b/7d/2026-11-
12/Qk7Lm2x', when storage = 1
          sha256          BYTEA    NOT NULL,
          created_at      TIMESTAMP NOT NULL,
          expires_at      TIMESTAMP,                   -- NULL = never
          burn_after_read BOOLEAN  NOT NULL,
          state           SMALLINT NOT NULL            -- 0 pending upload, 1 active, 2
burned, 3 deleted
        );

        CREATE TABLE paste_acl (code VARCHAR(16), principal VARCHAR(64), PRIMARY KEY
(code, principal));

        -- Expiry index: one partition per (hour bucket, shard), so sweeps read whole
partitions in order.
        CREATE TABLE expiry_index (
          bucket_hour  TIMESTAMP,        -- expires_at truncated to the hour
          shard        SMALLINT,         -- 0..63, hash(code) mod 64, spreads one hour
across partitions
          code         VARCHAR(16),
          PRIMARY KEY ((bucket_hour, shard), code)
        );
```

The blob/metadata split. Metadata is small, structured, read on every request and updated (state changes, ACL edits, burn). Content is immutable, variable in size and mostly large in bytes but small in count. Putting 10 MB values in a key-value store row hurts it in several ways: compaction rewrites them repeatedly (§13.9, write amplification), replication streams carry them, and cache layers fill with a few large values. Object storage (§15.4) is built for exactly the opposite profile: immutable blobs, cheap per gigabyte, designed for very high durability, with lifecycle rules. So content goes to the object store under a key derived from the paste code, and metadata goes to a partitioned key-value or relational store keyed by code.

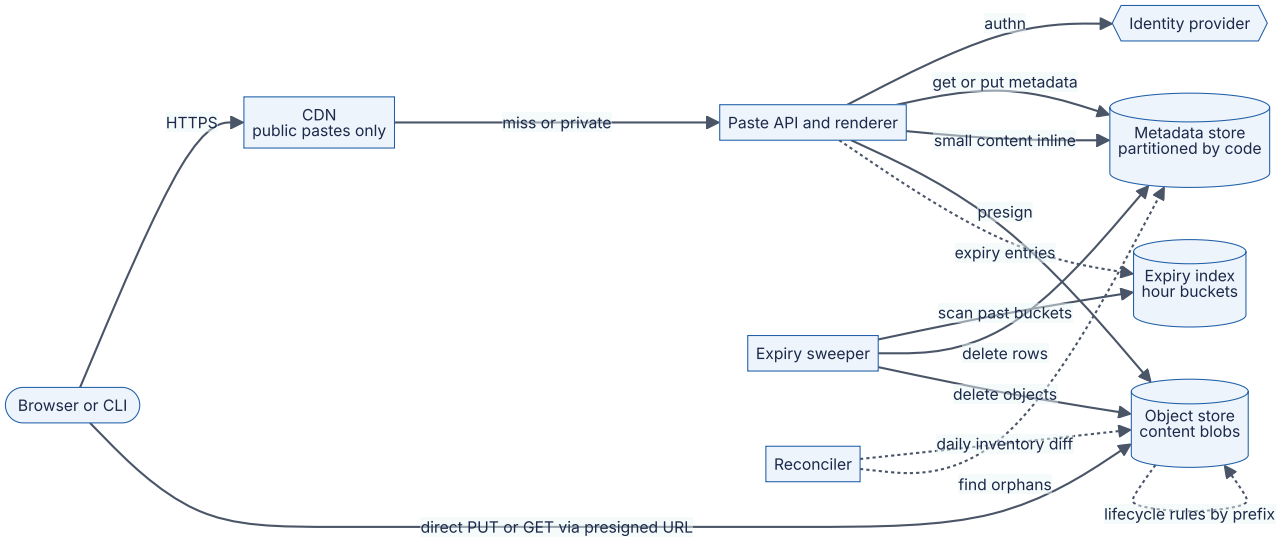
The inline optimization. Object stores have a per-request cost and a first-byte latency of tens of milliseconds. With a 2 KB median, most pastes are tiny, so the split is applied by size: content of 8 KB or less after compression is stored inline in the metadata row; larger content goes to the object store. Assuming 60% of pastes fall under the threshold, object

PUTs drop from 10 million to 4 million per day (about $20 per day at a list price of $0.005 per 1,000 PUTs, as of 2026), and most reads need a single metadata lookup.

Object key layout. The key `b/7d/2026-11-12/Qk7Lm2x` encodes the expiry class (`7d`) and expiry date. Grouping objects by expiry class lets the object store's own lifecycle rules delete them (§52.5.8), and the per-day component makes bulk inventory and reconciliation cheap. A leading component with enough distinct values spreads load across the store's internal partitions, which modern object stores handle automatically but which still helps very high request rates (§15.4).

52.5.7 High-level architecture

Figure 52.5 — Pastebin high-level architecture.



Reading the diagram. The read path runs from the client through the CDN, which caches only public pastes, to the stateless paste API, which reads metadata and, for small pastes, the inline content in one lookup. Large content moves directly between the client and the object store using short-lived presigned URLs, so the API never carries large bodies. The metadata store is the source of truth for whether a paste exists, is visible and has expired; the object store holds bytes and has no notion of visibility. The expiry machinery runs asynchronously (dotted): every create with an expiry also writes an entry into the hour-bucketed expiry index; the sweeper deletes metadata rows and objects for past buckets; object-store lifecycle rules delete whole expiry classes as a backstop; a daily reconciler compares an inventory of objects with the metadata store to find orphans in either direction. Failure points: a sweeper outage lets expired bytes linger (never served, because reads check `expires_at`); an object-store outage breaks reads of large pastes only. Scaling: the API scales horizontally; metadata by partitions; the sweeper by assigning bucket shards to workers.

52.5.8 Detailed component design

Component 1: content placement and the upload protocol

A create runs as a small state machine so that metadata and content never disagree in a way users can see:

1. The API validates the request, generates a code, and writes the metadata row with `state = pending` (or `active` directly for inline content).
2. For large content, the client uploads to the presigned URL. The object store holds the bytes; nothing references them as `active` yet.
3. `complete` reads the object's size and checksum, compares them with the declared values, and conditionally updates `state` from `pending` to `active`.
4. Pending rows older than one hour are abandoned uploads; the sweeper deletes them and their objects.

Because the metadata row is written *first* and flipped to `active` *last*, a reader can never see a paste whose content is missing. Orphaned objects (uploaded but never completed, or left behind by a failed delete) are possible but invisible; the reconciler removes them.

Component 2: expiration and TTL cleanup at scale

Expiration has two halves with different requirements.

Logical expiry (correctness). Every read compares `expires_at` with the current time and returns 404 if it has passed, regardless of whether the bytes still exist. Caches must respect this too: the CDN `max-age` for a public paste is the smaller of the normal cache lifetime and the time remaining until expiry, so an edge never serves a paste past its deadline.

Physical deletion (cost and privacy). Several mechanisms exist; production systems combine them.

Table 52.8 — TTL cleanup mechanisms compared.

Mechanism	How it works	Timeliness	Cost	Weakness
Lazy deletion on read	Delete when a read finds the paste expired	Only for pastes that are read again	Free	Most expired pastes are never read again
Full-table scan	Periodically scan all rows for `expires_at < now`	Hours	Reads the entire table each pass	Cost grows with total rows, not with expirations
Database-native TTL	Store marks rows with a TTL; background process deletes	Best effort; DynamoDB says "within a few days"	Low	No deadline; LSM stores create tombstones (§13.9)
Time-bucketed expiry index	Write `(hour bucket, shard, code)` at create; sweep past buckets	Minutes	One extra write per paste	Index and data can diverge; needs reconciliation
Object-store lifecycle rules	Rule expires objects under a prefix or tag after N days	About a day, asynchronous	Free in requests	Day granularity; cannot express "10 minutes"
Partition drop	Store each time window in its own table or partition; drop it whole	Window size	Cheapest per row	Only works if everything in a window expires together

This design uses the **time-bucketed expiry index as the primary mechanism**, with object lifecycle rules and a reconciler as backstops. The sweeper works like this:

1. Each worker owns a subset of the 64 shards (assigned by lease, §26.11). Every minute it reads the partitions `(bucket_hour, shard)` for hours that have fully passed and not yet been marked swept.
2. For each code, it re-reads the metadata row and confirms `expires_at` has passed (the owner might have changed the expiry), deletes the object if `storage = 1`, then deletes the metadata row, then the index entry.
3. When a partition is empty, the worker records the bucket as swept. Deletes are idempotent, so a worker that crashes halfway simply repeats the partition.

Reading by bucket makes the sweep's cost proportional to the number of *expiring* pastes (389 per second at peak), not to the table size. Sharding each hour into 64 partitions keeps any single partition from becoming a hot spot when many pastes share an expiry hour, and lets 64 workers sweep in parallel.

The **object-store lifecycle rules** act as a safety net for content: one rule per expiry class, for example "delete objects under `b/7d/` 8 days after creation". If the sweeper falls behind or loses track of an object, the store deletes it anyway, about a day late. "Never" objects live under a separate prefix with a tiering rule instead (move to an infrequent-access class after 90 days without reads, §15.9).

INDUSTRY EXAMPLE

Amazon S3 lifecycle rules and DynamoDB TTL. S3 lifecycle configurations can expire objects a set number of days after creation, filtered by key prefix or object tags; S3 queues objects for removal and deletes them asynchronously, so there can be a delay between the expiration date and actual removal, although billing for an expired object stops once it becomes eligible [AWS Docs: S3 Lifecycle]. DynamoDB TTL deletes items whose TTL attribute has passed, without consuming write throughput, typically within a few days of expiry; until then, expired items still appear in reads unless filtered [AWS Docs: DynamoDB TTL]. Both are background, best-effort mechanisms: they reduce cost, but neither replaces the read-time expiry check.

Evidence: Primary — [AWS Docs: S3 Lifecycle]; [AWS Docs: DynamoDB TTL]

COMMON MISTAKE

"Set a TTL in the database and the problem is solved." Database TTLs decide when bytes are *reclaimed*, not when data stops being *visible*. A paste that expired at 10:00 can be served at 10:05, or for days, unless every read checks `expires_at`. In LSM-based stores, mass expiry also produces tombstones that slow reads until compaction removes them; Cassandra-style stores recommend a time-window compaction strategy for TTL-heavy tables (§13.9).

Component 3: access control for private pastes

Table 52.9 — Paste visibility modes.

Mode	Who can read	Served by CDN?	Listed?	Enforcement
Public	Anyone	Yes, `Cache-Control: public`	Yes, in the recent feed	None beyond expiry and abuse checks
Unlisted	Anyone with the link	Yes	No	Unguessable code only (it is a capability URL)
Private	Owner and ACL principals	No: `Cache-Control: private, no-store`	No	Authentication plus ACL check on every request
Password	Anyone with link and password	No	No	Argon2id verification; rate-limited attempts
Client-encrypted	Anyone with the full link including key	Ciphertext may be cached	No	Decryption key in URL fragment, never sent to server

Three rules make private pastes safe:

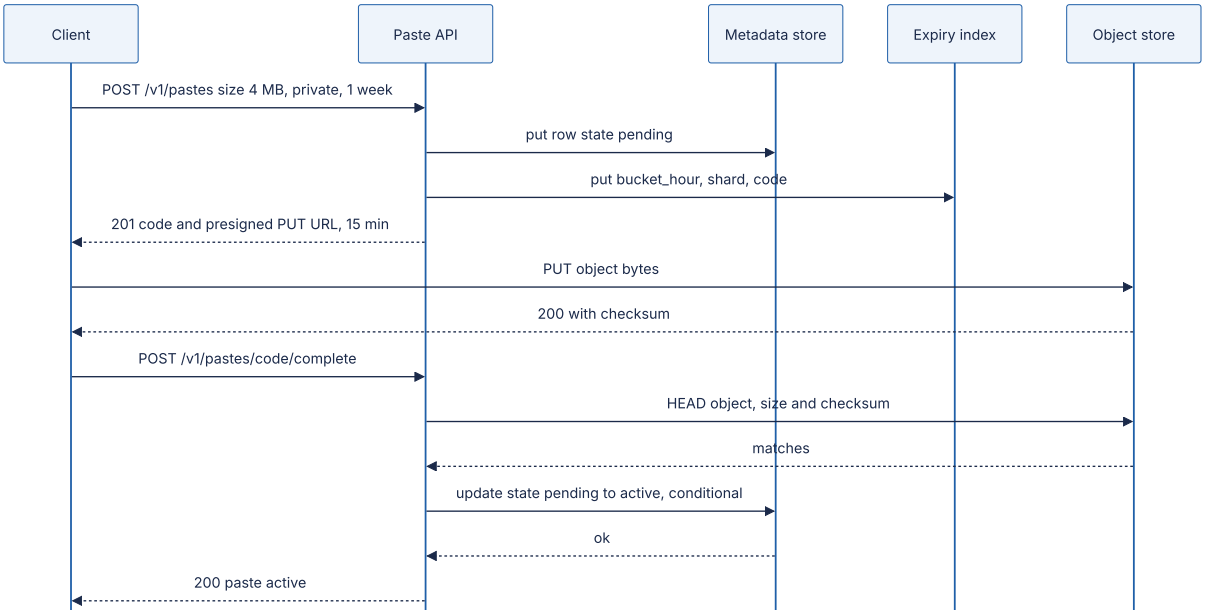
1. **Authorization happens on every request in the API**, never in the CDN or object store, which do not know about ACLs. Private responses carry `Cache-Control: private, no-store` and are never cached in shared layers (§21.6).
2. **Content URLs for large private pastes are presigned, short-lived (60 s) and generated only after the ACL check.** A presigned URL is a bearer token (§15.8.2): anyone holding it can read the object until it expires, so keep it short and never log it.
3. **The object store bucket blocks all public access.** Even public pastes are served through the CDN with origin authentication, not from a public bucket, so a misconfigured object cannot leak (threat T3 in Table 10.2, §10.3, is the same failure).

Burn-after-read needs one atomic step: a conditional update `SET state = burned WHERE code = ? AND state = active`, executed *before* returning content. Only the reader whose update succeeds receives the content; a concurrent reader's condition fails and it gets 410. The content is then deleted asynchronously. Never let a CDN cache a burn-after-read paste.

> INDUSTRY EXAMPLE
>
> **PrivateBin.** PrivateBin is an open-source pastebin in which the browser encrypts the paste with a random key before upload and places the key in the URL fragment (the part after `#`), which browsers do not send to the server; the server stores only ciphertext and cannot read pastes [PrivateBin]. This moves trust from the operator to the link: anyone who has the full URL can read the paste, and losing the URL loses the paste. It also makes server-side features such as abuse scanning and search impossible.
>
> *Evidence: Primary* — [PrivateBin]

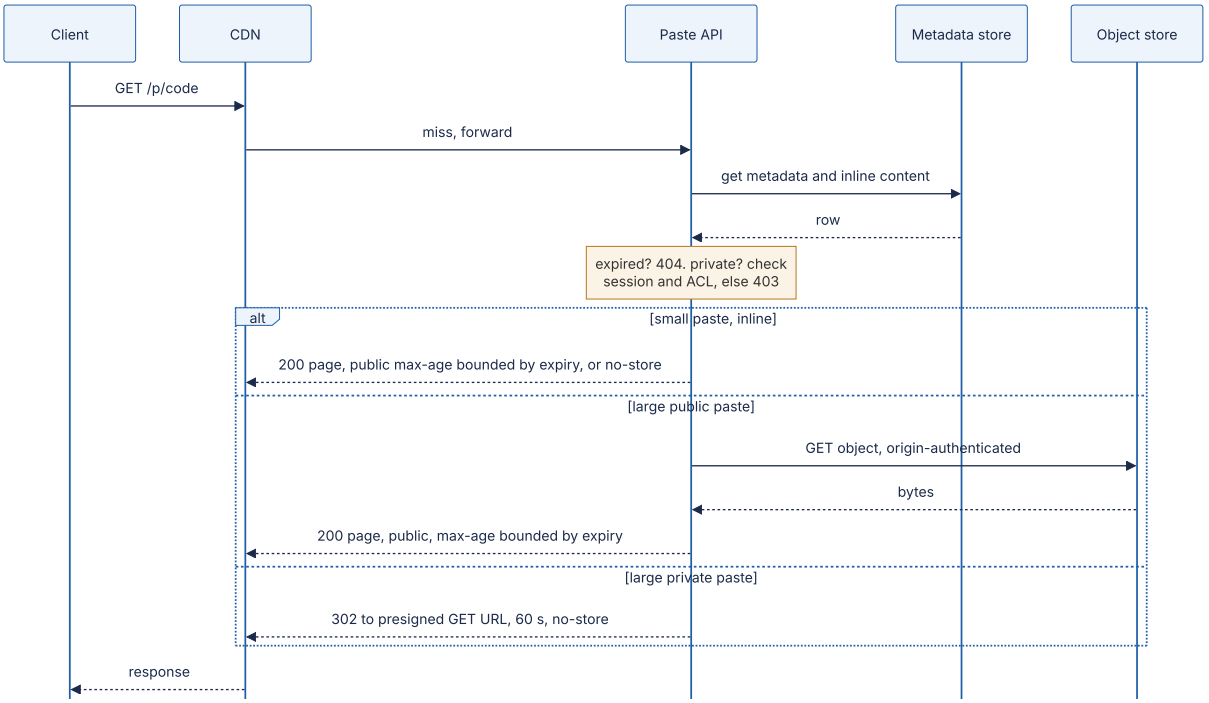
52.5.9 Data flow

Figure 52.6 — Write path: creating a large private paste.



Reading the diagram. Every step is synchronous from the client's point of view, but the bytes travel directly from the client to the object store, bypassing the API. The metadata row exists from the first step in `pending` state, so the paste is never visible before its content is complete; the conditional update in the last step is the commit point. The expiry index entry is written at creation so the sweeper will find the paste even if the upload is abandoned. Failure points: the client never completes (the sweeper removes the pending row and object after an hour); the checksum does not match (the API deletes the object and leaves the paste pending). Scaling: upload bandwidth scales with the object store, not with the API fleet.

Figure 52.7 — Read path: public and private pastes.



Reading the diagram. The CDN can answer repeated reads of public pastes; everything private passes through to the API. The metadata lookup is always first and decides existence, expiry and visibility before any content is touched. Small pastes are answered from the same row. Large public pastes are fetched by the API (or by the CDN directly with origin authentication) and cached with a lifetime that ends no later than the paste's expiry. Large private pastes get a short-lived presigned redirect issued only after the ACL check. Failure points: the object store is unavailable (small pastes still work; large pastes return 503); the metadata store is unavailable (cached public pastes still work; everything else fails). Scaling: CDN hit ratio for public pastes is the main lever on egress.

52.5.10 Bottlenecks

1. **Metadata store hot spots from the expiry index.** Without the shard component, all pastes expiring in the same hour land in one partition. With 64 shards, the peak hour's roughly 1.4 million entries ($389 \times 3,600$) spread to about 22,000 per partition.
2. **Object-store request rate for many small objects.** Inlining small pastes removes 60% of object requests.
3. **Egress for viral public pastes.** A paste linked from a popular forum behaves like a hot key; the CDN absorbs it, provided the response is cacheable.
4. **Abuse scanning.** Pastebins attract leaked credentials and malware payloads. Scanning 200 GB/day of new content for secrets and malware signatures is a significant asynchronous workload, separate from serving.

52.5.11 Failure scenarios

Table 52.10 — Pastebin failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Expiry sweeper stops	Expired bytes linger; storage grows; privacy exposure in backups	Oldest unswept bucket age	Restart; workers catch up idempotently	Alert on sweep lag; lifecycle rules as backstop
Delete of metadata succeeds, object delete fails	Orphan object (invisible, costs money)	Daily inventory diff	Reconciler deletes orphan	Delete object first, then row; idempotent retries
Object store regional outage	Large pastes unreadable	Object GET error rate	Serve 503 with retry; optional cross-region replica	Cross-region replication for "never" pastes
Private paste cached by CDN	Data leak	Canary private pastes probed through the CDN	Purge CDN; rotate affected codes	`no-store` on private responses; tests in CI
Presigned URL logged or shared	Unauthorized read until URL expiry	Access logs show unexpected IPs	Shorten expiry; rotate signing key	60 s expiry; strip query strings from logs
Concurrent burn-after-read readers	Content shown twice	Burn conflicts metric	None needed if conditional update is correct	Conditional state transition before returning content
Clock skew between API nodes	Pastes expire early or late by the skew	Clock offset monitoring (§24.9)	Fix NTP	Compare against store-assigned time where available

52.5.12 Scaling strategy

At 10× (100 million pastes per day). Peak creates reach about 5,600/s and reads about 28,000 RPS; still a small fleet. Permanent storage grows by 219 TB a year, so tiering of cold "never" pastes to infrequent-access or archive classes (§15.9) becomes the main cost decision; restoring from archive classes can take minutes to hours, so show a "restoring" page. The sweeper handles about 3,900 deletes/s at peak; raise the shard count to 256.

At 100×. Content deduplication becomes worthwhile: identical log files and configuration snippets are pasted repeatedly. Store objects by content hash (`sha256`) with a reference count in metadata (§15.8), so deleting a paste decrements a count instead of deleting bytes. Reference counting brings its own hazard (a wrong count deletes shared content), so the reconciler must verify counts. Serve from multiple regions with metadata replicated asynchronously and content replicated on first remote read.

52.5.13 Trade-offs

- **Inline versus object storage:** one lookup and fewer requests for small pastes, in exchange for a larger metadata store and two code paths.

- **Expiry index versus native TTL:** bounded deletion lag and control, in exchange for an extra write per paste and a reconciler.
- **CDN for public pastes:** low latency and egress offload, in exchange for having to bound cache lifetimes by expiry and never misclassifying a private response.
- **Client-side encryption:** the operator cannot read pastes, in exchange for no server-side abuse scanning, no search and no recovery of lost links.

52.5.14 Alternative designs

- **Everything in one relational database.** Fine up to tens of gigabytes: `TEXT` columns, a `DELETE … WHERE expires_at < now() LIMIT 10000` job and an index on `expires_at`. It stops working when table bloat and replication of large values dominate.
- **Time-partitioned tables.** Keep one table per expiry day and drop whole tables. Deletion becomes nearly free, but lookups by code must either query several partitions or consult a code-to-partition index, and owner-initiated deletes still need row-level deletes.
- **Pure object store with metadata in object tags.** Simple, but authorization, listing by owner and burn-after-read all need conditional metadata updates that object stores support only partially; you end up rebuilding a metadata store.

52.5.15 Interview discussion

Table 52.11 — 45-minute plan for Pastebin.

Minutes	Focus	What to produce
0–5	Requirements	Visibility modes, expiry options, burn after read, size limits
5–10	Estimates	2,800 read RPS at peak, 21.9 TB/yr permanent, 7 million deletions/day
10–15	API and data model	Presigned upload flow; metadata row with inline content
15–22	Architecture	Figure 52.5 with the blob/metadata split
22–35	Deep dive: expiry	Logical versus physical deletion; bucketed index; lifecycle backstop; reconciler
35–42	Access control	CDN rules, presigned URLs, burn-after-read atomicity
42–45	Failures and scaling	Orphans, sweep lag, deduplication at 100×

Likely follow-ups.

- *"Why not store pastes in the database?"* Size distribution and lifecycle: large immutable blobs inflate compaction, replication and caches; object storage is cheaper per byte and has lifecycle rules. Keep small pastes inline.
- *"How do you guarantee expired pastes are never shown?"* Check `expires_at` on every read and bound every cache lifetime by the remaining time to expiry; physical deletion is a separate, lagging process.
- *"How do you implement burn after reading?"* A conditional state transition before returning content; only one reader can win.
- *"What about the 10-minute expiry with day-granularity lifecycle rules?"* The read check makes it correct; the sweeper deletes within an hour; the lifecycle rule is only a backstop.

What distinguishes senior and staff answers. A senior candidate separates blobs from metadata and uses presigned URLs. A staff candidate notices from the estimate that permanent pastes dominate storage and proposes a product policy, distinguishes logical from physical deletion explicitly, designs reconciliation for the two stores, and treats private-content caching as a security property with tests.

52.5.16 Production considerations

- **Observability.** Sweep lag (age of the oldest unswept bucket), orphan counts from the reconciler, CDN hit ratio for public pastes, presigned URL issuance rate, and 403 rates on private pastes (a spike can indicate scraping).
- **Security.** Scan new content for leaked secrets and malware asynchronously; offer a fast abuse-takedown path; encrypt objects at rest with keys from a KMS (§10.9); keep presigned URLs out of logs. Treat "unlisted" as public in your threat model.
- **Cost.** Storage of permanent pastes dominates; tier and expire them by policy. Inline small pastes to cut request costs.
- **Operations.** Backups must honor expiry: restoring last week's backup must not resurrect expired or deleted pastes, so replay the deletion log after any restore, and keep backup retention shorter than the privacy promise.

52.6 Rate limiter (as a distributed service)

52.6.1 Problem statement

Design the rate-limiting service for a public API platform that serves 1 million requests per second at peak from three regions. Product teams declare limits ("each API key: 100 requests per second with bursts of 200"; "each tenant: 50,000 SMS sends per day"; "each IP: 10 failed logins per minute"), and every API gateway must enforce them on every request.

Chapter 22 already teaches the algorithms (§22.4–§22.7) and the basic distributed techniques (§22.8). This case does not re-derive them. It treats the limiter as a **shared service** that hundreds of gateways in several regions depend on, and its hard problems are therefore operational and distributed:

1. **Where the counters live (the distinctive hard problem).** A central store is exact but adds a network round trip to every request and concentrates hot keys; local counting is fast but overshoots. The design must mix them per rule.
2. **Atomicity.** Concurrent checks for the same key must not race (§22.8.2).
3. **Multi-region limits.** A tenant's limit is global, but a cross-region round trip costs 70–150 ms, more than the whole request budget.
4. **Failure policy.** When the limiter itself is slow or down, should requests pass (fail-open) or be rejected (fail-closed)? The answer differs by rule.

52.6.2 Functional requirements

- **Declarative rules.** A rule names a key template (API key, tenant, IP, user, endpoint, or combinations), an algorithm (token bucket, sliding window counter, concurrency limit), a rate and burst or window, a cost function (for example, a batch request costs 10), a scope (regional or global) and a failure mode.
- **Decision API.** Given request attributes, evaluate all matching rules and return allow or deny, the most restrictive remaining quota, and a retry-after time.
- **Shadow mode.** A new rule can run in "log only" mode, recording what it would have rejected, before enforcement (Stripe recommends this dark launch [Tarjan 2017]).
- **Dynamic configuration.** Rules and per-tenant overrides change without redeploying gateways and take effect within 30 seconds.
- **Client signaling.** Gateways return 429 with `Retry-After` and the draft `RateLimit` header fields (§22.3.4).
- **Usage visibility.** Tenants and operators can see current usage against limits.

52.6.3 Non-functional requirements

Property	Target
Added latency	p99 ≤ 0.1 ms for local decisions; p99 ≤ 2 ms for centrally checked rules, in-region
Availability of the API	The limiter must never be the cause of API unavailability: a limiter outage degrades enforcement, not service
Limiter availability	99.99% per month for the central tier
Accuracy, regional rules	Overshoot ≤ 5% of the limit per window under steady load
Accuracy, global rules	Overshoot ≤ 15% of the limit per window when traffic shifts between regions; exact for daily quotas within 1%
Configuration propagation	≤ 30 s from rule change to enforcement everywhere
Throughput	3 million decisions per second at peak, growing 2× per year

The first availability row is a design principle as much as a number: the limiter protects the platform, so a limiter that takes the platform down has failed at its only job.

52.6.4 Capacity estimation

WORKED EXAMPLE

Worked example — Decisions, central load and memory.

Assumptions. 1,000,000 API RPS at peak across all regions (US 50%, EU 30%, Asia-Pacific 20%). Each request matches 3 rules on average. One Redis shard sustains $c = 50,000$ Lua-script evaluations per second (scripts cost more than simple commands; measure yours); $u = 0.6$. A decision exchange is about 200 bytes on the wire. At most 20 million distinct keys are active in any 10-minute period; one bucket in Redis with key and overhead is about 150 bytes.

1. Decisions at peak: $10^6 \times 3 = 3 \times 10^6$ per second.
2. If every decision were central: $3 \times 10^6 / (50,000 \times 0.6) = 100$ Redis shards, and $3 \times 10^6 \times 200\ \text{B} \times 8 = 4.8\ \text{Gbps}$ of limiter traffic.
3. If only the 20% of decisions that need precision (paid-tier per-key limits, expensive endpoints, quotas) are central: $6 \times 10^5 / 30,000 = 20$ shards across the three regions.
4. Memory: $20 \times 10^6 \times 150\ \text{B} = 3\ \text{GB}$, small enough for every region to hold all its keys with replicas.
5. Hot tenant: one tenant at 100,000 RPS would need 100,000 script calls per second on one shard, twice a shard's capacity. With leased token batches of 100 (Component 2), it needs $100,000/100 = 1,000$ calls/s.

Interpretation. Memory is trivial; operations per second and per-key concentration are what matter. *Engineering implication.* Decide per rule which tier enforces it. Centralize only what needs precision, and batch hot keys.

Table 52.12 — Rate limiter capacity summary.

Quantity	Value	Consequence
Decisions at peak	3 million/s	In-process evaluation is the default path
Central decisions	≈ 600,000/s	≈ 20 Redis shards across three regions
Active keys	≈ 20 million; ≈ 3 GB	Memory is not a constraint
Hottest key	100,000 RPS	Token leasing, not more shards
Cross-region RTT	70–150 ms	No synchronous global check on the request path

52.6.5 API design

The decision API is a gRPC call (§8.8) for gateways that use the remote tier; most decisions run in an in-process library with the same interface.

```
        service RateLimiter {
          rpc ShouldRateLimit(LimitRequest) returns (LimitResponse);    // hot path
          rpc LeaseTokens(LeaseRequest) returns (LeaseResponse);        // batch leasing
for hot keys
        }
        message LimitRequest {
          string domain = 1;                          // "public-api"
          repeated Descriptor descriptors = 2;        // e.g. {api_key: "k_123"}, {ip:
"203.0.113.7"}, {endpoint: "POST /v1/sms"}
          uint32 cost = 3;                            // default 1
        }
        message LimitResponse {
          enum Code { OK = 0; OVER_LIMIT = 1; }
          Code overall = 1;
          repeated RuleStatus statuses = 2;           // per matched rule: limit, remain-
ing, reset_seconds, shadow
          double retry_after_seconds = 3;
        }
        message LeaseRequest  { string key = 1; uint32 tokens_wanted = 2; string node_id
= 3; }
        message LeaseResponse { uint32 tokens_granted = 1; double valid_for_seconds = 2;
}
```

```
Admin API (REST, authenticated, audited):
PUT  /v1/rules/{rule_id}     { "match": {"api_key": "*"}, "algorithm": "token_bucket",
                               "rate_per_s": 100, "burst": 200, "scope": "regional",
                               "on_failure": "open", "mode": "enforce" }
PUT  /v1/overrides/{tenant}  { "rule_id": "per-key-default", "rate_per_s": 1000,
"burst": 2000 }
GET  /v1/usage?key=api_key:k_123     -> { "rule": "...", "remaining": 37,
"reset_seconds": 0.4 }
```

52.6.6 Data model and database schema

There are two kinds of state with opposite requirements.

Rules and overrides are small (thousands of rules, millions of overrides), change rarely, must be durable and versioned, and must reach every gateway. Store them in a relational database (§11) with an audit trail, compile them into a versioned snapshot, and distribute the snapshot to gateways through a configuration service (watch-based, §26.9) or a pull every 10 seconds.

```
        CREATE TABLE rules (
          rule_id      TEXT PRIMARY KEY,
          domain       TEXT NOT NULL,
          match_expr   JSONB NOT NULL,        -- descriptor pattern
          algorithm    TEXT NOT NULL,         -- token_bucket | sliding_window | concur-
rency
          rate_per_s   DOUBLE PRECISION,      -- or window_s + limit for windowed rules
          burst        INT,
          scope        TEXT NOT NULL,         -- local | regional | global
          on_failure   TEXT NOT NULL,         -- open | closed | fallback_local
          mode         TEXT NOT NULL,         -- shadow | enforce
          version      BIGINT NOT NULL,
          updated_by   TEXT NOT NULL,
          updated_at   TIMESTAMPTZ NOT NULL
        );
        CREATE TABLE overrides (tenant_id TEXT, rule_id TEXT, rate_per_s DOUBLE
PRECISION, burst INT,
                                PRIMARY KEY (tenant_id, rule_id));
```

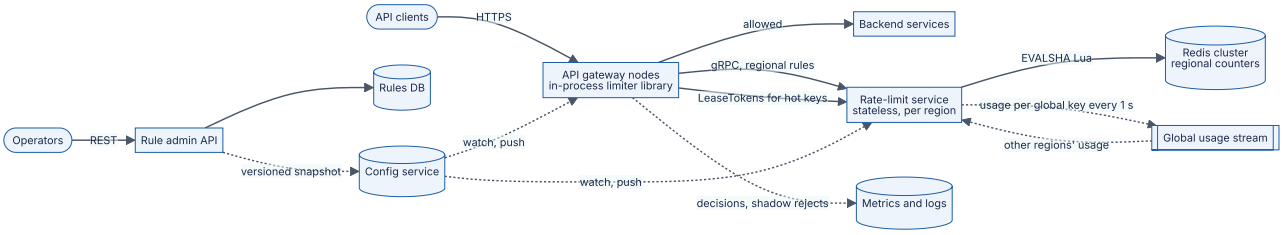
Counters are tiny, extremely hot, short-lived and individually unimportant: losing a bucket resets one key's allowance, which merely admits a short burst. They live in memory: in-process for local rules, and in a Redis cluster per region for regional rules. Key design:

```
rl:{api_key:k_123}:per-key-default        -> HASH {tokens, ts}        token bucket
(§22.4)
rl:{tenant:t_42}:sms-daily:20261105       -> STRING count             fixed window per
UTC day
rl:{ip:203.0.113.7}:login-fail:29384712   -> STRING count             sliding window
counter, minute buckets (§22.7)
```

The braces are a Redis Cluster **hash tag**: only the part inside braces is hashed to choose the slot, so all rules for one entity land on one shard and a single Lua script can update them atomically (§22.8.2). Every key carries a TTL slightly longer than its window so idle keys disappear on their own.

52.6.7 High-level architecture

Figure 52.8 — Rate limiting as a hybrid local and regional service.



Reading the diagram. Each gateway node embeds a limiter library and holds the current rule snapshot. For each request it evaluates matching rules: *local* rules (coarse per-IP protection, per-node concurrency) entirely in memory; *regional* rules through a synchronous gRPC call to the regional rate-limit service, which executes one atomic Lua script on the Redis shard owning the key; *hot* keys through tokens leased in batches. Only allowed requests reach backend services. Configuration flows asynchronously (dotted) from the admin API through a versioned snapshot in the configuration service to every gateway and limiter node. For *global* rules, each region's limiter publishes per-key usage every second to a cross-region stream and adjusts its regional allocation from the other regions' reports. Storage boundaries: rules are durable in the rules database; counters are volatile in Redis and memory. Failure points: Redis shard loss (buckets reset; affected rules fall back to their failure mode), limiter service latency (gateway timeout then failure mode), configuration service outage (gateways keep the last snapshot), cross-region stream lag (global rules overshoot more). Scaling: gateways and limiter nodes scale horizontally; Redis by shards; global coordination cost grows with the number of global keys, not with request rate.

52.6.8 Detailed component design

Component 1: choosing where each rule is counted

Algorithm choice is settled in Chapter 22: a **token bucket** (§22.4) or its single-timestamp form **GCRA** (§22.5.2) for per-key rates with bursts; a **sliding window counter** (§22.7) for per-minute limits such as login failures; a **fixed window** (§22.6) for daily quotas, where window-edge bursts do not matter; and a **concurrency limiter** (in-flight count) for expensive endpoints. The new decision in a service design is *where* each rule's counter lives.

Table 52.13 — Where to count, per rule.

Tier	How it works	Added latency	Accuracy	Use for
Local (in-process)	Each gateway enforces L/N for N nodes, or a per-node safety limit	~0	Poor if traffic is skewed across nodes (§22.8)	Per-IP flood protection, per-node concurrency, fallback
Regional central	Atomic Lua script on the Redis shard for the key	0.3–1 ms in-region	Exact within a region	Paid per-key rates, login failures, expensive endpoints
Regional with leases	Gateway leases a batch of tokens and spends them locally	~0 on most requests	Overshoot ≤ outstanding unspent leases	Hot keys (one tenant at 100,000 RPS)
Global	Regional allocation from a global limit, reconciled every Δ	Same as regional	Overshoot ≈ $\lambda\Delta$ during shifts (§22.8.3)	Tenant-wide contractual limits, daily quotas

Leasing deserves a closer look because it is what lets one design serve both a tenant at 10 RPS and a tenant at 100,000 RPS. A gateway that sees a key's local demand exceed a threshold (for example, 50 RPS) stops calling the limiter per request and instead calls `LeaseTokens` for 100 tokens; the Lua script deducts 100 from the central bucket atomically and the gateway spends them locally. Overshoot is bounded by unspent leased tokens: with 200 gateways each holding at most 100, at most 20,000 tokens are outstanding, so the lease size must be capped at a small fraction of the limit (for a 100,000 RPS limit, 20,000 is 0.2 seconds of quota). Leases expire after a second, so tokens held by a crashed gateway return to circulation quickly.

Component 2: atomic updates in Redis

The race in Figure 22.5 is avoided by running read, decide and write as one Lua script on the shard that owns the key (§22.8.2). Three service-level details matter:

1. **One script per entity, several rules per call.** Because the hash tag puts all of an entity's keys on one shard, one `EVALSHA` evaluates every rule for that entity and returns all statuses, so a request matching three rules on two entities costs two round trips, issued in parallel.
2. **Server time.** Scripts read the time with Redis `TIME`, so gateways with skewed clocks cannot corrupt buckets (§24.9).
3. **Replication is asynchronous.** A Redis primary acknowledges before its replica has the update; after a failover, recent decrements are lost and some keys are briefly over-admitted. For rate limits this is acceptable, and it is the reason not to put money-like quotas only in Redis: daily billing quotas are also accumulated in a durable store, and Redis serves as the fast front.

Component 3: multi-region limits

A global limit of 6,000 requests per minute for a tenant served from three regions cannot be checked synchronously in one place: a 100 ms cross-region round trip on every request is far outside the 2 ms budget. The options trade accuracy for latency:

Table 52.14 — Multi-region limit strategies.

Strategy	Worst-case admitted	Latency	Problem
Independent regional limits of L each	$R \times L$ (3× for 3 regions)	Regional	A client spreading traffic gets 3× its limit
Static split L/R	L	Regional	A client concentrated in one region gets only a third
Home region (all checks for a tenant go to one region)	L	Cross-region for remote traffic	70–150 ms added outside the home region
Demand-proportional allocation, reconciled every Δ	L + about $\lambda\Delta$ during shifts	Regional	Needs a usage stream and allocator logic

This design uses **demand-proportional allocation** for global rules: each region publishes its per-key usage every second; each region then sets its own share of the limit from the reported demand, with a floor so a region with no recent traffic can still admit a first burst.

FORMULA

Demand-proportional regional allocation with a floor

$$L_r = f \cdot \frac{L}{R} + (1 - f) \cdot L \cdot \frac{d_r}{\sum_{j=1}^{R} d_j}$$

Symbol	Meaning	Units
L_r	Limit enforced in region r for the next interval	requests per window
L	Global limit for the key	requests per window
R	Number of regions	regions
f	Fraction of the limit reserved as equal floors	fraction (0–1)
d_r	Recent demand observed in region r (smoothed)	requests per window

WORKED EXAMPLE

Worked example — A tenant limited to 6,000 requests per minute.

Assumptions. Recent demand: US 6,000, EU 3,000, Asia-Pacific 1,000 requests per minute (total 10,000, above the limit). Floor fraction $f = 0.10$. Reconciliation interval $\Delta = 1$ s.

1. Floor per region: $0.10 \times 6,000/3 = 200$.
2. Demand shares: US $6,000/10,000 = 0.6$, EU 0.3, Asia-Pacific 0.1. Remaining quota: $0.9 \times 6,000 = 5,400$.
3. Allocations: US $200 + 0.6 \times 5,400 = 3,440$; EU $200 + 1,620 = 1,820$; Asia-Pacific $200 + 540 = 740$. Sum: 6,000.
4. Overshoot during a sudden shift, applying §22.8's bound $E_{\max} \approx \lambda\Delta$ with offered rate $\lambda = 10,000/60 = 167$ requests/s: about $167 \times 1 = 167$ extra requests in the window, 2.8% of the limit. With $\Delta = 5$ s: 833, or 14%.

Interpretation. The global limit is respected in steady state, and each region's share follows its demand. *Engineering implication.* The reconciliation interval sets the overshoot during shifts; 1 s keeps it within the 15% target with margin, and the usage stream carries only active global keys, not requests.

Daily quotas (for example, SMS sends per tenant per day) are a special case: they are small in rate but must be nearly exact because they map to money. For these, each region leases quota in chunks from a durable global counter (a strongly consistent store in one region, §26.9) and refills before running out; a 100 ms round trip once per chunk of 1,000 sends is invisible.

Component 4: fail-open or fail-closed

Every rule declares its failure mode, because the right answer depends on what the rule protects.

Table 52.15 — Failure policy by rule type.

Rule protects	Example	On limiter failure	Reason
Fair sharing of capacity	100 RPS per API key	Fail open, with local per-node fallback limits	A limiter outage must not become an API outage; local limits still stop a flood
Security	10 failed logins per minute per account	Fail closed to a strict local limit	Credential stuffing during an outage is worse than slowing logins
Money	SMS sends per tenant per day	Fail closed beyond the locally leased chunk	Each unchecked send costs real money
Backend survival	Concurrency of an expensive report endpoint	Local concurrency limit, always on	Must not depend on any remote service

The mechanism: the gateway gives the limiter call a short timeout (for example, 5 ms), wraps it in a circuit breaker (§22.13), and on timeout or open circuit applies the rule's failure mode. "Fail open" never means "no protection": load shedding (§22.9) still protects backends.

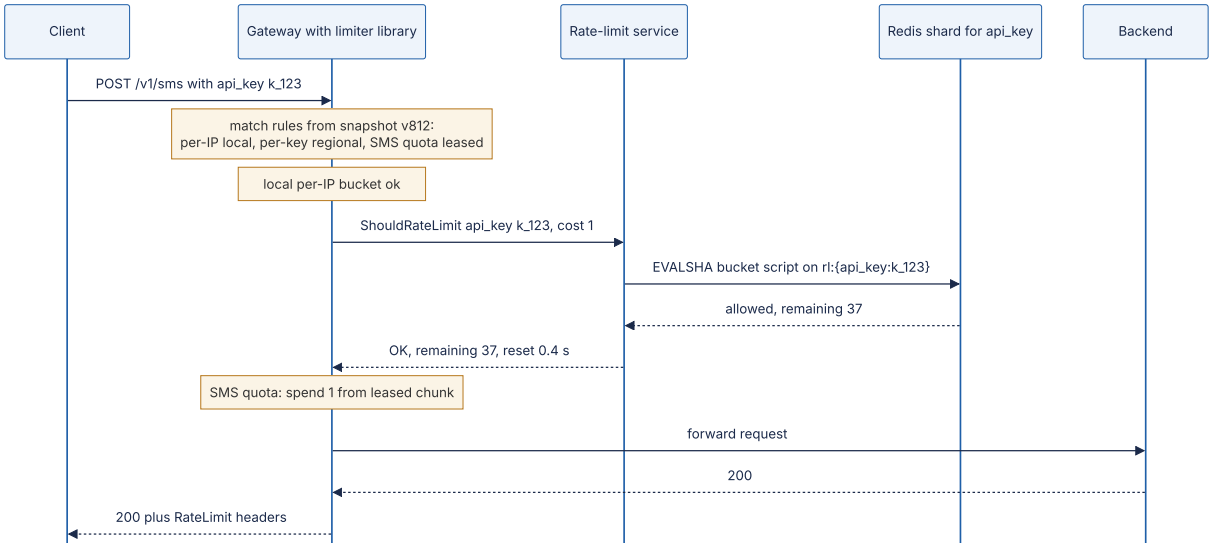
INDUSTRY EXAMPLE

Stripe's rate limiters and Envoy's global rate limit service. Stripe described four limiters in production: a per-user request rate limiter implemented as a token bucket in Redis, a concurrent-requests limiter, a fleet usage load shedder reserving capacity for critical requests, and a worker utilization load shedder; it recommended running new limiters in a mode that logs would-be rejections before enforcing them [Tarjan 2017]. Envoy supports both a local token-bucket rate-limit filter and calls to an external global rate-limit service over gRPC; Envoy's reference implementation of that service is open source and stores counters in Redis [Envoy Docs: rate limiting]. These match the hybrid shape of Figure 52.8: local enforcement for protection, a central counter service for shared limits.

Evidence: Primary — [Tarjan 2017]; [Envoy Docs: rate limiting]

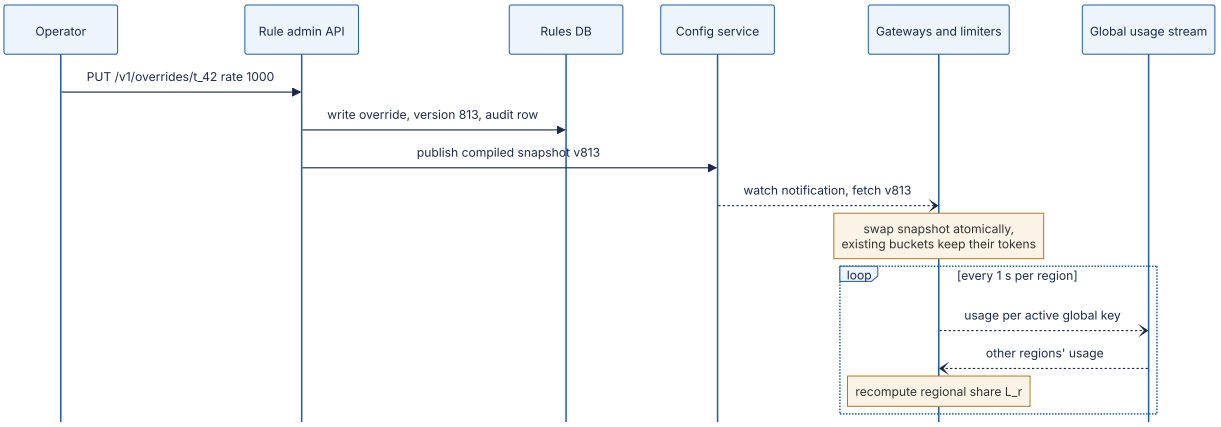
52.6.9 Data flow

Figure 52.9 — Hot path: a request checked against local and regional rules.



Reading the diagram. The gateway evaluates three rules. The per-IP rule is decided in memory. The per-key rule needs one synchronous gRPC call to the regional limiter, which runs one atomic script on the Redis shard owning the key and returns the decision with remaining quota. The SMS quota is spent from a chunk previously leased from the durable global counter, so it needs no call at all. Only then does the request reach the backend; the `RateLimit` headers go back even on success so clients can slow down early. If the limiter call exceeds its 5 ms timeout, the gateway applies the per-key rule's failure mode (fail open with the local fallback limit). Scaling: the regional call is the only remote step and can be skipped entirely for hot keys by leasing.

Figure 52.10 — Control path: rule change and global usage reconciliation.



Reading the diagram. The upper part is the configuration write path: the admin API writes the change durably with an audit record, compiles a new versioned snapshot and publishes it; gateways and limiter nodes receive a watch notification asynchronously and swap to the new snapshot atomically, typically within seconds, well inside the 30 s target. Counter state survives the swap: changing a rate does not refill or empty buckets. The loop is the global-limit write path: each region publishes usage for active global keys every second and recomputes its share from the others' reports. Failure points: a config ser-

vice outage freezes rules at the last snapshot (safe); a usage stream outage leaves regions on their last shares, which still sum to the global limit. Scaling: the snapshot size grows with rules and overrides; at millions of overrides, gateways fetch overrides lazily per tenant and cache them.

52.6.10 Bottlenecks

1. **Hot keys on one Redis shard.** Solved by leasing, not resharding: a key cannot be split across shards without losing atomicity.
2. **The round trip itself.** Even 0.5 ms per call at 600,000 calls/s is a fleet-wide cost in connections and CPU; pipelining and connection pooling (§7.16) matter.
3. **Rule evaluation cost.** Matching a request against thousands of rules must be an index lookup on descriptors, not a linear scan; compile rules into hash maps keyed by descriptor type.
4. **Key cardinality under attack.** A botnet with millions of IPs creates millions of per-IP buckets; local per-IP limits with bounded LRU tables keep memory flat, and the edge (§21.11) absorbs volumetric attacks before they reach gateways.

52.6.11 Failure scenarios

Table 52.16 — Rate limiter failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Redis shard down	Rules on its keys fall back to failure mode; buckets reset after failover	Limiter error rate, failover events	Replica promotion; buckets refill naturally	Replicas in other zones; short TTLs make reset harmless
Limiter service slow	Gateway p99 rises toward the timeout	Limiter p99 per region	Circuit opens; failure modes apply	5 ms timeout; leases for hot keys; capacity headroom
Bad rule pushed (limit 10 instead of 10,000)	Mass 429s for legitimate clients	429-rate alert per rule; shadow mode would have shown it	Roll back to previous snapshot version	Shadow mode first; review; staged rollout of snapshots by region
Config service unreachable	No new rules	Snapshot age per gateway	Keep last snapshot	Snapshots cached on disk; gateways start from last known good
Cross-region usage stream lags	Global overshoot during shifts	Stream lag	Regions keep last shares	Floor plus conservative shares when lag exceeds 10 s
Gateway clock skew	None for central rules (server time); local rules drift	Clock offset metric	Fix NTP	Use monotonic clocks locally
Retry storm after 429s	Load spikes as clients retry immediately	429 followed by retry rate	`Retry-After`, jittered client backoff (§22.12)	Document retry behavior; SDKs back off by default

52.6.12 Scaling strategy

At 10× (30 million decisions per second). Centrally checking 20% of decisions would need about 200 Redis shards. Push more rules to leases and local enforcement, and run the limiter library as an in-process component only; the remote tier then sees lease traffic, roughly proportional to the number of active hot keys times gateways, not to request rate. Partition the rate-limit service by key range so that each limiter node's Redis connection pool stays small.

At 100×. Every remote call becomes too expensive at this rate. Move to quota distribution for nearly all rules (§22.8.3): a coordinator per region assigns each gateway a per-key allowance from recent demand, and gateways enforce locally. Accept overshoot of a few percent everywhere except money-like quotas, which keep chunked leasing from a durable counter. Cell-based deployment (§33.12) caps each limiter cell's blast radius.

52.6.13 Trade-offs

- **Accuracy versus latency versus coordination traffic** (the triangle of §22.8): this design chooses per rule instead of globally.

- **Fail-open versus fail-closed**: availability of the API versus protection of money and security; decided per rule and documented.
- **Redis versus a durable store for counters**: speed versus exactness after failover; money-like quotas get both.
- **Global limits by allocation versus home region**: regional latency with small overshoot versus exactness with cross-region latency.

52.6.14 Alternative designs

- **Sidecar limiter per service** (as with Envoy's local filter): no shared service to operate, but only per-instance limits unless paired with a global service.
- **Limits enforced at the CDN edge** (§21.9): excellent for per-IP abuse limits and absorbing attacks, but edge nodes have weak coordination, so per-tenant contractual limits still need the origin tier.
- **Database-backed counters** (a row per key in a relational database with `UPDATE … SET count = count + 1 WHERE count < limit`): exact and durable, but 10–100× slower; suitable for daily quotas at low rates, not per-second limits.
- **Admission control by queueing instead of rejection** (leaky bucket as a queue, §22.5): smooths traffic for batch clients but adds latency and memory; rarely right for interactive APIs.

52.6.15 Interview discussion

Table 52.17 — 45-minute plan for the distributed rate limiter.

Minutes	Focus	What to produce
0–5	Requirements	Keys, rule types, accuracy, latency budget, failure policy question
5–9	Estimates	3 million decisions/s; 20% central; 3 GB of counters; hot tenant at 100,000 RPS
9–14	API and rule model	Decision RPC; rule schema with scope and failure mode
14–20	Architecture	Figure 52.8: library, regional service, Redis, config snapshots
20–33	Deep dive: where to count	Local vs central vs leased; Lua atomicity; hash tags
33–40	Multi-region and failure policy	Allocation formula; fail-open vs fail-closed by rule
40–45	Failures and scaling	Bad rule push, Redis failover, quota distribution at 100×

Likely follow-ups.

- *"Which algorithm would you use?"* Token bucket for per-key rates with bursts; sliding window counter for per-minute limits; fixed windows for daily quotas (§22.4–§22.7). Then move on: algorithm choice is not the hard part.
- *"What happens if Redis goes down?"* Per-rule failure modes: fail open to local limits for fairness rules, fail closed for security and money rules, all behind a short timeout and a circuit breaker.
- *"How do you limit globally across regions?"* Not synchronously; allocate regional shares from demand and reconcile every second, accepting a small overshoot during shifts.
- *"How do you handle one tenant sending 100,000 RPS?"* Lease tokens in batches so the central bucket is touched about 1,000 times per second instead of 100,000.

What distinguishes senior and staff answers. A senior candidate places counters in Redis with an atomic script, explains the race, and returns correct 429 semantics. A staff candidate designs the failure policy per rule, separates the control plane (rules, snapshots, shadow mode, rollback) from the data plane, handles hot keys and multi-region limits quantitatively, and insists that the limiter can never become the outage it exists to prevent.

52.6.16 Production considerations

- **Observability.** Per rule: decisions, rejections, shadow rejections and failure-mode activations; limiter p99 per region; snapshot version and age per gateway; Redis CPU per shard (hot keys show as one hot shard).
- **Security.** Rule changes are privileged operations: require review, audit every change, and rate-limit the admin API itself. Do not reveal internal rule names in client headers.
- **Cost.** Redis memory is cheap here; the cost is network calls and limiter CPU, which leasing and local evaluation reduce.
- **Operations.** Roll out rule snapshots region by region with automatic rollback when 429 rates jump; keep shadow mode as the default for new rules; run game days that kill a Redis shard to prove failure modes behave as declared (§39.11).

52.7 Notification system

52.7.1 Problem statement

Design a notification platform that every product team in a large consumer company uses to reach users by mobile push, email, SMS and in-app inbox. A team sends one request ("order 8812 has shipped, notify user 42") or launches a campaign ("tell 50 million users about the sale"), and the platform decides which channels to use, renders the content, re-

spects the user's preferences, sends through external providers, and tracks what happened.

Section 9.8 explains how a single push reaches a device through APNs or FCM. This case is about the platform around that: the **multi-channel fan-out** from one event to many users, devices and channels, under rules (the distinctive hard problem), together with:

- **User preferences**, quiet hours and frequency caps, checked for every message.
- **Templating and localization** for four channels with very different size limits.
- **Priorities**: a one-time password must not wait behind a marketing campaign.
- **Deduplication and idempotency**: retries at every layer must not send a user the same SMS twice (§22.15).
- **Provider failover** across several SMS and email vendors.
- **Delivery tracking** from "accepted" to "delivered", "bounced" or "opened".

52.7.2 Functional requirements

- **Send API** for a single user or a list of up to 1,000 users, naming a notification type (`order_shipped`), template parameters and an optional idempotency key.
- **Campaign API** for an audience segment (millions of users), with a schedule and a rate cap.
- **Channels:** push (iOS, Android, web), email, SMS, in-app inbox. A notification type declares which channels it may use and in what order of preference.
- **Preferences:** per user, per category (security, transactional, social, marketing) and per channel opt-in; quiet hours in the user's time zone; global unsubscribe; frequency caps for marketing.
- **Templates:** versioned, localized, per-channel variants with parameters.
- **Tracking:** per-notification status history and aggregate delivery, bounce and open rates per type and campaign.
- **Provider management:** multiple providers per channel with routing rules and automatic failover.

52.7.3 Non-functional requirements

Property	Target
Ingestion availability	99.99% per month for the send API (callers should never lose a notification request)
End-to-end latency	Critical (OTP, security): p99 ≤ 5 s from API call to provider acceptance; transactional: p99 ≤ 30 s; marketing: best effort within the campaign window
Delivery guarantee	At least once to the provider, with deduplication making duplicates rare (≤ 1 in 10^5 for SMS)
Durability	An accepted request is never silently dropped: it is sent, suppressed by a rule, or failed with a recorded reason
Campaign throughput	50 million recipients within 30 minutes without delaying transactional traffic
Preference correctness	An opt-out takes effect within 1 minute for all sends that have not yet reached a provider
Tracking freshness	Status visible within 1 minute of the provider's callback

52.7.4 Capacity estimation

WORKED EXAMPLE

Worked example — Notification volumes.

Assumptions. 500 million notifications per day: 400 million push, 80 million email, 10 million SMS, 10 million in-app. 30% (150 million) are transactional, with the usual $h = 0.10$, $b = 2$. The largest marketing campaign reaches 50 million users and must finish within 30 minutes. Each notification log record is 1 KB; each produces about 3 status events of 100 bytes. 300 million users with preferences of 500 bytes; 600 million device tokens of 200 bytes. SMS cost is an illustrative $0.01 per message (real prices vary several-fold by country and volume).

1. Average send rate: $5 \times 10^8 / 86,400 = 5,787$ per second.
2. Transactional peak: $1.5 \times 10^8 \times 0.10 / 3,600 \times 2 = 8,333$ per second.
3. Campaign rate: $5 \times 10^7 / 1,800\ \text{s} = 27,778$ per second.
4. Design capacity: transactional peak plus a full-speed campaign ≈ 36,000/s; provision **50,000 sends/s** for headroom.
5. Notification log: $5 \times 10^8 \times 1\ \text{KB} = 500\ \text{GB/day}$; 90 days of retention: **45 TB**. Status events: $5 \times 10^8 \times 3 \times 100\ \text{B} = 150\ \text{GB/day}$.
6. Preferences: $3 \times 10^8 \times 500\ \text{B} = 150\ \text{GB}$; device tokens: $6 \times 10^8 \times 200\ \text{B} = 120\ \text{GB}$. Both fit in a cache cluster.
7. SMS spend: $10^7 \times \$0.01 = \$100,000$ per day.

Interpretation. Average load is modest; the design is shaped by campaign bursts and by the need to keep critical messages fast during them. *Engineering implication.* Separate queues and worker pools by priority, and treat SMS as the expensive channel where duplicates cost real money.

The time to deliver a campaign depends on how much capacity is left after higher priorities take their share.

FORMULA

Campaign drain time under reserved priority capacity

$$T_{drain} = \frac{N}{C - \lambda_{hi}}$$

Symbol	Meaning	Units
T_{drain}	Time to hand all campaign messages to providers	seconds
N	Number of campaign messages	messages
C	Total sending capacity (workers and provider limits, whichever is lower)	messages/s
λ_{hi}	Rate consumed by higher-priority traffic during the campaign	messages/s

WORKED EXAMPLE

Worked example — Can the 50-million campaign finish in 30 minutes during the transactional peak?

1. $C = 50,000$/s; $\lambda_{hi} = 8,333$/s at the transactional peak.
2. Capacity left: $50,000 - 8,333 = 41,667$/s.
3. $T_{drain} = 5 \times 10^7 / 41,667 = 1,200$ s $= 20$ minutes.

Interpretation. The campaign meets its 30-minute window even at the transactional peak. *Engineering implication.* If a provider limits you to 20,000 sends/s for one channel, C for that channel is 20,000 and the same campaign takes $5 \times 10^7 / 11,667 = 4,286$ s, about 71 minutes; provider quotas, not your workers, often set C.

Table 52.18 — Notification system capacity summary.

Quantity	Value	Consequence
Average / design send rate	5,800/s / 50,000/s	Burst-driven; queues absorb campaigns
Transactional peak	8,333/s	Reserved capacity in separate queues
Campaign drain (50 million)	20 min at full capacity	Provider quotas are the real limit
Notification log, 90 days	45 TB	Partitioned wide-column or time-partitioned store
Preferences + tokens	270 GB	Cached in memory; source of truth in a database
SMS spend	≈ $100,000/day	Deduplication and suppression save money directly

52.7.5 API design

```
POST /v1/notifications                          (service-to-service, mTLS)
  Idempotency-Key: order-8812-shipped
  request:  { "type": "order_shipped", "recipients": [ { "user_id": 42 } ],
              "params": { "order_id": "8812", "carrier": "DHL", "eta": "2026-11-07" },
              "priority": "transactional",       // critical | transactional | marketing
              "channels": ["push", "email"],     // optional override of the type's de-
faults
              "expires_at": "2026-11-05T12:00:00Z" }
  202:      { "request_id": "nr_01J...", "accepted": 1 }

POST /v1/campaigns
  request:  { "type": "black_friday", "segment_id": "seg_eu_active_30d",
              "start_at": "2026-11-27T08:00:00", "timezone_mode": "recipient_local",
              "max_rate_per_s": 30000 }
  201:      { "campaign_id": "cmp_77", "estimated_recipients": 48211004 }

GET  /v1/notifications/{notification_id}       -> status history
GET  /v1/campaigns/{id}/stats                  -> sent, delivered, bounced, opened, sup-
pressed by reason
PUT  /v1/users/{user_id}/preferences           (from the app's settings screen)
POST /v1/providers/{provider}/callbacks        (provider webhooks, signature verified)
```

The send API returns **202 Accepted**, not 200: the request is durably queued, and delivery happens asynchronously. The idempotency key is required for transactional and critical types; the platform derives one per recipient and channel (`order-8812-shipped:42:email`).

52.7.6 Data model and database schema

```
        -- Durable record of every notification, partitioned by user, clustered by time
(wide-column store).
        CREATE TABLE notifications (
          user_id        BIGINT,
          created_at     TIMESTAMP,
          notification_id UUID,                -- UUIDv7, time-ordered (§17.10.2)
          type           TEXT,
          channel        TEXT,                 -- push | email | sms | inapp
          priority       TEXT,
          dedup_key      TEXT,                 -- idempotency key + recipient + channel
          template_ver   INT,
          provider       TEXT,
          provider_msg_id TEXT,                -- ID the provider returned, used to
match callbacks
          status         TEXT,                 -- see the state machine in Figure 52.12
          status_reason  TEXT,
          PRIMARY KEY ((user_id), created_at, notification_id)
        );

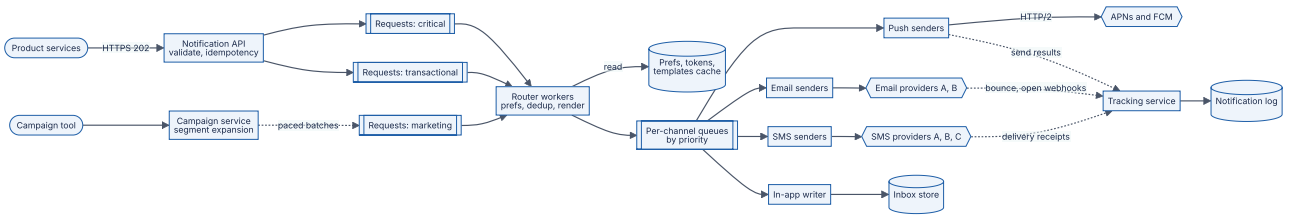
        -- Lookup from provider message ID to the notification, for callbacks.
        CREATE TABLE provider_msg_index (provider TEXT, provider_msg_id TEXT, user_id
BIGINT,
                                         created_at TIMESTAMP, notification_id UUID,
                                         PRIMARY KEY ((provider, provider_msg_id)));

        -- Preferences: relational source of truth, cached in memory.
        CREATE TABLE preferences (user_id BIGINT, category TEXT, channel TEXT, enabled
BOOLEAN,
                                  PRIMARY KEY (user_id, category, channel));
        CREATE TABLE user_settings (user_id BIGINT PRIMARY KEY, timezone TEXT, locale
TEXT,
                                    quiet_start TIME, quiet_end TIME, global_unsubscribe
BOOLEAN);
        CREATE TABLE device_tokens (user_id BIGINT, device_id TEXT, platform TEXT, token
TEXT,
                                    last_seen TIMESTAMP, PRIMARY KEY (user_id,
device_id));
        CREATE TABLE templates (type TEXT, channel TEXT, locale TEXT, version INT, body
TEXT,
                                PRIMARY KEY (type, channel, locale, version));
```

Choice of stores. The notification log is append-heavy (500 GB/day), read mostly by user and time (“show this user’s inbox”, “what did we send user 42?”), and expires after 90 days, which fits a wide-column store partitioned by `user_id` with time-window compaction and TTLs (§12.6, §13.9). Preferences, settings, tokens and templates are small, relational and read on every send, so they live in a relational database with an in-memory cache in front, invalidated by change events (§20.10). The deduplication keys live in Redis with a 24-hour TTL for speed, backed by a uniqueness check in the log (§22.15.3).

52.7.7 High-level architecture

Figure 52.11 — Notification platform architecture.



Reading the diagram. The send API validates the request, checks the idempotency key and writes it to a durable request queue for its priority, then returns 202; everything after that is asynchronous. The campaign service expands a segment into recipients in batches and feeds them into the marketing queue at a controlled rate (dotted). Router workers consume the three request queues with weighted priority, look up preferences, quiet hours, frequency caps and devices (from an in-memory cache backed by the preferences database), apply deduplication, render the template per channel and locale, and emit one message per recipient, device and channel onto per-channel queues, again separated by priority. Channel sender workers call external providers synchronously: APNs and FCM over HTTP/2 (§9.8), email and SMS providers over their APIs, choosing among providers by health and routing rules. Providers report outcomes asynchronously through webhooks and receipts to the tracking service, which updates the notification log. Storage boundaries: queues are the durable buffer; the log is the system of record for what happened; caches are disposable. Failure points: providers (throttling, outages), the preferences cache (stale opt-outs), and the router (the fan-out amplifier). Scaling: each worker pool scales independently on its queue lag; priorities never share a queue.

52.7.8 Detailed component design

Component 1: fan-out and routing

One API call fans out along three axes: recipients (1 to 50 million), devices per recipient (a user may have a phone, a tablet and a browser) and channels. The router handles a recipient as one unit of work:

1. **Expand.** Read the notification type's channel policy (for example `order_shipped`: push and in-app always, email if push is not deliverable) and the user's settings, preferences and devices from cache.
2. **Filter.** Drop channels the user opted out of for this category; drop marketing during quiet hours (defer it to the end of quiet hours instead, for campaigns in recipient-local time); apply frequency caps ("at most 3 marketing pushes per day", a per-user counter using the rate limiter of §52.6); drop expired requests (`expires_at` has passed). Every drop is recorded as `suppressed` with a reason, so "why didn't I get it?" has an answer.

3. **Deduplicate.** Build `dedup_key = idempotency_key + user + channel` and `SET dedup_key NX EX 86400` in Redis; if the key exists, skip.
4. **Render.** Pick the template version for the type, channel and locale, fill in parameters, and validate channel limits (Table 52.19).
5. **Emit.** Put one message per device and channel on the channel queue for the priority.

Campaigns are expanded upstream by the campaign service, which reads the segment from the data warehouse in pages of 10,000 user IDs and enqueues them at the campaign's rate cap. Expanding lazily, rather than writing 50 million messages at once, keeps queues small and lets an operator pause or cancel a campaign halfway; a canceled campaign simply stops enqueueing.

Table 52.19 — Channel characteristics that shape the design.

Channel	Payload limit	Cost per message	Delivery signal	Typical latency	Main failure
Push (APNs, FCM)	4 KB (4,096 bytes) for regular notifications (§9.8)	Free from the provider	Provider accepted; delivery and open only via app callback	Seconds	Stale tokens; OS throttling
Email	Practically large; keep under ~100 KB for deliverability	Low	Bounces, complaints, opens (pixel), clicks	Seconds to minutes	Spam filtering; reputation
SMS	160 GSM-7 characters or 70 UCS-2 per segment; 153 / 67 per segment when concatenated	High (illustratively $0.01 per segment)	Carrier delivery receipt (not always reliable)	Seconds	Carrier filtering; country rules
In-app inbox	Your own limit	Storage only	Read receipts from the app	Immediate on next open	None external

The SMS row explains why templates must be validated per channel: one emoji switches a message to UCS-2 encoding, cutting a segment from 160 to 70 characters, so a 150-character message becomes 3 concatenated segments and triples its cost.

Component 2: priorities and isolation

Priority is implemented by **separate queues and separate consumer pools**, not by a priority field in one queue. A single queue suffers head-of-line blocking: an OTP enqueued behind 50 million marketing messages waits for them. With separate queues:

- **Critical** (OTP, security alerts): its own topic, its own router and sender pool, provisioned for peak with large headroom, and a short message TTL (an OTP older than

5 minutes is useless and is dropped as `expired`).

- **Transactional** (order updates, receipts): its own pool, autoscaled on queue lag.
- **Marketing**: rate-capped at the campaign level and globally, so it can never take provider capacity that higher priorities need. Provider quotas are shared, so senders draw tokens from a per-provider token bucket in the rate limiter with priority-specific reservations: for example, 20% of an SMS provider's throughput is reserved for critical traffic.

Component 3: deduplication and idempotency

Duplicates arise at four points: the caller retries the API, the queue redelivers after a worker crash (at-least-once delivery, §30.8), the router processes a campaign batch twice, and a sender times out on a provider call that actually succeeded. The first three are handled by idempotency keys checked in Redis and backed by a unique `dedup_key` in the log (§22.15). The fourth is the hard one: when a provider call times out, the platform cannot know whether the SMS was sent. Retrying risks a duplicate; not retrying risks a loss.

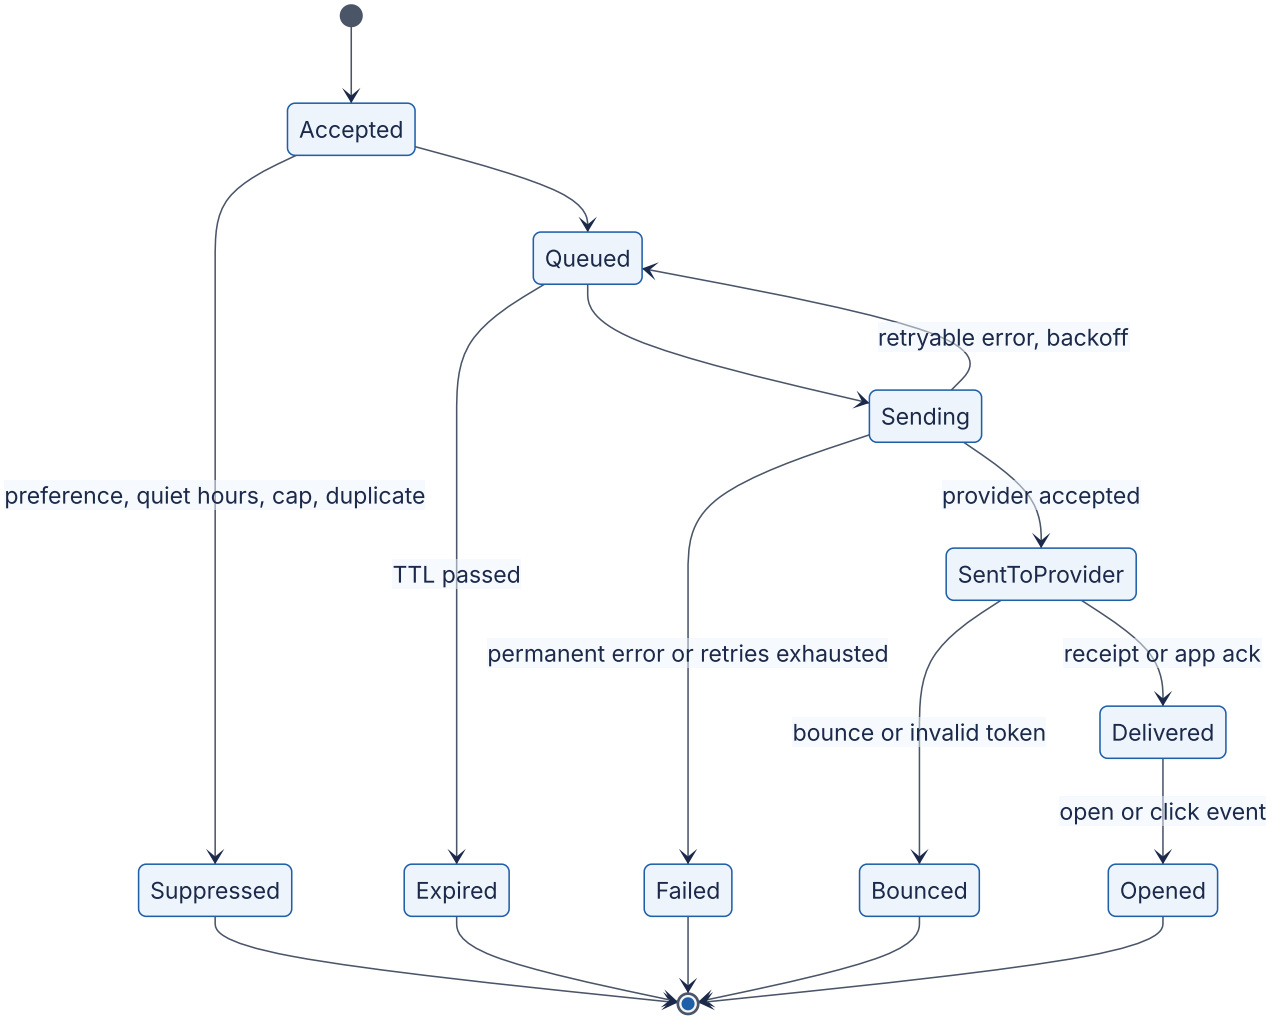
The design resolves it per channel. For push and email, retry with the same internal message ID; a rare duplicate is acceptable, and the provider's message ID, when returned, deduplicates callbacks. For SMS, where duplicates are costly and confusing, record `sending` before the call and, on timeout, query the provider's message-status API using a client reference you supplied, if the provider offers one, before retrying. Where no such API exists, choose by type: retry OTPs (a duplicate OTP is harmless, a missing one blocks login) and do not retry marketing.

Component 4: provider failover and delivery tracking

Each channel has a **provider router** that scores providers continuously on error rate, latency, delivery-receipt rate and cost, per destination country for SMS. Routing rules pick the cheapest healthy provider; a circuit breaker per provider (§22.13) opens on sustained errors and shifts traffic to the next provider. Two rules prevent failover from creating duplicates: fail over only on *definitive* failures (connection refused, 5xx with no message ID) or on circuit-open, never on a timeout for an SMS that may have been accepted; and include the idempotency key in the provider request where the provider supports one.

Delivery tracking is a state machine per message, advanced by events from senders and providers.

Figure 52.12 — Notification delivery state machine.



Reading the diagram. Every accepted request ends in exactly one terminal state, which is how the durability requirement (“never silently dropped”) is made checkable: a count of messages in non-terminal states older than an hour is an alert. `Suppressed` and `Expired` are deliberate non-sends with recorded reasons. `Sending` back to `Queued` is the retry loop with exponential backoff and jitter (§22.12); after the retry limit, the message moves to `Failed` and to a dead-letter queue for inspection (§30.11). `SentToProvider` is where the platform’s control ends: later transitions arrive asynchronously from provider webhooks (email bounces and complaints, SMS delivery receipts) or from the app (push delivery and open acknowledgments). Bounces feed back into the data: an invalid push token is deleted (§9.8), and a hard email bounce suppresses future email to that address. Events can arrive out of order (an open before a delivery receipt), so the tracking service applies only transitions that move forward in the machine.

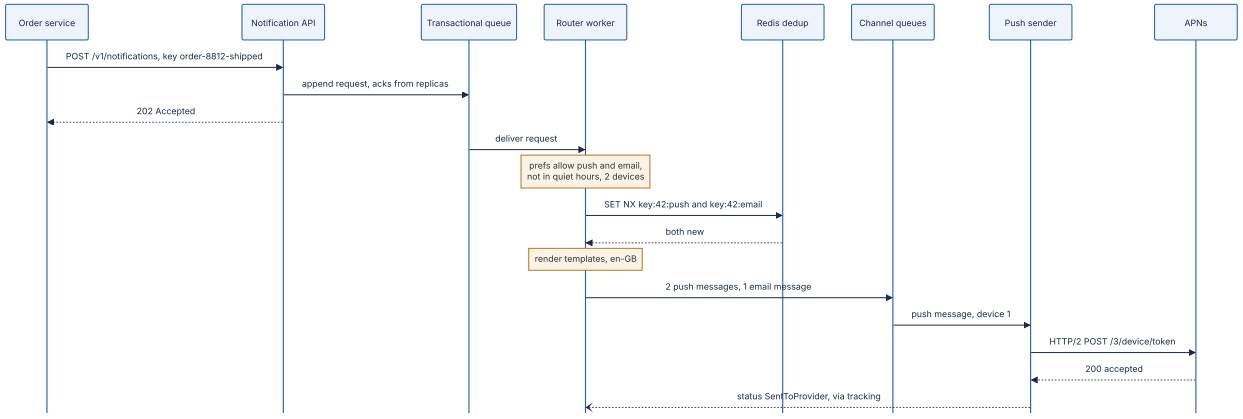
INDUSTRY EXAMPLE

Mobile push and bulk email rules. APNs and FCM accept notifications over HTTPS and report invalid tokens in their responses (APNs returns HTTP 410 for a token that is no longer active), which a sender must use to prune tokens; both cap regular notification payloads at 4 KB (§9.8) [Apple: Sending notification requests to APNs; FCM Docs]. For email, Google's sender guidelines (in force from 2024) require bulk senders to authenticate mail with SPF, DKIM and DMARC, to support one-click unsubscribe for marketing messages, and to keep reported spam rates low (Google states a threshold of 0.3%) [Google: Email sender guidelines]. These external rules shape the design directly: token pruning in the tracking service, unsubscribe handling in preferences, and complaint feedback loops that suppress future sends.

Evidence: Primary — [Apple: Sending notification requests to APNs]; [FCM Docs]; [Google: Email sender guidelines]

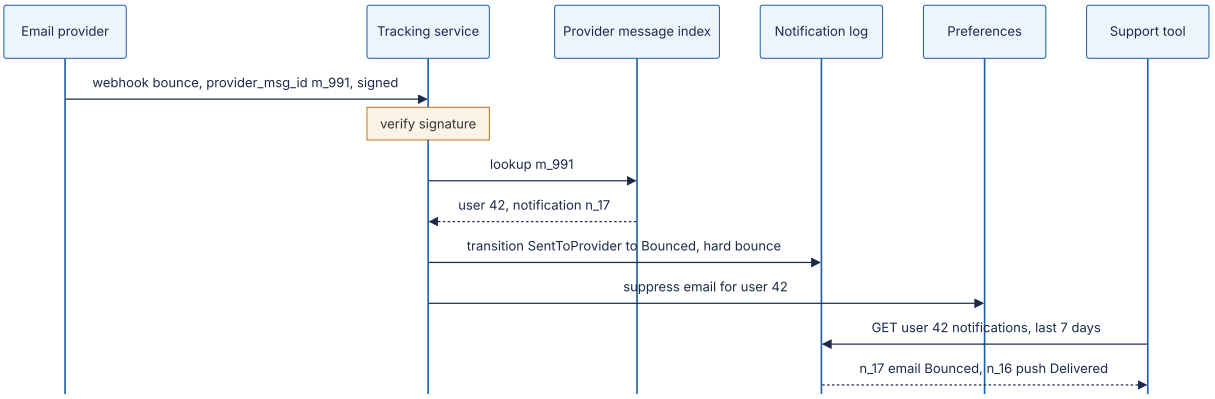
52.7.9 Data flow

Figure 52.13 — Write path: a transactional notification to push and email.



Reading the diagram. The caller's synchronous interaction ends at 202, once the request is durably in the transactional queue; from then on the platform owns delivery. The router processes the request asynchronously: preference and device lookups come from cache, deduplication keys are claimed atomically in Redis (one per recipient and channel), templates are rendered, and per-device messages go onto channel queues. The push sender calls APNs synchronously and records the result through the tracking service. The email message follows the same pattern through the email sender. Failure points: a router crash after claiming dedup keys but before emitting messages would lose the notification, so the router claims keys with a short "in progress" value and confirms them only after emitting; on redelivery, an in-progress key older than a minute is reclaimed. Scaling: router and sender pools scale on queue lag.

Figure 52.14 — Read path: provider callbacks and status queries.



Reading the diagram. Provider callbacks are the main “read” of external state: the tracking service verifies the webhook signature, maps the provider’s message ID to the notification through an index written at send time, applies the forward-only state transition to the log, and turns a hard bounce into an email suppression in preferences. Support tools and the user-facing inbox read the log by user and time, which is its partition and clustering key. Callbacks are at least once and may be out of order, so transitions are idempotent and forward-only. Failure points: a webhook endpoint outage (providers retry for hours; the endpoint must be highly available and quick to acknowledge, queueing work internally); an unknown message ID (a callback arriving before the index write commits, retried after a delay). Scaling: callbacks arrive at up to three per message, so the tracking service handles more events than the senders.

52.7.10 Bottlenecks

1. **Provider quotas**, not internal capacity, cap the drain rate (the worked example: 71 minutes instead of 20 at a 20,000/s SMS quota). Negotiate quotas, spread across providers, and schedule campaigns accordingly.
2. **Preference lookups.** 50,000 sends/s each reading preferences, settings and devices means 150,000 cache reads/s; batch lookups per page of recipients.
3. **Hot user partitions in the log.** A user in a busy group chat can receive hundreds of notifications per hour; aggregate them (“12 new messages”) with collapse keys (§9.8) instead of storing and sending each.
4. **Callback volume.** Opens and clicks for a 50-million email campaign arrive over days and can exceed send volume; process them in batches into aggregate counters.

52.7.11 Failure scenarios

Table 52.20 — Notification system failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
SMS provider outage	OTPs not delivered; logins blocked	Error rate and receipt rate per provider	Circuit opens; route to next provider	Two or more providers per country; synthetic OTP probes
Provider accepts but times out	Possible duplicate or loss	Timeout counter	Status query, then retry by type policy	Client references; per-type retry policy
Preferences cache stale	Opted-out user receives marketing	Opt-out-to-send lag metric	Invalidate on change events	Check opt-out against the source of truth for marketing at send time
Campaign floods queues	Transactional latency rises	Lag per priority queue	Pause campaign	Separate queues and pools; campaign rate caps
Router bug sends to wrong segment	Mass wrong notification; reputational harm	Anomalous send volume per type	Kill switch per type and campaign	Staged campaign start (1% first); approval for large audiences
Email reputation drops	Mail lands in spam	Complaint and bounce rates	Pause marketing email; clean lists	Authentication, unsubscribe, suppression of bounces
Webhook endpoint down	Statuses stuck at SentToProvider	Age of non-terminal messages	Providers retry; replay from provider logs	Highly available endpoint that only enqueues
Duplicate request from caller retry	Double send	Dedup hits	None needed	Required idempotency keys for transactional types

52.7.12 Scaling strategy

At 10× (5 billion per day; 500,000 sends/s design capacity). Internal components scale horizontally by queue partitions and worker pools. The external side does not: you need more providers, regional provider accounts, and dedicated email IP pools warmed gradually (mail providers distrust sudden volume from new IPs). The notification log grows to 450 TB for 90 days; store only a compact record for marketing messages and full records for transactional ones.

At 100×. Fan-out itself becomes the cost. Move from per-recipient rendering to rendering per (template, locale, parameter set) and reusing the result across recipients; send marketing push through provider-side topics where personalization is unnecessary (FCM topics deliver one request to many devices, §9.8); and run the platform in cells by user ID range, each with its own queues and provider quotas, so one cell's campaign cannot exhaust another's.

52.7.13 Trade-offs

- **At-least-once with deduplication versus at-most-once:** no lost OTPs, in exchange for rare duplicates on provider timeouts.
- **Separate queues per priority:** isolation and predictable OTP latency, in exchange for more infrastructure and idle reserved capacity.
- **Lazy campaign expansion:** pausable campaigns and small queues, in exchange for a dependency on the segment store during the campaign.
- **Cheapest-provider routing:** cost savings, in exchange for more failovers and inconsistent delivery quality; critical traffic routes by reliability, not cost.

52.7.14 Alternative designs

- **Single queue with priority field.** Simpler, but head-of-line blocking makes critical latency depend on campaign size.
- **Per-channel services owned by separate teams** with no shared router: each team implements preferences and dedup differently, and users get inconsistent behavior. A shared router is the point of a platform.
- **Buy instead of build.** Hosted notification platforms provide routing, templates and tracking; they fit companies below a few million messages per day or without strict data-residency needs. The architecture above is what such a platform must implement internally.

52.7.15 Interview discussion

Table 52.21 — 45-minute plan for the notification system.

Minutes	Focus	What to produce
0–5	Requirements	Channels, priorities, preferences, campaigns, tracking
5–10	Estimates	5,800/s average, 50,000/s design, campaign drain time, SMS cost
10–15	API and data model	202 send API with idempotency key; log partitioned by user
15–22	Architecture	Figure 52.11: priority queues, router, channel senders, tracking
22–35	Deep dive: fan-out, priorities, dedup	Router steps; separate pools; the provider-timeout problem
35–41	Provider failover and tracking	Health scoring, circuit breakers, state machine
41–45	Failures and scaling	Provider outage, stale preferences, cells at 100×

Likely follow-ups.

- *"How do you guarantee an OTP arrives quickly during a campaign?"* Separate queue, pool and reserved provider capacity; a short TTL; multi-provider failover.
- *"How do you avoid sending twice?"* Idempotency keys at the API, dedup keys per recipient and channel, forward-only state, and a per-channel policy for provider timeouts.
- *"How do you respect time zones for a campaign?"* Expand per time zone and schedule each slice at local 10:00; quiet hours defer rather than drop.
- *"Exactly-once delivery?"* Not achievable end to end with external providers; at-least-once plus deduplication is the honest answer (§32.9).

What distinguishes senior and staff answers. A senior candidate separates priorities, uses queues and handles retries with idempotency. A staff candidate identifies provider quotas as the real capacity limit, designs the provider-timeout ambiguity explicitly, makes every message end in a recorded terminal state, and treats email reputation and opt-out correctness as system requirements with metrics.

52.7.16 Production considerations

- **Observability.** End-to-end latency per priority (API to provider acceptance), queue lag per priority, suppression counts by reason, delivery and bounce rates per provider and country, and the count of messages stuck in non-terminal states.
- **Security and privacy.** Never put secrets beyond an OTP in a notification; keep OTPs out of logs; sign and verify all webhooks; enforce data residency for user contact data (§44.9).
- **Cost.** SMS dominates; suppress duplicates, prefer push or email when the user allows it, and route SMS by country to the cheapest reliable provider.
- **Operations.** Kill switches per notification type and per campaign; staged campaign starts; provider runbooks; regular failover drills that disable the primary SMS provider in production for a minute.

52.8 Distributed key-value store

52.8.1 Problem statement

Design a key-value store, in the style of Amazon's Dynamo, that many services in one company use for data such as shopping carts, session state, user preferences and feature flags. It must stay writable when nodes, racks and network links fail, scale to hundreds of nodes by adding machines, and let each table choose its own balance of consistency, latency and availability.

Every component of this design has its own section earlier in the book. The distinctive hard problem here is **composition**: making partitioning, replication, quorums, versioning, repair, storage and membership work together, so that a write accepted during a failure is neither lost nor silently overwritten, and the cluster heals itself afterward. The case therefore walks one key through the whole system and points to the owning sections for each mechanism.

52.8.2 Functional requirements

- `get(key) → (values[], context)`: returns one value, or several conflicting **siblings** with an opaque version context.
- `put(key, value, context)`: writes a value that supersedes the versions in `context`.
- `delete(key, context)`: a put of a tombstone.
- Per-table configuration: replication factor N, read quorum R, write quorum W, conflict policy (version vectors with siblings, or last-writer-wins), and TTL.
- Keys up to 256 bytes; values up to 1 MB (larger values go to object storage, §52.5).
- Adding and removing nodes online, with automatic data movement.
- Optional multi-datacenter replication.

Out of scope: secondary indexes, range scans across partitions, transactions across keys (§28).

52.8.3 Non-functional requirements

Property	Target
Write availability	99.99% per month, including during the loss of any one availability zone
Latency	`get` and `put` p99 ≤ 10 ms and p99.9 ≤ 50 ms within a region, for values ≤ 10 KB
Durability	No loss of a write acknowledged by $W \geq 2$ replicas in different zones unless both zones lose their disks permanently
Consistency	Eventual by default; read-your-writes when the client sets $R + W > N$ and no sloppy-quorum substitutes are involved (§27.9)
Convergence	After a failure heals, all replicas agree within 1 hour
Scalability	Linear throughput growth with nodes; adding a node moves only its share of data
Rebalancing impact	Data movement uses ≤ 20% of node bandwidth, so foreground p99 stays within target

The latency targets are stated at p99.9, as Dynamo's were, because a single page may call the store dozens of times and tail latency compounds (§23.6).

52.8.4 Capacity estimation

WORKED EXAMPLE

Worked example — Data, throughput and node count.

Assumptions. 100 TB of logical data; average item 1 KB (key and value). Peak 2 million reads/s and 1 million writes/s. $N = 3$. Reads contact all 3 replicas (one full read, two digest reads) and writes go to all 3. LSM space amplification 1.3 (§13.11). Each node: 8 TB of NVMe filled to at most 70%, and $c = 100,000$ replica operations per second; $u = 0.6$. Bloom filters at 10 bits per item (§17.4).

1. Items: $10^{14}/10^{3} = 10^{11}$ (100 billion).
2. Raw stored bytes: $100\,\text{TB} \times 3 \times 1.3 = 390\,\text{TB}$.
3. Nodes for capacity: $390/(8 \times 0.7) = 390/5.6 = 69.6$, so 70 nodes.
4. Replica operations: $10^{6} \times 3 + 2 \times 10^{6} \times 3 = 9 \times 10^{6}$ per second.
5. Nodes for throughput: $9 \times 10^{6}/(100,000 \times 0.6) = 150$ nodes.
6. Data per node at 150 nodes: $390/150 = 2.6$ TB, 46% of usable space, leaving room for compaction and growth.
7. Bloom filters: $10^{11} \times 3 \times 10\,\text{bits} = 3.75 \times 10^{11}$ bytes = 375 GB in total, 2.5 GB per node, which stays in memory.

Interpretation. Throughput, not capacity, sets the cluster size: 150 nodes (plus spares, about 156, 52 per zone). *Engineering implication.* Reducing replica work (for example, reading from $R = 2$ replicas instead of 3 for tables that tolerate it) cuts the node count directly; adding disk does not.

WORKED EXAMPLE

Worked example — Partitions, hints and rebuilds.

Assumptions. $Q = 16,384$ fixed partitions. One node fails for 1 hour. Rebuilding a node streams from many peers in parallel at 100 MB/s each.

1. Partition size: $390\ \text{TB}/16,384 = 23.8$ GB per partition replica. Partition replicas per node: $16,384 \times 3/150 = 328$.
2. Writes that would have gone to the failed node: $10^6 \times 3/150 = 20,000$ per second. Over 1 hour: 7.2×10^7 hinted writes, about 72 GB of hints spread over its neighbors (§27.9).
3. Rebuilding a dead node's 2.6 TB from one peer at 100 MB/s: $2.6 \times 10^{12}/10^8 = 26,000$ s, about 7.2 hours. From 50 peers at 100 MB/s each, because its 328 partitions have replicas spread across the cluster: $2.6 \times 10^{12}/(5 \times 10^9) = 520$ s, under 9 minutes.

Interpretation. Many small partitions turn a multi-hour single-source rebuild into minutes of parallel streaming, shrinking the window in which a second failure could lose data. *Engineering implication.* Choose Q much larger than the node count, and size hint storage for the longest outage you will tolerate before declaring a node dead and rebuilding it.

Table 52.22 — Key-value store capacity summary.

Quantity	Value	Consequence
Items	100 billion	Bloom filters and partition-aware routing are essential
Raw storage	390 TB	70 nodes would hold it; throughput needs more
Replica operations	9 million/s	150 nodes (≈ 156 with spares across 3 zones)
Partitions	16,384 × 3 replicas	≈ 328 partition replicas per node; 23.8 GB each
Hints for a 1-hour node outage	≈ 72 GB	Hint storage limit per node
Node rebuild	≈ 9 min from 50 peers	Low exposure to a second failure

52.8.5 API design

```
        service KV {
          rpc Get(GetRequest) returns (GetResponse);
          rpc Put(PutRequest) returns (PutResponse);
          rpc Delete(DeleteRequest) returns (PutResponse);
        }
        message GetRequest  { string table = 1; bytes key = 2; Consistency r = 3; }
// ONE, QUORUM, ALL or a number
        message GetResponse { repeated bytes values = 1; bytes context = 2; }
// >1 value = siblings
        message PutRequest  { string table = 1; bytes key = 2; bytes value = 3;
                              bytes context = 4;
// from the previous Get; empty = blind write
                              Consistency w = 5; uint32 ttl_seconds = 6; }
        message PutResponse { bytes context = 1; }
        message DeleteRequest { string table = 1; bytes key = 2; bytes context = 3;
Consistency w = 4; }
```

The **context** is the heart of the API. It carries the version vector (§24.11) of the versions the client read. A put with that context tells the store “this value supersedes those versions”, which is how the store distinguishes an update from a concurrent write. A client that writes without reading first (a blind write) creates a sibling whenever another version exists. Clients reconcile siblings on read (for a cart, the union of items) and write the merged value back with the combined context.

52.8.6 Data model and database schema

There is no schema beyond tables, keys and opaque values. What matters is the layout on each node and the cluster metadata.

```
On each node, one LSM tree per partition replica (§13.8):
  key:   partition_id | user key
  value: [ (version_vector, timestamp, value_bytes | tombstone, ttl), ... ]   -- sib-
lings stored together

Cluster metadata (gossiped, versioned):
  ring:        partition_id -> [node_a, node_b, node_c]   (preference list, zone-di-
verse)
  membership:  node_id -> {address, zone, status: joining|up|leaving|removed, genera-
tion}
  tables:      name -> {N, R, W, conflict_policy, default_ttl}

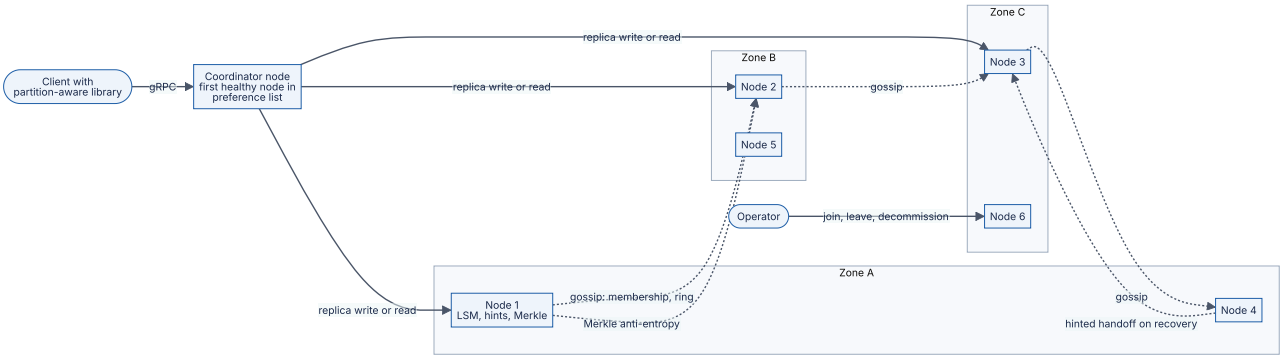
Hint store on each node:
  hint_key: target_node | partition_id | key | version  ->  value
```

Storing all siblings of a key in one record lets a read return them together and lets compaction discard versions dominated by newer ones. Partition IDs prefix every key so that

a partition’s data is contiguous on disk, which makes streaming a partition to a new node a sequential scan and lets each partition keep its own Merkle tree.

52.8.7 High-level architecture

Figure 52.15 — Dynamo-style key-value store architecture.



Reading the diagram. The client library holds a copy of the ring (learned from any node) and sends each request directly to a coordinator: the first healthy node in the key’s preference list. The coordinator forwards the operation synchronously to the $N = 3$ replicas, which are placed in three different zones, and answers the client once W (for writes) or R (for reads) replicas respond. All cluster maintenance is asynchronous and peer-to-peer (dotted): nodes gossip membership and ring changes; pairs of replicas compare Merkle trees per partition and stream differing keys; a node that held hints for a failed peer replays them when the peer returns. Membership changes are explicit operator actions, not automatic reactions to failure detection. There is no master node and no single point of failure; every node runs the same software. Storage boundary: each node’s local LSM trees, one per partition replica. Failure points: a zone outage (one replica of every partition, survivable with $W = 2$), network partitions (sloppy quorums keep writes flowing at the cost of consistency), and gossip disagreements during membership changes. Scaling: add nodes; each takes over partitions from many existing nodes.

52.8.8 Detailed component design

Table 52.23 — Each problem, its mechanism, and where the book covers it.

Problem	Mechanism in this design	Owning section
Spread keys over nodes; move little data on change	Consistent hashing with Q fixed partitions assigned to nodes	§14.8, §14.9
Survive node and zone loss	$N = 3$ replicas on zone-diverse nodes; leaderless writes	§27.7
Tunable consistency and latency	Quorums R, W; $R + W > N$ for overlap	§27.8
Stay writable when replicas are down	Sloppy quorum with hinted handoff	§27.9
Detect concurrent writes	Version vectors and siblings; or last-writer-wins	§24.11, §27.14
Repair divergence	Read repair; Merkle-tree anti-entropy	§27.13, §17.8
Fast local reads and writes	LSM tree with Bloom filters	§13.8, §13.10, §17.4
Know who is in the cluster and who is alive	Gossip membership; phi-accrual failure detection	§27.10

Component 1: partitioning, placement and routing

The key's hash (a 64-bit hash of the key, §17.3) selects one of $Q = 16,384$ fixed partitions; a ring map assigns each partition a **preference list** of N nodes. This is Dynamo's third partitioning strategy: equal-sized partitions decoupled from node tokens [DeCandia et al. 2007]. It has two advantages over placing many random virtual-node tokens on the ring (§14.8): partitions are the unit of transfer, so moving data is streaming whole files rather than filtering keys by hash range; and each partition has its own Merkle tree, so anti-entropy compares like with like.

Placement rules are applied when building the preference list: the N nodes must be in N different zones, and no node may hold two replicas of one partition. When a node joins, the placement algorithm takes roughly 328 partition replicas from across the cluster (not from its ring neighbors only), so the new node fills in parallel from many sources, and every existing node gives up about $1/151$ of its data. Data movement is throttled to 20% of node bandwidth (the rebalancing target), which at 100 MB/s per stream fills a new node in tens of minutes.

Routing uses a partition-aware client library, which avoids an extra network hop through a load balancer. Dynamo's paper reports that client-driven coordination reduced latency compared with routing through a generic load balancer [DeCandia et al. 2007]. Clients with a stale ring are corrected by the node they contact, which forwards the request and returns the newer ring version.

Component 2: replication, quorums, versioning and repair

A write with $N = 3$, $W = 2$ proceeds as follows (Figure 52.16 shows the failure case):

1. The coordinator, itself one of the replicas, increments its own entry in the version vector taken from the client's context, stores the new version locally and sends it to the other two replicas.
2. It acknowledges the client once one other replica has confirmed, so the write is durable in two zones.
3. If a replica is down, the coordinator sends the write to the next healthy node beyond the preference list, with a **hint** naming the intended owner; the substitute stores it in its hint store and replays it when the owner returns. This **sloppy quorum** keeps W achievable during failures, but the substitute is not in the preference list, so a subsequent read quorum may not overlap it: $R + W > N$ no longer guarantees reading the latest write (§27.9).

Reads ask all three replicas, return once R answer, and compare versions. If one version dominates the others, it is returned and the stale replicas are updated in the background (**read repair**, §27.13). If two versions are concurrent, neither vector dominates, and both are returned as siblings for the client to merge (§27.14.2). Tables that cannot merge (a profile photo URL) choose last-writer-wins instead, accepting that one of two concurrent writes is silently lost.

Read repair only fixes keys that are read. **Merkle-tree anti-entropy** repairs the rest: each partition replica maintains a hash tree over its key range (for example, 2^{15} leaves, about 730 keys each for a 24 million-key partition); replica pairs exchange tree roots periodically and descend only into differing subtrees, so a single divergent key costs one descent through 15 levels (a few dozen hashes) plus one leaf's keys, not a full scan (§17.8).

> WARNING / TRADE-OFF
>
> **Tombstones must outlive repair.** A delete writes a tombstone. If compaction purges the tombstone before every replica has seen it, a replica that missed the delete still holds the old value, and the next anti-entropy run copies it back: the deleted value is **resurrected**. Keep tombstones for longer than the maximum time a replica can be out of contact and still rejoin (Cassandra calls this `gc_grace_seconds`, 10 days by default), and require a node down longer than that to be rebuilt from scratch rather than rejoin.

Component 3: the storage engine on each node

Each node runs one LSM tree per partition replica (§13.8): a write appends to a commit log (fsync policy per table, §13.12), inserts into an in-memory memtable, and is acknowledged; full memtables flush to immutable sorted files (SSTables) with a Bloom filter each; compaction merges SSTables in the background, dropping versions dominated by newer ones and expired TTL data. LSM trees suit this workload because writes are frequent, keys are point-accessed, and replication means every logical write becomes three physi-

cal writes, so cheap sequential writes matter most. The Bloom filters (2.5 GB per node, in memory) keep a read for a missing key from touching disk, which matters because with $N = 3$ and digest reads, two of every three replica reads ask nodes whether they have a newer version.

Per-partition trees have a further benefit: dropping a partition after it moves to another node is deleting files, not deleting keys.

Component 4: membership and failure detection

Nodes learn about each other by **gossip**: every second, each node exchanges its membership table (node, address, zone, status, generation, heartbeat counter) with a random peer and merges newer entries (§27.10.3). Information reaches all 156 nodes in about $\log_2 156 \approx 7$ rounds, a few seconds. Liveness is judged locally with a **phi-accrual** detector over heartbeat arrivals (§27.10.2); a node that suspects a peer simply routes around it (sloppy quorum), without changing the ring.

The important separation is between *transient* failure and *permanent* membership change. A node that stops responding is treated as temporarily down, and its data is not moved; hints accumulate instead. Only an operator (or an automated policy after, say, 2 hours) declares it permanently gone, which changes the ring and triggers re-replication from the surviving replicas. Moving 2.6 TB every time a node reboots would be far more disruptive than the failures themselves; Dynamo likewise made membership changes explicit [DeCandia et al. 2007].

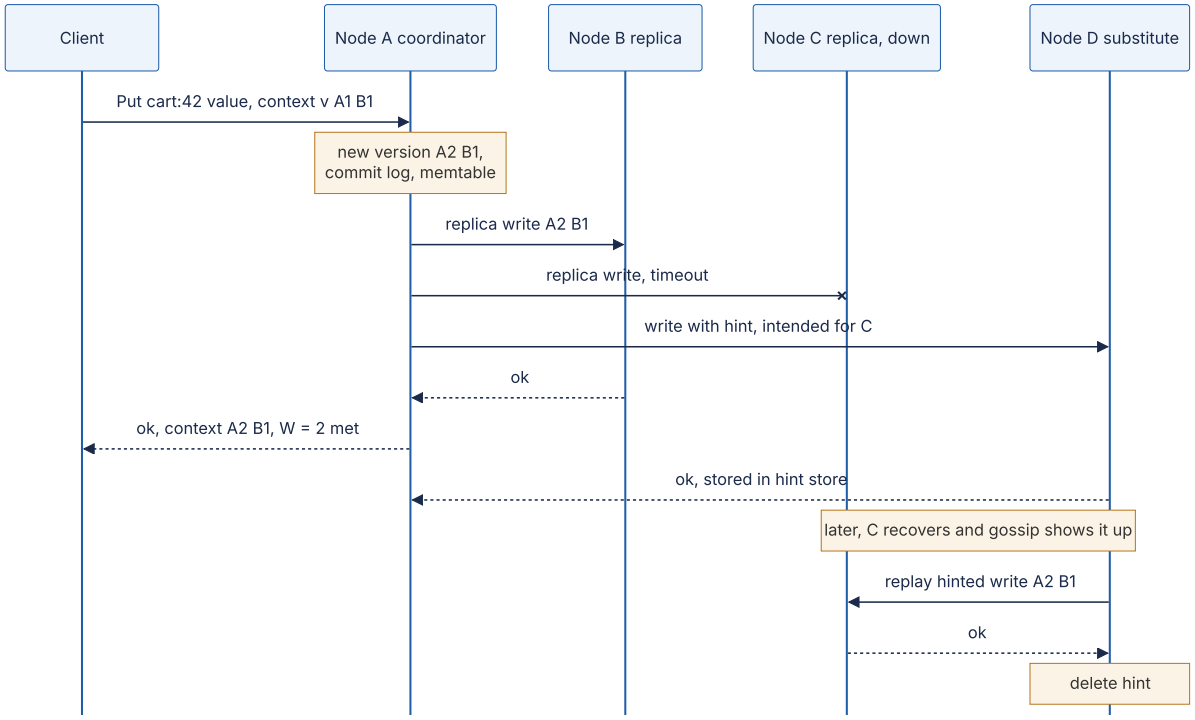
INDUSTRY EXAMPLE

Dynamo, Cassandra and DynamoDB. Amazon’s Dynamo paper combined consistent hashing with virtual nodes, sloppy quorums with hinted handoff, vector clocks with application-side reconciliation, Merkle-tree anti-entropy and gossip-based membership; it reported that its services commonly used $(N, R, W) = (3, 2, 2)$ and measured latency at the 99.9th percentile [DeCandia et al. 2007]. Apache Cassandra adopted Dynamo-style leaderless replication with tunable consistency levels, but resolves conflicts per column by timestamp (last-writer-wins) rather than with siblings [Apache Cassandra Docs]. Amazon DynamoDB, despite the name, is a different design: its 2022 paper describes partitions replicated across availability zones by Multi-Paxos with a leader per partition, offering strongly consistent reads [Elhemali et al. 2022]. The contrast is useful in interviews: leaderless quorums maximize write availability; per-partition leaders simplify consistency.

Evidence: Primary — [DeCandia et al. 2007]; [Apache Cassandra Docs]; [Elhemali et al. 2022]

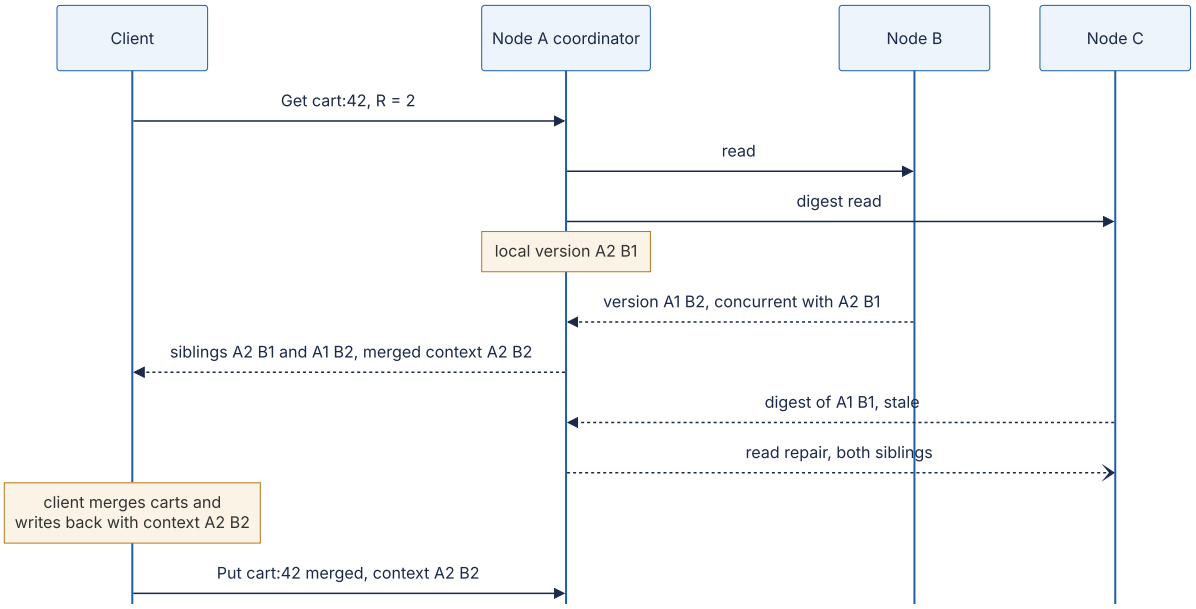
52.8.9 Data flow

Figure 52.16 — Write path: a put with one replica down (sloppy quorum and hinted handoff).



Reading the diagram. The client sends the put directly to node A, the first node in the key's preference list, which acts as coordinator and replica. A creates the new version vector by incrementing its own entry over the client's context, persists locally (commit log, then memtable) and sends replica writes in parallel. Node C does not answer within the timeout, so A sends the write to node D, the next healthy node beyond the preference list, tagged with a hint naming C. With A and B confirmed, $W = 2$ is met and the client receives the new context; D's acknowledgment arrives later. When gossip shows C is back, D replays the hint asynchronously and deletes it. Failure points: if A and B both fail before C recovers, the write survives only on D's hint store; if hints exceed D's limit, they are dropped and Merkle anti-entropy must repair C later. Scaling: per-write cost is N replica writes regardless of cluster size.

Figure 52.17 — Read path: quorum read with siblings and read repair.



Reading the diagram. The coordinator reads locally and from the other replicas in parallel (one full read, one digest read), answering when $R = 2$ versions are in hand. Its own version $\{A{:}\,2, B{:}\,1\}$ and B's $\{A{:}\,1, B{:}\,2\}$ are concurrent: neither vector dominates, so both are returned as siblings with a merged context. C's late digest reveals a stale version, so the coordinator repairs C asynchronously with both siblings. The client resolves the conflict with application logic (the union of cart items) and writes the merged value with the merged context, producing a version that dominates both siblings, so they disappear on the next compaction (§27.14.2). Failure points: a client that ignores siblings and writes blindly creates yet another sibling; very wide sibling sets indicate many blind writers. Scaling: reads touch N replicas, which is why tables that tolerate staleness can lower the read fan-out.

52.8.10 Bottlenecks

1. **Replica fan-out.** Each logical operation costs three replica operations; this, not disk capacity, set the node count to 150.
2. **Compaction.** LSM compaction competes with foreground I/O; under sustained writes, too little compaction throughput causes read amplification to grow and p99.9 to drift (§13.9). Throttle and schedule it, and provision I/O for it.
3. **Hot keys.** A single popular key's three replicas take all its traffic; consistent hashing cannot spread one key. Cache it in the client library or split it at the application layer (§14.10).
4. **Large partitions.** A wide value set or huge sibling lists slows reads; cap sibling counts and value sizes.
5. **Repair traffic after long outages.** Anti-entropy after a zone outage can saturate the network; throttle it like rebalancing.

52.8.11 Failure scenarios

Table 52.24 — Key-value store failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
One node (transient)	Its replicas miss writes	Phi-accrual suspicion	Hinted handoff replay; read repair	Sloppy quorum keeps W achievable
One node (permanent disk loss)	One replica of ~328 partitions lost	Node does not return; operator decision	Re-replicate from 50 peers in minutes	Zone-diverse placement; spare capacity
An availability zone	One replica of every partition	Zone-wide suspicion	Writes continue with $W = 2$; hints accumulate	$N = 3$ across 3 zones; hint storage sized for hours
Network partition between zones	Both sides accept writes via sloppy quorums	Gossip views diverge	Siblings or LWW resolution after healing; anti-entropy	Choose conflict policy per table deliberately
Tombstone purged too early	Deleted data resurrects	Deleted keys reappear	Re-delete; audit	Tombstone retention above maximum rejoin time
Clock skew with LWW tables	Newer write loses to an older one with a later clock	Hard to detect	None after the fact	Version vectors for important data; NTP monitoring (§24.9)
Stale ring in a client	Requests hit wrong coordinator	Forwarding counters	Node forwards and returns new ring	Ring version in every response
Correlated failure during rebuild	Possible data loss if all replicas lost	Under-replicated partition count	Restore from backup	Fast parallel rebuild; zone diversity; backups

52.8.12 Scaling strategy

At 10× (90 million replica operations per second, about 1 PB of logical data). The architecture scales by adding nodes, about 1,500, but two things need attention. Gossip of full membership tables grows with cluster size; move to gossiping digests and fetching changes on demand. And $Q = 16,384$ partitions over 1,500 nodes gives only about 33 partition replicas per node, coarsening load balance; choose a larger Q at creation (partition counts are hard to change later, the same lesson as Kafka's partition counts, §31.5), or support partition splitting.

At 100×. A single ring of 15,000 nodes has a large failure domain and slow membership convergence. Split into multiple independent clusters (cells) with a directory mapping tables or key ranges to clusters (§33.12), and replicate across regions asynchronously with conflict handling per table (§44.8).

52.8.13 Trade-offs

- **Leaderless quorums versus a leader per partition:** writes stay available through failures and network partitions, in exchange for conflicts, siblings and weaker consistency (§25.8 on CAP, §25.9 on PACELC).
- **Version vectors versus last-writer-wins:** no silent loss of concurrent writes, in exchange for client-side merge logic and larger metadata.
- **Sloppy quorum:** higher write availability, in exchange for losing the $R + W > N$ read guarantee during failures.
- **Fixed partitions:** fast parallel rebuilds and simple anti-entropy, in exchange for choosing Q up front.
- **Reading from all N replicas:** faster detection of stale replicas and lower tail latency (wait for the fastest R), in exchange for more replica operations.

52.8.14 Alternative designs

- **Leader-per-partition with consensus** (DynamoDB, CockroachDB-style ranges with Raft, §26.7): linearizable reads and writes per key, simpler client semantics, at the cost of unavailability for a partition while its leader is re-elected and of cross-zone latency on every write.
- **Primary-replica sharded Redis or MySQL** (§14.3): simplest to run at small scale; failover is a single point of fragility, and resharding is manual.
- **Chain replication** (§27.5): strong consistency with high read throughput from the tail; recovering a chain is more delicate than leaderless repair.

52.8.15 Interview discussion

Table 52.25 — 45-minute plan for the key-value store.

Minutes	Focus	What to produce
0–5	Requirements	API with context; tunable N, R, W; always writable
5–9	Estimates	100 billion items, 390 TB raw, 9 million replica ops/s, 150 nodes
9–13	API and placement	Partitions, preference lists, zone diversity
13–20	Architecture	Figure 52.15: coordinator, replicas, gossip, anti-entropy
20–35	Deep dive: write and read under failure	Sloppy quorum, hinted handoff, version vectors, siblings, read repair
35–41	Storage engine and repair	LSM, Bloom filters, Merkle trees, tombstones
41–45	Failures and scaling	Zone loss, rebuild time, cells at 100×

Likely follow-ups.

- *"What does $R + W > N$ buy you, and when does it fail?"* Overlapping read and write sets, so a read sees the latest acknowledged write, but not with sloppy quorums, concurrent writes, or failed partial writes that later spread by repair (§27.8).
- *"Why not use timestamps to resolve conflicts?"* Clocks skew, and LWW silently drops one of two concurrent writes; version vectors detect concurrency.
- *"How does a new node get its data?"* It is assigned partitions from across the cluster and streams them in parallel, throttled, then joins the preference lists.
- *"How do you know replicas agree?"* Merkle trees per partition, compared periodically.

What distinguishes senior and staff answers. A senior candidate explains each mechanism correctly. A staff candidate explains how they interact: sloppy quorums weaken $R + W > N$; tombstone retention must exceed the rejoin window; transient failures must not trigger rebalancing; the fixed-partition choice determines rebuild time and therefore durability; and conflict policy is a per-table product decision.

52.8.16 Production considerations

- **Observability.** Per-table p99 and p99.9 latency, sibling counts and sizes, hint backlog per node, read-repair rate, Merkle-detected divergence, under-replicated partitions, compaction backlog, and ring version skew across clients.
- **Security.** mTLS between nodes and clients (§10.10); encryption at rest; per-table access control in the client library.
- **Cost.** Replica fan-out drives node count; tables that tolerate weaker reads should use smaller R and fewer digest reads. Space amplification from compaction is the second lever.
- **Operations.** Rolling upgrades one zone at a time; regular backups by partition snapshot (the store's replication does not protect against bad writes or deletes); repair schedules tied to tombstone retention; tested runbooks for zone loss and full-node rebuild.

52.9 Distributed job scheduler

52.9.1 Problem statement

Design a multi-tenant job scheduler, a "cron as a service" for a large company. Teams register recurring jobs ("every day at 02:30 Europe/Berlin, run the invoice export"), one-off delayed jobs ("in 15 minutes, cancel this unpaid order") and workflows of dependent tasks ("extract, then transform, then load and notify"). The scheduler fires each job at the right time and hands it to a fleet of workers that execute it.

Chapter 46 covered cluster schedulers, which decide *where* work runs. This case is about deciding *when* work runs and making sure it runs. Its hard problems:

1. **Firing millions of timers on time (the distinctive hard problem).** Ten million schedules, and humans choose round times: about a million jobs fire in the same second at the top of each hour.
2. **Exactly-once versus at-least-once.** The scheduler must never silently skip a firing, and duplicate runs must be rare and harmless. True exactly-once execution is impossible when workers can crash mid-job, so the design must make jobs effectively-once through idempotency.
3. **Ownership without double firing.** Many scheduler nodes share the work; each schedule must have exactly one owner at a time, including during failover (§26.5).
4. **Retries, delays and dependencies.** Failed runs retry with backoff; workflows wait for upstream tasks.

52.9.2 Functional requirements

- **Schedules:** cron expressions with a time zone; fixed intervals; one-off “run at time T” or “run after delay D”.
- **Targets:** an HTTP callback, a message to a queue, or a container task on the batch cluster (§46).
- **Policies per job:** timeout, retry count and backoff, concurrency policy for overlapping runs (allow, forbid, replace), misfire policy for firings missed during an outage (run all, run once, skip), and a starting deadline.
- **Workflows:** a directed acyclic graph (DAG) of tasks with dependencies, triggered by a schedule or an API call.
- **Operations:** pause, resume, trigger now, cancel a run, view run history and logs.

52.9.3 Non-functional requirements

Property	Target
Firing accuracy	p99 dispatch delay ≤ 1 s after the scheduled time in normal minutes; ≤ 10 s at top-of-hour bursts
No lost firings	Every scheduled firing produces an execution attempt or a recorded misfire decision (0 silent skips)
Duplicates	Duplicate dispatch of one firing ≤ 1 in 10^4, and only around failovers; every dispatch carries a stable execution ID
Availability	99.99% per month for firing; the API may be 99.9%
Durability	Job definitions and run history: no loss (replicated database, backups)
Failover	A failed scheduler node's schedules resume firing within 15 s
Scale	10 million schedules, 250 million executions per day

52.9.4 Capacity estimation

WORKED EXAMPLE

Worked example — Executions and the top-of-hour burst.

Assumptions. 10 million recurring schedules: 1% every minute, 20% hourly, 79% daily. 50 million one-off delayed jobs per day. 40% of hourly and daily schedules are set to minute 0 (people like round numbers); daily jobs spread evenly over the 24 hours. Execution history record: 500 bytes, kept 30 days. Timer entry in memory: 100 bytes.

1. Per-minute schedules: $10^5 \times 1,440 = 1.44 \times 10^8$ executions/day.
2. Hourly: $2 \times 10^6 \times 24 = 4.8 \times 10^7$; daily: 7.9×10^6. Recurring total: 1.999×10^8.
3. All executions: $1.999 \times 10^8 + 5 \times 10^7 = 2.5 \times 10^8$ per day, an average of $2.5 \times 10^8 / 86,400 = 2,892$/s.
4. Top-of-hour burst: per-minute 10^5 + hourly at :00 $0.4 \times 2 \times 10^6 = 8 \times 10^5$ + daily at this hour's :00 $0.4 \times 7.9 \times 10^6 / 24 = 1.32 \times 10^5$. Total ≈ 1.03×10^6 firings due in the same second.
5. To dispatch them within 10 s: $1.03 \times 10^6 / 10 = 103,000$ dispatches/s, 36× the daily average.
6. History: $2.5 \times 10^8 \times 500\ \text{B} = 125\ \text{GB/day}$; 30 days ≈ 3.75 TB.
7. Timers due within the next hour: $5 \times 10^7 / 24 + 2 \times 10^8 / 24 = 1.04 \times 10^7$; at 100 bytes each, about 1 GB across the scheduler fleet.

Interpretation. Average load is small; the burst is 36× the average and dominates the design. *Engineering implication.* Timers must be pre-loaded into memory before they are due, dispatch must not require a database write per firing on the critical path, and the work must be partitioned across nodes. Encouraging jitter (spreading ":00" jobs over the first minutes) is cheaper than provisioning for the spike.

Table 52.26 — Job scheduler capacity summary.

Quantity	Value	Consequence
Executions	250 million/day; 2,900/s average	Modest steady state
Top-of-hour burst	≈ 1 million firings; 103,000 dispatches/s for 10 s	Pre-loaded in-memory timers; partitioned scheduling
Timers in the next hour	≈ 10 million; ≈ 1 GB	Fits in memory across 20 nodes
Run history	125 GB/day; 3.75 TB for 30 days	Time-partitioned store
Schedules	10 million; ≈ 20 GB at 2 KB each	Sharded relational store

52.9.5 API design

```
POST /v1/jobs
  request: { "name": "invoice-export", "schedule": { "cron": "30 2 * * *", "timezone":
"Europe/Berlin" },
             "target": { "type": "http", "url": "https://billing.internal/exports",

             "retry": { "max_attempts": 5, "backoff": "exponential", "initial_s": 30,
"max_s": 1800 },
             "concurrency_policy": "forbid", "misfire_policy": "run_once",
"starting_deadline_s": 3600 }
  201:     { "job_id": "job_8Hq...", "next_fire_at": "2026-11-06T01:30:00Z" }

POST /v1/delayed   { "run_at": "2026-11-05T10:45:00Z", "target": {...},
"idempotency_key": "cancel-order-8812" }
POST /v1/workflows { "name": "nightly-etl", "schedule": {...},
                     "tasks": [ {"id": "extract"}, {"id": "transform", "after": ["ex-
tract"]},
                                {"id": "load", "after": ["transform"]}, {"id": "notify",
"after": ["load"]} ] }
POST /v1/jobs/{id}:trigger · :pause · :resume
GET  /v1/jobs/{id}/runs?cursor=...    -> [{ "execution_id": "...", "scheduled_at",
"started_at",
                                           "attempt", "status", "worker", "error" }]

Worker protocol (gRPC): Lease(queue) -> Task{execution_id, attempt, payload,
fencing_token, lease_s}
                        Heartbeat(execution_id, fencing_token) · Complete(execution_id,
fencing_token, result)
```

Every dispatched task carries an **execution ID** derived deterministically from the job and its scheduled time, `execution_id = hash(job_id, scheduled_at)`. A duplicate dispatch of the same firing therefore has the same ID, and the target can use it as an idempotency key (§22.15). HTTP targets receive it in an `Idempotency-Key` header.

52.9.6 Data model and database schema

```
        -- Job definitions: sharded relational store, shard key = partition
(hash(job_id) mod 1024).
        CREATE TABLE jobs (
          job_id          TEXT PRIMARY KEY,
          partition_id    SMALLINT NOT NULL,          -- 0..1023
          tenant_id       TEXT NOT NULL,
          schedule_kind   TEXT NOT NULL,              -- cron | interval | once
          cron_expr       TEXT, timezone TEXT, interval_s INT, run_at TIMESTAMPTZ,
          target          JSONB NOT NULL,
          policies        JSONB NOT NULL,             -- timeout, retry, concurrency,
misfire
          paused          BOOLEAN NOT NULL DEFAULT false,
          next_fire_at    TIMESTAMPTZ NOT NULL,       -- maintained in UTC
          version         BIGINT NOT NULL
        );
        CREATE INDEX jobs_due ON jobs (partition_id, next_fire_at) WHERE NOT paused;

        -- Per-partition progress: everything scheduled at or before the watermark has
been dispatched.
        CREATE TABLE partition_watermarks (
          partition_id    SMALLINT PRIMARY KEY,
          dispatched_through TIMESTAMPTZ NOT NULL,
          fencing_token   BIGINT NOT NULL             -- owner's lease epoch (§26.13)
        );

        -- Runs: wide-column or time-partitioned table; one row per attempt.
        CREATE TABLE executions (
          execution_id    TEXT,                        -- hash(job_id, scheduled_at)
          attempt         SMALLINT,
          job_id          TEXT, scheduled_at TIMESTAMPTZ, started_at TIMESTAMPTZ,
finished_at TIMESTAMPTZ,
          status          TEXT,                        -- dispatched | running | suc-
ceeded | failed | timed_out
          worker_id       TEXT, error TEXT,
          PRIMARY KEY (execution_id, attempt)
        );

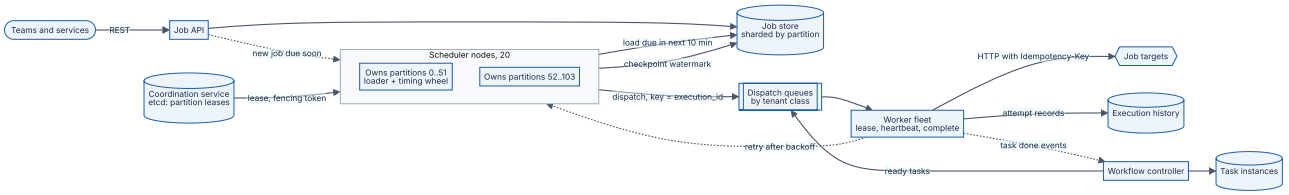
        -- Workflow runs: one row per task instance; transitions use conditional up-
dates.
        CREATE TABLE task_instances (
          dag_run_id TEXT, task_id TEXT, state TEXT, attempt SMALLINT,
upstream_remaining SMALLINT,
          PRIMARY KEY (dag_run_id, task_id)
        );
```

Choice of stores. Job definitions need transactions for edits, secondary lookups by tenant and an index on `next_fire_at` within a partition, so a sharded relational database fits (§11, §14.7), sharded by partition ID so each scheduler node's queries stay on one shard. The **watermark** table is the key to avoiding a database write per firing: instead of updating each job after it fires, the owner records "everything due up to 10:00:00.000 in partition 417 has been dispatched" once per second. Run history is append-heavy and time-or-

dered, so it goes to a store with time-partitioned tables and TTL-based expiry (§52.5.8 discusses the same cleanup pattern).

52.9.7 High-level architecture

Figure 52.18 — Distributed job scheduler architecture.



Reading the diagram. The job API stores definitions in the sharded job store; jobs due within the next few minutes are also pushed directly to their owning scheduler node (dotted), so they do not wait for the next load cycle. Each scheduler node holds leases on a set of the 1,024 partitions from the coordination service, with a fencing token per lease. For its partitions, a node loads all firings due in the next 10 minutes into an in-memory timing wheel, fires them on time by appending dispatch messages keyed by execution ID to the dispatch queues, and checkpoints a per-partition watermark once per second. Workers lease tasks from the queues, heartbeat while running, call the targets with the execution ID as an idempotency key, and record each attempt. Retries return to the scheduler as new delayed timers (dotted), and workflow task completions go to the workflow controller, which enqueues tasks whose dependencies are satisfied. Storage boundaries: job store (definitions and watermarks), queues (in-flight work), execution history and task instances. Failure points: a scheduler node (its leases expire and move within 15 s), the coordination service (no lease changes, but current owners continue until their leases expire), the queue (firing pauses; the watermark stops advancing, so nothing is lost). Scaling: more partitions per node or more nodes; queues by partitions; workers by queue lag.

52.9.8 Detailed component design

Component 1: sharded ownership with leases and fencing

A single leader that fires all ten million schedules is simple and is how many small schedulers work, but it caps throughput at one node’s dispatch rate and makes every failover a full reload. This design partitions schedules into 1,024 partitions and uses leader election *per partition* (§26.5): each scheduler node acquires leases on partitions from etcd (§26.9, §26.11), about 51 partitions per node with 20 nodes, spread by a balancing controller.

Each lease carries a **fencing token**, a number that increases on every change of ownership (§26.13). The owner writes its token with every watermark checkpoint, and the database rejects a checkpoint whose token is lower than the stored one. This handles the clas-

sic failure: a node pauses for 20 seconds in garbage collection, its lease expires, another node takes over and fires, and the first node wakes and tries to fire the same timers. Its checkpoint is rejected, and it learns it has lost the lease. Its stale dispatches, if any slipped out, carry the same execution IDs as the new owner's and are deduplicated downstream.

When a node takes over a partition, it reads the watermark and dispatches every firing scheduled after the watermark and up to now, applying each job's misfire policy for firings older than its starting deadline. Because the watermark is checkpointed every second, a failover re-dispatches at most about one second of firings plus the lease-expiry gap, and those re-dispatches are the only source of duplicates.

Component 2: timers, timing wheels and the top-of-hour burst

A scheduler node must fire about 52,000 timers in the same second at the top of the hour (one-twentieth of the burst) and then nothing for a while. A priority queue (binary heap) costs $O(\log n)$ per insert and per pop, which is fine for thousands of timers but adds up for millions with constant re-insertion of retries. A **timing wheel** [Varghese & Lauck 1987] makes insert and expiry $O(1)$: an array of slots, each a list of timers, with a pointer that advances one slot per tick. A timer due in d ticks goes into slot $(\text{now} + d) \bmod S$. **Hierarchical** wheels cover long ranges with few slots: a seconds wheel, a minutes wheel and an hours wheel, where timers cascade down a level when their higher-level slot comes up.

FORMULA

Span of a hierarchical timing wheel

$$T_{span} = \tau \times \prod_{i=1}^{k} S_i \qquad \text{slots in memory} = \sum_{i=1}^{k} S_i$$

Symbol	Meaning	Units
T_{span}	Longest delay the wheels can hold	seconds
τ	Tick duration (resolution of the finest wheel)	seconds
S_i	Number of slots in wheel level i	slots
k	Number of levels	levels

WORKED EXAMPLE

Worked example — A wheel for a 10-minute load window with 100 ms resolution.

1. Finest wheel: $\tau = 0.1$ s, $S_1 = 600$ slots, covering 60 s.
2. Second level: $S_2 = 60$ slots of 60 s each; span $0.1 \times 600 \times 60 = 3,600$ s, one hour, enough for the 10-minute load window and for short retry delays.
3. Adding a third level of $S_3 = 24$ hour-slots gives $0.1 \times 600 \times 60 \times 24 = 86,400$ s, one day, with only $600 + 60 + 24 = 684$ slots.
4. A single flat wheel at 100 ms resolution for one day would need 864,000 slots.

Interpretation. Hierarchy buys range with very few slots, at the cost of moving each long timer down one or two levels before it fires. *Engineering implication.* Hold only near-term timers in memory (the 10-minute window, about 1.7 million timers fleet-wide per load cycle) and leave the long tail in the database index, where it costs nothing until it becomes near-term.

```
        from collections import defaultdict

        class HierarchicalTimingWheel:
            """Timers with 1-tick resolution. Level i has `slots` buckets, each slots**i
ticks wide."""

            def __init__(self, slots: int = 60, levels: int = 3):
                self.slots, self.levels = slots, levels
                self.now = 0                                    # current tick
                self.wheels = [defaultdict(list) for _ in range(levels)]

            def schedule(self, due: int, job: str) -> None:
                if due <= self.now:
                    raise ValueError("due time must be in the future")
                self._place(due, job)

            def _place(self, due: int, job: str) -> None:
                delay = due - self.now
                for level in range(self.levels):
                    if delay < self.slots ** (level + 1):      # fits in this level's
span
                        slot = (due // self.slots ** level) % self.slots
                        self.wheels[level][slot].append((due, job))
                        return
                raise ValueError("beyond wheel span; keep it in the database for now")

            def tick(self) -> list:
                """Advance one tick; cascade higher levels down when their slot comes
up."""
                self.now += 1
                for level in range(self.levels - 1, 0, -1):    # cascade from the top
level down
                    width = self.slots ** level
                    if self.now % width == 0:
                        slot = (self.now // width) % self.slots
                        for due, job in self.wheels[level].pop(slot, []):
                            self._place(due, job)              # re-insert at a finer
level
                return [job for due, job in self.wheels[0].pop(self.now % self.slots,
[])]

        w = HierarchicalTimingWheel(slots=60, levels=3)        # span 60^3 ticks =
216,000 s = 60 h
        for due, name in [(5, "a"), (59, "b"), (61, "c"), (3_600, "d"), (3_725, "e"),
(86_399, "f")]:
            w.schedule(due, name)
        fired = {}
        for _ in range(90_000):
            for job in w.tick():
                fired[job] = w.now
        print(fired)
        assert fired == {"a": 5, "b": 59, "c": 61, "d": 3_600, "e": 3_725, "f": 86_399}
```

Output:

```
{'a': 5, 'b': 59, 'c': 61, 'd': 3600, 'e': 3725, 'f': 86399}
```

What to notice:

- Every timer fires at exactly its due tick, whether it started in the seconds, minutes or hours wheel; a randomized test of 45,000 timers with a 10-slot wheel also fired every timer on time.
- Cascading runs *before* the finest wheel is emptied, so a timer cascaded to the current slot still fires in this tick.
- Insert and expiry are constant time; the cost is the cascade, which moves each long timer at most `levels - 1` times.
- In the real scheduler, `tick()` returns a batch of up to 52,000 jobs at the top of the hour; the node dispatches them in batches of a few hundred messages per queue request to reach about 5,200 dispatches/s per node.

To soften the burst, the API offers a **hashed minute**: a schedule written as `H * * * *` fires at a minute derived from a hash of the job ID, the same idea as Jenkins' `H` symbol, and new jobs with `0 * * * *` are flagged with a suggestion to use it.

Component 3: execution guarantees

"Exactly once" has to be decomposed by stage, because each stage gives a different guarantee.

Table 52.27 — Execution guarantees by stage.

Stage	Guarantee	Mechanism	Residual risk
Firing	Each scheduled time dispatched at least once	Watermark replay after failover	Firings between last checkpoint and failure are dispatched again
Dispatch identity	All duplicates of one firing share one ID	`execution_id = hash(job_id, scheduled_at)`	None
Queue delivery	At least once (§30.8)	Leases with visibility timeouts	Redelivery after worker crash or lease expiry
Worker start	At most one concurrent attempt per execution ID	Conditional insert of the attempt row; fencing token per lease	A worker paused past its lease can still act; fencing protects storage that checks tokens
Job side effects	Effectively once only if the job is idempotent	Target uses the execution ID as idempotency key (§22.15)	Non-idempotent targets can run twice

The honest contract the scheduler offers is therefore: **at-least-once execution with a stable execution ID; idempotent jobs achieve effectively-once results.** This matches the general limits of exactly-once processing (§32.9). Concurrency policies sit on top: `forbid` skips a firing if the previous run of the same job is still running, `replace` cancels the running one, and `allow` runs both.

Retries. On failure or timeout, the worker records the attempt and asks the scheduler to fire the same execution ID again after a backoff of $\min(\text{max}, \text{initial} \times 2^{\text{attempt}})$ with jitter (§22.12); the retry is just another timer in the wheel. After the maximum attempts, the execution moves to a dead-letter state with an alert to the owning team.

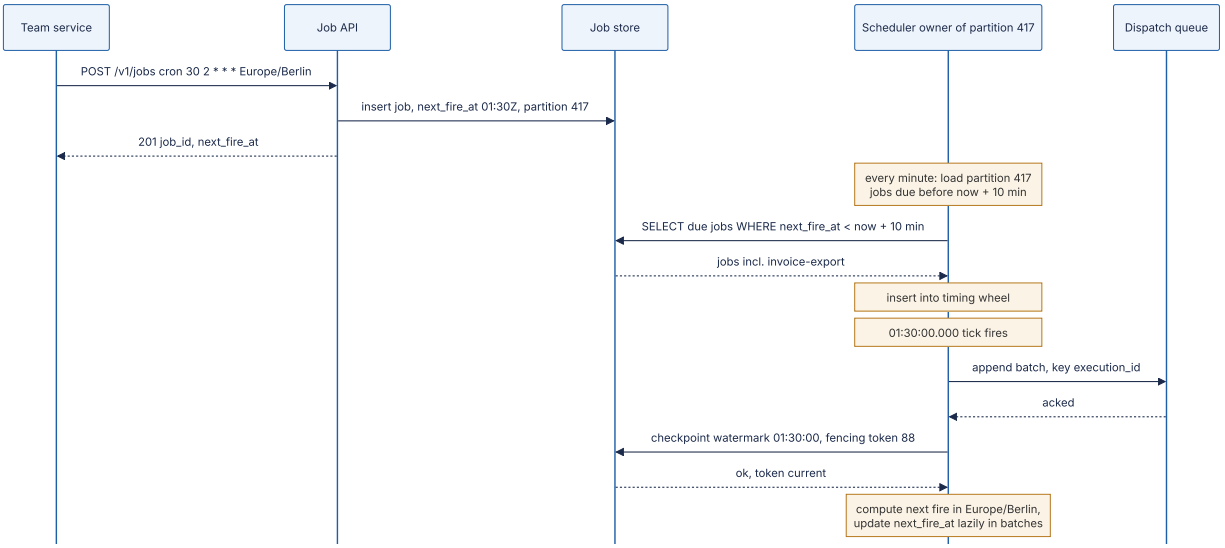
Component 4: workflows (DAG dependencies)

A workflow run creates one `task_instances` row per task, with `upstream_remaining` set to its number of dependencies. Tasks with zero remaining dependencies are enqueued immediately. When a task succeeds, the workflow controller decrements `upstream_remaining` for each downstream task with a conditional update and enqueues any task that reaches zero. Because task-completion events are delivered at least once, the decrement must be idempotent: record the (upstream task, downstream task) pair as applied, or recompute readiness from the upstream tasks' states instead of counting. A failed task, after its retries, marks its downstream tasks `upstream_failed`; operators can clear and re-run a task and its descendants. Long-running workflows with complex branching are better served by a durable-execution workflow engine (§32.11.1); the scheduler then simply triggers the engine.

> INDUSTRY EXAMPLE
>
> **Published designs for distributed cron and timers.** Google's SRE book describes its distributed cron service: replicas use Paxos to agree on state, only the leader launches jobs, and it records launch intentions and completions so a new leader can tell whether a launch happened; it stresses that jobs should be idempotent or able to check state, and describes extending crontab syntax with a `?` so the system can choose the time and spread load [Beyer et al. 2016, ch. 24]. Apache Kafka uses hierarchical timing wheels for its request purgatory, replacing a design based on a priority queue to make inserting and expiring large numbers of timed operations cheap [Matsuda 2015]. Kubernetes CronJobs expose the same per-job policies used here: `concurrencyPolicy` (Allow, Forbid, Replace) and `startingDeadlineSeconds` for missed schedules [Kubernetes Docs: CronJob].
>
> *Evidence: Primary* — [Beyer et al. 2016]; [Matsuda 2015]; [Kubernetes Docs: CronJob]

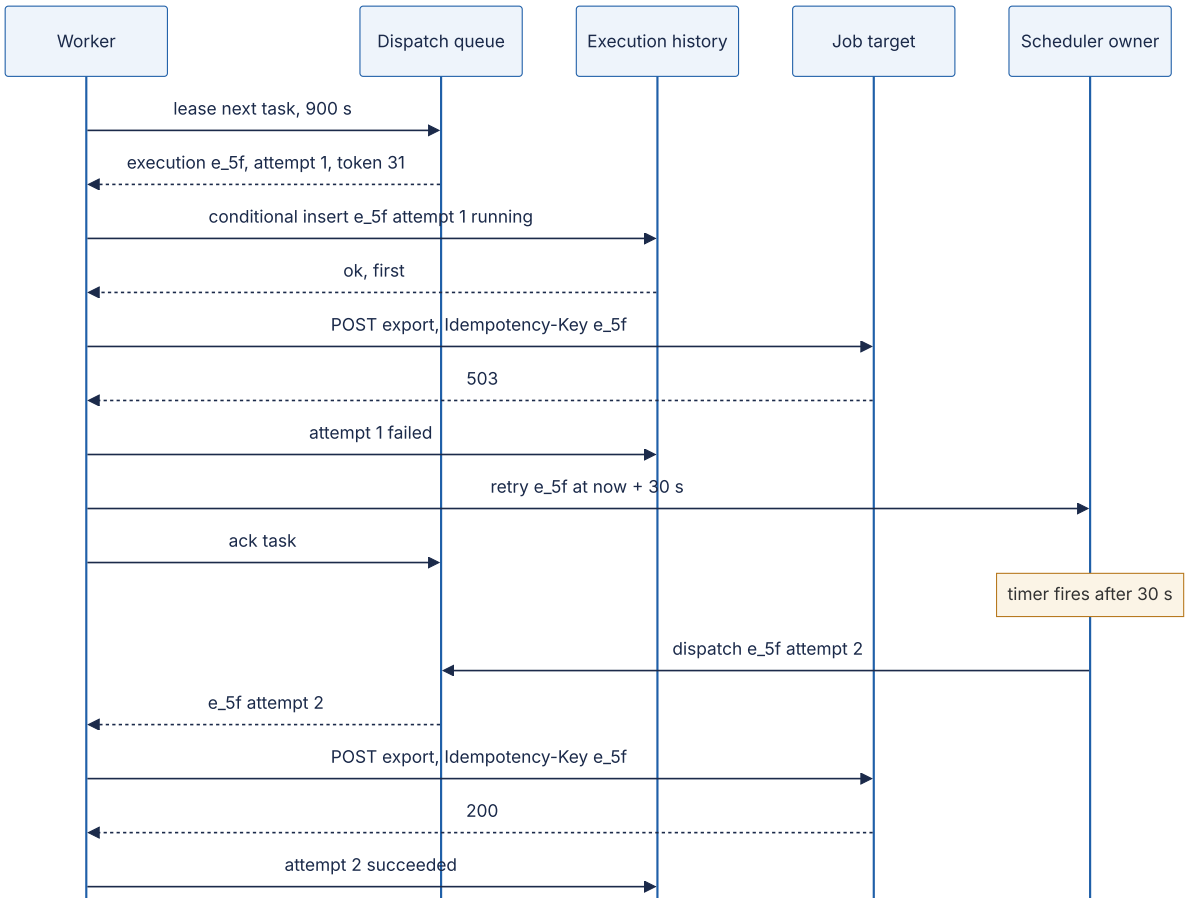
52.9.9 Data flow

Figure 52.19 — Write path: from job registration to dispatch.



Reading the diagram. Registration is a synchronous insert; the API computes the first fire time in the job's time zone and stores it in UTC. The owning scheduler node loads near-term firings from its partition's index every minute (and receives jobs due within the window directly from the API). At the due tick, the wheel releases the job, the node appends a dispatch message keyed by execution ID, and once the queue acknowledges, the node advances the partition watermark with its fencing token; a rejected checkpoint means the node has lost its lease and must stop. The job's `next_fire_at` is advanced in batched updates off the critical path, because correctness rests on the watermark. Failure points: a crash after the queue append and before the checkpoint causes the new owner to re-dispatch the same execution ID; a time-zone transition (the daylight-saving change) is handled when computing the next fire time (§52.9.11). Scaling: dispatch throughput scales with partitions per node and queue partitions.

Figure 52.20 — Read path: a worker executes, fails once and retries.



Reading the diagram. Workers pull work; the queue's lease (visibility timeout) returns the task to the queue if the worker dies. Before calling the target, the worker claims the attempt with a conditional insert, so two workers holding duplicate deliveries of the same attempt cannot both run it. The target receives the same idempotency key on every attempt, so if attempt 1 had actually done the work before failing, attempt 2 would return the stored result instead of exporting twice. The retry is scheduled as an ordinary timer on the owning scheduler with exponential backoff. Failure points: a target that ignores the idempotency key can run twice; a worker that exceeds its lease without heartbeating loses the task to another worker, and the fencing token makes its late writes to the execution history fail. Scaling: workers scale on queue lag, separately per tenant class so one tenant's backlog cannot starve others.

52.9.10 Bottlenecks

1. **The top-of-hour burst.** A million firings in one second; mitigated by pre-loading, batching dispatches and hashed minutes.
2. **Job store index scans.** Loading due jobs every minute from 1,024 partitions is 1,024 index range scans per minute, cheap; but a full reload after a mass failover must be rate-limited.
3. **Downstream targets.** A thousand tenants' jobs at 02:00 can overload a shared internal service; per-target concurrency limits in workers (using §52.6) protect it.

4. **History writes.** 250 million attempts per day, more with retries; batch writes and keep them off the dispatch path.

52.9.11 Failure scenarios

Table 52.28 — Job scheduler failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Scheduler node crash	Its partitions stop firing	Lease expiry in etcd	Other nodes take leases; replay from watermark	Short leases (10 s); spare capacity
GC pause or network partition of an owner	Two nodes believe they own a partition	Rejected checkpoint (stale fencing token)	Stale node stops; duplicates deduplicated by execution ID	Fencing tokens on every write
Coordination service down	No ownership changes	etcd health	Owners keep partitions until leases lapse; then firing stops safely	5-node etcd across zones (§26.9)
Dispatch queue unavailable	Firing pauses; watermarks stop advancing	Append errors	Resume; replay from watermark; misfire policies apply	Replicated queue; alert on watermark lag
Worker dies mid-job	Task redelivered after lease	Missing heartbeats	Another worker runs the same execution ID	Idempotent jobs; heartbeats
Daylight-saving transition	A 02:30 local job has no 02:30 on spring-forward day, two on fall-back day	Tests on time-zone transitions	Policy: fire once at the next valid time; fire only the first occurrence	Use a time-zone database; test transitions
Clock skew on a scheduler node	Jobs fire early or late	Clock offset monitoring	Fix NTP	Fire by node clock but checkpoint against store time
Poison job (always fails)	Retries waste capacity	Attempts per execution	Dead-letter after max attempts; alert owner	Retry caps; backoff

52.9.12 Scaling strategy

At 10× (100 million schedules, 10 million firings at the top of the hour). Raise the partition count (to 8,192) and the scheduler fleet (to about 200 nodes); make hashed minutes the default for new hourly schedules, with explicit opt-in for exact :00 firing; and split dispatch queues by tenant tier so free-tier bursts cannot delay paid tenants.

At 100×. Run independent scheduler cells per region and tenant group, each with its own coordination service, job store shards and queues (§33.12); a global directory maps

tenants to cells. Firing within a cell remains the same design; the cell bounds the blast radius of a bad deploy or a coordination outage.

52.9.13 Trade-offs

- **Partitioned ownership versus a single leader:** throughput and fast partial failover, in exchange for lease management and fencing.
- **Watermark checkpoints versus per-firing database writes:** dispatch at memory speed, in exchange for a window of duplicates after failover.
- **At-least-once plus idempotency versus attempting exactly-once:** a contract that can actually be kept, in exchange for requiring job authors to write idempotent jobs.
- **In-memory wheel for near-term timers only:** small memory and fast firing, in exchange for a loader loop and a direct-push path for newly created near-term jobs.

52.9.14 Alternative designs

- **Database polling** (`SELECT … WHERE next_fire_at <= now() FOR UPDATE SKIP LOCKED`): many workers poll one table and claim due rows. Simple and correct for thousands of jobs per minute; the polling load and lock contention fail at the million-per-second burst.
- **Delayed messages in the broker** (queues with per-message delivery delay, or Redis sorted sets scored by due time): good for one-off delays; recurring cron schedules and catch-up policies still need a scheduler on top.
- **Kubernetes CronJobs** for a few thousand cluster-local jobs: no new system to run, but each firing creates a pod, which is too heavy for millions of small HTTP callbacks.
- **Workflow engines** (§32.11) for complex, long-running, stateful workflows; the scheduler then only triggers them.

52.9.15 Interview discussion

Table 52.29 — 45-minute plan for the distributed job scheduler.

Minutes	Focus	What to produce
0–5	Requirements	Cron with time zones, delayed jobs, DAGs, retries, policies
5–10	Estimates	250 million/day; 1 million firings at :00; 103,000 dispatches/s
10–15	API and data model	Deterministic execution ID; jobs table; watermarks
15–22	Architecture	Figure 52.18: partitions, leases, wheels, queues, workers
22–34	Deep dive: ownership and firing	Leases, fencing tokens, watermark replay, timing wheel
34–41	Execution guarantees	At-least-once plus idempotency; retries; concurrency policy; DAG readiness
41–45	Failures and scaling	GC pause, DST, burst smoothing, cells

Likely follow-ups.

- *"Can you guarantee exactly-once execution?"* No: a worker can crash after the side effect and before recording success. Offer at-least-once with a stable execution ID and require idempotent jobs.
- *"How do you avoid two schedulers firing the same job?"* Partition leases with fencing tokens; even when they overlap briefly, duplicates share an execution ID.
- *"Why a timing wheel instead of a heap?"* Constant-time insert and expiry for millions of timers and frequent retries; a heap is fine at small scale.
- *"How do you handle a job that runs longer than its interval?"* The concurrency policy: forbid, replace or allow.

What distinguishes senior and staff answers. A senior candidate partitions the work, uses leader election and a queue, and adds retries. A staff candidate finds the top-of-hour burst from the estimate, avoids per-firing database writes with watermarks, decomposes exactly-once into per-stage guarantees, uses fencing tokens correctly, and treats time zones and daylight-saving changes as correctness requirements.

52.9.16 Production considerations

- **Observability.** Dispatch delay distribution (scheduled versus dispatched time) per partition; watermark lag; lease changes per hour; retries and dead-letters per job; duplicate attempts detected by the conditional insert.
- **Security.** Job targets execute with the job owner's credentials, stored in a secrets manager and injected at execution; never store secrets in job payloads; restrict which internal endpoints jobs may call.

- **Cost.** The scheduler is cheap; the jobs are not. Show tenants their run counts and durations, and pause jobs whose targets have returned errors for weeks.
- **Operations.** Freeze windows for schedule changes during incidents; a global "pause tenant" switch; replay tooling to re-run a time range of firings after an outage, honoring misfire policies.

52.10 Web crawler

52.10.1 Problem statement

Design a web crawler for a search engine that downloads 3 billion pages every 30 days, discovers new pages by following links, and keeps the collection fresh by recrawling pages as they change. The output feeds an indexing pipeline (§16.6).

A crawler is a loop: take a URL, fetch it, extract links, add the new ones, repeat. At scale the loop is easy to write and hard to run well, for reasons that are mostly about *other people's servers*:

1. **The URL frontier with politeness and priority (the distinctive hard problem).** The crawler must fetch thousands of pages per second in total but never more than about one request every few seconds from any single host, while fetching important and changed pages first.
2. **Duplicates at three levels.** The same URL discovered many times; the same content under different URLs; and nearly identical content (the same article with a different timestamp or advertisement).
3. **Robots.txt and DNS.** Every host has rules to obey and a name to resolve, and both must be cached or they become the bottleneck.
4. **Distribution.** Fifty crawler nodes must divide the web without two of them hammering the same host.
5. **Recrawl scheduling.** With a fixed fetch budget, which known pages should be fetched again, and how often?

52.10.2 Functional requirements

- Start from seed URLs and discover new URLs from fetched HTML pages (and sitemaps).
- Fetch over HTTP and HTTPS, follow redirects, and store the raw response with metadata (status, headers, fetch time, IP).
- Obey robots.txt (RFC 9309) for the crawler's user agent, and identify the crawler with a descriptive `User-Agent` and a contact URL.
- Limit request rate per host and per IP address; back off on errors and slow responses.

- Skip URLs already seen; detect exact and near-duplicate content.
- Prioritize URLs by estimated importance and freshness need; recrawl known pages on a schedule.
- Hand fetched pages to the indexing pipeline.

Out of scope: rendering JavaScript-heavy pages (a separate, far more expensive rendering service), indexing and ranking (Chapter 16), and crawling the non-public web.

52.10.3 Non-functional requirements

Property	Target
Throughput	3 billion pages per 30 days: about 1,160 pages/s average; 2,000 pages/s capacity
Politeness	At most one concurrent connection per host; default ≥ 5 s between requests to a host, adaptive to server response time
Robots compliance	100% of fetches checked against a robots.txt copy no older than 24 hours
Freshness	Important pages (top 10% by importance) recrawled at least daily; median page age in the index ≤ 15 days
Duplicate waste	≤ 5% of fetches return content that is an exact duplicate of stored content
Availability	The crawler is a batch system: a node failure must not lose frontier state or more than a few minutes of work
Storage durability	Fetched pages stored with object-storage durability (§15.4)

Availability matters less than for online services, but *politeness* failures are severe: a crawler bug that floods a small website can take it down, and the crawler gets blocked across hosting providers.

52.10.4 Capacity estimation

WORKED EXAMPLE

Worked example — Fetch rate, bandwidth and storage.

Assumptions. 3 billion pages per 30-day cycle; average page 100 KB uncompressed, 25 KB compressed; capacity provisioned at 2,000 pages/s to allow for retries, redirects and robots.txt fetches; average fetch time 1 s (connect, TLS, download); 50 links extracted per page; 30 billion distinct URLs known.

1. Average rate: $3 \times 10^9 / (30 \times 86,400\ \text{s}) = 3 \times 10^9 / 2,592,000 = 1,157$ pages/s.
2. Download bandwidth at capacity: $2,000 \times 100\ \text{KB} = 200\ \text{MB/s} = 1.6\ \text{Gbps}$ (0.93 Gbps at the average rate).
3. Storage per cycle: $3 \times 10^9 \times 25\ \text{KB} = 75\ \text{TB}$; keeping three cycles for change detection and reprocessing: 225 TB.
4. Fetches in flight, by Little's Law (§4.11): $2,000\ \text{pages/s} \times 1\ \text{s} = 2,000$ concurrent fetches, 40 per node with 50 nodes, trivial with asynchronous I/O.
5. Links discovered: $2,000 \times 50 = 100,000$ URLs/s to test against the seen set.
6. URL-seen set as a Bloom filter over 30 billion URLs (§17.4): at a 1% false-positive rate, 9.6 bits per URL = 36 GB; at 0.1%, 14.4 bits per URL = 54 GB, about 1.1 GB per node when partitioned across 50 nodes.
7. SimHash fingerprints for 3 billion pages: $3 \times 10^9 \times 8\ \text{B} = 24\ \text{GB}$; four lookup tables (Component 3): 96 GB across the cluster.

Interpretation. Bandwidth and storage are moderate. The URL-seen test at 100,000 lookups per second and the frontier's politeness constraints are the parts that need design. *Engineering implication.* Every per-URL structure must be partitioned and mostly in memory; a disk seek per discovered link would need 100,000 IOPS.

Politeness caps how fast the crawler can go, in a way more machines cannot fix.

FORMULA

Politeness bound on crawl throughput

$$R \le \frac{H_{active}}{d} \qquad d_{\max,host} = \frac{T_{cycle}}{P_{host}}$$

Symbol	Meaning	Units
R	Achievable crawl rate across all hosts	pages/s
H_{active}	Hosts with URLs ready in the frontier at any moment	hosts
d	Minimum delay between requests to one host	s
T_{cycle}	Time allowed to crawl a host's pages once	s
P_{host}	Pages on one host that must be crawled per cycle	pages
$d_{\max,host}$	Largest delay that still crawls the host within the cycle	s

WORKED EXAMPLE

Worked example — How many hosts must be ready, and what about large sites?

1. With $d = 5$ s and a target of 2,000 pages/s: $H_{active} \ge 2,000 \times 5 = 10,000$ hosts must have URLs ready at every moment, 200 per node.
2. A large site with $P_{host} = 10^7$ pages at $d = 5$ s takes $10^7 \times 5 = 5 \times 10^7$ s, which is 579 days, far longer than a 30-day cycle.
3. To crawl it in 30 days: $d_{\max,host} = 2,592,000/10^7 = 0.26$ s, about 3.9 requests per second.

Interpretation. The frontier must keep thousands of distinct hosts ready, and large sites need a per-host rate set from their capacity rather than a global default. *Engineering implication.* Make the delay adaptive (for example, a multiple of the host's recent response time, as Mercator-style frontiers do) and allow per-host overrides for large sites that can serve more; never raise the rate for a host without evidence it can take it.

Table 52.30 — Web crawler capacity summary.

Quantity	Value	Consequence
Fetch rate	1,157 pages/s average; 2,000 capacity	50 nodes with asynchronous I/O
Bandwidth	1.6 Gbps at capacity	Modest; spread across nodes
Storage	75 TB per cycle; 225 TB for three	Object storage, compressed WARC-style files
Discovered links	100,000/s	Partitioned in-memory URL-seen filter
URL-seen filter	36–54 GB	≈ 1 GB per node
Ready hosts needed	≥ 10,000	Frontier must be wide, not deep

52.10.5 API design

A crawler has few external clients; its interfaces are internal RPCs between components and a control API for operators.

```
Control API (operators):
POST /v1/seeds        { "urls": ["https://example.org/"], "priority": 0.9 }
PUT  /v1/hosts/{host}/policy  { "min_delay_s": 0.5, "max_connections": 2, "blocked":
false }
GET  /v1/hosts/{host}         -> { "robots_fetched_at": "...", "delay_s": 5.0, "queued":
1823,
                                   "errors_24h": 3, "last_status": 200 }
POST /v1/recrawl      { "url_prefix": "https://news.example.org/", "priority": 1.0 }

Internal RPCs (gRPC):
Frontier.Add(urls[], source_url, discovered_at)        -> accepted count (routed to
owner node by host)
Frontier.Next(worker_id, max)                          -> [ {url, host, ip, priority,
not_before} ]
Fetcher.Report(url, status, content_ref, fetch_ms, etag, last_modified)
Indexer feed: append to topic "fetched-pages" {url, content_ref, simhash, fetched_at}
```

52.10.6 Data model and database schema

```
URL store (per node, for its hosts; LSM key-value store, §13.8):
  key:   reversed host + path, e.g. "org.example.www/news/2026/11/budget"   -- groups a
host's URLs
  value: { url_fp: 64-bit, first_seen, last_fetched, last_changed, fetch_count,
change_count,
           etag, last_modified, content_fp, simhash, importance, next_fetch_at, status }

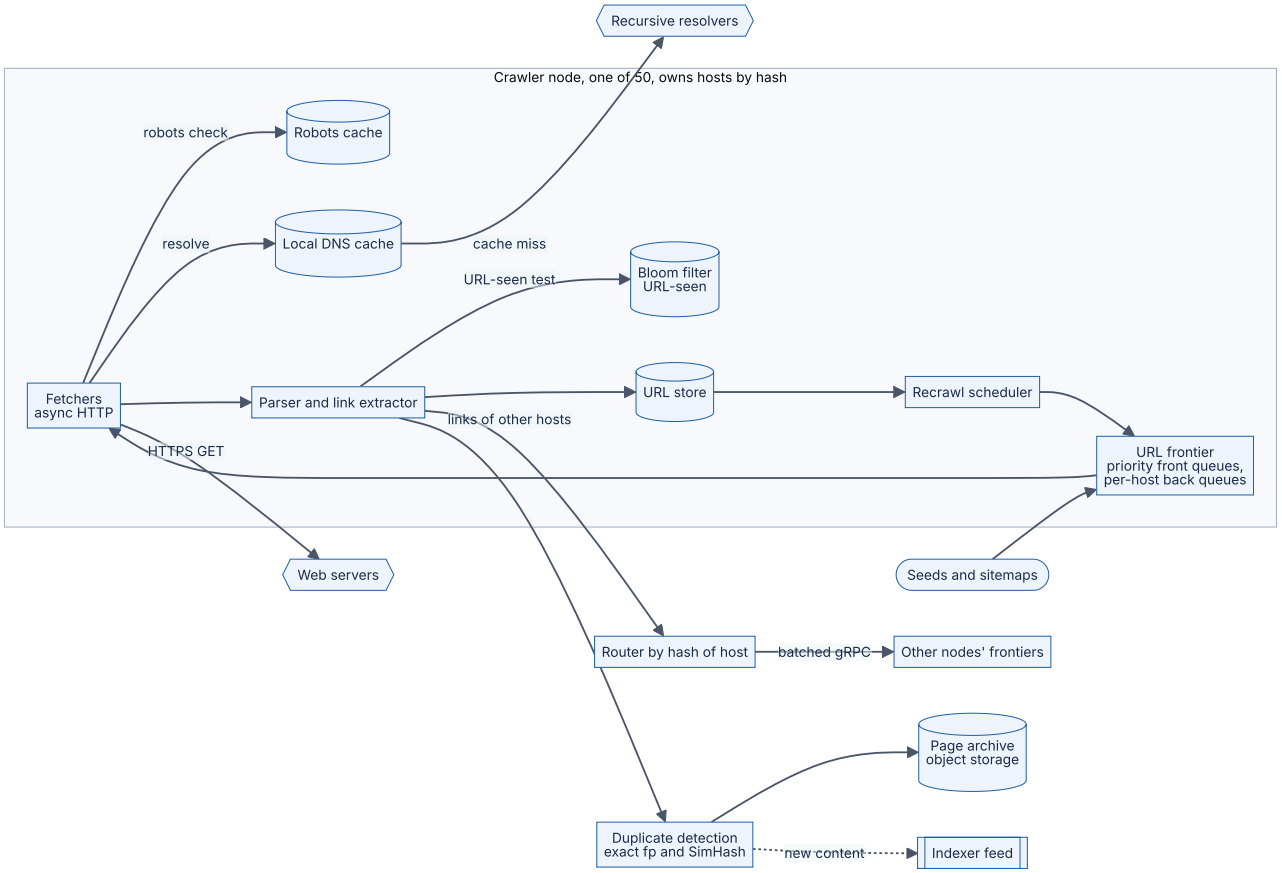
Host table (per node):
  host -> { ip, dns_expires_at, robots_rules, robots_fetched_at, delay_s,
next_allowed_at,
            consecutive_errors, max_connections }

URL-seen filter (per node, in memory, checkpointed): Bloom filter over url_fp
Content fingerprint index (cluster-wide, partitioned by fingerprint): content_fp ->
canonical URL
SimHash tables (cluster-wide): 4 tables keyed by one 16-bit block each -> list of
(simhash, url_fp)
Page archive (object storage): WARC-style files of ~1 GB, each holding many compressed
responses
```

Keying URLs by **reversed host name** stores a host's URLs together and a domain's hosts near each other, so the per-host frontier can read a host's URLs with one range scan, the same trick Bigtable's web table used [Chang et al. 2006]. Pages are stored in large archive files, not one object per page, because 3 billion small objects would be expensive in requests and metadata (§15.4); the URL store records each page's file and offset.

52.10.7 High-level architecture

Figure 52.21 — Distributed web crawler architecture.



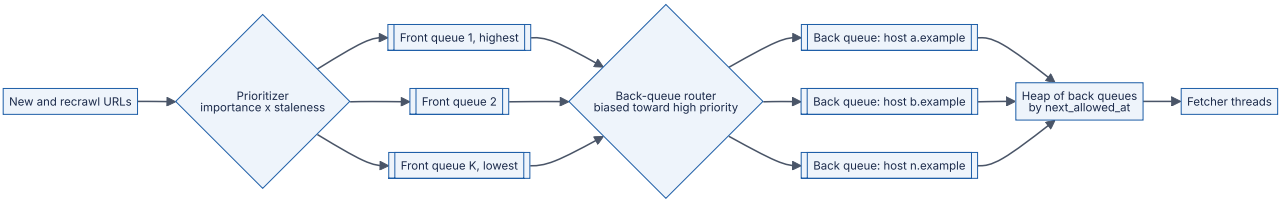
Reading the diagram. Each of the 50 nodes owns a set of hosts, chosen by hashing the host name (§14.6), and runs the whole loop for them inside the subgraph. The frontier releases a URL only when its host's politeness delay has passed; fetchers check the robots.txt cache and the local DNS cache before connecting synchronously to the web server; the parser extracts links, tests each against the node's URL-seen Bloom filter, records new URLs in the URL store, and routes links belonging to hosts owned by other nodes through the router, which batches them into gRPC calls to those nodes' frontiers. Fetched content passes through duplicate detection (exact fingerprint, then SimHash) before being written to the page archive and announced asynchronously to the indexer (dotted). The recrawl scheduler reads the URL store and feeds known URLs back into the frontier when they are due. Storage boundaries: per-node URL store and host table (local, replicated by checkpoint), the archive (object storage), and the cluster-wide fingerprint indexes. Failure points: a node failure stalls its hosts until another node takes over its hash range; slow DNS stalls fetchers; a misparsed robots.txt is a politeness incident. Scaling: add nodes and re-divide the host hash space (consistent hashing, §14.8, keeps movement small).

52.10.8 Detailed component design

Component 1: the URL frontier

The frontier is the design described for Mercator [Heydon & Najork 1999] and explained in detail by Manning, Raghavan and Schütze [Manning et al. 2008, ch. 20]: two layers of queues that separate *priority* from *politeness*.

Figure 52.22 — Mercator-style frontier: priority front queues and per-host back queues.



Reading the diagram. URLs enter at the left and are assigned a priority, then placed in one of *K* **front queues** (FIFO per priority level). The back-queue router pulls from front queues with a bias toward higher priority and places each URL in the **back queue** for its host; each back queue holds URLs of exactly one host, and there are a few times as many back queues as fetcher threads (Mercator's designers suggested about three times as many [Manning et al. 2008]). A **heap** keyed by each back queue's `next_allowed_at` time gives fetchers the host whose politeness delay expired earliest. When a fetch finishes, the host's `next_allowed_at` is set to now plus the delay, and the back queue goes back into the heap; when a back queue empties, the router refills it with URLs of a new host from the front queues. All flows are in-process and synchronous; front and back queues spill to the local URL store when they exceed memory. Failure points: too few distinct hosts in the back queues (throughput falls, per the politeness formula); one huge host monopolizing front queues (bounded by per-host admission caps). Scaling: per node, the structure is independent of other nodes because hosts never span nodes.

The **delay** for a host is adaptive: the larger of a floor (5 s by default, or a per-host override), and a multiple of the host's recent response time; the textbook description of Mercator's frontier uses ten times the last fetch duration as an example [Manning et al. 2008]. A slow, struggling server therefore automatically gets fewer requests. Errors increase the delay exponentially; HTTP 429 and 503 with `Retry-After` set `next_allowed_at` directly. Politeness is also enforced per **IP address**, because thousands of small hosts often share one server: the host table maps hosts to IPs, and a second heap limits concurrency per IP.

Priority combines estimated importance (link-based scores from the previous crawl, domain quality, depth from the site root) with the need to recrawl (Component 4). New URLs from a high-importance page inherit a share of its importance.

Component 2: DNS, robots.txt and fetching

DNS. Resolution can take tens to hundreds of milliseconds and is done once per host per TTL, but the standard blocking resolver library serializes lookups and was a known bottleneck in early crawlers; Mercator used its own multithreaded resolver for this reason [Heydon & Najork 1999; Najork & Heydon 2001]. Each node runs an asynchronous local caching resolver, resolves hosts when they enter the back queues (prefetching, so the fetch does not wait), honors TTLs with a minimum floor of, say, one hour to limit load, and records the IP for per-IP politeness. Because hosts are partitioned by node, each node's DNS cache covers only its own hosts and achieves a high hit ratio.

Robots.txt. RFC 9309 standardized the Robots Exclusion Protocol in 2022: the crawler fetches `/robots.txt` for each host (scheme, host and port), matches the most specific `User-agent` group, and applies `Allow` and `Disallow` rules by longest match [RFC 9309]. The RFC says crawlers should not use a cached copy for more than 24 hours unless the file is unreachable, and must parse at least 500 KiB of it. It also distinguishes failure cases: if robots.txt is *unavailable* (a 4xx status) the crawler may access any resources; if it is *unreachable* (a 5xx status or network error) the crawler must assume complete disallow. That asymmetry matters: a server error on robots.txt stops the crawl of that host, which is the polite default when a server is struggling. `Crawl-delay` is not part of RFC 9309; honor it anyway as a lower bound on the delay where present. The robots cache is the host table's `robots_rules` field, refreshed before expiry for hosts with queued URLs.

Fetching. Fetchers use asynchronous I/O with connection reuse per host (keep-alive, §7.16), a total timeout (30 s), a maximum body size (for example 10 MB, truncating beyond), and conditional requests for recrawls (`If-None-Match` with the stored ETag, `If-Modified-Since` with the stored date), which turn unchanged pages into small 304 responses. Redirects are not followed inline; the target URL goes back through the frontier so it obeys politeness and duplicate checks for its own host.

Component 3: duplicate detection

Table 52.31 — Duplicate detection layers.

Layer	Question	Mechanism	Cost	Error mode
URL normalization	Are these strings the same URL?	Lowercase scheme and host, remove default ports and fragments, sort or strip tracking parameters, resolve `.` and `..`	CPU only	Over-normalizing merges distinct pages
URL-seen	Have we seen this URL before?	64-bit fingerprint tested against a Bloom filter (§17.4), confirmed in the URL store when needed	100,000 lookups/s in memory	False positive skips a new URL (rate ≤ 0.1%)
Exact content	Is this content byte-identical to a stored page?	Hash of the normalized body, looked up in the fingerprint index	One lookup per fetch	None in practice
Near-duplicate	Is it nearly identical (different timestamp, ad, counter)?	SimHash fingerprint, Hamming distance ≤ 3	Four table lookups per fetch	Threshold misjudges very short pages

The URL-seen test runs on the node that owns the URL's host, after routing, so each node's filter covers only its own hosts. A Bloom filter cannot delete and only grows, so it is rebuilt from the URL store each cycle. Its false positives mean a truly new URL is occasionally skipped; at 0.1% that is acceptable because important pages are usually linked from many places and will be discovered again through another source. Mercator kept a disk-based set of URL fingerprints with an in-memory cache for the same test [Heydon & Najork 1999].

Near-duplicates are the bigger source of waste: mirrors, printer-friendly versions, session-ID URLs and pages differing only in boilerplate. Broder et al. introduced **shingling**, which compares sets of overlapping word sequences (shingles) and estimates their resemblance from small sketches [Broder et al. 1997]. Charikar's **SimHash** compresses a document into a single 64-bit fingerprint such that similar documents get fingerprints that differ in few bits [Charikar 2002]. Manku, Jain and Das Sarma showed that SimHash is practical for detecting near-duplicates at Google's crawl scale, reporting that 64-bit fingerprints with a Hamming-distance threshold of 3 worked well for a repository of 8 billion pages, and gave table-based methods for finding all fingerprints within distance 3 quickly [Manku et al. 2007].

```
        import hashlib
        import re

        def features(text: str, k: int = 3) -> list:
            """Word 3-shingles: overlapping sequences of k words."""
            words = re.findall(r"\w+", text.lower())
            return [" ".join(words[i:i + k]) for i in range(max(1, len(words) - k + 1))]

        def h64(s: str) -> int:
            return int.from_bytes(hashlib.blake2b(s.encode(), digest_size=8).digest(),
"big")

        def simhash(text: str) -> int:
            """Charikar's SimHash: each feature votes +1/-1 on each of 64 bits."""
            votes = [0] * 64
            for f in features(text):
                h = h64(f)
                for bit in range(64):
                    votes[bit] += 1 if (h >> bit) & 1 else -1
            return sum(1 << bit for bit in range(64) if votes[bit] > 0)

        def hamming(a: int, b: int) -> int:
            return bin(a ^ b).count("1")

        base = " ".join([
            "The city council approved the new budget on Tuesday after a long debate
about funding for",
            "public transport, schools and road repairs. The mayor said the plan adds
two bus lines,",
            "repairs forty bridges and hires sixty teachers, while opposition members
argued that the",
            "property tax increase would hurt small businesses in the old town and asked
for a review.",
            "Residents who attended the meeting raised concerns about parking near the
new tram depot,",
            "noise from night construction and the cost of replacing water pipes under
the main square.",
            "The finance director explained that interest rates had risen sharply since
last spring and",
            "that the city must refinance older loans before the end of the coming fis-
cal year. Several",
            "councillors proposed delaying the stadium renovation to free money for win-
ter heating help",
            "for pensioners, and the amendment passed by a narrow margin late in the
evening session.",
            "Local shop owners welcomed the extra bus lines but asked for loading zones
on market days,",
            "and the transport committee promised a traffic study before any street is
closed to cars.",
            "Teachers' unions said sixty new posts would barely cover retirements ex-
pected next summer,",
```

```
            "while parents asked whether the repaired school roofs would be finished be-
fore the rains.",
        ])
        page_a = base + "Posted 09:14. Share this article. 3 comments."
        page_b = base + "Posted 09:15. Share this article. 4 comments."          # same
story, new timestamp
        page_c = ("A recipe for sourdough bread needs flour, water, salt and a lively
starter that has "
                  "been fed the night before. Shape the loaf, let it rise for several
hours in a cool kitchen, "
                  "then bake it in a very hot oven with steam for the first twenty min-
utes until the crust is dark. ")

        a, b, c = simhash(page_a), simhash(page_b), simhash(page_c)
        print("exact duplicate?", hashlib.sha256(page_a.encode()).digest() ==
hashlib.sha256(page_b.encode()).digest())
        print("near-duplicate distance A-B:", hamming(a, b), "| unrelated distance A-
C:", hamming(a, c))

        # Pigeonhole lookup: if distance <= 3, at least one of four 16-bit blocks is
identical.
        blocks = lambda x: [(i, (x >> (16 * i)) & 0xFFFF) for i in range(4)]
        print("shared 16-bit blocks A-B:", len(set(blocks(a)) & set(blocks(b))))
```

Output:

```
exact duplicate? False
near-duplicate distance A-B: 3 | unrelated distance A-C: 26
shared 16-bit blocks A-B: 1
```

What to notice:

- An exact hash says pages A and B are different, although a reader would call them the same article; SimHash puts them 3 bits apart, within the threshold, while an unrelated page is 26 bits away (about 32 is expected for unrelated documents).
- The lookup trick is the pigeonhole principle: if two 64-bit fingerprints differ in at most 3 bits, at least one of their four 16-bit blocks is identical. Four tables, each keyed by one block, return a small candidate set to check exactly. Manku et al. refine this with permuted tables to balance memory and candidate counts [Manku et al. 2007].
- Short pages have few shingles, so a small edit moves many bits; apply the near-duplicate test only above a minimum length (for example 100 words) and rely on exact hashes below it.
- Production systems weight features (for example by term frequency) and strip boilerplate (navigation, footers) before fingerprinting, which makes distances more meaningful.

When a near-duplicate is found, the crawler stores the page compactly (as a reference to the canonical page) and lowers the recrawl priority of the duplicate URL; repeated dupli-

cates from one host suggest a URL pattern (session IDs, calendars) that should be blocked by a per-host rule, which also defends against **crawler traps**: infinite URL spaces such as calendars that link to the next day forever. Caps on URLs per host and on path depth bound the damage.

Component 4: recrawl scheduling

With a fixed budget of about 1,157 fetches per second, every recrawl of a known page displaces the discovery of a new one. The scheduler estimates each page's **change rate** from its history (number of observed changes over number of fetches, by comparing content fingerprints) and sets `next_fetch_at` from importance and change rate. Cho and Garcia-Molina analyzed refresh policies for a crawler with a fixed budget and found, counter-intuitively, that refreshing pages in proportion to how often they change can give *lower* average freshness than refreshing all pages uniformly; under their freshness metric, the optimal policy gives pages that change extremely often fewer refreshes, because a copy of such a page is stale again almost immediately [Cho & Garcia-Molina 2003]. In practice, schedulers bound recrawl intervals between a minimum (hours, for important news pages) and a maximum (months), weight by importance, use sitemap `lastmod` hints, and use conditional GETs so that checking an unchanged page costs a 304 response rather than a full download.

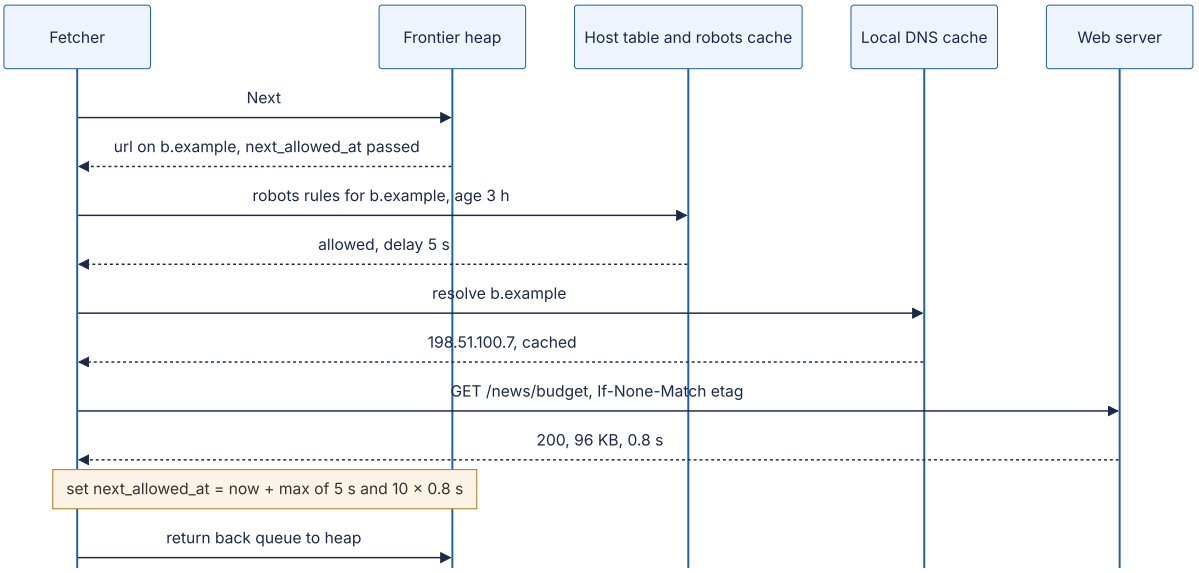
INDUSTRY EXAMPLE

Mercator and published crawler designs. Mercator, built at Compaq's Systems Research Center, was a scalable, extensible Java crawler whose design introduced the URL frontier structure, the URL-seen and content-seen tests with fingerprints, and a custom DNS resolver [Heydon & Najork 1999]; Najork and Heydon later described its high-performance configuration and lessons [Najork & Heydon 2001]. The robots.txt conventions crawlers had followed informally since 1994 became RFC 9309 in 2022 [RFC 9309]. Google researchers published the SimHash-based near-duplicate method described above [Manku et al. 2007]. The architecture in this section follows these published designs; it is not a description of any company's current production crawler.

Evidence: Primary — [Heydon & Najork 1999]; [Najork & Heydon 2001]; [RFC 9309]; [Manku et al. 2007]

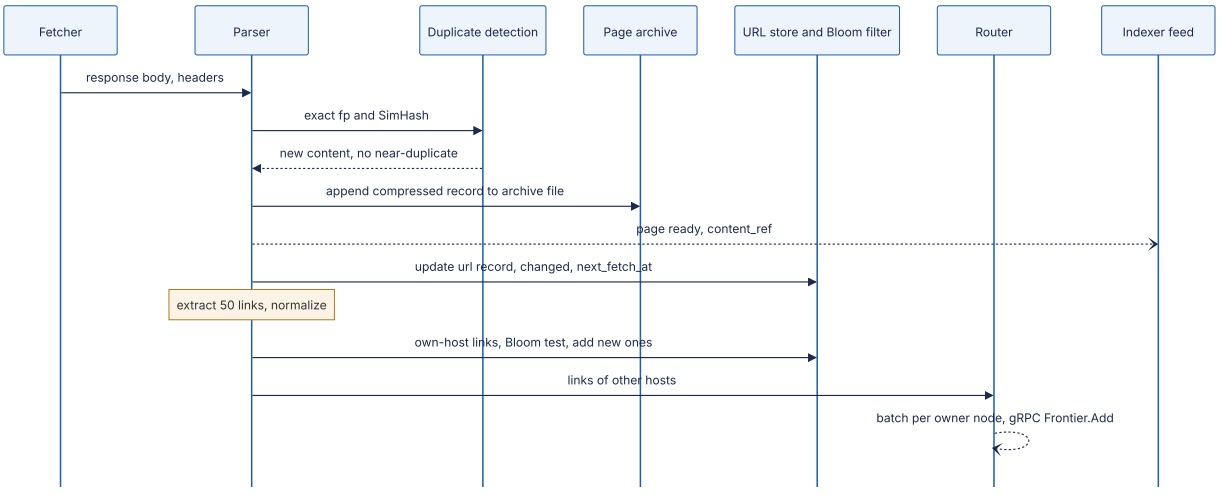
52.10.9 Data flow

Figure 52.23 — Read path: selecting and fetching the next URL.



Reading the diagram. The fetcher asks the frontier for work; the heap returns a URL only from a host whose politeness time has passed. Before connecting, the fetcher checks robots rules (cached for at most 24 hours; refreshed in the background) and resolves the host from the local DNS cache, both normally in memory. The fetch itself is synchronous over HTTPS with a conditional header for a recrawl. After the fetch, the host's next allowed time is set from the adaptive delay (here 8 s, because the server took 0.8 s) and the host's back queue returns to the heap. Failure points: a robots.txt that returns 5xx (treat the host as fully disallowed until it recovers), DNS timeouts (requeue with backoff), and slow servers (the adaptive delay backs off automatically). Scaling: thousands of hosts in the heap per node keep fetchers busy despite per-host delays.

Figure 52.24 — Write path: processing a fetched page.



Reading the diagram. The parser computes fingerprints first, so duplicates are stored only as references. New content is appended to the current archive file in object storage, and the indexer is notified asynchronously. The URL record is updated with the fetch result and change observation, which feeds the recrawl scheduler. Extracted links are nor-

malized; links to the node's own hosts are tested against the local Bloom filter and added to the URL store and frontier if new; links to other hosts are batched by owner node and sent asynchronously. Failure points: a crash before the archive file is closed loses the pages in that file since the last flush, so files are flushed every few minutes and the URL records point only to flushed data; the cross-node link stream can lag without harming politeness. Scaling: link routing traffic grows with the number of nodes but is batched; 100,000 links/s at about 100 bytes each is 10 MB/s cluster-wide.

52.10.10 Bottlenecks

1. **Host diversity in the frontier.** Throughput is capped by H_{active}/d; a frontier dominated by a few large hosts idles fetchers. Admission caps per host and a wide front-queue mix keep thousands of hosts ready.
2. **URL-seen lookups.** 100,000 per second; in-memory Bloom filters per node solve it, while any disk-based lookup per link would not.
3. **DNS.** Mitigated by prefetching and a local cache; a slow recursive resolver otherwise stalls fetchers.
4. **Parsing CPU.** HTML parsing and link extraction of 200 MB/s is a real CPU cost, often larger than networking; size nodes for it.
5. **Storage writes of small pages.** Solved by archive files instead of objects per page.

52.10.11 Failure scenarios

Table 52.32 — Web crawler failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Crawler node crash	Its hosts stall; in-memory queues lost	Heartbeat loss	Another node takes its hash range and rebuilds queues from the URL store	Checkpoint frontier state and Bloom filter regularly
Politeness bug (delay ignored)	A small site is overloaded; complaints, blocks	Per-host request-rate monitor	Kill switch per host and globally	Independent per-IP rate guard in the fetch path
Robots.txt misparsed	Crawling disallowed paths	Audits against a robots test suite	Purge fetched disallowed content	RFC 9309 test cases in CI
Crawler trap	Frontier fills with one host's infinite URLs	URLs per host growth	Block URL pattern; cap per host	Per-host URL caps; depth limits; near-duplicate signals
DNS resolver outage	Fetchers stall on new hosts	Resolution latency and errors	Fail over to secondary resolvers	Multiple resolvers; prefetching; TTL floor
Bloom filter lost	Many URLs re-added as new	Duplicate fetch rate rises	Rebuild from URL store	Periodic checkpoints
Host hash rebalancing	Two nodes briefly crawl one host	Overlapping ownership	Ownership by lease with fencing (§26.13)	Hand over hosts only after the old owner stops
Mass 5xx from one hosting provider	Many hosts error at once	Error rate per IP range	Back off per IP; pause range	Per-IP politeness and error backoff

52.10.12 Scaling strategy

At 10× (30 billion pages per cycle, 20,000 pages/s). Politeness now requires 100,000 ready hosts at a 5 s delay, which means the frontier must draw from a far wider slice of the web: improve host discovery and lower per-node host counts by adding nodes (about 500). Storage reaches 750 TB per cycle, so keep only changed pages from previous cycles. The URL-seen filters grow to about 540 GB in total and remain partitioned.

At 100×. Crawl from several regions, assigning hosts to the region nearest to their servers to cut latency and cross-ocean bandwidth, with host ownership still unique worldwide. Recrawl efficiency becomes the main lever: change prediction models, sitemaps and push-based notification of changes from cooperating sites reduce wasted fetches more than hardware does.

52.10.13 Trade-offs

- **Host-partitioned nodes:** politeness, DNS caching and robots caching become local problems, in exchange for cross-node link routing and uneven load when a node owns very large hosts.

- **Bloom filter for URL-seen:** fast and small, in exchange for occasionally skipping new URLs.
- **Near-duplicate suppression:** large savings in storage and indexing, in exchange for occasionally treating distinct short pages as duplicates.
- **Fixed fetch budget split between discovery and recrawl:** freshness of known pages versus coverage of new ones; the split is a product decision.

52.10.14 Alternative designs

- **Centralized frontier service** shared by stateless fetchers: simpler fetchers, but the frontier becomes a bottleneck and a single politeness authority that must be highly available.
- **Breadth-first crawl from a disk-based queue** (early crawlers): easy, but without per-host back queues, politeness requires sleeping threads and throughput collapses on hosts with many links.
- **Use a public crawl dataset** (such as Common Crawl's published archives) for research or bootstrap: no crawling infrastructure, but no control over freshness, coverage or recrawl.
- **Headless-browser rendering for all pages**: complete content for JavaScript-heavy sites, at one to two orders of magnitude more CPU per page; usually reserved for pages known to need it.

52.10.15 Interview discussion

Table 52.33 — 45-minute plan for the web crawler.

Minutes	Focus	What to produce
0–5	Requirements	Pages per cycle, politeness, robots, freshness, duplicates
5–10	Estimates	1,157 pages/s, 1.6 Gbps, 75 TB/cycle, 100,000 links/s, ready hosts formula
10–14	Data model	URL store keyed by reversed host; host table; archive files
14–20	Architecture	Figure 52.21: host-partitioned nodes, router, duplicate detection
20–33	Deep dive: frontier	Front and back queues, heap, adaptive delay, per-IP limits
33–40	Duplicates, robots, DNS	Bloom filter, exact hash, SimHash, RFC 9309 behavior
40–45	Recrawl and scaling	Change rates, conditional GETs, traps, 10× hosts

Likely follow-ups.

- *"How do you stay polite while crawling fast?"* Per-host back queues with a heap of next-allowed times, adaptive delays and per-IP limits; throughput comes from host diversity, not from hitting hosts harder.
- *"How do you detect duplicates?"* Normalize URLs; a Bloom filter for URL-seen; an exact content hash; SimHash with a 3-bit threshold for near-duplicates.
- *"How do you distribute the crawl?"* Partition by hash of the host so each host has one owner; route discovered links to owners.
- *"What if robots.txt returns 500?"* Treat the host as fully disallowed until it is reachable again, per RFC 9309.

What distinguishes senior and staff answers. A senior candidate builds the frontier with politeness and uses Bloom filters. A staff candidate derives the ready-hosts bound and the large-site problem from numbers, partitions by host to make politeness and caching local, separates exact from near-duplicate detection with costs, handles crawler traps, and treats recrawl scheduling as a budget allocation problem with a known counter-intuitive result.

52.10.16 Production considerations

- **Observability.** Fetches per second, ready hosts per node, per-host request rates (with alerts above policy), robots.txt fetch outcomes by status class, DNS latency, duplicate and near-duplicate rates, and index freshness (median page age).
- **Security and ethics.** Fetch only public content; respect robots.txt and opt-out requests promptly; publish the crawler's user agent, purpose and contact page; never send credentials; sandbox parsers, because hostile pages target parser bugs; filter content that must not be stored.
- **Cost.** Bandwidth, storage and parsing CPU; conditional requests and near-duplicate suppression reduce all three.
- **Operations.** A global and per-host kill switch; a complaint-handling process with fast host blocking; replayable archive files for reprocessing when parsers improve.

52.11 Summary and revision notes

SUMMARY

- **Method (§52.3).** Scope → size → contract → shape → depth → stress → judgment. Name the distinctive hard problem within ten minutes and spend most of the time there. Every number comes from stated assumptions; peak ≈ 4.8 × average with $h = 0.10$, $b = 2$.
- **URL shortener.** 280,000 redirect RPS at peak, 182.5 billion links in 10 years, 7 base62 characters ($62^7 = 3.52 \times 10^{12}$). Leased counter ranges plus a keyed permutation give unique, non-enumerable codes without per-create coordination; 302 keeps analytics correct; clicks go asynchronously to Kafka and are rolled up.
- **Pastebin.** Metadata in a key-value store, blobs in object storage, small pastes inline. Logical expiry is checked on every read; physical deletion uses a time-bucketed expiry index, lifecycle rules as backstop and a reconciler. Permanent pastes dominate storage. Private content is never cached in shared layers; burn-after-read is a conditional state transition.
- **Rate limiter.** Choose per rule where counting happens: local, regional Redis with atomic Lua, leased token batches for hot keys, or demand-proportional regional shares for global limits. Fail-open or fail-closed is a per-rule decision; the limiter must never cause the outage it exists to prevent.
- **Notification system.** Separate queues and pools per priority; the router applies preferences, quiet hours, caps and deduplication before rendering. Provider quotas often set campaign drain time. Provider timeouts make delivery ambiguous; resolve per channel. Every message ends in a recorded terminal state.
- **Key-value store.** Fixed partitions on a consistent-hashing ring; $N = 3$ zone-diverse replicas; quorums with sloppy quorum and hinted handoff; version vectors and siblings; read repair and Merkle anti-entropy; LSM storage; gossip membership with explicit permanent changes. Throughput, not capacity, sets node count; tombstones must outlive the rejoin window.
- **Job scheduler.** Partition ownership by lease with fencing tokens; near-term timers in hierarchical timing wheels; watermark checkpoints instead of per-firing writes; deterministic execution IDs; at-least-once execution plus idempotent jobs; top-of-hour bursts drive capacity.
- **Web crawler.** Mercator-style frontier: priority front queues, per-host back queues and a heap of next-allowed times. Throughput ≤ ready hosts ÷ delay. Partition by host; cache DNS and robots.txt (RFC 9309); URL-seen Bloom filter, exact hash and SimHash for duplicates; recrawl as budget allocation.

52.12 Knowledge checkpoint

1. With $h = 0.10$ and $b = 2$, what multiple of the daily average is the design peak?
2. How many base62 characters are needed for 1.825×10^{13} codes at 10% maximum fill?
3. Why does a counter-based shortener need a keyed permutation, and why must cycle-walking be used with a 42-bit Feistel network?
4. Why does a shortener with analytics return 302 rather than 301?
5. In the Pastebin estimate, why do never-expiring pastes dominate storage although 70% of pastes expire?
6. Why is a database's native TTL not sufficient to stop expired pastes from being served?
7. How is burn-after-read made safe under concurrent readers?
8. A global limit of 6,000 requests per minute; regional demand 6,000, 3,000 and 1,000 per minute; floor fraction 0.1. Compute the regional allocations.
9. Which rate limits should fail closed when the limiter is unavailable, and why?
10. A 50 million-message campaign; capacity 50,000/s; higher-priority traffic 8,333/s. How long does the campaign take?
11. Why does a single queue with a priority field fail for one-time passwords?
12. In the key-value store, why does reading from all three replicas cost nodes, and what does it buy?
13. Why must tombstones be retained longer than the maximum time a replica can be away and still rejoin?
14. What is the span of a three-level timing wheel with 100 ms ticks and 600, 60 and 24 slots?
15. Why can a job scheduler not promise exactly-once execution, and what does it offer instead?
16. A crawler needs 2,000 pages/s with a 5 s politeness delay. How many hosts must have URLs ready?
17. Why must links be routed to the node that owns their host?
18. What does RFC 9309 require when robots.txt returns a 5xx status?

Answers

1. $0.10 \times 24 \times 2 = 4.8$.
2. $\log_{62}(1.825 \times 10^{14}) = 7.96$, so 8 characters.
3. Sequential counters are enumerable; a keyed permutation maps consecutive counters to unrelated codes without collisions. The Feistel network permutes $[0, 2^{42})$, which is larger than 62^7, so out-of-range results are re-encrypted until they fall inside, preserving a permutation on the smaller set.
4. 301 is cacheable by default, so browsers stop asking and analytics undercounts; disabled links also keep redirecting from caches.

5. Expiring pastes reach a steady state (about 1.15 TB) while permanent ones accumulate (21.9 TB per year).
6. Native TTL deletion is asynchronous and best effort (DynamoDB: typically within a few days); visibility must be decided by a read-time check of `expires_at`.
7. A conditional transition from `active` to `burned` before returning content; only one reader's update succeeds.
8. Floors 200 each; remaining 5,400 split 0.6/0.3/0.1: 3,440, 1,820 and 740.
9. Security limits (login failures) and money limits (paid sends): an unchecked burst causes harm that cannot be undone; fall back to strict local limits.
10. $5 \times 10^7 / 41,667 = 1,200$ s, 20 minutes.
11. Head-of-line blocking: the OTP waits behind already queued campaign messages; isolation needs separate queues and consumers.
12. Each logical read becomes three replica reads, raising the node count to 150; it detects stale replicas promptly (read repair) and lets the coordinator answer with the fastest R replies, cutting tail latency.
13. Otherwise a replica that missed the delete still holds the old value and anti-entropy copies it back, resurrecting deleted data.
14. $0.1 \times 600 \times 60 \times 24 = 86,400$ s, one day.
15. A worker can crash after the side effect but before recording success, so the job may run again. It offers at-least-once execution with a stable execution ID; idempotent jobs then get effectively-once results.
16. $2,000 \times 5 = 10,000$ hosts.
17. So that exactly one node enforces politeness, holds robots and DNS state, and tests URL-seen for each host.
18. Treat the host as unreachable and assume complete disallow until it can be fetched.

52.13 Interview questions

Basic

Q1. Design the redirect path of a URL shortener for 280,000 RPS with p99 ≤ 20 ms. Answer. Stateless redirect nodes behind the CDN, with an in-process LRU cache, a Redis cluster and a partitioned link store keyed by code. Return 302 with a short private cache lifetime; cache negative results for unknown codes; collapse concurrent misses; emit click events asynchronously. At a 95% hit ratio the store sees about 14,000 reads/s; about 50 nodes at 10,000 RPS each and 60% utilization.

Q2. Why separate blobs from metadata in a Pastebin? Answer. Their access patterns and lifecycles differ: metadata is small, read on every request and updated; blobs are immutable and large. Large values in a key-value store inflate compaction, replication and caches. Object storage is cheaper per byte and has lifecycle rules. Keep small pastes inline to avoid an object request for the common case.

Intermediate

Q3. Your notification platform's OTPs are delayed during marketing campaigns. Diagnose and fix. Answer. OTPs share a queue, workers or provider quota with campaign traffic. Give critical traffic its own queue and worker pool, reserve a share of each provider's throughput for it, set a short TTL, cap campaign rates, and fail over SMS providers on definitive errors. Monitor end-to-end latency per priority.

Q4. How does a Dynamo-style store remain writable when one of three replicas is down, and what is the cost? Answer. The coordinator writes to a substitute node with a hint (sloppy quorum), meeting $W = 2$; the hint is replayed later. The cost: the substitute is outside the preference list, so $R + W > N$ no longer guarantees reading the latest write until handoff and repair complete, and concurrent writes during partitions produce siblings or LWW losses.

Advanced

Q5. Design global rate limits for a tenant served from three regions without adding cross-region latency. Answer. Enforce regional shares locally (Redis plus Lua per region), recomputed every second from published per-key usage with $L_r = fL/R + (1 - f)L\,d_r / \sum d$. Overshoot during demand shifts is about $\lambda\Delta$. Use chunked leases from a durable global counter for money-like daily quotas. Declare failure modes per rule and keep local fallback limits.

Q6. A job scheduler must fire one million jobs at 00:00:00 within 10 s and never fire a job twice in a way that matters. Design the core. Answer. Partition schedules (1,024 partitions) with leases and fencing tokens; pre-load the next 10 minutes of timers into hierarchical timing wheels; at the tick, batch-append dispatch messages keyed by `hash(job_id, scheduled_at)`; checkpoint a per-partition watermark each second instead of writing per firing; on failover, replay from the watermark. Workers claim attempts by conditional insert and pass the execution ID as an idempotency key. Encourage hashed minutes to flatten the burst.

52.14 Practical exercises

1. Run the short-code program with a different key and confirm that the first 200,000 codes are still unique; then measure the average number of Feistel encryptions per code and compare with 1.25.
2. Write a sweeper simulation for the Pastebin expiry index with 64 shards and the expiry mix of §52.5.4; measure the largest partition at the peak hour.
3. Extend the rate-limiter allocation formula into a simulation where demand moves from the US to the EU over 10 minutes; plot overshoot against $\Delta = 1$, 5 and 10 s.

4. Implement the notification state machine of Figure 52.12 with forward-only transitions and feed it shuffled, duplicated events; assert that final states are unchanged.
5. Add retries with exponential backoff to the timing-wheel program, re-scheduling failed jobs, and verify that every retry fires at its computed time.
6. Run the SimHash program on two versions of a real news page and on two unrelated pages; record distances with and without boilerplate removal.

52.15 Design challenges

1. **Link-in-bio service.** Extend the URL shortener so that each user has an editable page of links at `sho.rt/@name`. Links become mutable: redesign caching and invalidation, and estimate how often caches must be purged.
2. **Regional notification compliance.** Users in one jurisdiction must have contact data and notification logs stored only in that region. Redesign the notification platform’s stores, queues and provider routing, and state what happens to a global campaign.
3. **Crawler for a vertical search engine.** Crawl 50 million product pages from 20,000 shops daily with price-change detection within 4 hours for the top 1 million products. Size the frontier, choose recrawl intervals, and decide where near-duplicate detection is harmful (identical products in different shops).

52.17 Open verification items

- RFC 9309 details quoted in §52.10.8 (24-hour cache limit, 500 KiB parse minimum, 4xx "unavailable" versus 5xx "unreachable" behavior) were confirmed only through secondary sources; rfc-editor.org was unreachable from the build environment.
- Google's 2024 bulk-sender requirements (0.3% spam-rate threshold, one-click unsubscribe) and the exact help-page URL should be checked against the current page.
- The SRE book's description of the `?` crontab extension (§52.9.8) is cited from memory of ch. 24; confirm the wording.
- S3 request price ($0.005 per 1,000 PUTs, §52.5.6) is time-sensitive; confirm current list price.
- The Mercator "ten times the last fetch duration" heuristic is taken from Manning et al. ch. 20 as an example, not from the Mercator paper itself.

Chapter 53 — Case Studies II: Social and Communication

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 4 h

53.1 Learning objectives

After this chapter you should be able to:

- Design a chat service that orders messages per conversation with sequence numbers, tracks delivery and read state as watermarks, and lets a device that was offline for a week catch up with one ranged query.
- Explain, at the level of an architecture review, how an end-to-end encrypted messenger such as WhatsApp keeps plaintext off its servers, what the server still sees, and what multi-device support and large groups cost in ciphertexts per message.
- Design a photo-sharing service's upload pipeline (presigned upload, asynchronous resizing, CDN delivery), its sharded ID scheme and its counters for likes on very popular posts.
- Choose between fan-out-on-write, fan-out-on-read and a hybrid for a news feed using capacity arithmetic, and state precisely why celebrities break pure fan-out-on-write.
- Describe a graph-shaped read-through cache over a sharded relational store in the style of Facebook's TAO.
- Design the three distinct read products of a microblogging service (home timeline, real-time search and trends) and justify a different data structure for each.
- Run each design through the same sixteen-step template within a 45-minute interview, and separate what companies have published from teaching designs.

53.2 Prerequisites

These cases apply concepts taught earlier; they do not re-teach them. Read or skim the following first.

- **The case-study method — §52.3.** The sixteen-step template, how to read capacity estimates, and how evidence labels are used.
- **Capacity estimation — §2.11, §4.11 (Little's Law), §4.14 (availability arithmetic).** Every case converts daily actives into requests per second, storage and

servers.

- **Real-time communication — §9.6 (WebSockets) and §9.9 (connection gateways, registries, presence, reconnect storms).** The chat and WhatsApp cases reuse the gateway sizing formula of §9.9.2.
- **Mobile push — §9.8.** Offline delivery for chat.
- **Cryptography essentials — §10.4.** Diffie–Hellman, forward secrecy, authenticated encryption; needed for the WhatsApp case.
- **NoSQL data models — §12.4 (key-value), §12.6 (wide-column) and §12.7 (graph).** Message stores, feed stores and the social graph.
- **Partitioning — §14.6–§14.10.** Shard keys, consistent hashing (§14.8) and hot partitions (§14.10).
- **Object storage — §15.4 and §15.8 (multipart upload, presigned URLs).** Media pipelines.
- **Search — §16.3 (inverted indexes), §16.7 (distributed search) and §16.10 (near-real-time indexing).** Twitter search.
- **Sketches and IDs — §17.6 (Count-Min and heavy hitters) and §17.10 (Snowflake and Instagram IDs).**
- **Caching — §20.7 (cache-aside), §20.11 (stampede and leases), §20.15 (hot keys).** Feed and graph caches.
- **CDNs — §21.3–§21.6.** Photo delivery.
- **Messaging — §30.8 (delivery guarantees), §30.9 (ordering), §31.5 (Kafka partitions and keys).** Fan-out pipelines.
- **Stream processing windows — §29.8.** Trends.
- **Ranking — Chapter 68.** Feed ranking is summarized here and treated in depth there.

53.3 How to use these case studies

Work each case with the method of §52.3: read the problem statement, cover the rest of the section, and spend five minutes writing your own requirements and capacity estimate before comparing. The five cases share one domain, people talking to people, but each was chosen to teach a different hard problem: **ordering and synchronization** (chat, §53.4), **end-to-end encryption at billions of users** (WhatsApp, §53.5), **media pipelines and hot counters** (Instagram, §53.6), **fan-out economics and the social graph** (Facebook News Feed, §53.7) and **three read products over one write stream** (Twitter/X, §53.8). Concepts that appear in more than one case are taught once, in the case where they are hardest, and cross-referenced elsewhere; the feed fan-out trade-off, for example, is introduced in §53.6.8 and analyzed in full in §53.7.8. Industry facts carry *Evidence: Primary* or *Secondary* labels and come only from what the companies have published; every architecture in this chapter is a teaching design (*Evidence: Illustrative*) un-

less a callout says otherwise. All capacity estimates use decimal units (1 KB = 10^3 bytes, 1 TB = 10^{12} bytes).

53.4 Chat Application

53.4.1 Problem statement

Design a general-purpose chat service with one-to-one conversations and group conversations of up to 500 members, used on phones, desktops and the web. Messages are stored on the server so that a user who logs in on a new laptop sees their history (in the style of Slack, Discord or Facebook Messenger). Users see whether their contacts are online, whether a sent message has been delivered and whether it has been read.

The analogy is a set of numbered notebooks, one per conversation. Whoever writes in a notebook writes on the next numbered line, never between lines. Each reader keeps a bookmark: “I have read up to line 41”. To catch up after a holiday, a reader asks for “everything after line 41”. The whole design follows from making the line number authoritative and keeping the bookmark small.

The distinctive hard problem is **ordering and synchronization**: every member of a conversation, on every device, must see the same messages in the same order, without gaps or duplicates, even though phones disconnect constantly, retries create duplicates and the live delivery path is lossy by design (§9.9.3).

53.4.2 Functional requirements

1. Send a text message to a one-to-one or group conversation; attach an image or file.
2. Receive messages in real time while online; receive a push notification while offline.
3. Show per-message state to the sender: sent (stored on the server), delivered (reached at least one recipient device) and read.
4. Synchronize history to any of a user’s devices: open the app after a week offline and see every missed message, in order, with correct unread counts.
5. Show presence (online, last seen) for contacts and typing indicators within a conversation.
6. Create groups, add and remove members, and list a user’s conversations ordered by latest activity.
7. Out of scope: voice and video calls (§9.7), end-to-end encryption (deferred to §53.5), full-text search of history (§16).

53.4.3 Non-functional requirements

Table 53.1 — Non-functional requirements for the chat service.

Requirement	Target	Why this value
Availability (send and receive)	99.99 % per month (≈ 4.3 min of downtime)	Messaging is a primary communication channel; outages are visible and reported
Durability of an acknowledged message	No loss after the server says “sent”; RF = 3 across zones	A lost message breaks trust more than a delayed one
End-to-end latency, both users online	p99 < 500 ms within a region; p99 < 1 s cross-region	Conversation feels live below about half a second
Send acknowledgment latency	p99 < 200 ms	The sender’s tick must appear almost immediately
Ordering	Total order **per conversation**, identical on every device; no global order	Users reason about one conversation at a time
Delivery guarantee	At-least-once to each device, deduplicated by the client: effectively exactly-once display	§30.8
Sync after offline	Any gap closed with one ranged query per conversation; p99 < 2 s for 1,000 missed messages	Opening the app must not trigger a slow full reload
Presence freshness	Online/offline visible within 30–90 s; may be approximate	Presence is advisory (§9.9.5)
Consistency of receipts and unread counts	Eventually consistent within seconds	A late read tick is harmless

Notice what is *not* required: a global order across conversations, strongly consistent presence and synchronous receipts. Each relaxation removes a coordination point.

53.4.4 Capacity estimation

State the assumptions first; every later number derives from them.

- 100 million daily active users (DAU); each sends 40 messages per day.
- 70 % of messages go to one-to-one conversations and 30 % to groups with 20 members on average.
- Peak-to-average ratio of 3 (evening peaks within a region dominated by one time zone).
- Stored size per message, including metadata and index overhead: 300 bytes (100-byte text body, 200 bytes of IDs, timestamps, flags and index entries).
- 5 % of messages carry an attachment averaging 500 KB.
- At peak, 25 % of DAU hold an open connection.

WORKED EXAMPLE

Worked example — Message and delivery rates.

1. Messages per day: $100 \times 10^6 \times 40 = 4.0 \times 10^9$.
2. Average send rate: $4.0 \times 10^9 / 86,400 \approx 46,300$ messages/s; peak $\times 3 \approx 138,900$ messages/s.
3. Recipients per message (excluding the sender): $0.7 \times 1 + 0.3 \times 19 = 6.4$.
4. Deliveries per day: $4.0 \times 10^9 \times 6.4 = 25.6 \times 10^9$; average $\approx 296,300$/s; peak $\approx 888,900$/s.
5. Receipts if every delivery produced a “delivered” and a “read” event: $2 \times 25.6 \times 10^9 = 51.2 \times 10^9$/day, about 592,600/s on average — **more traffic than the messages themselves**.
6. Receipts as **watermarks** (“read up to seq 41”, one per conversation open, plus one “delivered up to” per sync), assuming 30 conversation opens and 30 syncs per user per day: $100 \times 10^6 \times 60 = 6.0 \times 10^9$/day, about 69,400/s — **8.5 times fewer**.

Interpretation. Group fan-out multiplies messages by 6.4 and naive receipts would multiply deliveries by 2. *Engineering implication.* Model receipts as per-member watermarks from the start; per-message receipts are a cost you cannot retrofit away cheaply.

WORKED EXAMPLE

Worked example — Storage, bandwidth and cache.

1. Message store growth: $4.0 \times 10^9 \times 300$ B $= 1.2$ TB/day, $1.2 \times 365 = 438$ TB/year; with replication factor 3, **1.31 PB/year**. Messages are stored **once per conversation**, not once per recipient, which saves a factor of 6.4.
2. Attachments: $4.0 \times 10^9 \times 0.05 \times 500$ KB $= 100$ TB/day, 36.5 PB/year; with erasure coding at 1.4× overhead (§15.6), 51.1 PB/year in object storage. Media is **40 times** the text volume.
3. Peak delivery egress: $888,900$/s × 1 KB on the wire (framing, TLS, JSON envelope) ≈ 0.89 GB/s ≈ 7.1 Gbit/s — small for a fleet.
4. Hot-message cache: assume 300 million conversations active per day, caching the latest 20 messages of each: $300 \times 10^6 \times 20 \times 300$ B $= 1.8$ TB, about 30 cache nodes with 60 GB usable each.

Interpretation. Text storage grows linearly forever and is the dominant cost of the database tier; throughput is not. *Engineering implication.* Choose a store whose cost per terabyte is low and which can tier old partitions (§15.9), and size the database by storage first.

WORKED EXAMPLE

Worked example — Gateways and database nodes.

1. Peak concurrent connections: $0.25 \times 100 \times 10^6 = 25 \times 10^6$.
2. Apply the gateway formula of §9.9.2 with a design ceiling of 500,000 connections per server and three zones, surviving the loss of one: servers per zone $= \lceil 25 \times 10^6 / (2 \times 500,000) \rceil = 25$, so 75 servers; add two per zone for deploys and surges: **81 gateways**, about 309,000 connections each in normal operation.
3. Peak database writes: 138,900 message inserts/s plus 888,900 per-member inbox updates/s (§53.4.6) ≈ 1.03 million writes/s; at replication factor 3, about 3.08 million replica writes/s. At an assumed 25,000 sustained writes/s per wide-column node, **≈ 124 nodes** for throughput.
4. Storage after one year: 1.31 PB ÷ 4 TB usable per node ≈ **329 nodes**.

Interpretation. After the first year the database is storage-bound (329 nodes) rather than write-bound (124 nodes), and the gap widens every year. *Engineering implication.* Re-run this estimate annually; tiering cold history to cheaper storage changes the node count more than any write-path optimization.

Table 53.2 — Capacity summary for the chat service.

Quantity	Value
Messages sent	4.0 × 10^9/day; 46,300/s average; 138,900/s peak
Deliveries	25.6 × 10^9/day; 888,900/s peak
Receipts (watermark model)	6.0 × 10^9/day; 69,400/s average
Text storage	1.2 TB/day; 1.31 PB/year at RF 3
Attachment storage	100 TB/day; 51.1 PB/year erasure-coded
Concurrent connections	25 million at peak; 81 gateway servers
Database nodes	≈ 124 for throughput; ≈ 329 for storage after year one

53.4.5 API design

Clients use two channels: a persistent **WebSocket** (§9.6) for real-time events in both directions, and **HTTPS** for history, uploads and anything that must be retried safely. Every client-originated message carries a `client_msg_id`, a UUID generated on the device, which serves as an idempotency key (§22.15).

```
# WebSocket frames (JSON or protobuf), client → server
SEND        {conv_id, client_msg_id, body, attachment_ref?}
ACK_SEND    ← {client_msg_id, conv_id, seq, server_ts}            # "sent" tick
MARK        {conv_id, delivered_upto?: seq, read_upto?: seq}       # watermarks
TYPING      {conv_id, state: start|stop}                           # ephemeral, never
stored
# server → client
MSG         {conv_id, seq, msg_id, sender_id, body, server_ts}
RECEIPT     {conv_id, user_id, delivered_upto, read_upto}
PRESENCE    {user_id, state: online|offline, last_seen}
CONV_CHANGED{conv_id, last_seq}                                    # sync hint

# HTTPS
GET  /v1/sync?cursor=<opaque>                → {changed: [{conv_id, last_seq}],
next_cursor}
GET  /v1/conversations/{conv_id}/messages?after_seq=41&limit=100
                                             → {messages: [...], has_more}
GET  /v1/conversations?before_ts=&limit=50    → {conversations: [{conv_id, title,
last_seq,
                                                 read_upto, unread: last_seq -
read_upto}]}
POST /v1/conversations                       {member_ids[], title?} → {conv_id}
POST /v1/conversations/{conv_id}/members     {add: [], remove: []}
POST /v1/uploads                             {content_type, size} → {upload_url,
attachment_ref}
```

Three API choices carry the design. `SEND` is idempotent on `(sender_id, client_msg_id)`, so a client that times out simply resends. History is paged by **sequence number** (`after_seq`), not by timestamp or offset, so pages never skip or repeat messages. Unread counts are computed (`last_seq − read_upto`), never stored and incremented.

53.4.6 Data model and database schema

The access patterns decide the store: “append to a conversation”, “read the latest *n* messages of a conversation”, “read everything after seq *s*” and “list my conversations by recent activity”. All are single-partition range reads and appends at very high volume, with storage growing without bound: the profile for which wide-column stores were built (§12.6). Discord’s published history shows the same choice (see the industry callout below).

```
        -- Wide-column (CQL-style) key design. Partition key in the inner parentheses.
        CREATE TABLE messages (
          conv_id     bigint,
          bucket      int,          -- seq / 10000: bounds partition size (§12.6.4)
          seq         bigint,       -- per-conversation sequence number: the order
          msg_id      bigint,       -- Snowflake-style ID (§17.10.3), globally unique
          sender_id   bigint,
          client_msg_id uuid,       -- idempotency key from the sender's device
          body        text,
          attachment  text,         -- object-store key, or null
          server_ts   timestamp,
          PRIMARY KEY ((conv_id, bucket), seq)
        ) WITH CLUSTERING ORDER BY (seq DESC);

        CREATE TABLE conversations (            -- one row per conversation
          conv_id   bigint PRIMARY KEY,
          kind      text,                       -- 'direct' | 'group'
          title     text,
          last_seq  bigint,                     -- advanced by the sequencer only
          members_version int
        );

        CREATE TABLE members (                  -- who is in a conversation, with water-
marks
          conv_id        bigint,
          user_id        bigint,
          delivered_upto bigint,
          read_upto      bigint,
          joined_seq     bigint,                -- members see history from this seq on-
ward
          PRIMARY KEY ((conv_id), user_id)
        );

        CREATE TABLE user_inbox (               -- "my conversations by recent activity"
          user_id   bigint,
          conv_id   bigint,
          last_seq  bigint,
          last_ts   timestamp,
          PRIMARY KEY ((user_id), conv_id)      -- upserted per message per member;
sorted client-side
        );

        CREATE TABLE dedup (                    -- idempotent SEND, short TTL
          sender_id bigint, client_msg_id uuid, seq bigint,
          PRIMARY KEY ((sender_id), client_msg_id)
        ) WITH default_time_to_live = 604800;   -- 7 days
```

Why `bucket = seq / 10000`? An active group can accumulate millions of messages; one partition per conversation would grow without limit, and wide-column stores degrade when partitions exceed roughly 100 MB (§12.6.4). Bucketing by sequence range keeps each partition at about $10,000 \times 300$ B $= 3$ MB, and a reader computes the bucket directly from the sequence number it needs. Discord bucketed by time instead [Discord 2017]; se-

quence buckets have the advantage that sparse conversations do not create thousands of nearly empty partitions.

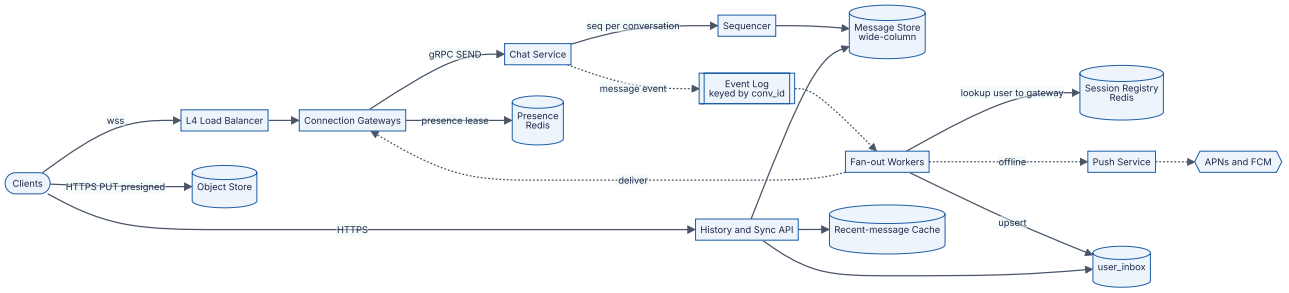
The `user_inbox` upsert per message per member is the expensive write in the capacity estimate (888,900/s at peak). It overwrites a single cell per (user, conversation), so its storage stays bounded at one row per membership; for very large groups it can be skipped and replaced by a pull of `conversations.last_seq` when the user opens the app.

INDUSTRY EXAMPLE

Discord's message store. Discord's 2017 post describes storing messages in Cassandra with primary key `((channel_id, bucket), message_id)`, where `message_id` is a time-ordered Snowflake ID and `bucket` a fixed time window, and the hot-partition and tombstone problems that followed. Its 2023 post describes migrating trillions of messages to ScyllaDB, putting Rust "data services" in front of the database that coalesce concurrent requests for the same channel and route by channel through consistent hashing, and shrinking the cluster from 177 Cassandra nodes to 72 ScyllaDB nodes with lower and more predictable tail latency. *Evidence: Primary* — [Discord 2017; Discord 2023]

53.4.7 High-level architecture

Figure 53.1 — High-level architecture of the chat service.



Reading the diagram. Clients hold a WebSocket through an L4 load balancer to a **connection gateway** (§9.9.1), which authenticates the session, registers `user → gateway` in the **session registry** and refreshes a **presence lease** (§9.9.5). A `SEND` goes synchronously over gRPC to the stateless **chat service**, which asks the **sequencer** for the next sequence number of that conversation and writes the message to the **message store**; only then is the sender's `ACK_SEND` returned, so the durable boundary is the store write. The chat service then publishes the message event asynchronously (dotted) to an **event log** partitioned by `conv_id`, which keeps each conversation's events in order (§31.5.3). **Fan-out workers** consume it, look up the members' gateways and deliver to online devices, send pushes to offline ones and upsert each member's inbox row. The **history and sync API** answers ranged reads over HTTPS from the store, fronted by a cache

of recent messages. Attachments bypass the chat path entirely: the client uploads to the object store with a presigned URL (§15.8.2) and sends only a reference. Failure points: a gateway crash drops its connections (clients reconnect and resync); an event-log or fan-out outage delays live delivery but loses nothing, because the store already holds the message; a sequencer outage stops sends for the conversations it owns. Gateways scale by connections, the chat service by request rate, fan-out workers by deliveries per second, the store by storage.

53.4.8 Detailed component design

The sequencer: one writer per conversation

A total order per conversation requires that, at any moment, exactly one component decides which message is number 42. Three implementations, from simplest to most scalable:

1. **Conditional write in the store.** Read `last_seq`, then write `last_seq + 1` with a compare-and-set (a lightweight transaction in Cassandra or a conditional put in DynamoDB). Correct, but every send in a busy group serializes on one Paxos-backed row: a few hundred sends per second per conversation at best.
2. **A counter service partitioned by `conv_id`.** Conversations are assigned to sequencer nodes by consistent hashing (§14.8); each node holds the counters of its conversations in memory and persists them. To survive a crash without reusing a number, a node **leases a block** ("seq 4,001–5,000 belong to me") with a conditional write, hands numbers out of memory and leases the next block when the current one runs out. After a crash, the new owner leases a fresh block; numbers in the dead node's unused block are skipped, which leaves a hole.
3. **Single-writer actor per conversation.** The chat service routes every send for a conversation to one actor (an Erlang process, an Akka actor or a partition of the event log); the actor assigns `seq` and writes. Ownership moves only through a fenced handover, so two actors never assign numbers at once (fencing tokens, §26.13).

The teaching design uses option 2. Holes from crashed leases are harmless if clients treat them correctly: a gap is a signal to *ask*, and the store's answer ("no message 4,812 exists; continue from 5,001") closes it. The sequencer never needs a global clock, and conversations never coordinate with each other: that is why per-conversation order scales and global order does not.

DEFINITION

Definition — Per-conversation sequence number. A strictly increasing integer assigned by the single owner of a conversation to each message at the moment it becomes durable. It defines the display order for every member and device, serves as the cursor for history paging and sync, and lets a client detect missing messages as gaps between consecutive numbers.

Why not order by timestamp? Two senders' clocks disagree by seconds, server clocks by milliseconds, and two messages can share a millisecond. Timestamp order would reorder messages differently on different devices whenever two arrive close together. Timestamps are for display ("10:42"); sequence numbers are for order.

COMMON MISTAKE

Mistake — Using the message ID as the order. A Snowflake ID (§17.10.3) is roughly time-ordered across machines, but only within clock skew: two messages sent to the same group from different chat-service nodes in the same few milliseconds can receive IDs in the opposite order from the one in which they were stored. Use the ID for identity and deduplication, and the dense per-conversation sequence number for order and gap detection.

Delivery state: watermarks instead of per-message receipts

Each member's progress through a conversation is two integers: `delivered_upto` (the highest seq that has reached at least one of the member's devices) and `read_upto` (the highest seq the member has seen on screen). Every per-message tick is derived from them:

- **Sent:** the sender received `ACK_SEND` with a `seq`.
- **Delivered:** for a one-to-one chat, `peer.delivered_upto ≥ seq`; for a group, the count of members with `delivered_upto ≥ seq`.
- **Read:** the same with `read_upto`.
- **Unread count:** `conversation.last_seq − me.read_upto` (minus my own messages, which the client tracks).

Watermarks are monotonic, so they merge trivially: a late or duplicate `MARK` with a lower value is ignored (`read_upto = max(old, new)`), which makes them safe to retry and reorder. They are also tiny: a group of 500 with a full read-state matrix needs 500 pairs of integers, not 500 receipts per message.

Offline sync

A device that was offline holds, per conversation, the last sequence number it applied. Opening the app runs three steps:

1. Call `GET /v1/sync?cursor=…` with the device's opaque sync cursor; the server returns the conversations whose `last_seq` changed since that cursor (from `user_inbox`), with their new `last_seq`.
2. For each changed conversation, fetch `messages?after_seq=<local last_seq>` in pages of 100, newest conversations first so the inbox renders before the backlog finishes.
3. Reconnect the WebSocket; live pushes that arrive during the fetch are buffered and applied only when contiguous.

The code below shows the rule that makes this correct: apply a message only if its `seq` is exactly one more than the last applied; ignore duplicates; treat a jump as a gap and fetch the range.

```
        import itertools

        class ConversationLog:
            """Server side: one ordered log per conversation (illustrative, in mem-
ory)."""
            def __init__(self):
                self.messages = []          # index i holds the message with seq = i + 1
                self.by_client_id = {}      # (sender, client_msg_id) -> seq, for idem-
potent retries

            def append(self, sender, client_msg_id, body):
                key = (sender, client_msg_id)
                if key in self.by_client_id:            # retry of a message already
stored
                    return self.by_client_id[key]
                seq = len(self.messages) + 1            # the single writer for this
conversation assigns seq
                self.messages.append((seq, sender, body))
                self.by_client_id[key] = seq
                return seq

            def fetch(self, after_seq, limit=100):
                return self.messages[after_seq:after_seq + limit]

        class Device:
            """Client side: applies live pushes in order, detects gaps, resyncs."""
            def __init__(self, log):
                self.log, self.last_seq, self.view = log, 0, []

            def on_push(self, msg):
                seq = msg[0]
                if seq <= self.last_seq:                # duplicate delivery: ignore
                    return
                if seq > self.last_seq + 1:             # gap: something was lost on the
live path
                    self.resync()
                    return
                self.view.append(msg); self.last_seq = seq

            def resync(self):
                for msg in self.log.fetch(self.last_seq):
                    self.view.append(msg); self.last_seq = msg[0]

        log = ConversationLog()
        ids = itertools.count(1)
        for text in ["hi", "are you there?", "lunch at 1?"]:
            log.append("alice", next(ids), text)
        assert log.append("alice", 2, "are you there?") == 2      # retried send returns
the same seq

        bob = Device(log)
        live = log.fetch(0)
        bob.on_push(live[0]); bob.on_push(live[0]); bob.on_push(live[2])   # dup, then a
gap (seq 2 lost)
```

```
        print([m[0] for m in bob.view], "last_seq =", bob.last_seq)
        # prints: [1, 2, 3] last_seq = 3
```

What to notice:

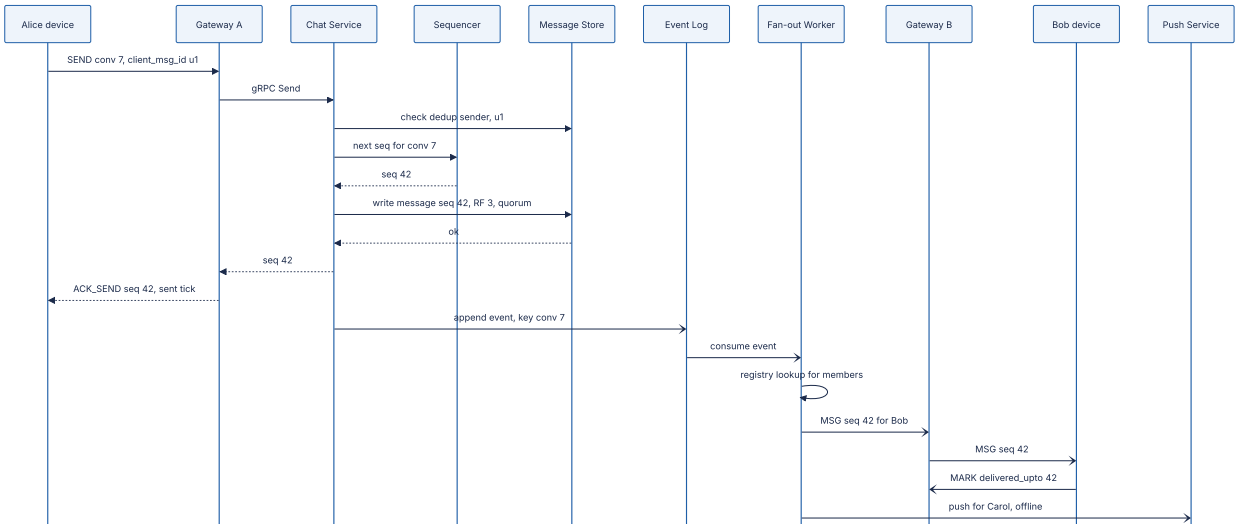
- `append` checks the idempotency key before assigning a number, so a retried `SEND` gets the *same* `seq` instead of a duplicate message.
- The client never trusts the live path for completeness: a duplicate is dropped, a gap triggers `resync`, and the store is the source of truth. This is the at-least-once-plus-deduplication pattern of §30.8, specialized to an ordered log.
- A production client also handles holes left by crashed sequencer leases: the store's answer to a range query is authoritative, so the client advances past numbers the server says do not exist.

INDUSTRY EXAMPLE

Facebook Messenger's Iris queue. Facebook described rebuilding Messenger's sync protocol around **Iris**, a totally ordered queue of messaging updates (new messages, read-state changes) per user, with separate pointers recording the last update sent to the user's app and the last written to the traditional storage tier. Each pointer advances only after a successful send, so an offline phone simply leaves its pointer behind, and recent updates are served from memory while about a week is served from the queue's backing store. The post reports that the new protocol cut non-media data usage by 40 % and, by reducing congestion, cut by about 20 % the number of people who saw errors when sending a message. *Evidence: Primary* — [Facebook Engineering 2014]

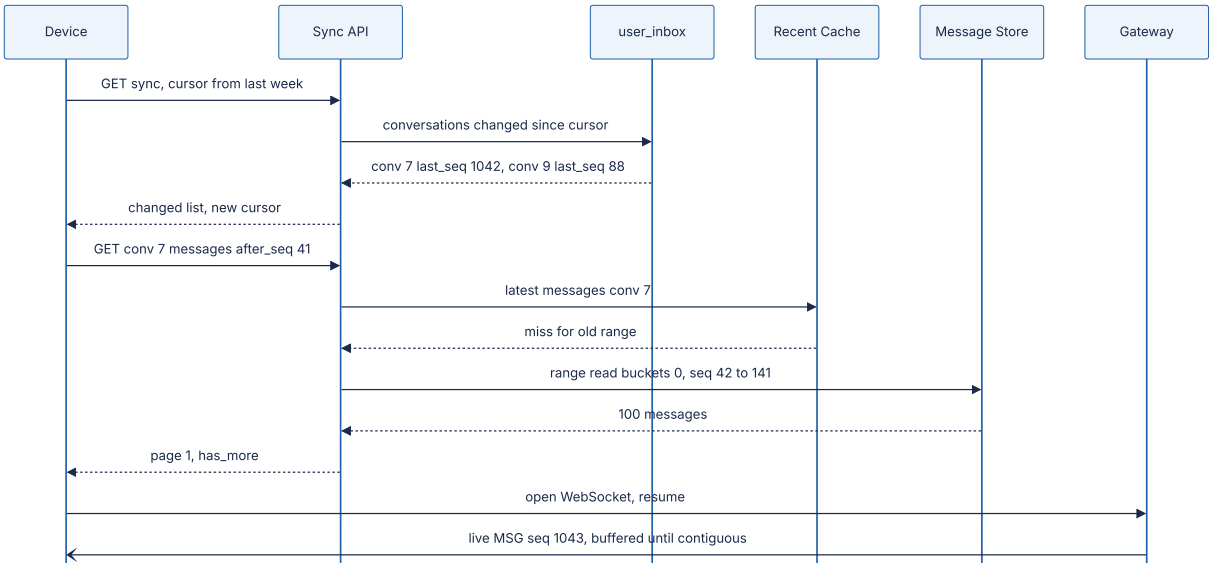
53.4.9 Data flow

Figure 53.2 — Write path: sending a message to an online and an offline recipient.



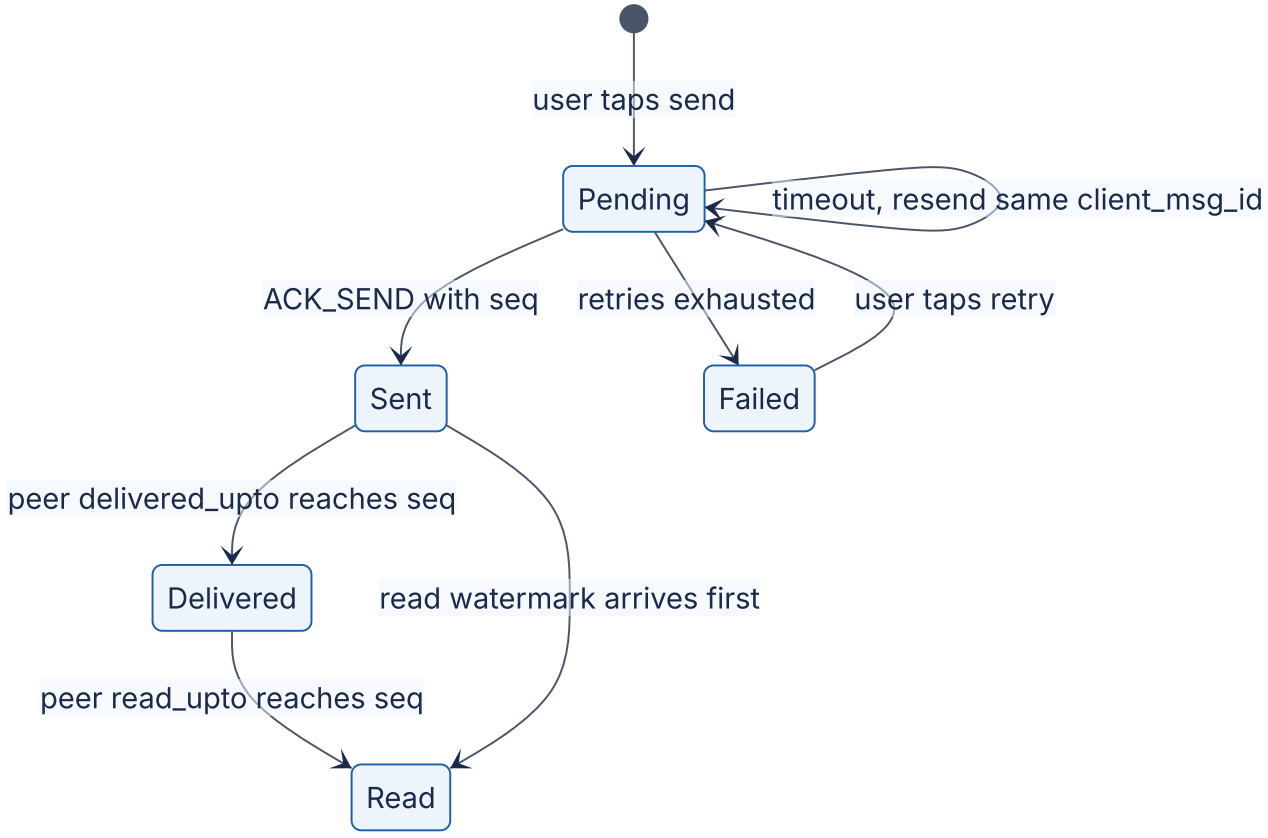
Reading the diagram. Solid arrows are synchronous calls and dashed open arrows asynchronous messages. Alice's `SEND` travels over her WebSocket to gateway A and on to the chat service, which first checks the dedup table, obtains `seq 42` from the conversation's sequencer and writes the message at quorum (two of three replicas, §27). Only after the store acknowledges does Alice see the "sent" tick: the store write is the commit point. Everything after it is asynchronous: the event goes to the log partition for conversation 7, a fan-out worker resolves the members, delivers to Bob's gateway (Bob is online) and asks the push service to notify Carol (offline, §9.8). Bob's device returns a `delivered_upto` watermark, which flows back through the same path to update the `members` row and reach Alice as a `RECEIPT`. Failure points: if the store write fails, the chat service returns an error and Alice's client retries with the same `client_msg_id`; if the chat service crashes after the write but before replying, the retry hits the dedup table and returns `seq 42` again; if the fan-out worker crashes, the log redelivers and Bob's client discards the duplicate by `seq`.

Figure 53.3 — Read path: a device reconnecting after a week offline.



Reading the diagram. The device first asks which conversations changed since its cursor, a single-partition read of its own `user_inbox` row set, and receives each conversation's new `last_seq`. For each, it pages forward from its local `last_seq`: the recent-message cache answers only the newest window, so a week-old range is read directly from the message store as a sequential slice of one or two bucket partitions. The WebSocket is reopened in parallel; a live message (seq 1043) that arrives before the backlog has been applied is buffered, because applying it would leave a gap. All calls are synchronous HTTPS except the live push. Failure points: a slow store slice delays only that conversation; a cache outage shifts reads to the store, which must be provisioned for it (§20.13). Scaling: the sync pattern costs one read per changed conversation plus one per 100 messages, independent of how long the device was offline.

Figure 53.4 — Message state as seen by the sender.



Reading the diagram. A message starts **Pending** on the sender's device, stored locally so it survives an app restart, and is resent with the same idempotency key until the server returns a sequence number. **Sent** means durable on the server. **Delivered** and **Read** are derived from the peer's watermarks, so a read watermark can arrive before the delivered one and skip a state. Only **Failed** needs the user. All transitions after Pending are driven by asynchronous server events.

53.4.10 Bottlenecks

1. **Hot conversations.** A 500-member group during a live event funnels every send through one sequencer owner and one bucket partition. At 200 messages/s, each producing 499 deliveries, one conversation generates about 100,000 deliveries/s. Mitigations: per-conversation send rate limits (§22.3), batching several sequence numbers per sequencer call, and delivering to each gateway once, then fanning out locally (§9.9.3).
2. **Inbox write amplification.** The `user_inbox` upsert is 6.4 writes per message. For large groups, skip it and let clients pull `conversations.last_seq` on open.
3. **Presence.** Status-change fan-out can exceed message traffic (§9.9.5). Subscribe only to presence of contacts visible on screen, and drop presence entirely for groups above a size threshold.
4. **Storage growth.** 1.3 PB/year with replication: tier partitions older than, for example, 12 months to cheaper storage or compress them into columnar archives served by a slower history API.
5. **Reconnect storms.** A gateway failure triggers a wave of reconnects *and* sync queries; jittered backoff (§9.9.6) and the cost-per-sync bound in Figure 53.3 keep the store from being overwhelmed.

53.4.11 Failure scenarios

Table 53.3 — Failure scenarios for the chat service.

What fails	Impact	Detection	Recovery	Prevention
Gateway node crash	~309,000 users disconnected; live delivery to them stops	Connection-count drop, load-balancer health checks	Clients reconnect with jitter and sync by seq; presence leases expire in ≤ 90 s	Blast-radius limit per gateway; graceful drain on deploy (§9.9.7)
Sequencer node crash	Sends to its conversations fail for seconds	Error rate on `next seq` calls; lease expiry	New owner leases a fresh block; skipped numbers become holes clients step over	Short leases, fenced ownership transfer
Message store replica loss	None at quorum; higher latency	Node-down alerts, hinted-handoff growth	Repair from replicas (§27)	RF 3 across zones; quorum writes
Event log or fan-out lag	Messages stored but delivered late; sender sees “sent” but not “delivered”	Consumer lag (§31.7.3)	Workers catch up; clients poll sync on foreground	Partition count sized for peak deliveries; autoscaling on lag
Fan-out worker crash mid-batch	Duplicate deliveries after redelivery	Redelivery metrics	Clients drop duplicates by seq	Idempotent delivery by `(conv_id, seq)`
Push provider outage	Offline users not notified	Provider error rate	Messages wait in the store; delivered on next open	Multiple notification paths (§9.8.2)
Registry (Redis) outage	Targeted delivery and presence fail	Error rate, latency	Fall back to broadcasting conversation events to all gateways for minutes; clients poll	Replicated registry; per-gateway liveness keys
Client clock wrong	None for order (seq-based); odd display times	—	Display server timestamps	Never order by client time

53.4.12 Scaling strategy

At 10× (1 billion DAU, 40 billion messages/day). Peak sends reach about 1.4 million/s and deliveries 8.9 million/s. Gateways grow to about 800; this is linear and routine. What breaks first is **storage** (13 PB/year at RF 3) and the **inbox writes** (8.9 million/s). Changes: aggressive tiering of cold buckets; drop per-member inbox writes for groups larger than about 50; move to **multiple regions with a home region per conversation** (§44.6.4), where the conversation’s sequencer and primary replicas live in the region of most of its members, and cross-region members are served by replicas with a few hundred milliseconds of extra delay.

At 100×. The sequencer limits only single conversations, never the system, because conversations are independent; the system-wide limits are cross-region bandwidth and operating thousands of database nodes. Changes: cell-based deployment (§44.10), with each

cell owning a set of conversations and a thin global directory mapping conversations to cells, plus media deduplication by content hash.

53.4.13 Trade-offs

Table 53.4 — Key trade-offs in the chat design.

Decision	Chosen	Gave up	Why acceptable
Order scope	Per conversation	Global order across conversations	Users never compare the order of two different chats
Commit point	Store write before “sent” tick	10–30 ms of extra send latency	Durability of acknowledged messages is a requirement
Live delivery	At-least-once, best effort	Guaranteed push delivery	Seq-based gap detection and sync recover anything lost
Receipts	Per-member watermarks	Exact per-message timestamps of reads	8.5× less receipt traffic; ticks still correct
Store	Wide-column, bucketed partitions	Ad hoc queries and joins	Every access path is a key and a range
Message copies	One per conversation	Per-recipient mailboxes with independent deletion	6.4× less storage; deletion handled as tombstones

53.4.14 Alternative designs

1. **Per-recipient inboxes (fan-out-on-write of messages).** Copy each message into every member’s mailbox. Reads become a single-partition scan of one’s own mailbox and per-user deletion is easy, but storage and writes multiply by the group size. This is the right choice when server-side history is *not* kept and the server is only a relay, which is exactly the WhatsApp model of §53.5.
2. **Relational store sharded by conversation.** PostgreSQL or MySQL sharded by `conv_id` (§14.7) with `(conv_id, seq)` as the primary key works well up to tens of terabytes per shard group and gives transactions for membership changes. Slack has described moving to sharded MySQL with Vitess (§14.13.3) [Slack Engineering 2020]. It becomes costly when history grows to petabytes, because storage on primary database nodes is expensive.
3. **Federated chat (Matrix, XMPP).** Servers in different domains replicate conversation state; order becomes a partial order resolved by an algorithm instead of one sequencer. More resilient to a single provider, harder to make simple.

53.4.15 Interview discussion

Table 53.5 — 45-minute pacing plan for “Design a chat application”.

Minutes	Activity	Output on the whiteboard
0–5	Clarify: 1:1 and groups, group size, history on server, multi-device, receipts, presence, E2E in or out	Functional list, explicit out-of-scope
5–10	Non-functional targets and capacity	46 k/s sends, 889 k/s peak deliveries, 1.2 TB/day, 25 M connections
10–20	High-level architecture	Figure 53.1: gateways, chat service, store, log, fan-out, push
20–35	Deep dive: ordering and sync	Sequencer, `client_msg_id` dedup, watermarks, gap detection
35–42	Failures and scale	Gateway crash, fan-out lag, hot groups, storage tiering
42–45	Trade-offs and extensions	Global vs per-conversation order; E2E pointer to §53.5

Likely follow-ups, with short answers:

- *"How do you guarantee no duplicates?"* — The sender's `client_msg_id` makes sends idempotent; the per-conversation `seq` makes delivery idempotent at the client. Exactly-once *display*, not exactly-once delivery.
- *"Two people send at the same moment — who is first?"* — Whoever the sequencer numbers first. Both devices then display the server's order, even if it differs from the local optimistic order; the client re-sorts pending messages when their `seq` arrives.
- *"How does a new device get history?"* — Ranged reads by seq from the store, newest first; it never replays the push stream.
- *"What if the user is in 5,000 conversations?"* — Sync returns only changed conversations; the client fetches lazily as the user scrolls.
- *"How do you implement 'delete for everyone'?"* — A new message of type `delete(seq=42)` in the same log; clients apply it in order and the store tombstones the body.

What distinguishes answers: a mid-level answer draws gateways and a database. A **senior** answer makes ordering explicit (per-conversation sequence numbers with idempotent sends), separates the durable path from the lossy live path and models receipts as watermarks. A **staff** answer quantifies which resource dominates over time (storage, not throughput), designs the sequencer's failure behavior (leased blocks, holes, fencing) and discusses multi-region homing of conversations and the product consequences of each consistency choice.

53.4.16 Production considerations

- **Observability.** End-to-end delivery latency from synthetic “canary conversations” in every region; fan-out consumer lag; gap-resync rate per client version (a rising rate reveals a live-path bug); reconnect rate per gateway; traces by `msg_id` (§40.6).
- **Security.** Short-lived tokens on WebSockets; authorization of every `SEND` and history read against `members` (no reads before `joined_seq` or after removal); per-user and per-conversation rate limits (§22.3); encryption at rest (§10.9). Server-side history means the operator can read messages, which must be stated honestly or replaced by E2EE (§53.5).
- **Cost.** Storage dominates; attachments are about 40× text, so deduplicate by content hash and set lifecycle rules (§15.9). Presence can quietly become the largest Redis bill.
- **Operations.** Gateways are deployed rarely and drained gracefully; the chat service often. Game days kill a gateway zone to verify reconnect and resync budgets. Keep kill switches for presence and typing indicators (§22.9).

53.5 WhatsApp

53.5.1 Problem statement

Design a messenger in the style of WhatsApp: one-to-one and group messaging, voice notes, photos and videos, for about two billion users on phones, with optional companion devices (desktop, web, tablet). The defining constraint is **end-to-end encryption (E2EE)**: messages, media and calls are encrypted on the sender’s device and decrypted only on the recipients’ devices. The operator’s servers relay and temporarily store ciphertext but never hold the keys to read it.

The analogy is a post office that only handles locked boxes. Each recipient publishes padlocks anyone may take; senders lock letters with them, and only the recipient has the key. The post office still sees addresses, sizes and postmarks, but can never open a box. Compared with §53.4, the server cannot index, search or moderate content; it must run a **key directory** that it can be trusted not to lie about; every recipient *device* is a separate encryption target; and server-side history disappears, leaving a store-and-forward relay.

The distinctive hard problems are **the E2EE architecture and its cost at scale** (multi-device and large groups multiply ciphertexts), **media handling without server-side access** and **very high connection counts per server**.

INDUSTRY EXAMPLE

WhatsApp's published scale and stack. WhatsApp completed end-to-end encryption for all users in April 2016 using the Signal Protocol, and documents the design in a security white paper [WhatsApp 2016; WhatsApp Security White Paper]. It announced two billion users in February 2020 [WhatsApp 2020]. Earlier, its engineers described an Erlang/FreeBSD server stack: in January 2012 the team reported more than 2 million concurrent TCP connections on one server [WhatsApp 2012; Reed 2012], and a 2014 Erlang Factory talk on scaling to hundreds of millions of users is summarized by third parties as describing roughly 550 servers, of which about 150 were chat servers each holding about a million phone connections [Reed 2014; High Scalability 2014]. *Evidence: Primary* for the 2012 connection count, encryption launch and user count; *Secondary* for the 2014 server counts, which come from a third-party summary of the talk.

53.5.2 Functional requirements

1. Register a phone number and a primary device; link up to four companion devices (a limit WhatsApp published in 2021 [Meta Engineering 2021a]).
2. Send end-to-end encrypted text, voice notes, images, video and documents to a contact or a group.
3. Groups with up to 1,024 members (the limit reported when WhatsApp launched Communities in November 2022; Secondary), with admins who add and remove members.
4. Delivery and read receipts ("two ticks", "blue ticks"), and last-seen/online status subject to privacy settings.
5. Offline delivery: messages wait on the server, encrypted, until the recipient device connects.
6. Users can verify each other's keys (security codes) and are warned when a contact's key changes.
7. Out of scope: voice and video calls (signaling would reuse the same key infrastructure; media flows peer-to-peer or through relays, §9.7), payments, channels, and encrypted cloud backup (mentioned in §53.5.16).

53.5.3 Non-functional requirements

Table 53.6 — Non-functional requirements for an end-to-end encrypted messenger.

Requirement	Target	Note
Confidentiality	Server never has plaintext or message keys; forward secrecy and post-compromise recovery per conversation	The security requirement is the product
Availability	99.99 % for send and receive	Primary communication channel in many countries
Latency, both online	p99 < 1 s globally, including encryption on both devices	Encryption costs microseconds; network dominates
Durability before delivery	An accepted message survives a single server or zone failure until delivered or expired	After delivery, the server deletes it
Undelivered retention	Expire after 30 days	Bounds storage; WhatsApp's privacy policy describes a 30-day limit (see §53.15)
Ordering	Per conversation per sender, as seen by each recipient device	No server-side global sequence (server cannot read content)
Connections	≥ 500 million concurrent device connections at peak	Phones keep a connection while the app is active
Bandwidth efficiency	Works on 2G and expensive mobile data	Compact binary protocol, media resized on device

The ordering requirement is weaker than in §53.4 on purpose: with a relay that deletes delivered messages and devices that each hold their own history, the order that matters is "the order in which this sender's messages reach this device", which the Double Ratchet's per-chain message counters already provide.

53.5.4 Capacity estimation

Assumptions (teaching values, not WhatsApp's figures):

- 100 billion messages per day (an order of magnitude consistent with public statements by Meta around 2020; treat as an assumption).
- Peak-to-average ratio of 2: the user base spans every time zone, which flattens the daily curve, though holidays such as New Year's Eve spike far above it.
- 80 % of messages are one-to-one; 20 % go to groups with 10 members on average.
- 1.6 devices per user on average (a phone plus companions for some users).
- 20 % of recipient devices are offline when a message is sent, and stay offline for 6 hours on average.
- 7 % of messages carry media averaging 300 KB after on-device compression.
- 500 million devices connected at peak.

FORMULA

Ciphertexts per message with per-device encryption

$$C_{1:1} = d + (d - 1), \qquad C_{\text{grp,pairwise}} = (n - 1)\,d + (d - 1), \qquad C_{\text{grp,sender key}} = 1, \qquad K_{\text{rekey}} = (n - 1)[(n - 2)\,c$$

Symbol	Meaning	Units
d	Average devices per user	devices/user
n	Group size including the sender	members
$C_{1:1}$	Ciphertexts the sender produces for a one-to-one message (recipient's devices plus the sender's own other devices)	ciphertexts/message
$C_{\text{grp,pairwise}}$	Ciphertexts per group message if each device pair has its own session	ciphertexts/message
$C_{\text{grp,sender key}}$	Ciphertexts the sender uploads per group message with sender keys; the server copies it to every device	ciphertexts/message
K_{rekey}	Pairwise-encrypted key-distribution messages after a member leaves, once every remaining member has re-sent its new sender key	messages

WORKED EXAMPLE

Worked example — Uploads, deliveries and the cost of large groups.

1. One-to-one: $C_{1:1} = 1.6 + 0.6 = 2.2$ ciphertexts uploaded and delivered per message.
2. Group of 10 (sender keys): the sender uploads 1 ciphertext; the server delivers $9 \times 1.6 + 0.6 = 15$ copies.
3. Uploads per message: $0.8 \times 2.2 + 0.2 \times 1 = 1.96$; deliveries per message: $0.8 \times 2.2 + 0.2 \times 15 = 4.76$.
4. Message rate: $100 \times 10^9 / 86,400 \approx 1.16$ million/s average, 2.31 million/s at peak. Uploads ≈ 2.27 million/s average (4.54 million/s peak); deliveries $= 476 \times 10^9$/day ≈ 5.51 million/s average.
5. Group of 1,024 without sender keys: $1,023 \times 1.6 + 0.6 \approx 1,637$ encryptions and uploads *per message* from one phone. With sender keys: 1.
6. When one member leaves a 1,024-member group, every remaining member must distribute a new sender key: $K_{\text{rekey}} = 1,023 \times (1,022 \times 1.6 + 0.6) \approx 1.67$ million pairwise messages, spread over time because each member re-keys lazily on its next send.

Interpretation. Multi-device multiplies every message by d; sender keys move group fan-out from the phone to the server, but membership changes cost $O(n^2 d)$.
Engineering implication. Group size limits are a cryptographic-cost decision as much as a product one; raise them only after measuring re-key storms.

WORKED EXAMPLE

Worked example — Offline queue, connections and media.

1. **Pending ciphertexts (Little's Law, §4.11).** Items waiting = arrival rate × time in system. Offline deliveries arrive at $5.51 \times 10^6 \times 0.2 = 1.10 \times 10^6$/s and wait 21,600 s on average: $1.10 \times 10^6 \times 21,600 \approx 23.8 \times 10^9$ pending envelopes. At 500 bytes each, **11.9 TB**, or 35.7 TB at three replicas. Online deliveries wait about a second: $5.51 \times 10^6 \times 1\ \text{s} \times 500\ \text{B} \approx 2.8$ GB, negligible.
2. **Connections.** 500 million devices at 1 million per chat server is 500 servers; to survive the loss of one of three zones in each region, $3 \times \lceil 500 \times 10^6 / (2 \times 10^6) \rceil = 750$ servers. At 40 KB per connection (Table 9.12), 1 million connections need 40 GB of RAM per server, comfortable on a large host.
3. **Media uploads.** $100 \times 10^9 \times 0.07 = 7 \times 10^9$ items/day × 300 KB **= 2.1 PB/day**, uploaded once per item regardless of recipients (the same encrypted blob serves every device).
4. **Media downloads.** Each item is fetched by every recipient device: $7 \times 10^9 \times 4.76 \times 300\ \text{KB} \approx 10$ PB/day, about 116 GB/s or **0.93 Tbit/s** on average.
5. **Media retention.** Keeping encrypted blobs for 30 days for late downloads and forwards: $2.1 \times 30 = 63$ PB, or 88 PB erasure-coded at 1.4×.

Interpretation. Because delivered messages are deleted, the message store is tiny (tens of terabytes) compared with a history-keeping chat service; media dominates storage and egress. *Engineering implication.* Spend engineering effort on the media path and on connection density, not on the message database.

Table 53.7 — Capacity summary for the E2EE messenger.

Quantity	Value
Messages	100 × 10⁹/day; 1.16 M/s average; 2.31 M/s peak
Ciphertext uploads	1.96 per message; 2.27 M/s average
Device deliveries	4.76 per message; 5.51 M/s average
Pending offline queue	≈ 23.8 × 10⁹ envelopes; 11.9 TB (35.7 TB at RF 3)
Concurrent connections	500 M; 750 chat servers at 1 M each with zone headroom
Media	2.1 PB/day up; ≈ 10 PB/day down (0.93 Tbit/s); 88 PB retained for 30 days

53.5.5 API design

The client speaks a compact binary protocol over a long-lived TLS-protected connection (WhatsApp's published materials describe a Noise Protocol-based transport encryption

between client and server in addition to E2EE; see the white paper). The RPCs below are a teaching API.

```
# Key directory (server stores only PUBLIC keys)
RegisterDevice   {account_id, device_id, identity_pub, signed_prekey{id, pub, sig},
                  one_time_prekeys[{id, pub}] x 100, device_list_signature}
                 → {ok}
UploadPrekeys    {device_id, one_time_prekeys[]}                    # refill when low
GetPrekeyBundles {account_id}
                 → {devices: [{device_id, identity_pub, signed_prekey,
one_time_prekey?}],
                    device_list, device_list_signature}             # one-time key con-
sumed

# Messaging (payloads are opaque ciphertext to the server)
Send             {client_msg_id, to_account, envelopes: [{device_id, type:
prekey|normal,
                  ciphertext}]}                                     # client fan-out,
1:1
SendGroup        {client_msg_id, group_id, ciphertext, distribution: [{device_id,
                  ciphertext}]?}                                    # sender-key message
                 → {server_ts}  | {error: stale_device_list, current_list}
Deliver (push)   {from, from_device, client_msg_id, ciphertext, server_ts}
Ack              {client_msg_id, from}                              # server deletes en-
velope
Receipt          {to, client_msg_ids[], kind: delivered|read}       # also E2E-encrypted
payload

# Media
RequestUpload    {size, sha256_of_ciphertext}  → {upload_url, media_id}
                 # the client encrypts first, then uploads; the server never sees the
media key
GetMedia         {media_id}  → bytes (ciphertext), served via CDN-like edge caches
```

Two choices stand out. `Send` carries **one envelope per recipient device**, and the server rejects it with `stale_device_list` if the sender's view of the recipient's devices is out of date, so a newly linked device is never silently skipped. And `Ack` deletes: after the device acknowledges, the server holds nothing.

53.5.6 Data model and database schema

The server-side data model is small and deliberately forgetful.

```
# Key directory: strongly consistent, replicated (losing it breaks new sessions)
account/{account_id}                -> {phone_hash, primary_device_id,
device_list_version}
device/{account_id}/{device_id}     -> {identity_pub, signed_prekey, registration_ts}
otpk/{account_id}/{device_id}/{id}  -> one_time_prekey_pub      # deleted when handed
out
device_list/{account_id}            -> {devices[], version, signature_by_primary}

# Offline mailbox per device: write-once, delete-on-ack, TTL 30 days
mailbox/{account_id}/{device_id}/{arrival_seq} -> {from, from_device, client_msg_id,
                                                   ciphertext, server_ts}

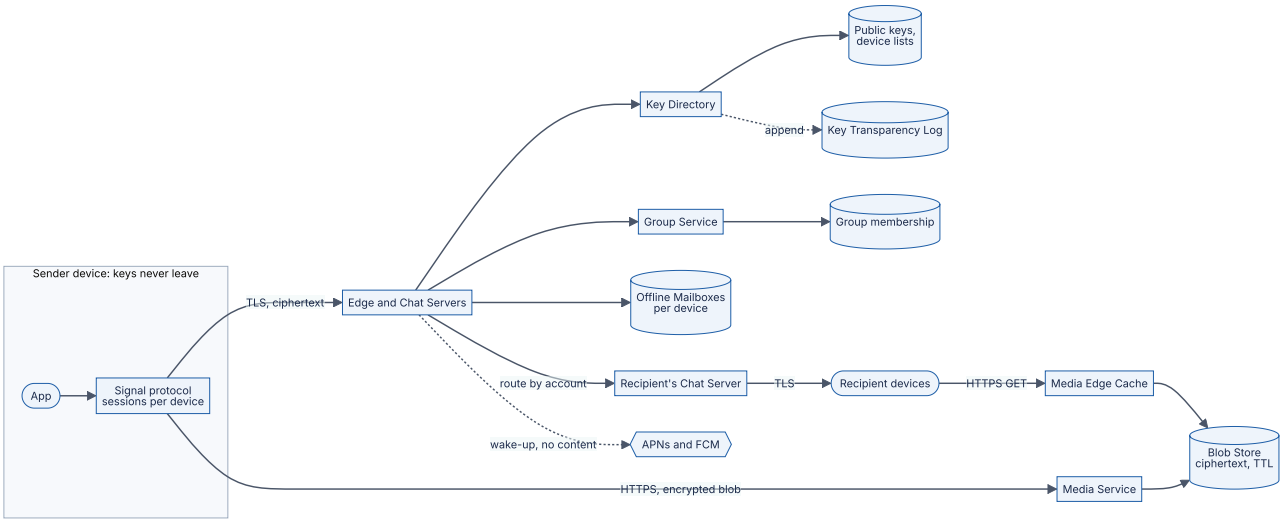
# Groups: metadata visible to the server (membership is needed for fan-out)
group/{group_id}                    -> {members[], admins[], version}

# Media: encrypted blobs, TTL
blob/{media_id}                     -> ciphertext bytes  (object store, erasure-coded)
```

Store choices follow access patterns. The **key directory** is read on every new session and must never return a stale or forged key, so it lives in a linearizable replicated store (§25.3) with change logging for key transparency. The **mailbox** is a queue per device with an extreme write-then-delete pattern: most envelopes live for less than a second. An LSM-based store (§13.7) would turn each delete into a tombstone and compact constantly, so the teaching design keeps envelopes in memory on the chat server that owns the recipient’s connection, replicated synchronously to one peer in another zone, and **spills to a disk-backed store only if undelivered after about 30 seconds**. Of the 5.51 million deliveries per second, only the 20 % for offline devices reach disk. WhatsApp’s own talks described Erlang’s built-in Mnesia database among its components (Secondary); the general lesson is that a queue whose items mostly die young belongs in memory with a durable fallback.

53.5.7 High-level architecture

Figure 53.5 — High-level architecture of an end-to-end encrypted messenger.



Reading the diagram. The trust boundary is the device: identity keys, session state and message keys exist only inside the app's protocol layer. Everything crossing to the servers is ciphertext plus routing metadata. The sender's app opens sessions using public keys fetched from the **key directory**, whose changes are appended to a **key-transparency log** (dotted, asynchronous) so clients can audit that the directory is not serving different keys to different people. Messages go over the device's long-lived TLS connection to a **chat server**, which routes each per-device envelope to the chat server holding the recipient device's connection (synchronous inter-server RPC); if the device is offline, the envelope waits in that device's **mailbox** and a content-free wake-up goes through APNs/FCM (§9.8). Media is encrypted on the device and uploaded as an opaque blob; recipients fetch it through **edge caches** using the pointer and key carried inside the encrypted message. The **group service** stores membership in plaintext because the server must know whom to fan out to. Failure points: a chat-server crash drops a million connections (reconnect storm, §9.9.6) and must not lose in-memory envelopes (hence the synchronous peer replica); a key-directory outage blocks new sessions but not existing conversations; a blob-store outage blocks media but not text. Scaling: chat servers scale by connections, the media path by bytes, the key directory by session setups.

53.5.8 Detailed component design

Session setup: X3DH with prekeys

Two phones are rarely online at the same moment, yet they must agree a secret key without the server learning it. **X3DH** ("Extended Triple Diffie–Hellman") solves this asynchronously [Marlinspike & Perrin 2016]:

1. Each device generates a long-term **identity key pair**, a medium-term **signed prekey** (signed by the identity key) and a batch of **one-time prekeys**, and uploads the public halves to the key directory.

2. To start a session, the sender fetches the recipient device's **prekey bundle**: identity key, signed prekey with signature, and one one-time prekey, which the server hands out once and deletes.
3. The sender verifies the signature, generates an **ephemeral key pair**, and computes three or four Diffie–Hellman values (§10.4.4) between its identity and ephemeral keys and the recipient's identity, signed and one-time prekeys. These are concatenated and fed through a key-derivation function to produce the initial shared secret.
4. The sender's first message carries its identity and ephemeral public keys and the IDs of the prekeys it used. The recipient, whenever it comes online, recomputes the same secret from its private keys.

The server's role is a *mailbox for public keys*. It never learns the secret, because every Diffie–Hellman input it holds is public. Its one dangerous power is substitution: a malicious or compromised directory could hand out an attacker's key. That is what **security codes** (users comparing a fingerprint of both identity keys, a 60-digit number or QR code in WhatsApp) and **key transparency** address.

Per-message keys: the Double Ratchet

After X3DH, each pair of devices runs the **Double Ratchet** [Perrin & Marlinspike 2016]. Picture two interlocking gears:

- A **symmetric-key ratchet**: each message key is derived from a chain key by a one-way function, and the chain key is then advanced and the old one deleted. Stealing today's chain key does not reveal yesterday's messages: **forward secrecy**.
- A **Diffie–Hellman ratchet**: whenever the conversation changes direction, the devices exchange new ephemeral public keys inside their messages and mix a fresh Diffie–Hellman output into the root key. An attacker who stole a device's state loses access once a new exchange happens: **post-compromise security** (sometimes called "break-in recovery").

Each message header carries a counter within its chain, so the receiver can derive keys for messages that arrive out of order and store the skipped keys briefly. This is how ordering is recovered without any server-side sequence number.

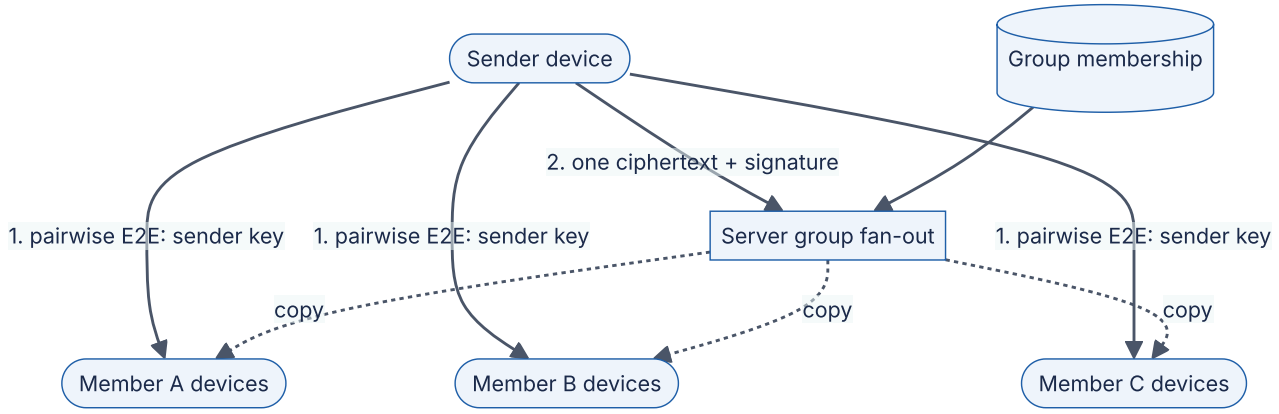
> DEFINITION
>
> **Definition — End-to-end encryption (E2EE).** Encryption in which the keys needed to decrypt a message exist only on the communicating endpoints, so intermediaries that store or forward the message, including the service operator, cannot read it. Transport encryption (TLS) protects each hop; E2EE protects the content from every hop.

Multi-device and groups: where the ciphertexts multiply

Originally an account had one identity key on the phone, and companion clients relayed through it. WhatsApp's 2021 multi-device design gave **each device its own identity key** and uses **client fan-out**: the sender encrypts a message separately for each of the recipient's devices and each of its own other devices, using a pairwise session per device; the server keeps the mapping from account to device identities, and the primary device signs the device list so other users can detect an unauthorized device [Meta Engineering 2021a]. The cost is the $C_{1:1} = 2d - 1$ of §53.5.4.

For groups, WhatsApp's white paper describes **Sender Keys**: the first time a member sends to a group, it generates a random chain key and a signing key pair, and distributes them to every other member device over the pairwise sessions; afterwards each group message is encrypted once with a key derived from that chain and signed, uploaded once, and **fanned out by the server** [WhatsApp Security White Paper]. When a member leaves, the remaining members discard their sender keys and distribute new ones, so a removed member cannot read future messages; this is the K_{rekey} term.

Figure 53.6 — Group message with sender keys: first message and later messages.



Reading the diagram. Step 1 runs once per sender per group (and again after any membership removal): the sender's device sends its new sender key to each other member device through the existing pairwise Signal sessions, so the server relays only ciphertext. Step 2 runs for every subsequent message: the device encrypts once with the current sender-key chain, signs, and uploads one ciphertext; the server consults plaintext group membership and copies it asynchronously (dotted) to every member device's connection or mailbox. Failure points: a member device that missed step 1 cannot decrypt step 2 and must request the sender key again; a stale membership list at the server either leaks ciphertext to a removed member (harmless without the new key) or omits a new member (who then misses messages until the next distribution). Scaling: step 2 costs the sender $O(1)$, the server $O(nd)$; step 1 costs the sender $O(nd)$ pairwise encryptions.

Media: encrypt, upload once, send the key

Media is too large to send through the message path for every device. The white paper describes the scheme: the sender generates a random key, encrypts the file (AES-256 in CBC mode with an HMAC-SHA256 authentication tag), uploads the ciphertext to a blob store, and then sends an ordinary E2E-encrypted message containing the key, a SHA-256 hash of the ciphertext and a pointer to the blob [WhatsApp Security White Paper]. Recipients download the blob, check the hash and decrypt. The server stores and serves opaque bytes, so it can use ordinary object storage and caches (§15.4, §21), resumable uploads, and lifecycle expiry. Because forwarding a photo can reuse the same encrypted blob and key, popular forwards need not be re-uploaded; the server can deduplicate by the ciphertext hash without learning content.

What the server cannot do is equally important: it cannot transcode, generate thumbnails or run content classifiers on media. Resizing and thumbnailing move to the sender's device (the thumbnail travels inside the encrypted message), which is why on-device compression appears in the capacity assumptions.

Table 53.8 — What the server can and cannot see in the E2EE design.

Server can see	Server cannot see
Account and device identifiers, public keys	Message text, media content, thumbnails
Who sends to whom and when; message sizes	Message keys, session state, sender-key chains
Group membership and admin changes	Group message content and group names if encrypted client-side (teaching design)
IP addresses and connection times	Content of voice and video calls
Encrypted media blob size and hash	Media keys

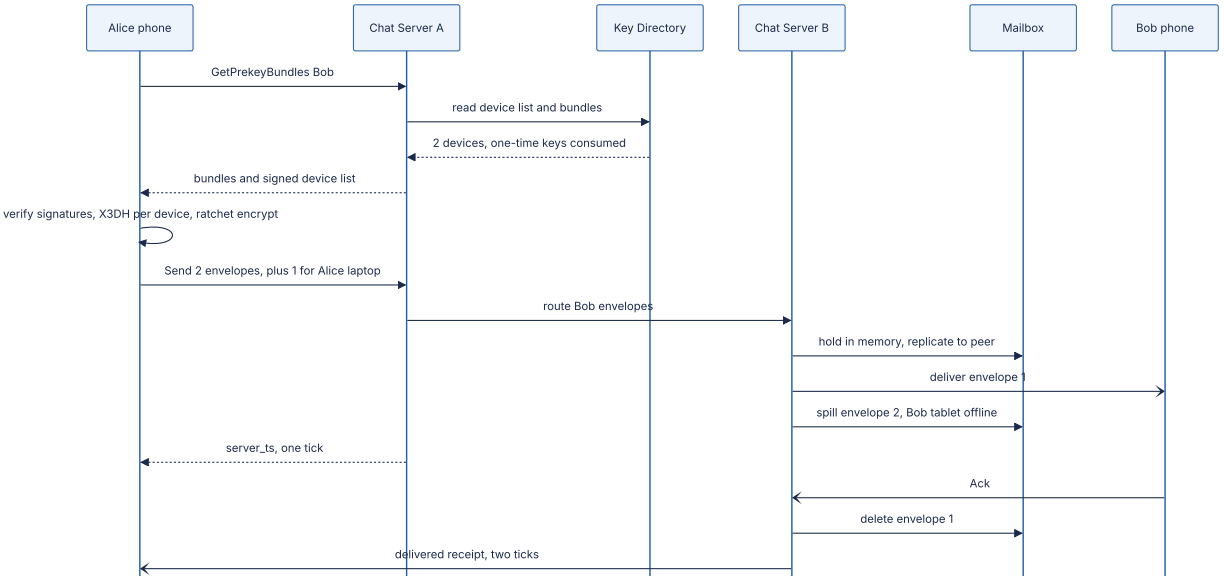
Honesty about metadata is part of the design: E2EE protects content, not the social graph of who talks to whom.

Connection density

The published Erlang stack used one lightweight process per connection and a kernel tuned for very many sockets [Reed 2012]. The rules generalize to any runtime: keep per-connection memory near the budget of Table 9.12, size servers by blast radius as well as RAM, and keep reconnects cheap, which E2EE helps with because session state lives on the device.

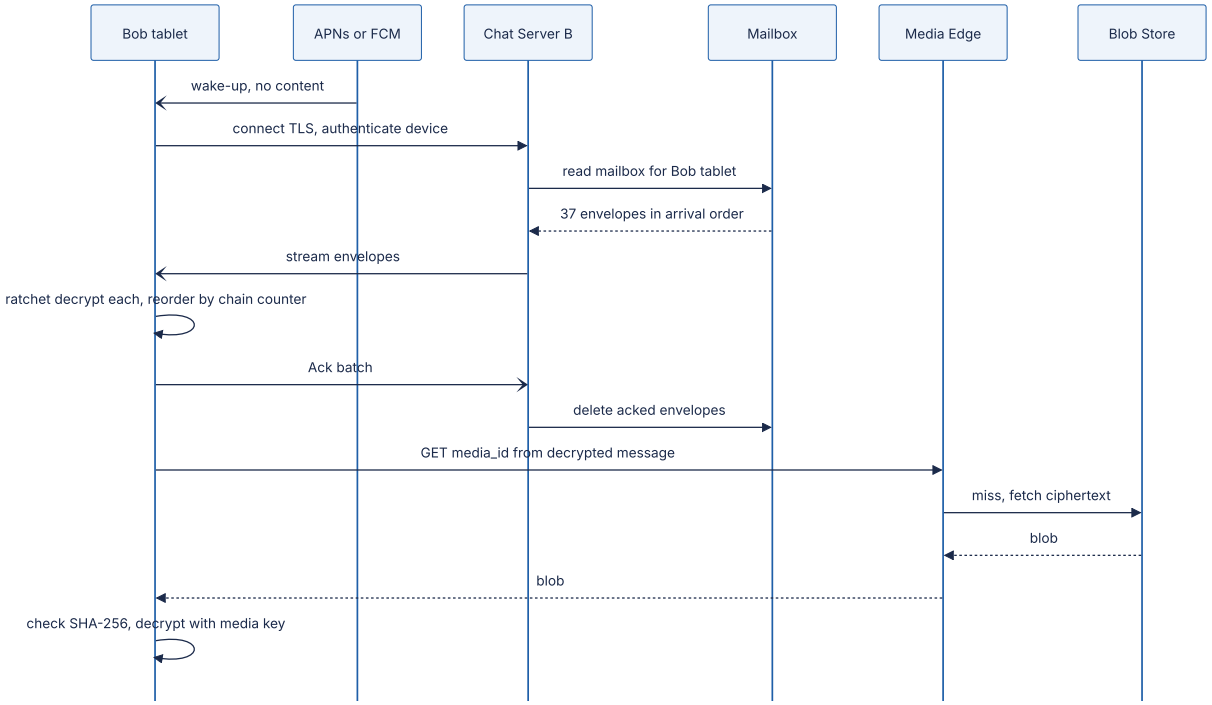
53.5.9 Data flow

Figure 53.7 — Write path: first message to a contact with two devices.



Reading the diagram. Alice’s phone first fetches Bob’s prekey bundles and his device list signed by Bob’s primary device; the key directory hands out each one-time prekey once. All cryptography happens on Alice’s phone: verifying signatures, running X3DH for each of Bob’s two devices and encrypting with each new ratchet. The send carries three envelopes (Bob’s phone, Bob’s tablet, Alice’s laptop). Alice’s chat server routes Bob’s envelopes to the chat server holding Bob’s connections, which keeps them in memory with a synchronous replica in a peer before Alice gets her single tick: that is the durability boundary. Bob’s phone is online and receives its envelope immediately (asynchronous push over the connection); the tablet is offline, so its envelope spills to the disk-backed mailbox and a content-free push wakes it (§9.8). Bob’s phone acknowledges; the server deletes its envelope and sends Alice a delivered receipt. Failure points: if Bob’s device list changed since Alice cached it, the server rejects the send with the current list and Alice re-encrypts; if the one-time prekeys run out, X3DH proceeds with the signed prekey alone (slightly weaker against replay of the first message); if Bob’s chat server crashes before the peer replica acknowledges, Alice never received a tick and retries with the same `client_msg_id`.

Figure 53.8 — Read path: an offline device reconnects and fetches media.



Reading the diagram. The push notification carries no message content; it only prompts the app to connect. The tablet authenticates as a specific device, and the chat server streams its mailbox in arrival order; the tablet decrypts each envelope, using the ratchet's per-chain counters to reorder and to derive keys for skipped messages, then acknowledges in batches so the server can delete. Media referenced inside a decrypted message is fetched from an edge cache by `media_id`; on a miss the edge reads the blob store. Integrity is end to end: the tablet checks the hash carried in the encrypted message, so a corrupted or substituted blob is detected even though the server cannot read it. Failure points: an envelope that fails to decrypt (lost session state) triggers a client request for the sender to re-establish a session; expired media (beyond retention) shows a "no longer available" placeholder.

53.5.10 Bottlenecks

1. **Re-key storms in large groups.** A removal in a 1,024-member group costs about 1.7 million pairwise messages. Mitigations: lazy re-keying on next send, rate limits on membership churn, and treating very large broadcast use cases as a different product (one-to-many channels with different cryptographic trade-offs).
2. **Multi-device multiplication.** Every additional device per user adds a ciphertext to every one-to-one message and every group delivery. A cap on companion devices bounds d.
3. **Key directory hot spots.** Mass re-registration after an outage causes bursts of bundle fetches and one-time prekey depletion; clients refill when told their count is low, and the signed prekey is the fallback.

4. **Media egress.** About 1 Tbit/s on average; edge caching of viral forwards (shared blob and hash) is the main lever.

53.5.11 Failure scenarios

Table 53.9 — Failure scenarios for the E2EE messenger.

What fails	Impact	Detection	Recovery	Prevention
Chat server crash	~1 M devices disconnected; in-memory envelopes at risk	Health checks, connection-count drop	Devices reconnect with jitter; envelopes recovered from peer replica	Synchronous peer replica before the sender's tick; blast-radius sizing
Key directory unavailable	New sessions and new devices blocked; existing chats unaffected	Bundle-fetch error rate	Fail over to replica region	Consensus-replicated store (§26) across zones
Key directory compromised or coerced	Attacker can substitute keys (man-in-the-middle)	Key-transparency audits; users' security-code checks; key-change warnings	Revoke, rotate, notify	Key transparency log; warn on key change
Device loses session state (reinstall without backup)	Cannot decrypt in-flight messages	Decryption failures reported by client	Sender re-establishes the session; old messages lost unless backed up	Encrypted backups; retry with new session
One-time prekeys exhausted	Sessions fall back to signed prekey only	Prekey-count metric per device	Device refills when next online	Upload large batches; alert on low counts
Mailbox store outage	Offline devices cannot receive; online delivery continues	Spill error rate	Keep envelopes in memory longer; senders retry	Replicated mailbox store with TTL
Blob store region outage	Media fails to send or load	Upload/download error rates	Route to replica region	Cross-region replication of blobs
Stale device list at sender	Envelope missing for a new device	Server-side version check	Server rejects send with current list	Device-list version in every `Send`

53.5.12 Scaling strategy

At 10×. The pattern is already global, so 10× is mostly more of everything: about 7,500 chat servers, 10 PB/day of media uploads and roughly 9 Tbit/s of media egress. What breaks is the **media path** (egress cost and cache capacity) and **key-directory throughput** during mass events. Changes: regional media stores with geo-routing of downloads; content-addressed caching of forwarded blobs; directory read replicas serving bundles while one-time-key consumption stays on the strongly consistent primary for each account shard.

At 100×. The limiting factors become cryptographic and product-level rather than server-level: large groups and many devices per user make $O(n^2 d)$ re-keying and $O(nd)$ fan-out the dominant costs. Group key-agreement protocols designed for large groups, such as Messaging Layer Security (MLS, RFC 9420) [Barnes et al. 2023], reduce membership-change cost to roughly logarithmic in group size by organizing keys in a tree; adopting one is an architectural change to every client and is the natural answer to "how would you support 100,000-member encrypted groups?".

53.5.13 Trade-offs

Table 53.10 — Trade-offs in the E2EE messenger.

Decision	Chosen	Gave up	Why acceptable
Content visibility	E2EE; server sees ciphertext	Server-side search, ranking, content moderation, server-side history	The product promise is privacy; moderation shifts to metadata and user reports
History	Store-and-forward, delete on ack	Seamless history on new devices from the server	History is transferred device to device, or via encrypted backups
Multi-device	Per-device keys, client fan-out	Upload bandwidth and battery for each extra device	Keeps the server keyless; capped device count
Groups	Sender keys	Weaker post-compromise security within a group chain; $O(n^2)$ re-key	$O(1)$ sender cost per message
Key trust	Server-run directory plus transparency and security codes	Pure out-of-band trust	Usable by two billion people who will never compare fingerprints
Mailbox	In memory with synchronous peer replica, spill to disk	Simplicity of one durable store	Most envelopes live under a second

53.5.14 Alternative designs

1. **Server-side encryption only (TLS plus encryption at rest).** Enables search, multi-device history and server-side moderation, as in §53.4, but the operator can read every message: a different product.
2. **Pairwise encryption for groups (no sender keys).** Stronger per-recipient ratcheting; acceptable for small groups, prohibitive at 1,024 members.
3. **MLS for groups** (§53.5.12): logarithmic membership changes, at the cost of protocol complexity and a server that must order handshake messages.
4. **Federated E2EE (Matrix with Megolm)** removes the single operator but weakens spam control and slows protocol changes; **sealed-sender** designs (Signal) additionally hide the sender's identity from the server.

53.5.15 Interview discussion

Table 53.11 — 45-minute pacing plan for “Design WhatsApp”.

Minutes	Activity	Output
0–5	Clarify: E2EE in scope? groups size? multi-device? history on server?	Decide E2EE yes, store-and-forward
5–10	Capacity	1.16 M msg/s, 4.76 deliveries per message, 500 M connections, media PB/day
10–18	Architecture without crypto	Chat servers, routing, mailboxes, push, media store
18–33	E2EE deep dive	Key directory, X3DH, Double Ratchet, multi-device fan-out, sender keys
33–40	Media and failures	Encrypt-then-upload; chat-server crash; key substitution
40–45	Trade-offs	What the server sees; group size limits; MLS

Likely follow-ups:

- *“How does the server deliver a message it cannot read?”* — Routing uses the envelope’s header (recipient account and device), which is not secret; only the payload is encrypted.
- *“How does a new phone get old messages?”* — Not from the server, which deleted them; from another device of the same user over an encrypted transfer, or from an encrypted backup whose key the server does not hold.
- *“How do you fight spam without reading messages?”* — Metadata signals (sending rate, account age, how many recipients block or report), forwarding limits, and user reports, in which the reporting user’s client forwards the reported messages.

A **senior** answer separates transport security from E2EE, explains prekeys as the answer to asynchronous key agreement and counts ciphertexts per message. A **staff** answer quantifies the multi-device and group multipliers, identifies the key directory as the trust anchor and discusses key transparency, lists exactly what metadata remains visible, and explains why group size and device limits are cryptographic-cost decisions.

53.5.16 Production considerations

- **Observability without content.** Metrics describe envelopes, not messages: delivery latency by region and network type, client-reported decrypt failures (the earliest sign of a session bug), prekey depletion, device-list rejects, re-key volume by group size.

- **Security.** Protect the key directory like a certificate authority: change logs, multi-party approval for operator access, and key transparency (WhatsApp described deploying it in 2023 [Meta Engineering 2023]). Client binaries are the security boundary, so release signing matters (§50.6). WhatsApp also described end-to-end encrypted backups whose key is held in a hardware-security-module-based vault or by the user [Meta Engineering 2021b].
- **Cost.** Media dominates; on-device compression, reuse of forwarded blobs and lifecycle expiry are the levers. The relay design keeps database cost unusually small.
- **Operations.** Every message format carries a version, because servers must route ciphertexts from clients years old that they cannot interpret.

53.6 Instagram

53.6.1 Problem statement

Design a photo-sharing service in the style of Instagram: users upload photos with captions, follow other users, scroll a home feed of posts from accounts they follow, like and comment, and post **stories** that disappear after 24 hours. The service runs on phones over mobile networks and serves several hundred million daily users.

Think of a newspaper that prints a different edition for every reader. Photographers file pictures at the front door (uploads); a darkroom makes prints in four sizes (resizing); delivery vans keep copies in every neighborhood (the CDN); and the editor decides which pictures each reader sees first (the feed). Most of the bytes flow through the darkroom and the vans; most of the *decisions* happen at the editor's desk.

The distinctive hard problems are the **media upload pipeline** (getting large files from flaky phones into durable storage and onto CDNs without passing them through application servers), **sharded identifiers** that let any service find a post's shard from its ID, **expiring content** (stories) and **counters on very popular posts**. The feed is introduced here; its fan-out economics are analyzed in depth in §53.7.8, and video transcoding belongs to Chapter 54.

53.6.2 Functional requirements

1. Upload a photo (or carousel of up to 10) with caption, location and tagged users; the post appears on the author's profile immediately.
2. Follow and unfollow accounts; view a profile grid of an account's posts.
3. Home feed of posts from followed accounts, ranked, with infinite scroll.
4. Like and unlike a post; show the like count and whether the viewer has liked it; comment.

5. Stories: post a photo story visible to followers for 24 hours; a story tray shows which followed accounts have unseen stories.
6. Out of scope: video transcoding (Chapter 54), direct messages (§53.4), search and Explore recommendations (Chapter 68).

53.6.3 Non-functional requirements

Table 53.12 — Non-functional requirements for the photo-sharing service.

Requirement	Target	Note
Availability, feed and image reads	99.95 %	Reads degrade gracefully to cached feeds
Availability, upload	99.9 %	Client retries uploads in the background
Durability of uploaded originals	11 nines per year (object-store class, §15.6)	Photos are irreplaceable to users
Feed API latency	p99 < 300 ms server time	Excludes image download
Image first byte from CDN	p95 < 100 ms at the edge	§21
Post visible on own profile	Immediately (read-your-writes)	Users check their post at once
Post visible in followers' feeds	Within 10 s, eventual	Nobody notices a few seconds
Like counts	Approximate while hot; exact within minutes	"1.2M likes" need not be exact
Story expiry	Not visible after 24 h ± 1 min	Product promise

53.6.4 Capacity estimation

Assumptions: 500 million DAU; 100 million new posts per day (photos only); original upload 3 MB; four renditions totaling 390 KB per post (150, 320, 640 and 1,080 pixels wide); 20 feed loads per user per day, each rendering 10 posts; images delivered at 150 KB on average; 20 likes per user per day; peak-to-average ratio 3; CDN hit ratio 95 %; 250 million stories per day.

WORKED EXAMPLE

Worked example — Upload, storage and delivery.

1. Posts: $100 \times 10^6 / 86,400 \approx 1,160$/s average, 3,470/s at peak.
2. Bytes per post: 3 MB original + 0.39 MB renditions = 3.39 MB. Per day: $100 \times 10^6 \times 3.39$ MB = 339 TB; per year ≈ 124 PB; with erasure coding at 1.4×, **≈ 173 PB/year**.
3. Metadata (post rows, captions, tags) at 1 KB per post: 100 GB/day, 36.5 TB/year: small enough for a sharded relational store.
4. Feed requests: $500 \times 10^6 \times 20 = 10 \times 10^9$/day, $\approx 115,700$/s average and **347,000/s at peak**.
5. Image fetches: 10 per feed load, 100×10^9/day, 1.16 million/s average, 3.47 million/s at peak.
6. Image egress: $100 \times 10^9 \times 150$ KB = 15 PB/day, about **1.39 Tbit/s average and 4.2 Tbit/s at peak**, nearly all served by the CDN.
7. Origin load at a 95 % hit ratio: 5 % of 1.16 million/s ≈ 57,900 fetches/s and 0.75 PB/day from storage to the CDN.

Interpretation. Upload *requests* are modest (thousands per second) but carry most of the stored bytes; reads are a hundred times more frequent and served almost entirely from edge caches. *Engineering implication.* Keep image bytes off the application tier entirely: uploads go straight to object storage, downloads come from the CDN, and application servers handle only metadata.

WORKED EXAMPLE

Worked example — Likes and stories.

1. Likes: $500 \times 10^6 \times 20 = 10 \times 10^9$/day, 115,700/s average, 347,000/s at peak.
2. A celebrity post receiving 2 million likes in its first 10 minutes concentrates $2 \times 10^6 / 600 \approx 3,330$ likes/s on **one counter row**, on one shard.
3. Stories live at any moment (Little's Law, §4.11): 250 million/day × 1 day = **250 million**; at 1 MB per story, 250 TB of hot story media, replaced entirely every 24 hours.

Interpretation. Aggregate like traffic is easy to shard; one hot post is not. *Engineering implication.* Design counters for the hottest key, not the average key (§53.6.8).

Table 53.13 — Capacity summary for the photo-sharing service.

Quantity	Value
Posts	1,160/s average; 3,470/s peak
Media storage	339 TB/day; ≈ 173 PB/year erasure-coded
Feed API	115,700/s average; 347,000/s peak
Image fetches	1.16 M/s average; 3.47 M/s peak; 1.39 Tbit/s average egress
Origin fetches (95 % CDN hit)	≈ 57,900/s
Likes	115,700/s average; one hot post ≈ 3,330/s
Live stories	≈ 250 million; ≈ 250 TB

53.6.5 API design

```
POST /v1/uploads                {content_type, size_bytes, sha256}
                                → {upload_id, url: <presigned PUT, 15 min>,
max_part_size}
POST /v1/posts                  {upload_ids[], caption, location?, tagged_user_ids[],
                                 client_post_id}             # idempotency key
                                → 202 {post_id, status: processing}
GET  /v1/posts/{post_id}        → {post_id, author, caption, media: [{w, h, url}...],
                                   like_count, viewer_has_liked, created_at}
GET  /v1/users/{user_id}/posts?max_id=<post_id>&limit=24        # profile grid
GET  /v1/feed?cursor=<opaque>&limit=10
                                → {items: [post...], next_cursor}
PUT    /v1/posts/{post_id}/like    → 204   # idempotent
DELETE /v1/posts/{post_id}/like    → 204
POST /v1/stories                {upload_id} → {story_id, expires_at}
GET  /v1/stories/tray           → [{user_id, latest_story_ts, has_unseen}]
GET  /v1/users/{user_id}/stories → [{story_id, media_url, expires_at}]
```

Likes use `PUT` / `DELETE` on a resource rather than `POST /like`, so retries are naturally idempotent. Profile grids page by `max_id` (a post ID), which works because IDs sort by time (§53.6.6). Image URLs returned to clients point at the CDN and include the rendition size.

53.6.6 Data model and database schema

Metadata lives in a relational database sharded by user, the same choice Instagram described in 2012 (see the industry callout below), because posts, follows and likes have relational structure and modest volume (tens of terabytes), and transactions within one user's shard are useful.

```
        -- One PostgreSQL schema per logical shard; 8,192 logical shards on far fewer
servers.
        CREATE TABLE posts (
          post_id     bigint PRIMARY KEY,          -- 41-bit ms | 13-bit shard | 10-bit
seq
          author_id   bigint NOT NULL,             -- shard key: post lives on author's
shard
          caption     text,
          media       jsonb NOT NULL,              -- [{key, width, height}] renditions
in object store
          status      text NOT NULL,               -- processing | live | deleted
          like_count  bigint NOT NULL DEFAULT 0,   -- denormalized, updated by the
counter service
          created_at  timestamptz NOT NULL
        );
        CREATE INDEX posts_by_author ON posts (author_id, post_id DESC);

        CREATE TABLE follows (                     -- stored twice: by follower and by
followee (§14.7.3)
          follower_id bigint, followee_id bigint, created_at timestamptz,
          PRIMARY KEY (follower_id, followee_id)
        );

        CREATE TABLE likes (                       -- sharded by post_id's shard
          post_id bigint, user_id bigint, created_at timestamptz,
          PRIMARY KEY (post_id, user_id)
        );

        CREATE TABLE stories (
          story_id bigint PRIMARY KEY, author_id bigint, media_key text,
          created_at timestamptz, expires_at timestamptz    -- created_at + 24 h
        );
        CREATE INDEX stories_live ON stories (author_id, expires_at);
```

Sharded IDs

An ID that embeds its shard lets every service route a request for post 11637205506832265 without a lookup table. The scheme Instagram published uses 41 bits of milliseconds since a custom epoch, 13 bits of logical shard ID and 10 bits of a per-shard sequence, generated inside PostgreSQL by a function in each shard's schema [Instagram Engineering 2012]. Its properties: IDs sort roughly by time across shards (good for "newest first" pages without a separate timestamp index), 1,024 IDs per millisecond per logical shard, and about 69 years of range from the epoch (§17.10.3 derives the limits).

```
        EPOCH_MS = 1293840000000          # 2011-01-01 00:00:00 UTC, a custom epoch
        N_LOGICAL_SHARDS = 8192           # 2**13 logical shards

        def make_id(now_ms: int, shard_id: int, seq: int) -> int:
            """41 bits of ms since epoch | 13 bits logical shard | 10 bits per-shard se-
quence."""
            assert 0 <= shard_id < N_LOGICAL_SHARDS
            return ((now_ms - EPOCH_MS) << 23) | (shard_id << 10) | (seq % 1024)

        def parse_id(post_id: int):
            return {"ms_since_epoch": post_id >> 23,
                    "shard_id": (post_id >> 10) & 0x1FFF,
                    "seq": post_id & 0x3FF}

        user_id = 31341
        shard = user_id % N_LOGICAL_SHARDS        # a user's posts live on the user's
logical shard
        pid = make_id(EPOCH_MS + 1_387_263_000, shard, 5001)
        print(pid, parse_id(pid))
        a = make_id(EPOCH_MS + 1000, 7, 1); b = make_id(EPOCH_MS + 1001, 3, 0)
        print("later millisecond sorts later across shards:", a < b)
        # prints: 11637205506832265 {'ms_since_epoch': 1387263000, 'shard_id': 6765,
'seq': 905}
        #         later millisecond sorts later across shards: True
```

What to notice:

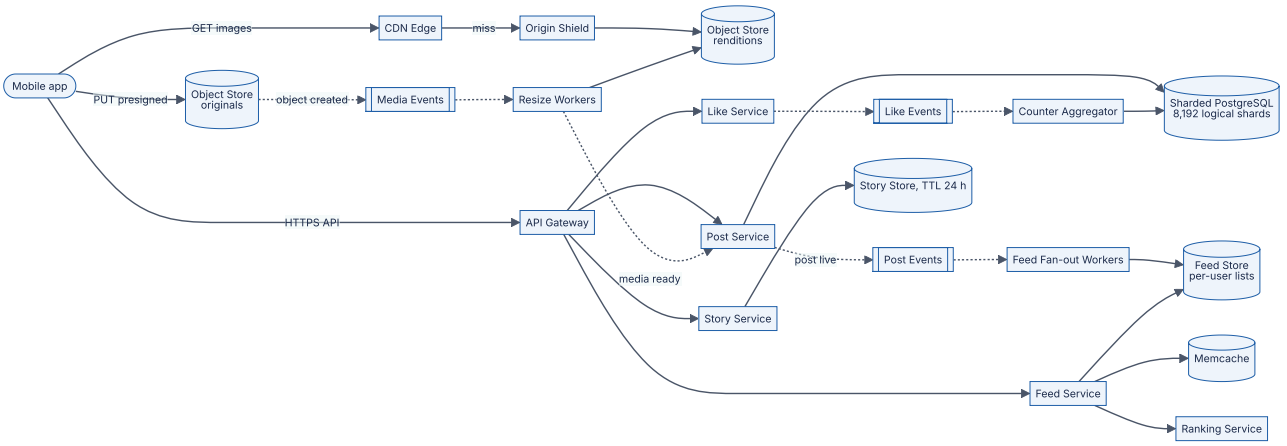
- The shard is chosen from the **author**, so a user's posts share a shard and the profile grid is a single-shard range scan on `(author_id, post_id DESC)`.
- `seq % 1024` comes from a per-shard database sequence, so uniqueness needs no coordination between shards; the only cross-shard guarantee is "roughly time-ordered", within clock skew.
- Logical shards (8,192) are fixed forever; physical servers are not. Moving logical shards between servers (§14.9.2) changes a mapping table, never an ID.

INDUSTRY EXAMPLE

Instagram: sharding and IDs (2012) and counters across data centers (2015). Instagram described partitioning PostgreSQL into several thousand logical shards held as schemas on fewer physical servers, with the 41/13/10-bit ID generated in PL/pgSQL [Instagram Engineering 2012]. A 2015 post on expanding to multiple data centers described a counter problem: with caches invalidated on every new like, popular posts triggered many expensive `COUNT` queries, so the team **denormalized the like count onto the post row** and incremented it in the database, and used memcache **leases** so that when a celebrity's cached count was invalidated, one request refilled it while others waited or read a slightly stale value [Instagram Engineering 2015]. The leases are the mechanism of §20.11 [Nishtala et al. 2013]. *Evidence: Primary* — [Instagram Engineering 2012; Instagram Engineering 2015]

53.6.7 High-level architecture

Figure 53.9 — High-level architecture of the photo-sharing service.



Reading the diagram. The app talks to an **API gateway** for metadata and directly to the **object store** for uploads, using a presigned URL (§15.8.2), so multi-megabyte bodies never touch application servers. The object store emits an asynchronous "object created" event; **resize workers** produce renditions into a second bucket and then tell the **post service** that the media is ready, which flips the post to `live` in **sharded PostgreSQL** and publishes a "post live" event. **Fan-out workers** consume it and append the post ID to followers' lists in the **feed store** (push for most authors; see §53.6.8). The **feed service** reads a user's list, hydrates posts from **memcache** and the database, and asks a **ranking service** to order them (Chapter 68). Images are fetched from the **CDN**, whose misses go through an **origin shield** to the renditions bucket (§21.5.3). Likes are written as events and aggregated into counters (§53.6.8). Stories live in a separate store with a 24-hour TTL. Failure points: the resize pipeline (posts stuck in `processing`), a hot shard for a celebrity's post row, and CDN purge mistakes. Scaling: object storage and CDN scale by bytes; the post service and database by metadata writes; the feed tier by reads.

53.6.8 Detailed component design

The upload pipeline

1. **Client preparation.** The app resizes the photo to at most 1,080 pixels wide and re-compresses it before upload, cutting a 12-megapixel camera file of several megabytes to well under one; it computes a SHA-256 hash for integrity and deduplication.
2. **Presigned upload.** `POST /v1/uploads` returns a presigned `PUT` URL scoped to one object key, one content type and a 15-minute lifetime. Large files use multipart upload so a dropped connection resumes from the last part (§15.8.1).
3. **Create the post early.** `POST /v1/posts` with a `client_post_id` creates the row in state `processing` and returns a `post_id`; the app shows the post on the author's own

profile from its local copy immediately (read-your-writes without waiting for resizing).

4. **Asynchronous resize.** The object-created event triggers workers that validate the file (magic bytes, dimensions, decompression-bomb limits), strip location metadata if the user did not share location, generate four renditions, and write them with content-addressed keys such as `/{post_id}/{width}/{hash}.jpg`. Workers are idempotent: a redelivered event regenerates identical keys.
5. **Publish.** When all renditions exist, the post becomes `live` and its "post live" event starts fan-out. If resizing fails after retries, the post goes to a dead-letter queue (§30.11) and the user sees "couldn't post, tap to retry".

Content-addressed rendition keys make CDN caching simple: an object at a given URL never changes, so it can carry `Cache-Control: max-age=31536000, immutable` (§21.6), and deleting a post is a metadata change plus an asynchronous purge.

Feed: push for most, pull for a few

The feed service must return ten good posts in under 300 ms. Two basic strategies exist, and §53.7 analyzes them with full capacity arithmetic:

- **Fan-out-on-write (push):** when a post goes live, append its ID to every follower's feed list. Reads are one list fetch. Cost: one write per follower per post. With 100 million posts per day and, say, 150 followers on average, $100 \times 10^6 \times 150 / 86,400 \approx 174,000$ list inserts per second: affordable.
- **Fan-out-on-read (pull):** at read time, fetch recent posts from each followed account and merge. No write amplification, but each feed load touches hundreds of accounts.

The teaching design pushes for ordinary accounts and pulls for accounts above a follower threshold, merging the two at read time. The feed list holds post IDs only (8 bytes each, 500 per user); post bodies are hydrated from memcache. Ranking then reorders a few hundred candidates; Instagram has publicly described moving from a reverse-chronological to a ranked feed in 2016 [Instagram 2016].

Likes and counters at scale

Two separate questions hide in a like button: "has *this viewer* liked it?" (exact, per user) and "how many people liked it?" (approximate is fine while hot). Treat them differently.

1. **The like edge** `(post_id, user_id)` is written synchronously to the `likes` table on the post's shard: idempotent by primary key, so double taps and retries are harmless. The viewer's own state is therefore always exact.
2. **The count** is updated asynchronously. The like service emits a `+1` or `−1` event keyed by `post_id`; a **counter aggregator** consumes events, sums them in memory

per post for an interval T, and flushes one `UPDATE posts SET like_count = like_count + Δ` per post per interval: **write coalescing**.

3. **Reads** return the denormalized `like_count` from cache. For very hot posts, the cache entry is refreshed by the aggregator on each flush rather than invalidated, avoiding the refill stampede that Instagram's lease work addressed.
4. **Reconciliation.** A periodic job recomputes `COUNT(*)` from `likes` for posts whose count changed recently and corrects drift caused by lost or duplicated events.

FORMULA

Write coalescing for counters

$$W_{\text{db}} = \sum_{k} \min\left(\lambda_k, \frac{1}{T}\right), \qquad \text{staleness} \le T + \text{lag}$$

Symbol	Meaning	Units
W_{db}	Database counter writes after coalescing	writes/s
λ_k	Like events per second on post k	events/s
T	Flush interval of the aggregator	s
lag	Event-pipeline delay before aggregation	s

WORKED EXAMPLE

Worked example — Coalescing the celebrity post and the long tail.

1. Hot post: $\lambda = 3{,}330$/s, $T = 1$ s: $\min(3{,}330, 1) = 1$ write/s instead of 3,330 — a **3,330× reduction** on the hottest row in the system.
2. Whole system at peak: 347,000 likes/s. Suppose these touch 150,000 distinct posts in any one second, most receiving one or two likes. Then $W_{\text{db}} \approx 150{,}000$ writes/s: only a **2.3× reduction** overall.
3. Staleness: with $T = 1$ s and a pipeline lag of 2 s, a displayed count is at most about 3 s old.

Interpretation. Coalescing is decisive for hot keys and nearly irrelevant for the long tail. *Engineering implication.* Use coalescing to protect hot rows; size the database for the long tail's distinct-key write rate. For keys hotter still, split the counter into N sub-counters on different rows and sum them on read (a **sharded counter**), trading read cost for write spread.

COMMON MISTAKE

Mistake — `SELECT COUNT(*)` on every page view. Counting a celebrity post's two million `likes` rows for every one of its millions of views turns a cheap read into a table scan per view. Store the count; recompute it rarely.

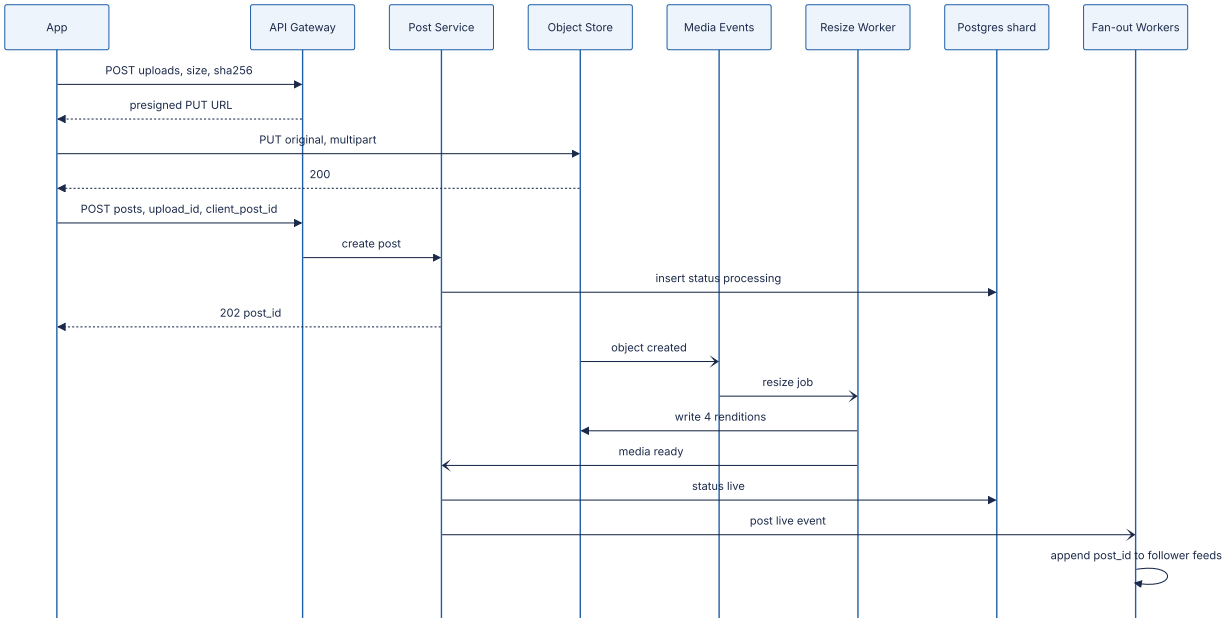
Stories with a 24-hour TTL

Stories are written once, read many times for a day, then hidden. The story store keeps rows keyed by `(author_id, created_at)` with `expires_at`; the tray query asks, for each followed account, whether any story has `expires_at > now()` and is unseen by the viewer. Three details make expiry reliable:

- **Filter on read, delete later.** Readers always filter by `expires_at > now()`; a background job (or the store's native TTL, as in Cassandra or DynamoDB) deletes expired rows hours later. Correctness never depends on the deleter being on time.
- **Media lifecycle.** Story media uses an object-store lifecycle rule (§15.9) that moves objects older than 24 hours to the author's archive tier or deletes them; CDN entries carry `max-age` no longer than the remaining lifetime.
- **Tray precomputation.** The tray is a small per-user list (accounts with live stories) maintained by fan-out on story creation and trimmed on read, the same push pattern as the feed.

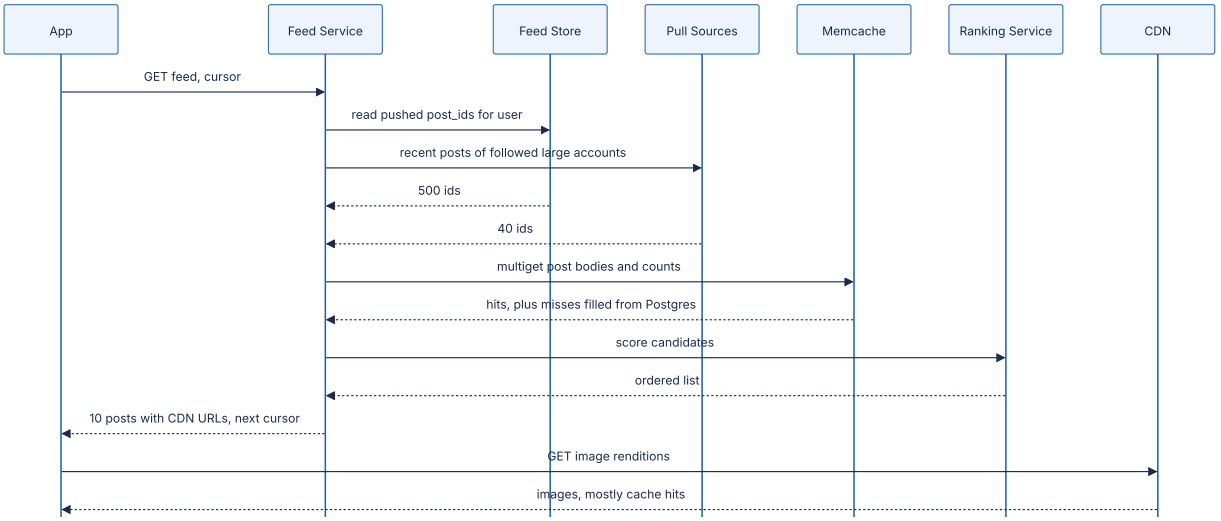
53.6.9 Data flow

Figure 53.10 — Write path: uploading a photo post.



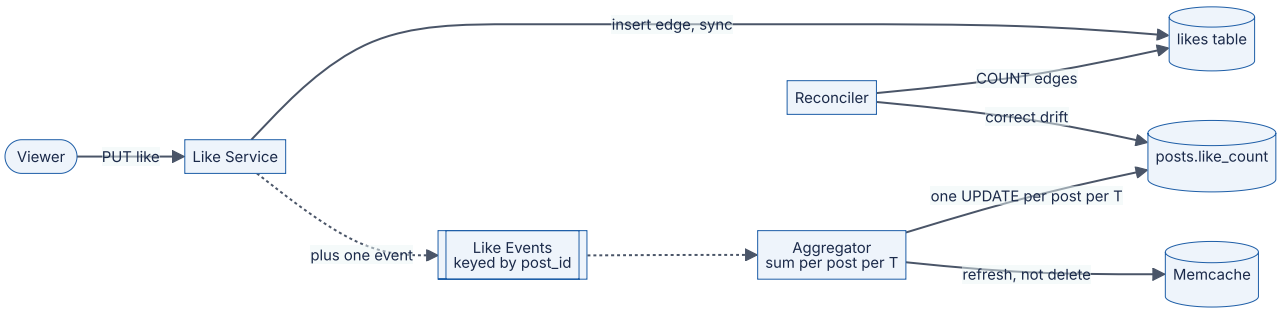
Reading the diagram. The app obtains a presigned URL and uploads the original directly to the object store (synchronous, possibly multipart and resumed). Only then does it create the post, which is inserted on the author's shard in state `processing`, and the app receives a `post_id` at once. The rest is asynchronous: the object-created event drives the resize worker, which writes renditions and reports back; the post becomes `live` and a "post live" event starts fan-out. Failure points: an upload that never completes leaves an orphan object, deleted by a lifecycle rule on the uploads prefix; a resize crash redelivers the job (idempotent keys); a post stuck in `processing` beyond a timeout is retried and then surfaced to the user.

Figure 53.11 — Read path: loading the home feed.



Reading the diagram. The feed service reads the user's pushed list and, in parallel, the recent posts of the few followed accounts that are served by pull; it merges about 540 candidate IDs, hydrates bodies and counts with one memcache multiget (misses filled from the post's shard), filters deleted and blocked content, and calls the ranking service for an order. It returns ten posts with rendition URLs sized for the device; the app then downloads images from the CDN, which is where most latency and almost all bytes are. Failure points: if ranking times out, return the merged list in reverse-chronological order; if the feed store is unavailable, fall back to a pull-only feed for that user at higher cost; memcache misses for a viral post are protected by leases.

Figure 53.12 — Like counting with write coalescing.



Reading the diagram. The like edge is written synchronously so the viewer's own heart is exact. The count change travels asynchronously through an event stream partitioned by `post_id`, so all events for one post reach one aggregator instance, which sums them for T seconds and issues one update. The aggregator refreshes the cached count instead of deleting it, so a hot post never causes a refill stampede. A reconciler periodically recounts edges and fixes drift. Failure points: an aggregator crash loses at most one interval of unflushed sums (fixed by the reconciler, or avoided by committing consumer offsets only after the flush, §31.8.2).

53.6.10 Bottlenecks

1. **Hot rows for celebrity posts** (counts, comments): coalescing, sharded counters, cache refresh instead of invalidation.
2. **Celebrity shards.** All of a celebrity's posts live on one logical shard; read traffic to that shard is absorbed by memcache and read replicas, and a very hot logical shard can be moved to a dedicated physical server.
3. **Resize backlog after an outage or a holiday spike.** Autoscale workers on queue depth; prioritize the small renditions used by feeds so posts can go live before large sizes finish.
4. **Origin egress on CDN misses** after a purge or for long-tail content: origin shielding (§21.5.3) and tiered caching.
5. **Feed fan-out for large accounts:** deferred to pull (analysis in §53.7.8).

53.6.11 Failure scenarios

Table 53.14 — Failure scenarios for the photo-sharing service.

What fails	Impact	Detection	Recovery	Prevention
Resize workers down	New posts stuck in `processing`	Queue depth, age of oldest job	Scale out; drain backlog by priority	Autoscaling on lag; multiple instance types
Object store region degraded	Uploads fail; misses on uncached images	Upload error rate; origin 5xx	Fail uploads over to a second region bucket	Cross-region replication of originals
PostgreSQL shard primary fails	Writes to that shard's users fail for seconds	Replication health checks	Promote replica (§14.3)	Semi-synchronous replica in another zone
Memcache cluster loss	Database read surge	Hit-ratio drop, DB latency	Gutter pool, leases (§20.11)	Spread keys across clusters; warm-up
Like aggregator crash	Counts stale for seconds; un-flushed sums lost	Consumer lag	Restart from committed offsets	Commit offsets after flush; reconciler
CDN purge of wrong prefix	Origin flooded	Origin request spike	Rate-limit purges; shield absorbs	Immutable keys; purge by exact key only
Story deleter late	None visible (read filter)	Expired-row backlog metric	Catch up	Filter on read, never trust delete timing

53.6.12 Scaling strategy

At 10× load (from more engagement and richer media rather than ten times as many people). Image egress reaches about 14 Tbit/s on average and storage about 1.7 EB/year erasure-coded. What breaks: **storage cost** and **CDN egress**. Changes: modern formats with better compression (AVIF, WebP), device-aware rendition selection, cold-tiering of originals older than a year (§15.9), and placing cache appliances inside large ISPs in the style of Netflix Open Connect (§21.10).

At 100×. The metadata tier, which looked small, becomes the operational problem: thousands of PostgreSQL servers. Fixed logical shards keep rebalancing a mapping exercise, but cross-region writes and failover require a home-region-per-user design (§44.6.4). Counters and feed lists move to purpose-built stores; Instagram's own published history includes multi-data-center expansion and the counter redesign it forced [Instagram Engineering 2015].

53.6.13 Trade-offs

Table 53.15 — Trade-offs in the photo-sharing design.

Decision	Chosen	Gave up	Why acceptable
Upload path	Presigned direct-to-store	Server-side inspection before storage	Inspection happens asynchronously before the post goes live
Post visibility	`processing` then `live`	Instant visibility to followers	Author sees it at once from the local copy
IDs	Time-ordered, shard-embedded 64-bit	Fully random IDs that hide creation time	Routing without lookups, natural time order
Counters	Coalesced, approximate while hot	Exact real-time counts	Users do not notice ±0.1 % on a million
Feed	Push with pull for large accounts	Simplicity of one strategy	Bounded write amplification (§53.7)
Stories	Filter on read, lazy delete	Physical deletion exactly at 24 h	Expiry is exact for users; storage lags harmlessly

53.6.14 Alternative designs

1. **Upload through application servers.** Simpler authentication and immediate validation, but ties up servers and memory for slow mobile uploads at 3 MB each; acceptable at small scale only.
2. **On-the-fly resizing at the edge** (an image service that renders sizes on request and caches them). Fewer stored renditions and easy addition of new sizes, at the cost of compute on cache misses; common for product catalogs.
3. **Exact counters with `UPDATE … + 1` per like.** Correct and simple until one row receives thousands of updates per second and lock contention caps throughput.
4. **Probabilistic counters** (HyperLogLog of distinct likers, §17.5): tiny memory, fine for view counts, but a visible like count must not wobble.

53.6.15 Interview discussion

Table 53.16 — 45-minute pacing plan for “Design Instagram”.

Minutes	Activity	Output
0–5	Scope: photos, feed, likes, stories; video out	Requirements list
5–10	Capacity	1.2 k posts/s, 339 TB/day, 3.5 M image fetches/s peak, 1.4 Tbit/s egress
10–18	Architecture	Figure 53.9: presigned upload, resize, CDN, sharded metadata
18–30	Deep dive 1: upload pipeline and IDs	State machine, idempotent workers, 41/13/10 IDs
30–38	Deep dive 2: feed and counters	Push vs pull sketch, coalesced likes
38–45	Failures, stories, trade-offs	Table 53.14 highlights; TTL by read filter

Likely follow-ups: *"How do you avoid serving a photo before it is checked?"* — It is not referenced by any live post until the worker validates it; the uploads bucket is private. *"How would you show 'liked by your friend X'?"* — Intersect the viewer's following set with recent likers via a bounded query on the `likes` table, or precompute in the feed pipeline. *"Delete a post?"* — Mark deleted, filter at hydration, purge CDN keys asynchronously, remove from feed lists lazily.

A **senior** answer keeps image bytes off application servers, designs idempotent asynchronous processing and separates the exact per-user like state from the approximate count. A **staff** answer quantifies egress cost and CDN hit ratio, explains why coalescing helps only hot keys, and connects ID design to sharding and rebalancing.

53.6.16 Production considerations

- **Observability.** Upload success rate by network type and app version; time from upload to `live` (p50/p99); resize queue age; CDN hit ratio and origin egress per region; hot-key detection on counters and post rows (§20.15).
- **Security and privacy.** Presigned URLs scoped to one key, type and size, with short lifetimes; strip EXIF location by default; scan media for malware and policy violations before `live`; private accounts enforced at hydration *and* at the CDN by signed, expiring URLs for private media (§21.11).
- **Cost.** Storage and egress dominate; tiering, better codecs and CDN hit ratio matter far more than server tuning.
- **Operations.** Backfills of new rendition sizes run as throttled batch jobs; schema changes walk all 8,192 logical shards.

53.7 Facebook News Feed

53.7.1 Problem statement

Design the home feed of a social network in the style of Facebook: when a user opens the app, show a ranked list of recent posts, photos, shares and activity from their friends, the groups they belong to and the pages they follow. Friendships are mutual and capped (a few thousand friends at most), but pages and public figures can have hundreds of millions of followers. Every post must be checked against privacy settings for each viewer.

A useful picture is a personal newspaper assembled at the moment the reader sits down. One option is to have every reporter deliver a copy of each story to every subscriber's mailbox as soon as it is written (**fan-out-on-write**); the other is to keep each reporter's recent stories on their own desk and have an editor walk round the desks when the reader arrives (**fan-out-on-read**). The first is fast to read but expensive when a famous columnist has 100 million subscribers; the second is cheap to write but makes every reader's visit a tour of hundreds of desks.

The distinctive hard problem is the **fan-out decision with its capacity arithmetic**, followed by the **social-graph store** that every feed request reads dozens of times (a TAO-style graph cache) and a **ranking stage** whose cost scales with the number of candidates.

53.7.2 Functional requirements

1. Return the first page of a user's feed: about 10–20 ranked stories, each with author, content, counts and comments preview; then further pages by cursor.
2. Stories come from friends, joined groups and followed pages; include new posts and selected activity ("X commented on Y's photo").
3. Respect privacy: a story is shown only if the viewer may see it at read time (audience settings, blocks, deletions).
4. New posts by friends appear in the feed within seconds; edits and deletions take effect on the next load.
5. Do not show the same story repeatedly; remember what was seen.
6. Out of scope: the design of ranking models (Chapter 68), ads insertion, notifications (Chapter 52).

53.7.3 Non-functional requirements

Table 53.17 — Non-functional requirements for the news feed.

Requirement	Target	Note
Availability	99.95 %; degrade to an older cached feed rather than fail	An empty feed is the worst outcome
Feed latency	p50 < 200 ms, p99 < 800 ms server time for the first page	Includes candidate retrieval, hydration and ranking
Freshness	Friend's new post eligible within 10 s	Eventual consistency is acceptable
Privacy correctness	Zero stories shown to viewers not permitted at read time	A privacy leak is a severity-1 incident
Graph read throughput	~10^8 reads/s at peak (§53.7.4)	Every feed load reads the graph many times
Consistency of counts	Approximate, seconds stale	As in §53.6

53.7.4 Capacity estimation

Assumptions: 2 billion DAU, 3 billion monthly users; 1 billion new posts and shares per day; an ordinary author reaches 400 people (friends plus followers); each DAU loads the feed 15 times per day; peak-to-average ratio 2 (global audience); 100,000 accounts with at least a million followers, averaging 5 million followers and posting 4 times per day; 1,000 ranking candidates per feed load.

FORMULA

Fan-out load and fan-out completion time

$$W_{\text{push}} = \sum_a p_a F_a, \qquad T_{\text{fan}} = \frac{F_a}{R_{\text{post}}}$$

Symbol	Meaning	Units
W_{push}	Feed-list inserts per day under fan-out-on-write	inserts/day
p_a	Posts per day by author a	posts/day
F_a	Followers (audience) of author a	users
T_{fan}	Time to finish delivering one post to all followers	s
R_{post}	Insert throughput the fan-out tier devotes to one post	inserts/s

WORKED EXAMPLE

Worked example — Pure fan-out-on-write.

1. Ordinary authors: 1×10^9 posts/day × 400 = 4×10^{11} inserts/day ≈ **4.63 million/s** average, 9.26 million/s at peak.
2. Large accounts: $10^5 \times 4 \times 5 \times 10^6 = 2 \times 10^{12}$ inserts/day ≈ **23.1 million/s**: five times all ordinary fan-out combined, produced by 0.005 % of accounts.
3. One post by an account with 100 million followers, given $R_{\text{post}} = 10^6$ inserts/s: $T_{\text{fan}} = 10^8/10^6 = 100$ s. The last followers see it nearly two minutes after the first, and the burst competes with every other post's fan-out.
4. Storage of per-user lists: 3 billion users × 500 entries × 24 bytes = 36 TB (108 TB at three replicas): manageable.

Interpretation. Storage is not the problem; the **write rate and burstiness caused by the heavy tail** are. *Engineering implication.* Never push for accounts in the tail; the question is where to cut.

WORKED EXAMPLE

Worked example — Pure fan-out-on-read.

1. Feed loads: $2 \times 10^9 \times 15 = 3 \times 10^{10}$/day ≈ 347,000/s average, **694,000/s at peak**.
2. Naive pull: each load consults 400 sources: $694,000 \times 400 \approx 278$ million source lookups/s.
3. With sources sharded by author across an in-memory index tier, an aggregator sends one request per shard group rather than per author; at about 40 requests per load, $694,000 \times 40 \approx 27.8$ million index requests/s.
4. Index size: 5 billion recent actions/day (posts, comments, likes worth showing) × 2 days × 100 bytes ≈ **1 TB** per replica: small enough for RAM.
5. Ranking 1,000 candidates per load at peak: $694,000 \times 1,000 \approx 694$ million candidate scorings/s, which is why ranking is staged (§53.7.8).

Interpretation. Pull moves the cost to reads, but the data it reads, recent activity, is small and fits in memory. *Engineering implication.* Pull is viable when the recent-activity index fits in RAM and ranking needs all candidates at read time anyway.

Table 53.18 — Capacity summary for the news feed.

Quantity	Value
Feed loads	347,000/s average; 694,000/s peak
Push inserts, ordinary authors	4.63 M/s average
Push inserts, 100,000 large accounts	23.1 M/s average
Worst single-post fan-out	100 M inserts; 100 s at 1 M/s
Pull: index requests	≈ 27.8 M/s at peak; index ≈ 1 TB per replica
Ranking	≈ 694 M candidate scorings/s at peak before pruning

53.7.5 API design

```
GET  /v1/feed?cursor=<opaque>&count=15&viewport=<w,h>&network=<4g|wifi>
     → {stories: [{story_id, actors[], object_id, type, snippet, counts,
comments_preview,
                   rank_context}], next_cursor, served_at}
POST /v1/feed/seen   {story_ids[], served_at}          # impression logging, batched
POST /v1/posts       {author_id, content, audience: public|friends|custom_list_id,
                      attachments[], client_post_id}   → {post_id}
DELETE /v1/posts/{post_id}
# Internal graph API (TAO-style, §53.7.8)
obj_get(id) · assoc_get(id1, atype, id2_set) · assoc_range(id1, atype, offset, limit)
assoc_time_range(id1, atype, high, low, limit) · assoc_count(id1, atype)
assoc_add(id1, atype, id2, time, data) · assoc_delete(id1, atype, id2)
```

The cursor is opaque because it encodes the *served* ranked list's identity and position, not a timestamp: page 2 must continue the ranking that produced page 1, even if new stories arrived in between. Impressions are logged so that "seen" stories are demoted next time.

53.7.6 Data model and database schema

The social graph is modeled the way TAO models it [Bronson et al. 2013]: **objects** (users, posts, comments, pages, photos) with typed fields, and **associations**, directed typed edges with a timestamp and small payload.

```
object:  (id) -> (otype, {field: value})
           e.g. 9001 -> (post, {author: 42, text: "...", audience: friends})
assoc:   (id1, atype, id2) -> (time, {data})
           e.g. (42, authored, 9001), (42, friend, 77), (77, liked, 9001)
assoc list (id1, atype) -> [id2 ...] ordered by time descending
           e.g. (42, authored) -> newest posts by user 42 first
```

Objects and associations are stored in sharded MySQL: an object's shard is encoded in its ID, and an association lives on the shard of `id1`, so "all of 42's friends" or "42's latest posts" is a single-shard, time-ordered range read. Inverse edges (`friend` both ways, `liked` / `liked_by`) are written as separate associations. A relational store suffices because

nearly all graph queries are one hop; the scale problem is read volume, which the cache solves (§12.7.3 discusses when a graph database is preferable).

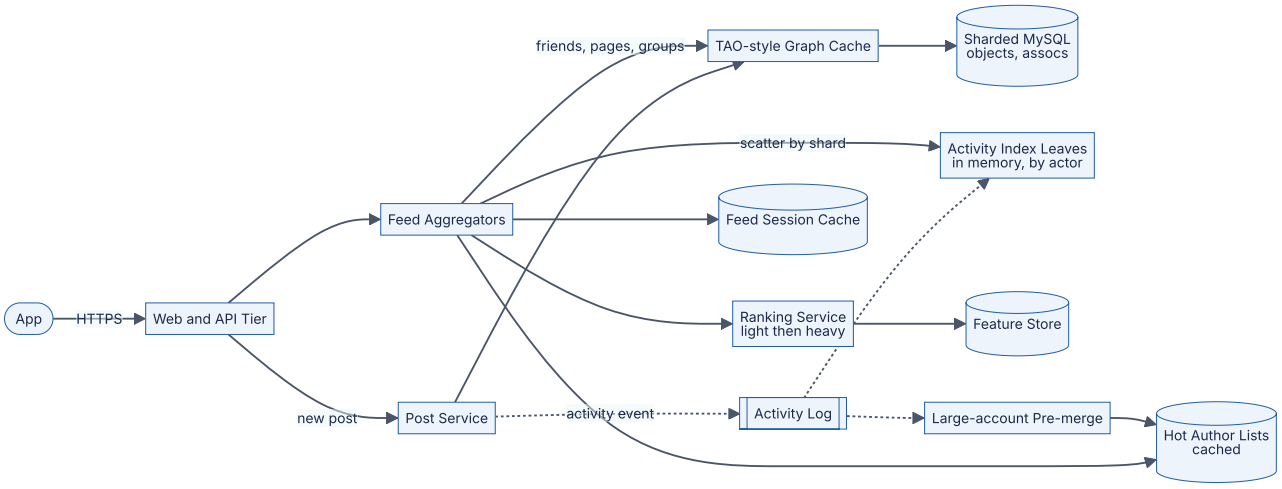
The feed tier adds two read-optimized stores:

```
# Recent-activity index (in-memory leaves), sharded by actor_id
activity/{actor_id} -> ring buffer of (action_id, type, object_id, time,
light_features), 2 days

# Feed session cache, per viewer, TTL 30 min
served/{viewer_id}/{served_at} -> [story_id ...]   # supports stable pagination
seen/{viewer_id}               -> compact set of story_ids seen in the last N days
```

53.7.7 High-level architecture

Figure 53.13 — High-level architecture of a read-time aggregated news feed.



Reading the diagram. A feed request reaches an **aggregator**, which first reads the viewer's friends, groups and followed pages from the **TAO-style graph cache** (backed by sharded MySQL). It then scatters requests to the **activity-index leaves**, in-memory servers that hold the last two days of actions sharded by actor, asking each shard for recent actions by the viewer's sources; leaves return candidates with cheap features. Very large accounts are not scattered to: their recent posts sit in a small set of heavily cached **hot author lists** that every aggregator reads. The aggregator hydrates candidates (objects, counts, privacy checks) from the graph cache, calls the **ranking service** (a light model prunes, a heavy model scores, using a **feature store**) and stores the served list in a **feed session cache** for pagination. On the write side, the **post service** writes the object and associations through the graph cache and emits an activity event (dotted, asynchronous) that leaves consume within seconds. Failure points: a slow leaf shard delays every feed (mitigated by replicas and hedged requests, §16.7.3); a graph-cache miss storm on a viral object (leases, §20.11); ranking overload (fallback to light-ranked or chronologi-

cal order). Scaling: leaves by memory and request rate, aggregators by CPU, the graph cache by reads.

53.7.8 Detailed component design

Choosing the fan-out strategy

The three strategies are compared with this case's numbers.

Table 53.19 — Fan-out strategies for a 2-billion-DAU feed.

Aspect	Fan-out-on-write (push)	Fan-out-on-read (pull)	Hybrid (push, pull for large accounts)
Write cost	4.6 M/s ordinary + 23 M/s large accounts	One index append per action	≈ 4.6 M/s
Read cost	One list read per load	~40 shard requests per load (27.8 M/s)	One list read + a few hot lists
Worst-case burst	100 M inserts for one post	None	Bounded by the threshold
Freshness	Seconds, minutes for the largest accounts	Immediate at read time	Seconds
Storage	36 TB of per-user lists	≈ 1 TB recent-activity index	Lists + hot lists
Ranking fit	Lists must be re-scored at read anyway	Candidates gathered at read, scored once	Re-scored at read
Wasted work	Writes to inactive users' lists	None	Some, for inactive followers
Choose when	Small audiences, chronological feeds, read-heavy	Ranked feeds, bounded friend graph, index fits RAM	Follower graphs with a heavy tail (§53.8)

A useful way to see why the heavy tail, rather than total cost, drives the decision is to compare push and pull costs for a single author.

FORMULA

Per-author push-to-pull ratio

$$\frac{W_a}{R_a} = \frac{p_a F_a}{\alpha_a F_a r} = \frac{p_a}{\alpha_a r}$$

Symbol	Meaning	Units
W_a	Push writes per day caused by author a	writes/day
R_a	Pull reads per day of author a's recent-post list	reads/day
p_a	Posts per day by author a	posts/day
α_a	Fraction of a's followers active on a given day	dimensionless
r	Feed loads per active user per day	loads/day
F_a	Followers of a (cancels out)	users

WORKED EXAMPLE

Worked example — Ordinary user versus celebrity.

1. Ordinary user: $p = 0.5$, $\alpha = 0.6$, $r = 15$: $W/R = 0.5/9 \approx 0.056$. Push performs about 18 times fewer operations than pull for this author.
2. Celebrity: $p = 4$, $\alpha = 0.3$ (many dormant followers), $r = 15$: $W/R = 4/4.5 \approx 0.89$. Operation counts are similar.
3. But the operations differ. The celebrity's R_a reads all hit **one hot list** that sits in every cache, so each costs almost nothing; the W_a writes go to **100 million distinct lists** in one burst.

Interpretation. Follower count cancels from the ratio: celebrities are not costly because of total operations but because push turns one event into a synchronized burst of distinct writes, while pull turns it into many reads of one cached object.
Engineering implication. Cut over to pull by follower count (burst size) and posting frequency, and measure where the knee is.

The following simulation makes the knee visible on a scaled-down population with a heavy-tailed follower distribution:

```
        import random

        random.seed(7)
        N_USERS = 1_000_000                # scaled-down population
        MEAN_FOLLOWEES = 200               # average accounts each user follows

        def posts_per_day(f):              # popular accounts post more often
            return 5.0 if f >= 10_000 else 0.5

        # Heavy-tailed follower counts: Pareto with shape 1.2, capped at 10% of users,
        # rescaled so that total follow edges = N_USERS * MEAN_FOLLOWEES.
        raw = [min(10 * random.paretovariate(1.2), N_USERS / 10) for _ in
range(N_USERS)]
        scale = N_USERS * MEAN_FOLLOWEES / sum(raw)
        followers = [max(1, int(f * scale)) for f in raw]

        def hybrid(threshold):
            pushed = [f for f in followers if f < threshold]
            push_per_day = sum(f * posts_per_day(f) for f in pushed)
            biggest_burst = max(pushed, default=0)          # inserts caused by one post
            pull_per_load = sum(f for f in followers if f >= threshold) / N_USERS
            return push_per_day, biggest_burst, pull_per_load

        print(f"follow edges = {sum(followers):,}; largest account = {max(followers):,}
followers")
        for t in (float("inf"), 100_000, 10_000, 1_000):
            push, burst, pull = hybrid(t)
            print(f"threshold {t!s:>7}: push inserts/day {push:>12,.0f} | "
                  f"largest single fan-out {burst:>7,} | pulls per feed load
{pull:5.1f}")
```

```
follow edges = 199,500,793; largest account = 381,390 followers
threshold     inf: push inserts/day  308,107,772 | largest single fan-out 381,390 |
pulls per feed load   0.0
threshold  100000: push inserts/day  214,971,622 | largest single fan-out  99,183 |
pulls per feed load  18.6
threshold   10000: push inserts/day   76,599,577 | largest single fan-out   9,994 |
pulls per feed load  46.3
threshold    1000: push inserts/day   54,665,146 | largest single fan-out     999 |
pulls per feed load  90.2
```

What to notice:

- Moving the threshold from “never pull” to 10,000 followers cuts push inserts by **4×** (308 million to 77 million per day in this population) and caps the largest burst at 10,000, because the accounts above the threshold are few but post often to huge audiences.
- The price is paid on reads: each feed load now merges about 46 pulled author lists. Those are shared, hot, cached lists, so 46 keys in one multiget is cheap.
- Lowering the threshold further to 1,000 saves little more on writes but doubles the pulls. The knee, not the extreme, is the design point; recompute it on your own fol-

lower distribution.

Why the teaching design reads at query time

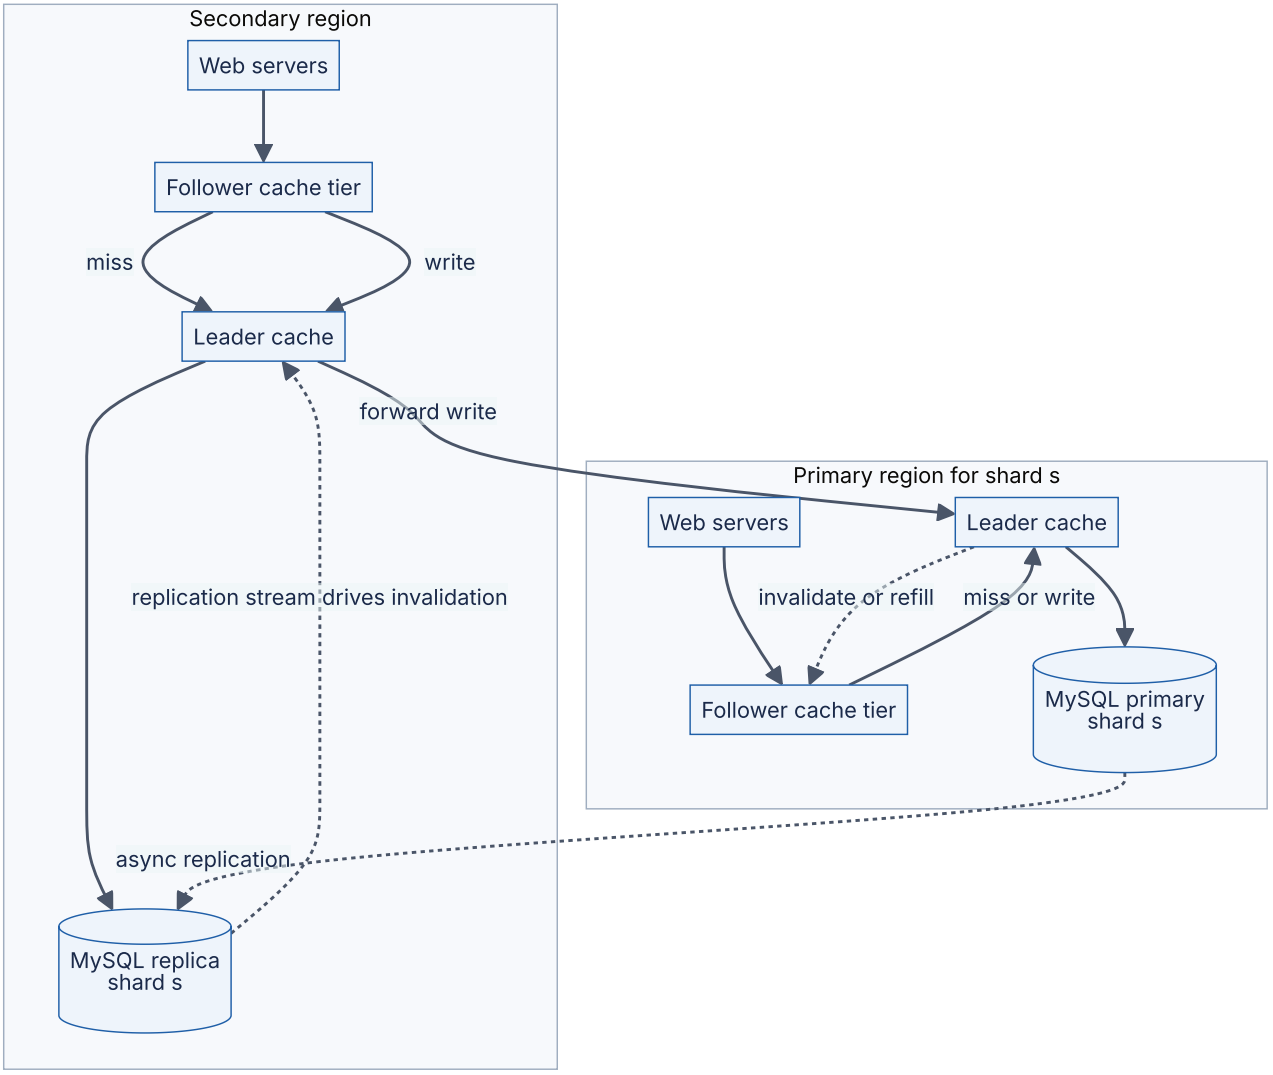
For a *ranked* feed with a *bounded* friend graph, read-time aggregation has three further advantages: ranking must score candidates at read time anyway (using fresh features such as “your friend commented two minutes ago”), privacy and deletion are evaluated against current state, and nothing is written for the many users who will not open the app today. Its cost is a large, latency-critical in-memory tier. The teaching design therefore aggregates at read time from activity leaves, and uses hot author lists for very large pages; §53.8 shows the opposite choice for a chronological, follower-based product.

> INDUSTRY EXAMPLE
>
> **Facebook’s Multifeed.** Facebook has described its feed backend, Multifeed, as **aggregators** that query **leaf** servers holding recent activity in memory, then rank the results; a 2012 conference presentation described leaves holding most of the RAM and aggregators most of the CPU. A 2015 engineering post described splitting aggregators and leaves onto separate machine types, reporting about 40 % efficiency gains in memory and CPU use and a 10 % reduction in aggregator latency. *Evidence: Primary* — [Facebook Engineering 2015]; the 2012 presentation detail is *Secondary* (conference slides as summarized by third parties).

The social-graph cache (TAO style)

Every feed load reads the graph dozens of times: the viewer’s friends and pages, each candidate’s author, audience and counts, whether the viewer liked it, the first comments. At 694,000 loads/s and about 100 graph reads per load, that is roughly 70 million reads/s from feed alone. TAO is Facebook’s published answer: a geographically distributed, read-optimized, **graph-aware write-through cache** in front of sharded MySQL, which the paper reports sustaining a billion reads per second [Bronson et al. 2013].

Figure 53.14 — TAO-style cache tiers across two regions.



Reading the diagram. Web servers read from a **follower** cache tier; there are several follower tiers per region, each holding all shards, so read capacity scales by adding tiers. A follower miss or any write goes to the shard's **leader** cache, the only cache that talks to the database for that shard, which protects MySQL from thundering herds. In the shard's **primary region**, the leader writes to the MySQL primary and then sends asynchronous invalidation or refill messages (dotted) to followers. In a **secondary region**, writes are forwarded to the primary region's leader (synchronous, cross-region), while reads are served locally from a MySQL replica; invalidations there are driven by the replication stream, so a region's caches are invalidated only after its replica has the change. The follower that handled a write updates its own copy immediately, giving the writer read-after-write consistency within its tier, while other tiers converge asynchronously. Failure points: a leader failure (reads route around it to the database or another leader; writes queue), replication lag (secondary regions read slightly stale data), and cross-region write latency. Scaling: add follower tiers for reads, shards for data, leaders per shard for database protection.

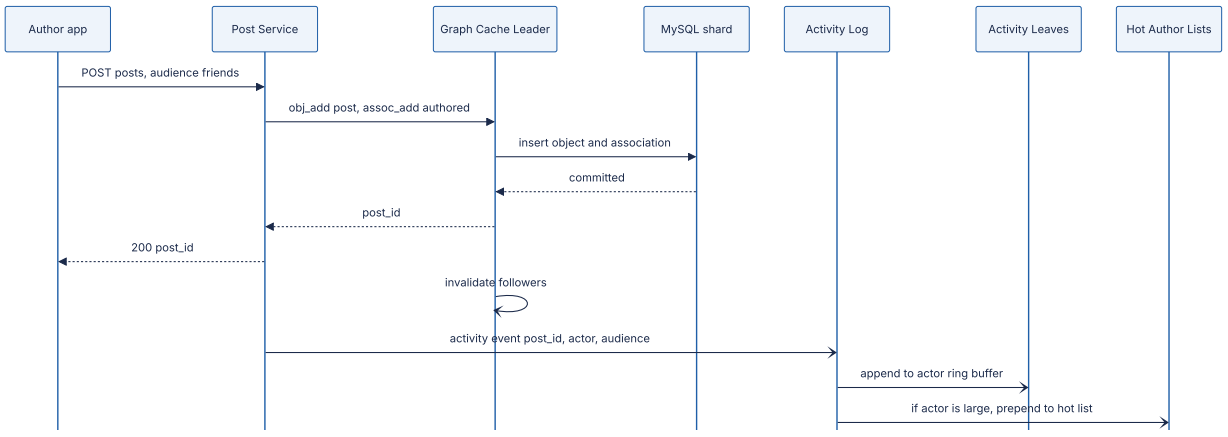
The API is shaped by the data model: `assoc_range(42, friend, 0, 50)` returns the newest 50 friends; `assoc_count(9001, liked_by)` returns a stored count, not a scan; `assoc_time_range` serves "posts by 42 in the last two days". Because association lists are time-ordered and most reads touch the newest entries, caching the head of each list captures most traffic. The design inherits Memcache's lessons, including leases against stale sets and stampedes [Nishtala et al. 2013] (§20.7, §20.11).

Ranking: staged to control cost

Scoring 1,000 candidates with a large model for 694,000 loads/s is about 694 million model evaluations per second. The standard answer, treated in Chapter 68, is a funnel: **candidate retrieval** (leaves return a few thousand actions), **light ranking** (a cheap model or heuristic prunes to a few hundred), **heavy ranking** (a model predicting probabilities of actions such as like, comment, share or hide, combined into one value), and a **final pass** for diversity, integrity demotions and de-duplication of stories about the same object. Facebook has published a description of this approach, predicting multiple engagement outcomes per candidate and combining them into a relevance score [Lada et al. 2021]. If heavy ranking overloads, serve the light-ranked order: a less personalized feed is better than none.

53.7.9 Data flow

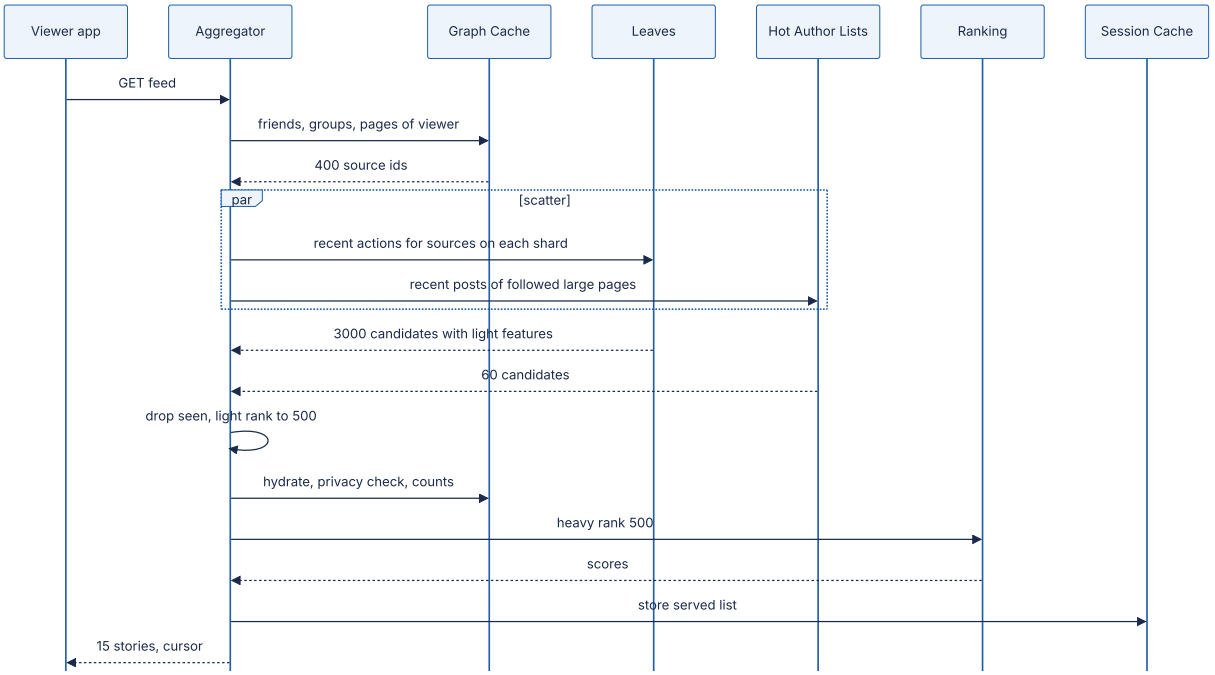
Figure 53.15 — Write path: a user publishes a post.



Reading the diagram. The post is written synchronously through the graph cache's leader into the author's MySQL shard; the author gets a `post_id` as soon as it commits, and their own profile reads it back through the same follower tier (read-your-writes). Everything else is asynchronous: cache followers are invalidated, an activity event goes to a log partitioned by actor, and the leaf that owns the actor appends the action to its in-memory ring buffer, making it a feed candidate for all friends within seconds. For very large accounts, the event also updates a hot author list. Note what does *not* happen: no per-follower writes. Failure points: if the activity log lags, posts appear late in feeds but

are already durable; a leaf restart rebuilds its buffers by replaying two days of the log or reading recent associations from the graph.

Figure 53.16 — Read path: loading the first page of the feed.



Reading the diagram. The aggregator reads the viewer's sources from the graph cache, then scatters in parallel to the leaf shards and the hot author lists (the `par` block). It removes stories already seen, prunes with the light ranker, hydrates the survivors, which is also where **privacy is checked against current audience settings**, and asks the heavy ranker to score them. The ranked list is stored in the session cache so the next page continues the same ordering. Failure points: the slowest leaf shard sets the latency, so aggregators use replicas and hedged requests and return partial candidates after a deadline; a ranking timeout falls back to light-ranked order; a hydration miss storm on a viral object is absorbed by leases. Scaling: aggregators scale with feed loads; leaf replicas with request rate.

53.7.10 Bottlenecks

1. **Leaf tail latency.** A load touches dozens of shards; the slowest sets the latency (§16.7.3). Replicas, hedging and deadlines with partial results are mandatory.
2. **Ranking compute.** Hundreds of millions of scorings per second; the light ranker and candidate caps are the levers.
3. **Viral objects in the graph cache.** One post read by millions in minutes: leases, hot-key replication across follower tiers (§20.15).
4. **Cross-region writes.** Writes from secondary regions pay a cross-region round trip to the shard's primary region (§44.4).

5. **Privacy checks** on every candidate multiply graph reads; cache audience lists and evaluate cheap rules first.

53.7.11 Failure scenarios

Table 53.20 — Failure scenarios for the news feed.

What fails	Impact	Detection	Recovery	Prevention
Leaf shard slow or down	Missing or late candidates for many feeds	Per-shard latency, partial-result rate	Hedge to replica; return partial after deadline	≥ 2 replicas per shard; restart from log replay
Ranking service overload	Latency SLO missed	Queue depth, timeouts	Serve light-ranked or chronological order	Load shedding by priority (§22.9)
Graph cache leader failure	Misses fall through to MySQL	Leader health	Route to alternate leader; queue writes	Leases; protect DB with request limits
Cache invalidation lost	Stale counts or deleted post visible	Consistency sampling	TTL backstop; replayed invalidations	Invalidation from replication stream
Activity log lag	New posts missing from feeds	Consumer lag	Catch up; leaves read graph for last minutes	Lag alerts; capacity headroom
Privacy check bug	Story shown to wrong audience	Audits, user reports	Kill switch on story type; purge session caches	Check at hydration time, fail closed
Region evacuation	Traffic shifts to other regions	Global health	Promote replicas to primary for shards	Capacity headroom per region (§44.11)

53.7.12 Scaling strategy

At 10×. Feed loads reach about 7 million/s at peak. The leaf tier grows linearly in memory (≈ 10 TB per replica) and requests; ranking compute grows tenfold and becomes the largest cost. Changes: stronger candidate pruning (smaller heavy-ranker input), caching of ranked feeds for users who reload within minutes, and precomputing partial feeds for the heaviest readers during off-peak hours.

At 100×. Scatter-gather to every leaf shard stops scaling: more shards mean each request touches more servers and tail latency worsens. Changes: shard the activity index by **viewer** for the heaviest readers (a push of candidates for them, effectively a hybrid), introduce embedding-based retrieval to replace exhaustive source enumeration (Chapter 68), and partition users into regional cells with a home region (§44.6.4) so most graph reads and writes stay local.

53.7.13 Trade-offs

Table 53.21 — Trade-offs in the news-feed design.

Decision	Chosen	Gave up	Why acceptable
Fan-out	Read-time aggregation; hot lists for large pages	One-read feeds	Ranking and privacy need read-time evaluation anyway
Graph store	Sharded MySQL behind a graph cache	Multi-hop graph queries	Feeds need one-hop reads at enormous rates
Cache consistency	Read-after-write within a tier, eventual elsewhere	Linearizable reads	A friend seeing a like 1 s late is harmless
Ranking	Staged funnel	Scoring every candidate with the best model	10–100× lower compute for a small quality loss
Pagination	Session-cached ranked list	Always-fresh page 2	Stable scrolling without duplicates

53.7.14 Alternative designs

1. **Pure push with ranking at read.** Precompute per-user candidate lists (bounded length) and rank at read time; simpler read path, but write amplification and wasted writes for inactive users.
2. **Hybrid by follower count** (as in §53.6 and §53.8). Push for ordinary authors, pull for large ones; well suited to follower-based, chronological products.
3. **Graph database** for the social graph (§12.7). Natural for multi-hop queries, but harder to scale to this read rate; multi-hop questions are better served by offline jobs.

53.7.15 Interview discussion

Table 53.22 — 45-minute pacing plan for “Design the Facebook News Feed”.

Minutes	Activity	Output
0–5	Scope: friends vs followers, ranking, privacy	Requirements
5–12	Capacity, push vs pull math	694 k loads/s, 4.6 M/s vs 23 M/s inserts, 100 s burst
12–20	Architecture	Figure 53.13
20–32	Deep dive: fan-out choice	Table 53.19, per-author ratio, threshold knee
32–40	Deep dive: graph cache and ranking funnel	TAO tiers, light/heavy ranking
40–45	Failures, privacy, trade-offs	Degrade to cached or chronological feed

Likely follow-ups: *"A user unfriends someone; when does the feed stop showing them?"* — On the next load: sources are read at request time and privacy is checked at hydration. *"How do you avoid showing a story twice?"* — Seen-set per viewer and session-cached ranked lists. *"What about a user who follows 5,000 pages?"* — Cap and prioritize sources by affinity before scattering.

A **senior** answer compares push and pull with numbers and lands on a justified hybrid or pull design. A **staff** answer shows that follower count cancels from total cost and that burstiness and inactive followers decide the threshold, sizes the in-memory index, budgets ranking compute, and keeps privacy evaluation at read time.

53.7.16 Production considerations

- **Observability.** Latency by stage, partial-result rate, empty-feed rate, freshness (post to first impression), ranking fallback rate.
- **Security and privacy.** Privacy checks at hydration, failing closed; audit sampling against audience rules; fast deletion propagation to leaves and caches (§50.9).
- **Cost.** Ranking compute and leaf memory dominate; track cost per thousand feed loads by stage.
- **Operations.** Ranking changes ship behind experiments with guardrails (Chapter 68); leaves restart shard by shard with log replay.

53.8 Twitter/X

53.8.1 Problem statement

Design a microblogging service in the style of Twitter (now X): users post short public messages (tweets), follow other accounts without needing approval, and read three different products built from the same stream of tweets. The **home timeline** shows tweets

from followed accounts; **search** finds tweets containing words or hashtags, including tweets posted seconds ago; **trends** list the topics whose volume is rising unusually fast right now.

Think of a single river of short notes feeding three different mills. One mill sorts notes into every reader’s pigeonhole (timeline); one indexes every word as the notes flow past (search); one counts how fast each word is flowing and raises a flag when a trickle becomes a flood (trends). The river is the same, but each mill needs a different machine.

The distinctive hard problem is that **one write stream feeds three read products, each with its own data structure and freshness target**: per-user timeline caches for a follower graph with an extreme heavy tail, a real-time inverted index, and streaming heavy-hitter detection over sliding windows. Feed fan-out economics were analyzed in §53.7.8; this case applies them to a follower-based, burst-prone product and uses Twitter’s published architecture as the anchor.

53.8.2 Functional requirements

1. Post a tweet of up to 280 characters with optional media; reply, retweet (repost) and like.
2. Follow and unfollow accounts; the follow graph is asymmetric.
3. Home timeline: tweets from followed accounts, newest first (a ranked “For You” variant is discussed in §53.8.8), with pagination.
4. User timeline: an account’s own tweets.
5. Search tweets by keyword, hashtag or user, with results seconds old.
6. Trends: the top 10 rising topics globally and per country, updated every few minutes.
7. Out of scope: direct messages (§53.4), media transcoding (Chapter 54), ads.

53.8.3 Non-functional requirements

Table 53.23 — Non-functional requirements for the microblogging service.

Requirement	Target	Note
Availability, timeline reads	99.99 %	The product is reading
Availability, posting	99.95 %	Writes can queue briefly
Home timeline latency	p99 < 200 ms	Served from memory
Tweet delivery to followers' timelines	p99 < 5 s for ordinary accounts	Matches the published goal of the 2012 design (see callout)
Search freshness	Tweet searchable within 10 s	Real-time search during events
Trends freshness	Updated every 1–5 min	Trends are a lagging indicator by design
Burst tolerance	Absorb 25× average tweet rate for minutes	Published record spikes (see callout)
Durability	No loss of acknowledged tweets	Timelines and indexes are rebuildable; tweets are not

INDUSTRY EXAMPLE

Twitter's published scale and timeline design (2012–2013). In a 2012 QCon talk, *Timelines at Scale*, Raffi Krikorian described the home-timeline architecture; Kleppmann's summary of the same figures is 4.6k tweets/s on average and over 12k/s at peak against about 300k home-timeline reads/s, with each tweet delivered to about 75 followers on average, so 4.6k tweets/s became about 345k writes/s into home-timeline caches [Krikorian 2012; Kleppmann 2017]. Third-party summaries of the talk add that each active user's home timeline was a list of tweet IDs in a Redis cluster capped at 800 entries and replicated three times, that fan-out could take minutes for accounts with tens of millions of followers, and that tweets from the largest accounts were merged in at read time rather than fanned out [High Scalability 2013]. In August 2013 Twitter reported a record of 143,199 tweets per second during a television broadcast in Japan, against a then-typical average of about 5,700 tweets/s and more than 500 million tweets per day [Krikorian 2013]. *Evidence: Primary* for the record and averages (Twitter engineering blog) and the talk; *Secondary* for the Redis details (third-party summaries of the talk).

53.8.4 Capacity estimation

Assumptions (teaching values informed by the published figures above): 250 million DAU; 500 million tweets/day; a design burst of 150,000 tweets/s lasting 30 s; 400 million users active in the last 30 days, whose timelines are cached; an average **delivered** fan-out of 100 timeline inserts per tweet (after excluding inactive followers and large accounts); 30 home-timeline loads per DAU per day; peak-to-average ratio 3 for reads; 5 indexable entities (hashtags, phrases) per tweet; search keeps the last 7 days in memory.

WORKED EXAMPLE

Worked example — Timeline fan-out and reads.

1. Tweets: $500 \times 10^6 / 86,400 \approx 5,790$/s average, consistent with the published 5,700.
2. Timeline inserts: $500 \times 10^6 \times 100 = 5 \times 10^{10}$/day ≈ **579,000/s** average.
3. Burst: 150,000 tweets/s × 100 = 15 million inserts/s. Over 30 s, $150,000 \times 30 \times 100 = 450$ million inserts. With a fan-out tier provisioned for 2 million inserts/s, the backlog drains in $450 \times 10^6 / 2 \times 10^6 = 225$ s: delivery is minutes late during the spike, while posting itself stays fast because fan-out is asynchronous.
4. Timeline reads: $250 \times 10^6 \times 30 = 7.5 \times 10^9$/day ≈ 86,800/s average, **260,000/s at peak**.
5. Timeline cache: 400 million users × 800 entries × 16 bytes (tweet ID, author ID and flags) = **5.1 TB**; 15.4 TB at three replicas, in memory.

Interpretation. The cache is modest; the write rate and its bursts are the challenge. *Engineering implication.* Decouple posting from fan-out with a durable queue, size fan-out for sustained load plus a drain target, not for the peak second.

WORKED EXAMPLE

Worked example — Search index and trends.

1. Search corpus: 7 days × 500 million = 3.5 billion tweets. At 15 indexed terms per tweet and about 4 bytes per compressed posting (§16.3.4–§16.3.5), $3.5 \times 10^9 \times 15 \times 4 = 210$ GB per index replica: an in-memory index fits on a modest cluster.
2. Trend entities: $500 \times 10^6 \times 5 = 2.5 \times 10^9$/day ≈ 28,900/s average; 750,000/s during a 150,000 tweets/s burst.
3. Count-Min sizing per 5-minute window (§17.6.1): $N \approx 28,900 \times 300 = 8.7$ million events. With $\varepsilon = 10^{-5}$ the error bound is about 87 counts; $w = \lceil e/10^{-5} \rceil = 271,829$ and, for $\delta = 0.001$, $d = \lceil \ln 1,000 \rceil = 7$, so 1.9 million 4-byte counters ≈ **7.6 MB** per window.
4. Keeping 12 five-minute windows plus 24 hourly windows for the baseline: 36 sketches ≈ 274 MB per region of interest.

Interpretation. Search and trends are small in bytes but strict in freshness. *Engineering implication.* Both are in-memory streaming systems fed by the tweet log, not queries against the tweet database.

Table 53.24 — Capacity summary for the microblogging service.

Quantity	Value
Tweets	5,790/s average; 150,000/s design burst
Timeline inserts	579,000/s average; 450 M backlog per 30 s burst, drained in ≈ 4 min
Home-timeline reads	86,800/s average; 260,000/s peak
Timeline cache	5.1 TB (15.4 TB at RF 3)
Search index (7 days)	≈ 210 GB per replica
Trend entities	28,900/s average; Count-Min ≈ 7.6 MB per 5-min window

53.8.5 API design

```
POST /2/tweets                {text, media_ids?, reply_to?, client_tweet_id}   →
{tweet_id}
DELETE /2/tweets/{tweet_id}
GET  /2/timeline/home?max_id=<tweet_id>&since_id=<tweet_id>&count=20
                              → {tweets: [...], newest_id, oldest_id}
GET  /2/users/{id}/tweets?max_id=&count=20
GET  /2/search?q=<query>&max_id=&count=20&mode=latest|top
GET  /2/trends?location=<woeid>  → [{name, tweet_volume_estimate, rank}]
POST /2/users/{id}/following  {target_user_id}
```

Pagination uses `max_id` and `since_id`: because tweet IDs are Snowflake IDs that sort by time (§17.10.3), "older than X" and "newer than Y" are ID comparisons, stable even when new tweets arrive during scrolling [Twitter 2010].

53.8.6 Data model and database schema

```
# Tweet store (system of record): key-value / wide-column, sharded by tweet_id
tweet/{tweet_id} -> {author_id, text, created_at, reply_to, media[], entities[]}

# User timeline: sharded by author, newest first
user_tweets/{author_id} -> sorted set of tweet_id (desc)

# Social graph: both directions, sharded by the first ID
following/{user_id} -> set of user_id
followers/{user_id} -> set of user_id      # used by fan-out; huge for large accounts

# Home timeline cache (in memory, active users only)
home/{user_id} -> list of (tweet_id, author_id, flags), capped at 800

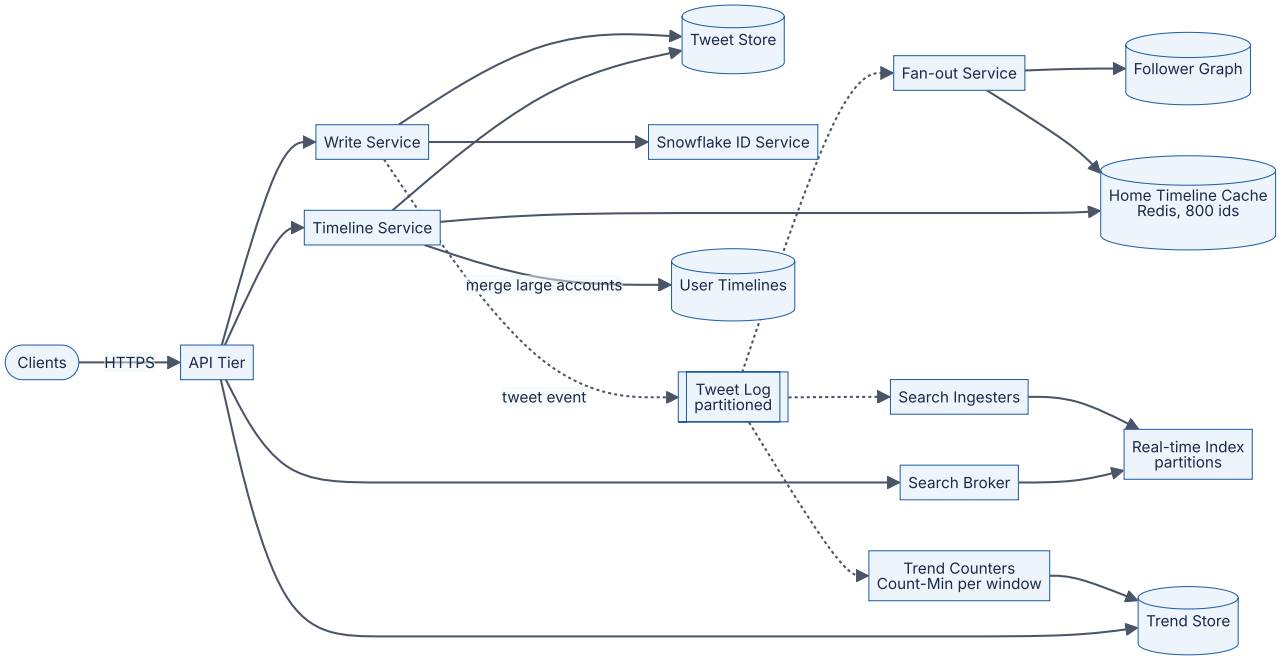
# Large-account registry
large/{author_id} -> true                  # authors excluded from fan-out
```

The tweet store needs high write throughput, point reads by ID and no joins: a wide-column or key-value store (§12.4, §12.6). The home timeline is a **cache**, not a source of

truth: it can be rebuilt from the graph and the user timelines, so it lives in memory with replication for availability rather than durability. The follower lists of large accounts are read once per tweet by fan-out and must be paged in chunks.

53.8.7 High-level architecture

Figure 53.17 — High-level architecture of the microblogging service.



Reading the diagram. A tweet is written synchronously to the **tweet store** with a **Snowflake ID** and acknowledged; a tweet event is then appended to a partitioned **tweet log**, the single river that feeds three asynchronous consumers (dotted). The **fan-out service** reads the author's followers from the **follower graph** and inserts the tweet ID into each active follower's **home-timeline cache**, skipping registered large accounts. **Search ingesters** tokenize tweets into in-memory **real-time index** partitions, and **trend counters** update per-window sketches that periodically publish to the **trend store**. On the read side, the **timeline service** reads a user's cached ID list, merges in recent tweets from followed large accounts' **user timelines**, and hydrates tweet bodies; the **search broker** scatters queries to index partitions and merges results (§16.7). Failure points: the log is the backbone (a log outage stops all three products from updating, though posting can continue if the store is up); fan-out lag delays timelines; an index partition loss reduces search recall until a replica takes over. Scaling: each consumer scales independently by adding partitions and instances.

53.8.8 Detailed component design

Home timeline: push with read-time merge for large accounts

The design applies §53.7.8 to a follower graph. Ordinary accounts' tweets are pushed: the fan-out service pages through the follower list in chunks (for example 5,000 at a time), issues pipelined `LPUSH` + `LTRIM 0 799` commands per follower to the shard holding that follower's list, and skips followers whose timelines are not cached (inactive for 30 days). Large accounts, above a follower threshold, are not fanned out; at read time the timeline service fetches the newest tweet IDs from the user timelines of the large accounts the reader follows and merges them with the cached list by ID order, which is time order because IDs are Snowflakes.

Three details matter in production:

1. **Cache misses rebuild.** A user returning after 30 days has no cached list; the timeline service rebuilds it by merging the recent user timelines of everyone they follow (a pull, once), then writes it back.
2. **Deletes and unfollows** are handled at read time: hydration drops deleted tweets and tweets from accounts no longer followed, and the list is cleaned lazily. Fan-out is never "undone" eagerly.
3. **Burst handling.** The tweet log absorbs spikes; fan-out workers drain it at a provisioned rate, and partitions are keyed by author so that one account's tweets stay in order.

> KEY CONCEPT
>
> **Key insight — The timeline cache is an index, not a database.** It stores only IDs, only for active users, only the newest 800, and it can always be rebuilt from durable sources. That is what makes it cheap to hold in memory and safe to lose a replica of.

The ranked "For You" timeline, which Twitter published in 2023, changes the read path rather than the write path: candidates come from in-network sources (accounts the user follows) and out-of-network sources (recommendations), and the published description extracts about 1,500 candidates per request and ranks them with a neural network of about 48 million parameters before applying filters and heuristics [Twitter 2023]. The funnel is the one sketched in §53.7.8 and detailed in Chapter 68.

Real-time search

Search over recent tweets has the opposite shape to web search: the corpus is small but changes every millisecond, and users want results seconds old, sorted mostly by time. Twitter's published system, **Earlybird**, kept recent tweets in in-memory inverted indexes

partitioned by document across many servers, with a front end scattering queries and merging results; indexing used a single writer with many concurrent readers per index segment, coordinated by memory barriers rather than locks, so that tweets were searchable within about 10 seconds [Busch et al. 2012] (see also §16.7).

The teaching design follows that shape:

1. **Partition by time, then by document.** Each index partition covers a time slice; within a slice, tweets are hash-partitioned across servers. New tweets go to the current slice; old slices are frozen, compacted and eventually dropped from memory to a disk-based archive index.
2. **Postings in arrival order.** Because tweet IDs increase with time, appending to postings lists keeps them sorted by recency for free; a "latest" query walks postings backward and stops after k hits (§16.5.6).
3. **Single writer, many readers.** One ingest thread per segment appends postings and publishes a "max visible document" pointer after each batch; readers never see a half-written posting. This avoids locks on the hot path, which is what makes 10-second freshness compatible with high query rates.
4. **Scatter-gather with deadlines.** The broker queries all partitions of the recent time slices in parallel and returns what arrived before the deadline (§16.7.3); "top" mode adds a lightweight relevance score (engagement, author quality) at merge time.

Trends: heavy hitters over sliding windows

A trend is not the most frequent topic ("#music" is always frequent) but the one whose rate has risen most against its own baseline. Three components compute it:

1. **Counting.** Trend counters consume the tweet log, extract entities and update a Count-Min sketch for the current 5-minute window, plus a small heap of candidate heavy hitters (§17.6.2). Sketches from parallel counters merge by addition.
2. **Windows.** Closed windows are retained: the last 12 (one hour) for the "now" rate and hourly windows for a 24-hour baseline (sliding windows, §29.8.2).
3. **Scoring.** For each candidate, compare the current count with the baseline mean using a variance-aware score, filter spam and near-duplicates, and publish the top k per location every minute.

FORMULA

Trend score (Poisson-style z-score)

$$z = \frac{c_{\text{now}} - \bar{c}_{\text{base}}}{\sqrt{\bar{c}_{\text{base}} + 1}}$$

Symbol	Meaning	Units
c_{now}	Count of the term in the current window	mentions/window
$\bar{c}_{\text{base}}$	Mean count per window over the baseline windows	mentions/window
z	Standardized surprise; higher means more unusual	dimensionless
$+1$	Smoothing so that brand-new terms do not divide by zero	mentions/window

WORKED EXAMPLE

Worked example — A new topic beats a large steady one.

1. "#music": $c_{\text{now}} = 420$, $\bar{c}_{\text{base}} = 400$: $z = 20/\sqrt{401} \approx 1.0$. Large, but not trending.
2. "#eclipse": $c_{\text{now}} = 180$, $\bar{c}_{\text{base}} = 0$: $z = 180/\sqrt{1} = 180$. Small, but extremely unusual.
3. "#football": $c_{\text{now}} = 400$, $\bar{c}_{\text{base}} = 250$: $z = 150/\sqrt{251} \approx 9.5$. A genuine rise on a large base.

Interpretation. Dividing by the square root of the baseline (the standard deviation of a Poisson count) lets small, sudden topics compete fairly with large ones.
Engineering implication. Require a minimum absolute count and a Count-Min error bound well below it (87 counts in §53.8.4, so require, say, at least 500), or sketch noise will create false trends.

```
        import math
        import random
        from collections import Counter, deque

        class TrendDetector:
            """Counts terms in fixed windows; scores the newest window against a base-
line."""
            def __init__(self, baseline_windows=12):
                self.current = Counter()
                self.history = deque(maxlen=baseline_windows)   # older windows, newest
last

            def add(self, term):
                self.current[term] += 1

            def close_window(self):
                self.history.append(self.current)
                self.current = Counter()

            def top(self, k=3, min_count=50):
                *base, now = self.history
                scores = {}
                for term, c in now.items():
                    if c < min_count:
                        continue                                  # ignore tiny counts:
too noisy
                    mean = sum(w[term] for w in base) / len(base)
                    scores[term] = (c - mean) / math.sqrt(mean + 1)   # Poisson-style z-
score
                return sorted(scores.items(), key=lambda kv: -kv[1])[:k]

        random.seed(1)
        steady = {"#music": 400, "#news": 300, "#football": 250}       # per-window
rates
        det = TrendDetector()
        for window in range(13):
            for term, rate in steady.items():
                for _ in range(random.randint(int(rate * 0.9), int(rate * 1.1))):
                    det.add(term)
            if window == 12:                                          # a sudden event
                for _ in range(180):
                    det.add("#eclipse")
                for _ in range(150):
                    det.add("#football")
            det.close_window()

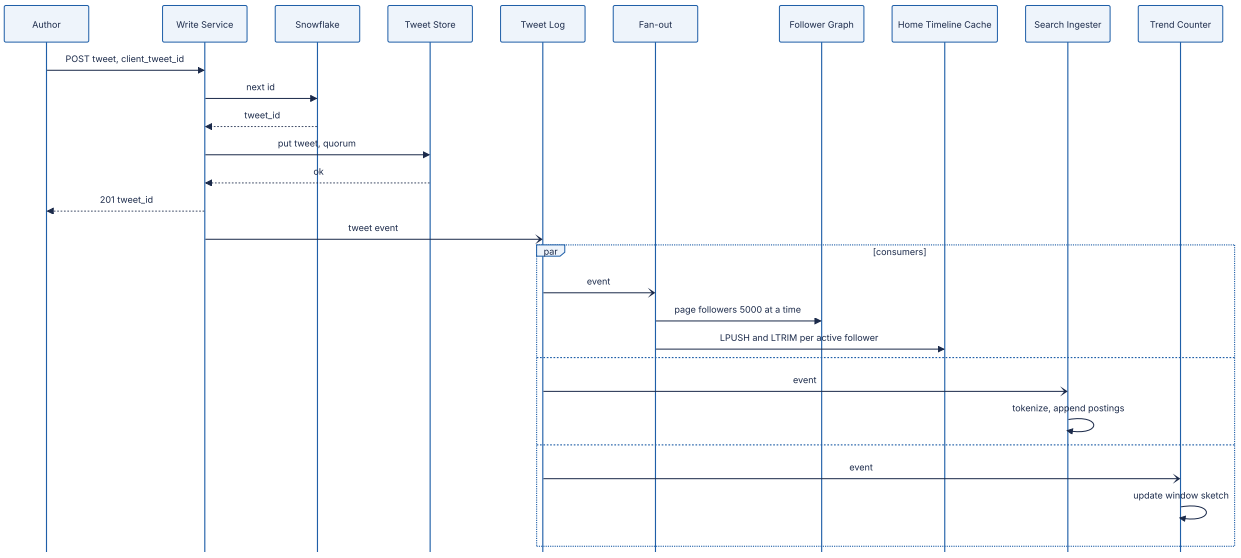
        for term, z in det.top():
            print(f"{term:10s} z = {z:6.1f}")
        # prints:
        # #eclipse   z =  180.0
        # #football  z =    9.6
        # #news      z =    1.4
```

What to notice:

- `#music`, the most frequent term, does not appear among the top three: it is large but not rising.
- Exact `Counter`s keep the example readable; in production each window is a Count-Min sketch plus a candidate heap, and `top` scores only heap candidates, because a sketch cannot enumerate its keys.
- The baseline here is the previous 12 windows; a production system also compares with the same hour on previous days to avoid “trending” every morning.

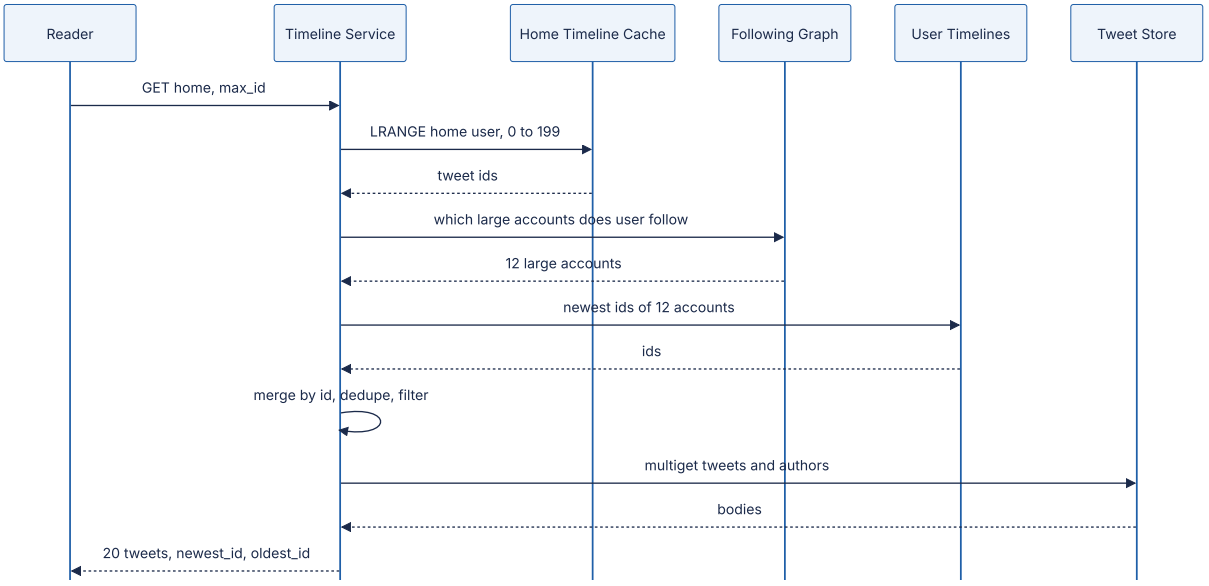
53.8.9 Data flow

Figure 53.18 — Write path: posting a tweet.



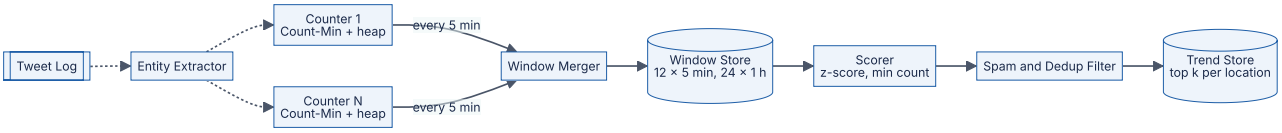
Reading the diagram. The author’s request is synchronous only up to the durable write of the tweet with its Snowflake ID; the client gets `201` within tens of milliseconds regardless of follower count. The tweet event then feeds three independent consumers in parallel (`par` block), each at its own pace: fan-out pages through followers and pushes the ID into active followers’ cached timelines (skipping large accounts entirely); the search ingester appends postings to the current index segment; the trend counter updates the current window’s sketch. Failure points: a fan-out backlog delays timelines but not search or trends; a crashed consumer resumes from its committed log offset, and duplicate inserts into a timeline are removed at read time by tweet ID.

Figure 53.19 — Read path: loading the home timeline.



Reading the diagram. The timeline service reads the cached list (one memory read on one shard), looks up the few large accounts the reader follows (cached per user), reads their newest tweet IDs from user timelines, which are hot keys replicated across caches, and merges everything by ID, which is time order. It then filters deleted or blocked content and hydrates bodies with one multiget. All steps are synchronous and in memory. Failure points: a cache miss triggers a rebuild by pull (slower, once); a missing large-account read degrades to “no tweets from that account in this load”; hydration misses fall through to the tweet store.

Figure 53.20 — Trend pipeline over sliding windows.



Reading the diagram. The entity extractor consumes tweets asynchronously and partitions entities across counter instances, each maintaining a Count-Min sketch and a candidate heap for the current window. Every five minutes the merger adds the sketches (identical hash functions make this exact) and unions the candidate heaps, storing the closed window. The scorer compares the newest window with the baseline windows, the filter removes spam bursts and near-duplicate phrasings, and the result is published per location. Failure points: a crashed counter loses one partial window, which slightly undercounts until the next window; a skewed partition is avoided by hashing entities rather than routing by location. Scaling: add counters; memory per window is fixed by ε and δ, not by the number of distinct terms.

53.8.10 Bottlenecks

1. **Fan-out bursts** during global events: the log absorbs them, and workers drain at a provisioned rate; consider temporarily raising the large-account threshold during spikes to cut inserts.
2. **Follower lists of large accounts** (tens of millions of IDs): read in pages and never fanned out.
3. **Search tail latency** across many partitions: replicas, deadlines, and fewer partitions per query by restricting "latest" queries to recent time slices.
4. **Trend manipulation:** coordinated accounts can push a term; filter by account quality and distinct-author counts (HyperLogLog per candidate, §17.5).
5. **Hot tweets** (a viral tweet read by millions): replicate the tweet body across cache shards (§20.15).

53.8.11 Failure scenarios

Table 53.25 — Failure scenarios for the microblogging service.

What fails	Impact	Detection	Recovery	Prevention
Timeline cache shard lost	Its users see slow first load	Shard health, miss rate	Promote replica; else rebuild lists by pull	Three replicas; rebuild path tested
Fan-out backlog	Timelines minutes late	Log consumer lag	Add workers; raise large-account threshold	Provision for drain target
Tweet log outage	Timelines, search, trends stop updating	Produce errors	Buffer in write service; replay	Replicated log (§31.9)
Index partition loss	Lower search recall	Missing-partition responses	Replica takeover; rebuild from log	Replicas per partition
Snowflake clock step backward	ID generation pauses	Generator errors	Wait or fail over to another worker	NTP slewing (§17.10.3)
Trend spam attack	Bogus trend displayed	Distinct-author ratio, reports	Remove; block term	Quality filters before publish
Large-account read slow	Some tweets missing in a load	Merge timeouts	Return without them	Replicate hot user timelines

53.8.12 Scaling strategy

At 10×. Timeline inserts average 5.8 million/s and the cache grows to about 51 TB at three replicas. What breaks first is burst drain time (bursts ten times larger) and memory cost. Changes: lower the large-account threshold so fewer inserts are produced, shorten cached lists for light readers, compress lists, and move cold users to rebuild-on-demand.

At 100×. Push becomes the exception rather than the rule: timelines become mostly ranked and assembled at read time from candidate sources, as in Twitter's 2023 description, with push retained for the in-network candidates of active users. Search moves to more time slices with tiered memory and flash; trends are computed per region with global merge.

53.8.13 Trade-offs

Table 53.26 — Trade-offs in the microblogging design.

Decision	Chosen	Gave up	Why acceptable
Timeline	Push with large-account merge	Uniform simplicity	Bounded inserts; fast reads
Timeline storage	In-memory IDs, 800 cap, active users only	Unlimited scrollback from cache	Older tweets come from user timelines
Search	In-memory, time-partitioned index	Full history in the fast path	Users search recent events; archive serves the rest
Trends	Approximate counts, windowed z-scores	Exact counts	Error bound far below thresholds
IDs	Snowflake, time-ordered	Unpredictable IDs	Merge and paginate by ID without timestamps
Ordering	Approximate time order across authors	Strict global order	Clock skew of milliseconds is invisible

53.8.14 Alternative designs

1. **Pure pull timelines.** Simpler writes, no backlog, but each read merges hundreds of user timelines; viable with an in-memory index as in §53.7.
2. **General-purpose search engine** (Elasticsearch with a 1 s refresh, §16.10). Easier to operate, adequate at smaller scale; harder to reach high ingest and query rates with second-level freshness on a fast-changing corpus.
3. **Exact counting for trends** with a stream processor keyed by term (§29.9). Exact, but memory grows with distinct terms, which spam can inflate without bound.

53.8.15 Interview discussion

Table 53.27 — 45-minute pacing plan for "Design Twitter".

Minutes	Activity	Output
0–5	Scope: timeline, search, trends; ranking?	Three products, one stream
5–10	Capacity	5.8 k tweets/s, 150 k burst, 579 k inserts/s, 260 k reads/s
10–18	Architecture	Figure 53.17 with the tweet log at the center
18–30	Timeline deep dive	Push, 800-ID cache, large-account merge, rebuild
30–38	Search and trends	Time-partitioned index; Count-Min windows, z-score
38–45	Failures and trade-offs	Bursts, cache loss, spam

Likely follow-ups: *"A user with 100 million followers tweets; what happens?"* — Nothing fans out; followers merge the tweet at read time from the account's user timeline, which is a hot, replicated key. *"How do you show 'N new tweets' at the top?"* — Poll with `since_id`, or a lightweight push of the newest ID. *"How quickly is a tweet searchable?"* — Seconds: the ingester appends postings to the in-memory segment and publishes a visibility pointer. *"Why are trends not just the most frequent hashtags?"* — Because frequency without a baseline surfaces the same topics every day.

A **senior** answer separates the three products and explains push with large-account merge. A **staff** answer quantifies burst drain time, sizes the cache and sketches, explains why the timeline is a rebuildable index, and connects each product to the data structure and freshness it needs.

53.8.16 Production considerations

- **Observability.** Fan-out lag, timeline cache hit and rebuild rates, post-to-searchable delay, query latency by partition, trend pipeline delay.
- **Security and abuse.** Rate limits on posting and following (§22.3); manipulation defenses; protected accounts excluded from search at ingest and at query time.
- **Cost.** Memory for timeline caches and indexes dominates.
- **Operations.** Rebuild paths for every derived structure (timelines, indexes, trend windows) must be exercised regularly by replaying the log, because they are the recovery plan.

53.9 Summary and revision notes

SUMMARY

- **Chat (§53.4):** single-writer sequence numbers per conversation; idempotent sends via a client message ID; lossy live delivery with gaps closed by ranged reads; receipts and unread counts as watermarks (8.5× less traffic); one copy per conversation in a bucketed wide-column store that ends up storage-bound.
- **WhatsApp (§53.5):** keys and history live on devices; the server runs a public-key directory and relays per-device ciphertext, deleting on acknowledgment. X3DH gives asynchronous session setup; the Double Ratchet gives forward secrecy and post-compromise recovery. Multi-device costs about $2d - 1$ ciphertexts per message; sender keys make group sends $O(1)$ but re-keying $O(n^2 d)$. Metadata stays visible.
- **Instagram (§53.6):** presigned uploads, idempotent asynchronous resizing and immutable CDN URLs; shard embedded in a time-ordered 64-bit ID; story expiry by read filter; exact per-user like state, approximate coalesced counts (decisive for hot keys only).
- **News Feed (§53.7):** follower count cancels from the push-to-pull ratio; celebrities hurt push through bursts and writes to inactive followers. Read-time aggregation over an in-memory activity index suits ranked, bounded-graph feeds; a TAO-style cache absorbs the graph reads; ranking is a staged funnel.
- **Twitter/X (§53.8):** one tweet log feeds push timelines (rebuildable 800-ID lists, large accounts merged at read time), a time-partitioned in-memory search index and windowed heavy-hitter trends; Snowflake IDs make time order an integer comparison.
- **Across cases:** separate the durable commit point from asynchronous fan-out; derive caches and indexes from a log so they can be rebuilt; size by the hottest key and the burst, not the average.

53.10 Knowledge checkpoint

1. Why does a chat service order messages per conversation rather than globally?
2. A client receives seq 41 and then seq 43. What should it do, and why is this safe?
3. How does a `client_msg_id` prevent duplicate messages when the chat service crashes after writing but before replying?
4. Why do watermarks reduce receipt traffic, and why are they safe to retry out of order?
5. In the chat estimate, why does the database become storage-bound rather than write-bound?
6. What does the WhatsApp key directory store, and what is its one dangerous power?

7. What problem do one-time prekeys solve?
8. Distinguish forward secrecy from post-compromise security in the Double Ratchet.
9. With 1.6 devices per user, how many ciphertexts does a one-to-one message require under client fan-out?
10. Why does removing a member from a 1,024-member group cost about 1.7 million pairwise messages?
11. Why does the photo service create the post row before resizing finishes?
12. What do the 41, 13 and 10 bits of an Instagram-style ID encode, and why is the shard chosen from the author?
13. Why does write coalescing help a celebrity post enormously but the whole like system only a little?
14. Show that the per-author push-to-pull ratio does not depend on follower count. What, then, makes celebrities expensive for push?
15. What do TAO's leader and follower cache tiers each do?
16. Why is Twitter's home-timeline cache safe to lose?

Answers

1. Users only compare order within one conversation, and per-conversation order needs one writer per conversation, which partitions perfectly; global order would need a global sequencer or consensus for every message.
2. Treat it as a gap: fetch messages after 41 from the store (or learn that 42 is a hole) before applying 43. Safe because the store is the source of truth and the client ignores duplicates by `seq`.
3. The retry carries the same `(sender, client_msg_id)`; the dedup table returns the already assigned `seq` instead of storing a second copy.
4. One watermark per member summarizes all earlier messages, so one event replaces many; they are monotonic, so `max(old, new)` makes late or duplicate updates harmless.
5. Writes are about 1 million/s (≈ 124 nodes), but storage grows by 1.31 PB/year (≈ 329 nodes after year one) and keeps growing.
6. Public identity keys, signed prekeys, one-time prekeys and signed device lists. It could substitute an attacker's key; security codes and key transparency detect this.
7. They let a sender establish a session with a recipient who is offline, with a fresh Diffie–Hellman input used only once.
8. Forward secrecy: compromising current keys does not reveal past messages (symmetric ratchet deletes old keys). Post-compromise security: after a new Diffie–Hellman exchange, an attacker who stole state loses access to future messages.
9. $d + (d - 1) = 1.6 + 0.6 = 2.2$.
10. Each of the 1,023 remaining members must send its new sender key to the other 1,022 members' devices (×1.6) and its own other devices:
    $1,023 \times (1,022 \times 1.6 + 0.6) \approx 1.67$ million.

11. So the author gets a `post_id` and sees the post at once from the local copy (read-your-writes), while resizing proceeds asynchronously and the post goes live to others when ready.
12. Milliseconds since a custom epoch, logical shard, per-shard sequence. The author's shard keeps a profile grid on one shard as a single range scan.
13. Coalescing reduces each key's writes to at most $1/T$; a hot post drops from thousands to one per second, but most posts receive about one like per interval and gain nothing.
14. $W/R = pF/(aFr) = p/(ar)$. Push turns one post into a synchronized burst of F distinct writes (100 s for 100 million at 1 M/s) and writes to inactive users; pull reads one hot, cached list.
15. Followers serve reads and forward misses and writes; the leader for a shard is the only cache that queries or writes the database, sends invalidations to followers, and protects the database from stampedes.
16. It holds only IDs for active users and can be rebuilt from the follow graph and user timelines; replicas exist for availability, not durability.

53.11 Interview questions

Basic

Q1. Design the "unread count" badge for a chat app with groups of up to 500 members. **Answer.** Do not store and increment counters per member. Store `last_seq` per conversation and `read_upto` per member; unread = `last_seq − read_upto` minus the user's own messages. The badge total is the sum over conversations changed since the last sync. This is exact, cheap to update (one watermark write when the user reads) and safe under retries because watermarks only increase.

Q2. Why should photo uploads go directly to object storage? **Answer.** A 3 MB upload over a slow mobile link holds a connection for seconds; at thousands per second that ties up application servers and memory for no benefit. A presigned URL scoped to one key, type, size and lifetime lets the client upload straight to storage, which is built for large, resumable transfers, while servers handle only metadata and validation runs asynchronously before the post goes live.

Intermediate

Q3. A news feed product has 1 billion DAU, authors average 300 followers, and 1,000 accounts have more than 50 million followers. Choose a fan-out strategy. **Answer.** Compute push load: ordinary posts × 300 is affordable (a few million inserts/s), but each large-account post creates a 50-million-write burst, a minute or more of delivery skew, and many writes to inactive users. Use push below a threshold and pull for large accounts, merging

at read time from a hot, replicated per-author list. Choose the threshold by measuring the knee (the simulation in §53.7.8): where pushed inserts stop falling quickly and pulled lists per load start rising. If the feed is ranked and the graph is bounded, also consider read-time aggregation over an in-memory activity index.

Q4. How does WhatsApp deliver media without the server being able to read it, and what does the server lose? **Answer.** The device encrypts the file with a random key, uploads the ciphertext once and sends the key, hash and pointer inside an E2E-encrypted message to each recipient device; recipients download, verify the hash and decrypt. The server cannot transcode, thumbnail, scan or deduplicate by content (only by identical ciphertext, as in forwards), so compression and thumbnails move to the device and abuse detection relies on metadata and reports.

Advanced

Q5. Your chat service must add multi-region support with users in one group spread across continents. Where does ordering live? **Answer.** Each conversation has a home region holding its sequencer and primary replicas, chosen by where most members are (§44.6.4). Remote members send to the home region (one cross-region round trip for the send acknowledgment) and read from local replicas with replication lag. Moving a conversation's home requires a fenced handover of the sequencer (lease epoch) so two regions never number messages at once. Per-conversation order is preserved; there is still no global order, which no user needs.

Q6. Twitter's timeline fan-out falls 20 minutes behind during a global event. What do you do now, and what do you change afterward? **Answer.** Now: add fan-out workers, temporarily lower the large-account threshold so more authors are merged at read time (cutting inserts), skip timelines of users inactive for days, and make the client poll with `since_id` so it still sees new tweets through read-time merging. Afterward: provision fan-out for a drain-time target (for example, a 30 s, 25× burst drained in under 5 minutes), make the threshold dynamic on lag, and alert on lag before users notice.

53.12 Practical exercises

1. **Sequencer failover.** Extend the §53.4.8 code so the server leases blocks of 100 sequence numbers and a crash discards the rest of the block. Change `Device` so it asks the server which numbers in a gap exist, and test that clients step over holes without stalling.
2. **Ciphertext calculator.** Write a script that, for $d \in \{1, 1.5, 2, 3\}$ and $n \in \{10, 100, 256, 1,024\}$, prints per-message uploads and deliveries and the re-key cost after a removal. At what group size does the re-key cost exceed one day of that group's normal traffic, assuming 200 messages per day?

3. **Counter coalescing.** Simulate a Zipf-distributed stream of likes over one million posts and measure database writes for flush intervals $T \in \{0.1, 1, 10\}$ s. Plot the reduction for the top 100 posts versus all posts.
4. **Fan-out knee.** Re-run the §53.7.8 simulation with Pareto shapes 1.1, 1.5 and 2.0. How does the best threshold move as the tail gets heavier?
5. **Trends with sketches.** Replace the `Counter` windows in §53.8.8 with Count-Min sketches (width 2,000, depth 4) plus a top-k heap. Measure false trends caused by sketch noise as you lower `min_count`.

53.13 Design challenges

1. **Slack-style workspace chat.** Channels with up to 100,000 members, threads, edits and enterprise retention policies. Decide how ordering works for threads inside channels, how to keep “unread” cheap for huge channels and how retention deletes data that is also in search indexes.
2. **E2EE for 10,000-member communities.** Compare sender keys with MLS for this size, estimate re-key traffic under 1 % daily churn, and design how new members obtain recent history without the server reading it.
3. **Live-event feed.** A sports app where 50 million users follow one match and 1,000 commentators post during it. Design delivery so every fan sees a post within 2 s, and explain why neither pure push nor pure pull works.

53.15 Open verification items

- WhatsApp: 30-day retention of undelivered messages (privacy policy wording); Noise-based transport and media-encryption details against the current white paper; group limit of 1,024 (November 2022) confirmed only via news reports; 2014 server counts (≈ 550 servers, ≈ 150 chat servers at ≈ 1 M connections) from a third-party summary.
- Meta posts on encrypted backups (2021) and key transparency (2023): exact titles and URLs not fetched.
- Twitter: Redis timeline details (800 cap, three replicas) from secondary summaries; exact title/URL of Krikorian's August 2013 post; 2023 algorithm figures (1,500 candidates, ~48 M parameters) seen only in search snippets.
- Facebook: Multifeed 40 %/10 % figures and the 2012 "≈ 40 requests per query" detail (secondary); author list and URL of Lada et al. 2021.
- Discord 2023: 177 → 72 nodes confirmed via secondary summaries.
- Instagram 2016 ranked-feed post title; Instagram 2015 like-count and lease details confirmed via search snippets only.
- Capacity assumptions (DAU, messages per day, device counts) are illustrative, not company figures.

Chapter 54 — Case Studies III: Media and Files

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 5 h

Video, music and files are the heaviest, mostly immutable things people move across the Internet, and each system in this chapter has one hard problem that dominates its design. **YouTube** must transcode hundreds of hours of upload per minute cheaply enough to keep the long tail. **Netflix** must start playback in seconds while its control and data planes live in different places. **Spotify** must feel local, enforce licensing on devices it does not control, and count plays accurately enough to pay rights holders. **Google Drive** must let many people edit one document at once and decide, on every request, who may see what. **Dropbox** must keep many devices' folders identical without ever losing an edit.

54.1 Learning objectives

After this chapter you should be able to:

- Design a chunked, resumable upload path and a transcoding pipeline expressed as a DAG of jobs, and size its compute, storage and egress with explicit assumptions.
- Decide which codecs and renditions to produce for a video from its expected popularity, using a break-even calculation of encoding cost against delivery savings.
- Separate a streaming service into a cloud-hosted control plane and an ISP-embedded data plane, and trace the playback-start path from manifest to license to first byte.
- Apply chaos engineering and regional evacuation to a streaming control plane, and explain why running streams survive control-plane failures.
- Design client-side prefetch and caching, offline-download licensing, collaborative playlists and an exactly-once-ish play-count pipeline for a music service.
- Design a file metadata service, a relationship-based sharing model and a real-time collaborative editor, and compare operational transformation with CRDTs at a conceptual level.
- Design a file-synchronization engine: block-level chunking and deduplication, delta sync, a per-namespace change journal, conflict handling and change notification by long polling.
- Lead a 45-minute interview on any of these five systems, spending most of the time on the problem that distinguishes it.

54.2 Prerequisites

- Capacity estimation — Chapter 4 and §2.11; every case applies these methods.
- REST and gRPC API design — §8.6, §8.8; each case's API section uses them.
- Authorization models and Zanzibar — §8.12; Google Drive sharing applies them directly.
- Long polling, WebSockets and mobile push — §9.4, §9.6, §9.8; Dropbox change notification and Drive collaboration sessions use them.
- Encryption at rest, envelope encryption and KMS — §10.9; all five cases store user or licensed content.
- Relational and NoSQL stores — Chapters 11 and 12; metadata stores in every case.
- Partitioning and consistent hashing — §14.6–§14.8; metadata, counters and block indexes are partitioned.
- Object storage, erasure coding, multipart upload, chunking and deduplication, storage tiers — §15.4, §15.6, §15.8, §15.9; the storage layer of every case.
- Search — Chapter 16; Spotify and Drive search.
- HyperLogLog and Count-Min sketch — §17.5, §17.6; view and play counting.
- Caching and hot keys — §20.3, §20.15; metadata caching and viral content.
- CDNs, video delivery and Netflix Open Connect — §21.8, §21.10; YouTube and Netflix delivery.
- Conflict resolution and CRDTs — §27.14; Drive editing and Dropbox conflicts.
- Stream processing — §29.8–§29.9; view and play counting.
- Delivery guarantees, transactional outbox, exactly-once and idempotent consumers — §30.8, §32.5, §32.9, §32.10; counting pipelines and sync commits.
- Chaos engineering — §39.11; Netflix resilience.
- Regional failover and evacuation — §44.11; Netflix and every global control plane.
- Distributed scheduling — Chapter 46 and the job-scheduler case in §52.9; transcoding job scheduling.

54.3 How to use these case studies

Work each case with the method of §52.3: state the problem and its scope, pin down functional and numeric non-functional requirements, estimate capacity before drawing anything, sketch the API and data model, then draw the high-level architecture and spend most of your effort on the two or three components that make this system hard. The cases in this chapter share a storage substrate (object storage with erasure coding, §15.6) and a delivery substrate (CDNs, Chapter 21), so do not re-derive those; name them, cite them and move on to what is distinctive: the transcoding DAG for YouTube, the control-plane/data-plane split for Netflix, client caching and royalty counting for Spotify, sharing and concurrent editing for Google Drive, and the sync engine for Dropbox. Every archi-

tecture below is a teaching design labeled *Evidence: Illustrative*; facts about the real companies appear only in `industry` callouts with their published sources.

54.4 YouTube

54.4.1 Problem statement

Design a user-generated video platform in the style of YouTube: anyone can upload a video of almost any length and format from a phone or a studio, and within minutes anyone in the world can watch it at a quality matched to their device and network. The service must keep every upload forever, even though most videos are watched a handful of times while a tiny fraction are watched billions of times.

Think of a print shop that reprints every manuscript in several editions and keeps the originals forever; most sell three copies and a few sell millions, so its economics depend on not typesetting every edition up front. The hard problem is the **upload and transcoding pipeline**: a resumable upload that survives flaky mobile networks, followed by a directed acyclic graph (DAG) of encoding jobs, run in parallel over segments of the video, whose outputs are chosen according to how popular the video is likely to become.

DEFINITION

Definition — Transcoding. Decoding a video from its uploaded format (the **mezzanine** or source file) and re-encoding it into one or more target formats, each defined by a codec, a resolution, a frame rate and a target bitrate. A set of renditions of one video at increasing bitrates is a **bitrate ladder** (§21.8.1).

DEFINITION

Definition — Group of pictures (GOP) and closed GOP. Encoded video consists of **keyframes** (I-frames), which can be decoded alone, and predicted frames that reference other frames. A GOP is the run of frames from one keyframe to the next. A **closed GOP** references no frame outside itself, so a segment that starts at a closed-GOP keyframe can be encoded, stored and decoded independently of its neighbors. This independence is what makes parallel segment encoding and adaptive streaming possible.

54.4.2 Functional requirements

1. **Upload.** Authenticated creators upload files from 1 MB to 256 GB over unreliable networks; uploads resume after interruption without restarting.

2. **Process.** Each upload is validated, scanned (policy and copyright matching), transcoded into a bitrate ladder of streamable renditions, and given thumbnails, captions (automatic speech recognition) and metadata.
3. **Publish.** The creator sets title, description, visibility (public, unlisted, private) and a publish time; the video becomes watchable when the first playable rendition exists.
4. **Watch.** Viewers stream with adaptive bitrate on web, mobile and TV clients, seek anywhere, and resume where they left off.
5. **Count.** Every video shows a view count and like count; creators see analytics (views, watch time, audience retention) with a delay of minutes to hours.
6. **Discover.** Search, channel pages and recommendations (the recommender itself is Chapter 81).
7. Out of scope: live streaming (mention the differences in §54.4.14), comments, monetization and ads.

54.4.3 Non-functional requirements

Table 54.1 — YouTube teaching design: non-functional targets.

Property	Target	Why
Watch availability	99.99% of playback starts succeed	Watching is the product; 52 min/yr of total failure is the budget
Upload availability	99.9% (resumable, so short outages only delay)	Creators retry; a lost upload session is the real failure
Playback start latency	p50 < 1 s, p99 < 2.5 s to first frame	Abandonment rises steeply with start delay
Rebuffer ratio	< 0.5% of watch time	Measured per session by the player
Time to first playable rendition	p50 < 2 min for a 10-minute video; full ladder < 30 min	Creators expect to share quickly
Durability of originals	99.999999999% (11 nines) per object per year	Originals are irreplaceable; renditions can be regenerated
Metadata consistency	Read-your-writes for the creator; eventual (seconds) for viewers	Creators must see their edits; viewers tolerate seconds of lag
View counts	Eventually consistent, minutes of lag, < 0.1% error after validation	Counts are public and monetized, so spam must be filtered

The durability target is set on originals only. A rendition is a pure function of an original and an encoding recipe, so losing one is a recompute, not a data loss. This single observation drives the storage design in §54.4.8.

54.4.4 Capacity estimation

All figures use decimal units (1 PB = 10^{15} bytes) and are teaching assumptions sized to the publicly stated order of magnitude: YouTube has said that more than 500 hours of video are uploaded every minute and, in 2017, that people watch over a billion hours a day [Goodrow 2017]. Treat both as round inputs, not current measurements.

WORKED EXAMPLE

Worked example — Upload ingest and original storage. Assumptions: 500 hours of video uploaded per minute; average source bitrate 10 Mb/s (mostly 1080p phone video); average video length 6 minutes.

1. Video-seconds uploaded per wall-clock second: $500 \times 3,600/60 = 30,000$ s/s.
2. Average ingest bandwidth: $30,000 \times 10$ Mb/s $= 300,000$ Mb/s $= 300$ Gb/s; at a 2× daily peak, 600 Gb/s.
3. Hours uploaded per day: $500 \times 60 \times 24 = 720,000$ h.
4. Uploads per day: $720,000 \times 60/6 = 7.2$ million videos, about 83 uploads/s on average.
5. Original bytes per day: $720,000 \times 3,600 \times 10^7/8 = 3.24 \times 10^{15}$ B $= 3.24$ PB/day.
6. Originals per year: $3.24 \times 365 = 1,183$ PB ≈ 1.18 EB/yr of logical data; with erasure coding at 1.5× overhead (§15.6), about 1.8 EB/yr of raw disk.

Interpretation. The upload rate in *requests* is tiny (83/s); the upload rate in *bytes* is enormous. **Engineering implication.** Uploads must bypass application servers and go straight to an upload front end backed by object storage, and the original archive is an exabyte-per-year cold-storage problem.

WORKED EXAMPLE

Worked example — Rendition storage and transcoding compute. Assumptions: an H.264 ladder of six renditions at 0.4, 0.8, 1.5, 3.0, 4.5 and 6.0 Mb/s (sum 16.2 Mb/s, the ladder of §21.8.2); a VP9 ladder at 60% of H.264 bitrates (sum 9.72 Mb/s); encoding cost 4 core-seconds per video-second for the whole H.264 ladder and 20 core-seconds per video-second for the VP9 ladder (VP9 encoders are slower).

1. Eager H.264 ladder bytes per day: $720,000 \times 3,600 \times 16.2 \times 10^6/8 = 5.25 \times 10^{15}$ B $= 5.25$ PB/day, more than the originals.
2. Eager H.264 compute: $30,000$ video-s/s $\times 4 = 120,000$ cores busy continuously, about 1,900 servers of 64 cores at 100% utilization; at a realistic 60% utilization and 2× peak, about $1,900 \times 2/0.6 \approx 6,300$ servers.
3. VP9 for *every* upload would add $30,000 \times 20 = 600,000$ cores, five times the H.264 cost, and another 3.1 PB/day of storage.

Interpretation. Encoding every codec for every upload multiplies transcoding compute by six and adds 60% to rendition storage, mostly for videos almost nobody watches. **Engineering implication.** Encode a universally playable ladder eagerly and the expensive codecs lazily, when a video's views justify them; §54.4.8 makes the break-even precise.

WORKED EXAMPLE

Worked example — Watch egress and view events. Assumptions: 1 billion watch-hours per day; average delivered bitrate 2.5 Mb/s; average view lasts 6 minutes; the player sends a watch-time heartbeat every 30 s; peak-to-average ratio 2.

1. Average egress: $10^9 \times 3,600 \times 2.5 \times 10^6/86,400 = 1.04 \times 10^{14}$ b/s ≈ 104 Tb/s; peak about 208 Tb/s.
2. Views per day: $10^9 \times 60/6 = 10^{10}$; average $10^{10}/86,400 = 115,700$ views/s; peak about 231,000 views/s.
3. Heartbeats per day: $10^9 \times 3,600/30 = 1.2 \times 10^{11}$; average 1.39 million/s; peak about 2.8 million events/s.
4. Playback-start API calls: one per view plus manifest fetch, about 230,000 RPS at peak; metadata reads for watch pages and lists, assume 10 per view, about 2.3 million RPS at peak, almost all served from cache.

Interpretation. Egress dwarfs everything else and belongs to the CDN (Chapter 21); the event stream (millions per second) is the second-largest load and drives the counting design. **Engineering implication.** Keep video bytes entirely off the origin; design view counting as a stream-processing pipeline, never as row updates per view.

WORKED EXAMPLE

Worked example — Metadata and cache size. Assumptions: 7.2 million new videos/day; 2 KB of core metadata per video (title, description, owner, state, rendition list); 20% of each day's views go to videos uploaded in the last week; the hottest 1% of videos receive 80% of views.

1. New metadata per year: $7.2 \times 10^6 \times 365 \times 2,000 = 5.3 \times 10^{12}$ B $= 5.3$ TB/yr: small enough for a partitioned relational store (§14.6).
2. Total videos after ten years: about 26 billion, 53 TB of core metadata.
3. Metadata cache to cover 80% of views: 1% of 26 billion $= 263$ million videos $\times 2$ KB ≈ 530 GB, a modest distributed cache cluster (§20.14).

Interpretation. Metadata is small and highly skewed. **Engineering implication.** A cache tier of a few hundred gigabytes absorbs most watch-page reads; the hard problems are hot keys for viral videos (§20.15) and keeping counts off the metadata row.

54.4.5 API design

Uploads use a **resumable upload** protocol: the client first creates an upload session, then sends the file in chunks, each identified by its byte range, and can ask the server how many bytes it has received before resuming. Google's public APIs, including the YouTube Data API, use exactly this pattern: a POST that returns a session URI, then PUTs carrying `Content-Range` headers, with chunk sizes that are multiples of 256 KiB [Google Developers: Resumable uploads].

```
POST /upload/v1/videos?uploadType=resumable
  Authorization: Bearer <token>
  X-Upload-Content-Length: 1572864000
  X-Upload-Content-Type: video/mp4
  { "title": "Trip", "visibility": "private", "idempotencyKey": "c1f..." }
→ 200 OK  Location: /upload/v1/sessions/us-3a91f    { "videoId": "v_8KQ2..." }

PUT /upload/v1/sessions/us-3a91f
  Content-Range: bytes 0-8388607/1572864000          (8 MiB chunk, multiple of 256 KiB)
→ 308 Resume Incomplete  Range: bytes=0-8388607

PUT /upload/v1/sessions/us-3a91f                     (status query after a disconnect)
  Content-Range: bytes */1572864000
→ 308 Resume Incomplete  Range: bytes=0-402653183     (resume from byte 402653184)

PUT ... final chunk
→ 201 Created  { "videoId": "v_8KQ2...", "processingStatus": "queued" }

GET  /v1/videos/{videoId}                    → { title, state, renditions[], viewCount,
... }
PATCH /v1/videos/{videoId}                   { title?, description?, visibility?, pub-
lishAt? }
GET  /v1/videos/{videoId}/processing         → { stage, progressPct, playable: bool }
GET  /v1/player/{videoId}?client=android&res=1080
     → { manifestUrl: "https://r4---edge.example/...m3u8?sig=...&exp=...",
         resumeAtSec: 312, captions: [...], heartbeatUrl: "..." }
POST /v1/watch/heartbeat                     { viewId, videoId, positionSec, playedSec,
ts }
POST /v1/videos/{videoId}/rating             { rating: "like" | "none" }
```

What to notice:

- The session URI, not the user's token, identifies the upload; it expires (say after a week) and is bound to the authenticated user.
- `308 Resume Incomplete` plus the `Range` header lets the client resume after any failure, including a lost response to a chunk that actually arrived.
- The player endpoint returns a **signed, expiring manifest URL** pointing at a CDN host, so authorization happens once and the CDN serves segments without calling back.
- `viewId` in heartbeats is generated by the player at playback start and is the deduplication key for counting (§54.4.8).

54.4.6 Data model and database schema

Video metadata is relational in shape (owner, state machine, renditions, policy flags) and needs transactions for state transitions, so a horizontally partitioned relational store partitioned by `video_id` is a good fit (§14.6–§14.7). Counts never live on this row; they live in a counter store fed by the counting pipeline. Originals and renditions live in object storage (§15.4), keyed by content-addressed or video-scoped paths.

```
        -- Partitioned by video_id (hash); channel lookups via a secondary table parti-
tioned by channel_id.
        CREATE TABLE videos (
          video_id        CHAR(11)     PRIMARY KEY,         -- random base64url ID, not
sequential
          channel_id      BIGINT       NOT NULL,
          title           VARCHAR(100) NOT NULL,
          description     TEXT,
          visibility      VARCHAR(10)  NOT NULL,            -- public | unlisted | pri-
vate
          state           VARCHAR(16)  NOT NULL,            -- uploading | processing |
playable | complete | blocked | deleted
          duration_ms     INT,
          source_object   VARCHAR(200),                     -- object-store key of the
original
          source_sha256   BINARY(32),
          publish_at      TIMESTAMP,
          created_at      TIMESTAMP    NOT NULL,
          version         INT          NOT NULL DEFAULT 0    -- optimistic concurrency
for edits
        );

        CREATE TABLE channel_videos (                       -- partitioned by channel_id
          channel_id  BIGINT, created_at TIMESTAMP, video_id CHAR(11),
          PRIMARY KEY (channel_id, created_at DESC, video_id)
        );

        CREATE TABLE renditions (                           -- co-located with videos by
video_id
          video_id     CHAR(11),
          codec        VARCHAR(8),                          -- h264 | vp9 | av1 | aac |
opus
          height       SMALLINT,
          bitrate_kbps INT,
          storage_tier VARCHAR(8),                          -- hot | warm | cold | ab-
sent
          manifest_key VARCHAR(200),
          PRIMARY KEY (video_id, codec, height)
        );

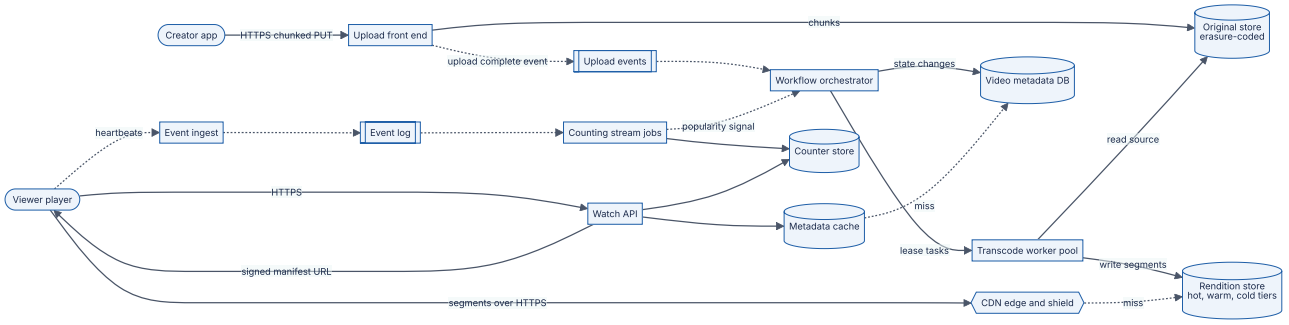
        CREATE TABLE transcode_tasks (                      -- workflow state, parti-
tioned by video_id
          video_id    CHAR(11),
          task_id     VARCHAR(64),                          -- e.g. "enc/h264/720/seg-
0042"
          depends_on  VARCHAR(64)[],
          status      VARCHAR(10),                          -- pending | leased | done |
failed
          lease_until TIMESTAMP,
          attempt     SMALLINT,
          output_key  VARCHAR(200),
          PRIMARY KEY (video_id, task_id)
        );
```

Counters use a key-value design in a wide-column or key-value store (§12.4, §12.6): key `views:{video_id}` → `{validated_count, last_window_end}`; key `likes:{video_id}:{user_id}` → rating, with a separately aggregated like count. Segments are stored under `renditions/{video_id}/{codec}/{height}/seg-{n}.m4s` in CMAF format (§21.8.1), so the same objects serve both HLS and DASH manifests.

> RECOMMENDATION
>
> **Use random, non-sequential video IDs.** Sequential IDs leak upload volume and let anyone enumerate unlisted videos. An 11-character base64url ID carries 66 bits, so guessing an unlisted video is hopeless; generate it with a secure random source and retry on the rare collision (§17.10).

54.4.7 High-level architecture

Figure 54.1 — YouTube teaching design: upload, processing and watch paths.



Reading the diagram. The *creator app* sends chunked, resumable HTTPS PUTs to the *upload front end*, which writes chunks directly into the erasure-coded *original store* (§15.6) and, when the last chunk lands, publishes an *upload complete* event asynchronously (dotted). The *workflow orchestrator* turns that event into a DAG of tasks, records state in the *video metadata DB* and hands out leases to the *transcode worker pool*, which reads the original and writes CMAF segments to the tiered *rendition store*. On the watch path, the *viewer player* calls the *watch API* synchronously; the API serves metadata from a *cache* (misses go to the database) and returns a signed manifest URL; the player then fetches segments from the *CDN*, whose misses fall through its shield to the rendition store (§21.5). Heartbeats flow asynchronously into an *event log* consumed by *counting stream jobs*, which update the *counter store* that the watch API reads, and feed popularity back to the orchestrator so that it can order more codecs for videos that take off. Storage boundaries: original store (durable, cold), rendition store (regenerable, tiered), metadata DB (transactional), counter store (eventually consistent). Failure points: the orchestrator (processing stalls but watching continues), the metadata cache (a stampede on the database), and CDN shields for viral videos. Scaling: every box except the orchestrator's state store is stateless or partitioned by `video_id`.

54.4.8 Detailed component design

Component 1 — The resumable upload front end

A phone uploading a 1.5 GB video over a cellular network will lose its connection, change IP address when it moves from Wi-Fi to cellular, and be suspended by the operating system. The upload front end therefore treats an upload as a **session** with server-side state: total length, bytes durably received, and the object-store multipart upload behind it (§15.8.1).

1. **Create session.** The client sends metadata and the total length; the front end authenticates, checks quota and file-size limits, allocates a `video_id`, starts a multipart upload in the original store, and stores the session record `{session_id, video_id, user_id, length, received, part_etags[], expires_at}` in a small replicated database.
2. **Append chunks.** Each PUT carries a byte range that must start exactly at `received`. The front end streams the bytes into the next multipart part, verifies a per-chunk checksum (CRC32C or MD5 supplied by the client), and only after the part is durable advances `received` and replies `308` with the new range. A chunk that starts anywhere else is rejected with the current range, so a client that lost a response simply resends from the server's value.
3. **Complete.** When `received == length`, the front end completes the multipart upload, computes or verifies the whole-file SHA-256, marks the video `processing`, and writes the upload-complete event through a transactional outbox (§32.5), so the event exists if and only if the state change committed.

Chunk size balances overhead against retransmission: with 8 MiB chunks, a 1.5 GB upload is 179 requests and a failure wastes at most 8 MiB; mobile clients start small and grow the chunk size while the network is good. Front ends are stateless apart from the session table, so any front end in the region can accept the next chunk; the session record pins only the region, because the multipart upload lives in that region's object store.

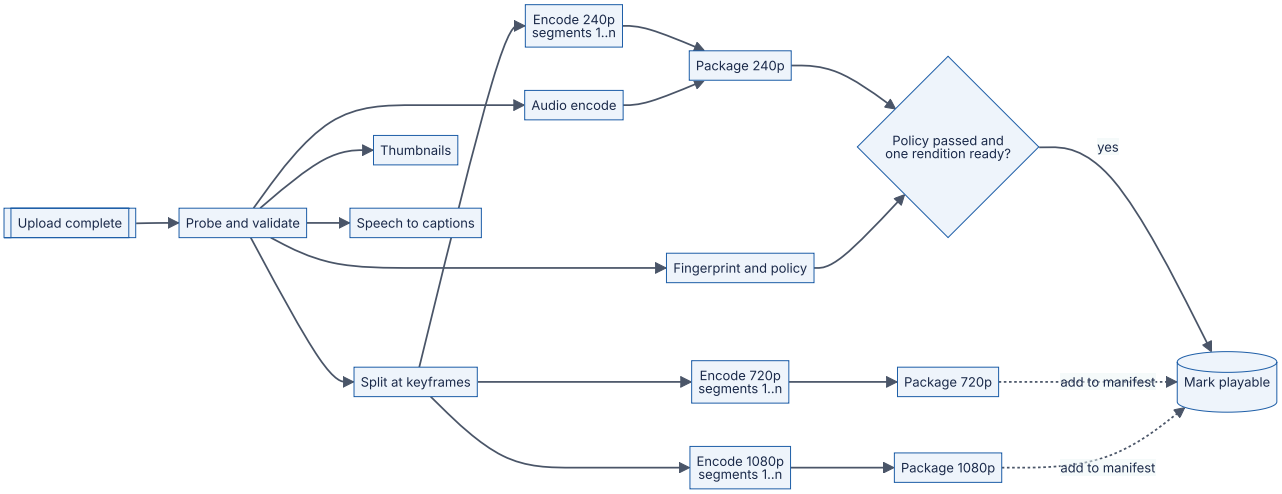
> WARNING / TRADE-OFF
>
> **Do not proxy video bytes through application servers.** An API server that buffers a 10 GB upload in memory, or holds a thread for an hour, will fall over at 300 Gb/s of ingest. Upload front ends are a specialized, streaming tier (or presigned direct-to-object-store uploads, §15.8.2) sized for bandwidth and connection count, not request rate.

Component 2 — The transcoding DAG and its scheduler

Processing one upload is not one job; it is a **DAG** of tasks with dependencies:

1. **Probe and validate** the source: container, codecs, duration, resolution, corruption. Reject or quarantine early, before spending compute.
2. **Split** the source at closed-GOP keyframes into segments of a few seconds to a few tens of seconds. If the source's keyframes are far apart, decode and re-split; this is why the split itself takes time.
3. **Encode** each segment into each rendition of the ladder. These are independent tasks: 60 segments × 5 renditions is 300 tasks that can run on 300 workers at once.
4. **Package** each rendition: concatenate or index the encoded segments as CMAF fragments, write HLS and DASH manifests, and verify segment durations align across renditions so that the player can switch at segment boundaries (§21.8.1).
5. **Side branches** run in parallel with encoding: audio normalization and encoding, thumbnail extraction, automatic speech recognition for captions, content-ID fingerprinting and policy classification.
6. **Publish** when the policy check has passed and at least the lowest rendition is packaged: the video becomes `playable`. Higher renditions are added to the manifest as they finish, and the state becomes `complete` when the eager ladder is done.

Figure 54.2 — The transcoding DAG for one upload.



Reading the diagram. Each rectangle is a task the orchestrator schedules on the worker pool; arrows are dependencies, not network calls. After probing, five branches run concurrently. The split fans out into per-segment encoding tasks for every rendition (shown as one box per rendition, each standing for *n* segment tasks), which fan in at the packaging step for that rendition. The decision node joins the policy result with the first packaged rendition: only then is the video marked playable in the metadata store. Later renditions are added asynchronously (dotted) without blocking publication. Failure points: a failed segment task is retried alone; a failed probe or policy check stops the whole DAG; a straggler segment delays only its rendition. Scaling: segment tasks are the unit of parallelism, so a 3-hour upload simply has more tasks.

The orchestrator is a workflow engine (§32.11) specialized for this DAG, and the worker pool is a batch cluster managed by a cluster scheduler (Chapter 46). Its design follows the distributed job scheduler of §52.9: tasks are durable rows (`transcode_tasks` above), workers **lease** a ready task for a bounded time, renew the lease while working, and write output to a deterministic object key so that a retried task overwrites rather than duplicates. Because outputs are deterministic functions of inputs, every task is idempotent, which turns at-least-once execution into effectively-once results (§32.9).

Three policies make the difference between a pipeline that works and one that works cheaply:

- **Priority.** Tasks that unblock publication (probe, split, policy, lowest rendition) run first; higher renditions and expensive codecs fill the remaining capacity. Uploads from creators with large audiences can be given higher priority, because their first hour of views is large.
- **Straggler mitigation.** The slowest of 300 segment tasks sets the time to finish a rendition. Speculatively re-run any task that exceeds, say, three times the median duration of its siblings, and take whichever copy finishes first, as MapReduce does with backup tasks [Dean and Ghemawat 2004].
- **Preemptible capacity.** Lazy codec work has no deadline, so it runs on spare or preemptible capacity (§46.8); the short, independent segment tasks lose little when preempted.

FORMULA

Makespan bounds for parallel segment encoding (list scheduling)

$$\max\left(\frac{W}{w},\ T_{\text{cp}}\right) \ \le\ T_w \ \le\ \frac{W}{w} + T_{\text{cp}}$$

Symbol	Meaning	Units
T_w	Makespan: time from upload complete until the last task in the DAG finishes, with w workers	s
W	Total work: sum of all task durations	core-s
w	Number of workers (one task per worker at a time)	count
T_{cp}	Critical path: the longest chain of dependent tasks	s

The lower bound holds for any schedule: the work must fit on w workers, and dependent tasks cannot overlap. The upper bound holds for any **list scheduler**, which never leaves a worker idle while a task is ready [Graham 1969].

WORKED EXAMPLE

Worked example — A 10-minute upload. The source is cut into 60 segments of 10 s. Encoding one segment takes 2, 3, 5, 9 and 15 s for 240p, 360p, 480p, 720p and 1080p; the split takes 20 s and packaging each rendition 5 s.

1. Total work: $W = 20 + 60 \times (2 + 3 + 5 + 9 + 15) + 5 \times 5 = 20 + 2,040 + 25 = 2,085$ s.
2. Critical path: split, one 1080p segment, package: $T_{\text{cp}} = 20 + 15 + 5 = 40$ s.
3. One worker: $T_1 = W = 2,085$ s, almost 35 minutes.
4. 50 workers: bounds $\max(41.7, 40) = 41.7$ s and $41.7 + 40 = 81.7$ s.
5. 300 workers: bounds $\max(6.95, 40) = 40$ s and $6.95 + 40 = 46.95$ s.

Interpretation. Beyond about $W/T_{\text{cp}} \approx 52$ workers, more parallelism cannot help: the critical path dominates. **Engineering implication.** To cut latency further, shorten the critical path (faster split, shorter segments, faster per-segment encoders or hardware encoders), not the worker count; and assign more workers only to long videos, whose W is larger.

The simulation below runs a priority list scheduler on this DAG. It shows the second lever, priority: the 240p rendition, which makes the video playable, finishes far earlier than the full ladder.

```
        # Simulate a transcoding DAG on a pool of workers: split -> encode segments
        # per rendition -> package each rendition. Lowest rendition first (priority),
        # so the video becomes playable long before the full ladder finishes.
        import heapq

        SEGMENTS = 60                       # a 10-minute video cut into 10 s segments
        RENDITIONS = {"240p": 2, "360p": 3, "480p": 5, "720p": 9, "1080p": 15}  # s per
segment
        SPLIT, PACKAGE = 20, 5              # seconds for the split and per-rendition
packaging

        def build_tasks():
            tasks = {"split": (SPLIT, [], 0)}              # name -> (duration, deps,
priority)
            for prio, (r, cost) in enumerate(RENDITIONS.items()):
                segs = [f"{r}/seg{i}" for i in range(SEGMENTS)]
                for s in segs:
                    tasks[s] = (cost, ["split"], prio)
                tasks[f"{r}/package"] = (PACKAGE, segs, prio)
            return tasks

        def schedule(tasks, workers):
            done_at, waiting = {}, dict(tasks)
            free = [0.0] * workers                         # time each worker becomes
free
            heapq.heapify(free)
            while waiting:
                ready = [(p, n) for n, (d, deps, p) in waiting.items()
                         if all(x in done_at for x in deps)]
                prio, name = min(ready)                    # lowest rendition first
                dur, deps, _ = waiting.pop(name)
                start = max(heapq.heappop(free), max((done_at[x] for x in deps),
default=0.0))
                done_at[name] = start + dur
                heapq.heappush(free, done_at[name])
            return done_at

        for w in (1, 50, 300):
            t = schedule(build_tasks(), w)
            print(f"workers={w:>3}  first playable (240p) at {t['240p/package']:7.0f} s
"
                  f"full ladder at {max(t.values()):7.0f} s")
```

Output:

```
workers=  1  first playable (240p) at     145 s  full ladder at    2085 s
workers= 50  first playable (240p) at      29 s  full ladder at      76 s
workers=300  first playable (240p) at      27 s  full ladder at      42 s
```

What to notice:

- With one worker the video is playable after 145 s but complete only after 2,085 s; priority alone gives a 14× faster time to playable.
- At 50 workers the full ladder takes 76 s, inside the bounds of 41.7–81.7 s; at 300 workers it takes 42 s, just above the 40 s critical path.
- The time to playable barely moves from 50 to 300 workers, because it is bounded by the split (20 s) plus one 240p segment and packaging.

INDUSTRY EXAMPLE

Google's video transcoding accelerators. Google has published the design and deployment of the Video Coding Unit (VCU), a custom accelerator deployed in its data centers for video transcoding, including YouTube uploads. The paper describes transcoding each upload into many output resolutions and formats, the importance of encoding the same source to several outputs in one pass, and a cluster-level system that schedules transcoding work across accelerators; it reports a 20–33× improvement in efficiency over the previous optimized software-encoding baseline on the authors' workloads [Ranganathan et al. 2021]. *Evidence: Primary* — [Ranganathan et al. 2021]

INDUSTRY EXAMPLE

Netflix chunked encoding. Netflix has described splitting each source into chunks, encoding the chunks in parallel on large numbers of cloud instances and reassembling them, and later moving from a fixed bitrate ladder to **per-title encoding**, in which each title's ladder is chosen from an analysis of that title's complexity, so that simple content (animation) gets lower bitrates for the same perceived quality [Aaron et al. 2015]. *Evidence: Primary* — [Aaron et al. 2015]

Component 3 — Codec ladder and storage tiers by popularity

Views follow a heavy-tailed distribution: in a typical UGC catalog, a small fraction of videos receives most of the watch time, and most videos are watched rarely after their first week. Two decisions follow from popularity.

Which codecs to encode. H.264 (AVC) plays on essentially every device and is cheap to encode, so the eager ladder uses it. Newer codecs such as VP9 and AV1 deliver the same perceived quality at substantially lower bitrate, which saves egress on every view, but cost several times more compute to encode. Encoding an extra codec is worth it only when the expected delivery savings exceed the encoding and storage cost.

FORMULA

Break-even views for adding a codec to a video

$$V^* = \frac{C_{\text{enc}} + C_{\text{store}}}{t_w \times \Delta b \times p_{\text{egress}}}$$

Symbol	Meaning	Units
V^*	Number of future views above which the extra codec pays for itself	views
C_{enc}	One-time cost to encode the extra ladder	$
C_{store}	Cost to store the extra ladder over the planning horizon	$
t_w	Average seconds watched per view	s
Δb	Bitrate saved per second of delivery by the new codec, at equal quality	bytes/s
p_{egress}	Delivery cost per byte	$/byte

WORKED EXAMPLE

Worked example — When does a 6-minute video earn a VP9 ladder? Assumptions (illustrative prices): VP9 ladder encoding costs 20 core-s per video-second at $0.02 per core-hour; the VP9 ladder is 9.72 Mb/s in total and is kept for 12 months at $0.01 per GB-month; an average view watches 180 s at 2.5 Mb/s; VP9 saves 35% of bitrate; delivery costs $0.005 per GB.

1. Encode: $360 \times 20 = 7,200$ core-s $= 2$ core-hours $\times \$0.02 = \$0.04$.
2. Storage: $360 \times 9.72/8 = 437$ MB $= 0.437$ GB; $0.437 \times 0.01 \times 12 = \$0.052$.
3. Saving per view: $\Delta b = 0.35 \times 2.5 = 0.875$ Mb/s $= 109,375$ B/s; $180 \times 109,375 = 19.7$ MB $= 0.0197$ GB; $\times \$0.005 = \$0.0000984$.
4. Break-even: $V^* = (0.04 + 0.0525)/0.0000984 \approx 940$ views.

Interpretation. A video that will receive fewer than about a thousand views is cheaper to serve in H.264 forever; above that, VP9 pays for itself, and for a video with a million views it saves about $98 of delivery for $0.09 of cost. **Engineering implication.** Trigger the expensive codecs from the popularity signal (early view velocity), not at upload; recompute the threshold whenever encoder efficiency (for example, hardware encoders) or delivery prices change.

Where to store renditions. The rendition store has three tiers (§15.9):

- **Hot:** renditions of videos with recent views, replicated on fast media close to CDN shields; most CDN misses land here.
- **Warm:** erasure-coded HDD storage for videos watched occasionally; a CDN miss costs tens of milliseconds more, which the player's buffer hides after the first segments.
- **Cold:** the original only, in archival erasure-coded storage. For a video not watched for, say, two years, delete most renditions and keep the original plus one low rendition; if someone watches it, serve the low rendition immediately and re-transcode the ladder in the background. This is the payoff of treating renditions as regenerable.

A lifecycle job moves objects between tiers from per-video view statistics produced by the counting pipeline, and updates `renditions.storage_tier` so that the manifest generator only lists renditions that exist.

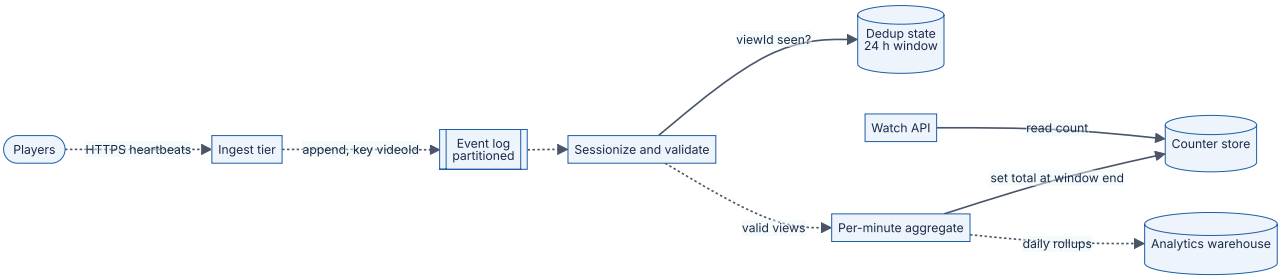
Component 4 — View counting at scale

A view count looks like `UPDATE videos SET views = views + 1`, and at 231,000 views/s with viral videos receiving tens of thousands of views per second each, that design melts a single row (§20.15). Counts are also money: creators are paid by views and watch time, and fraudsters run bots to inflate them. So view counting is a **stream-processing pipeline** with validation:

1. **Ingest.** Players send heartbeats `{viewId, videoId, positionSec, playedSec, ts}` to a stateless ingest tier, which appends them to a partitioned event log (Chapter 31) keyed by `videoId`.
2. **Sessionize and validate.** A stream job (§29.8) groups events by `viewId`, decides whether the session qualifies as a view (for example, a minimum of watched seconds), and drops sessions that look automated (impossible event rates, known bad clients, data-center IP ranges). Validation can lag; it is better to show a count a few minutes late than to show a fraudulent count and retract it.
3. **Deduplicate.** A `viewId` counts at most once, so the job keeps the set of counted `viewId`s within a window long enough to cover retries and replays (for example, 24 hours) in its state store; a replayed event with a known `viewId` is ignored (§32.10).
4. **Aggregate.** Validated views are pre-aggregated per `(videoId, minute)` inside the job, so a viral video produces one counter update per minute per partition, not 50,000 per second.
5. **Publish.** The job writes `views:{videoId}` with an idempotent "set to total as of window end" operation, not an increment, so that re-running a window after a crash produces the same value (§31.11 for Kafka transactions that make read-process-write atomic).

For approximate, cheap metrics such as unique viewers per video per day, a HyperLogLog per video (§17.5) gives about 1% error in a few kilobytes; for “top trending videos in the last hour”, a Count-Min sketch with a heap finds heavy hitters without a counter per video (§17.6). The exact, monetized count stays in the deduplicated pipeline.

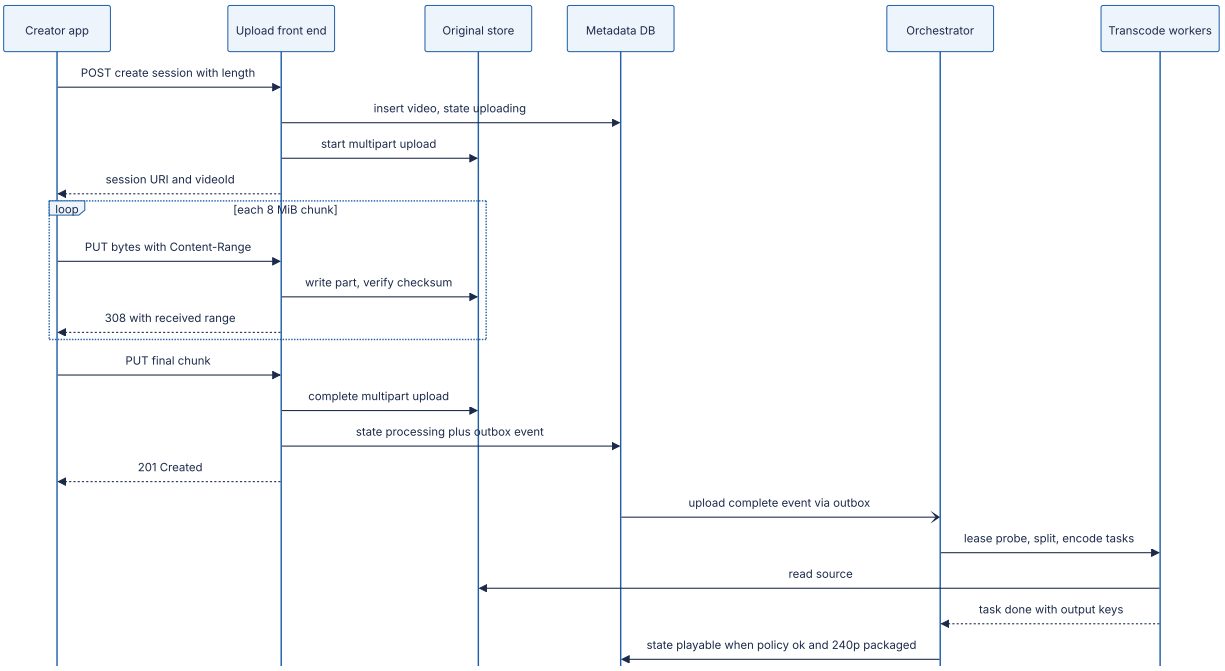
Figure 54.3 — View-counting pipeline.



Reading the diagram. Players send heartbeats asynchronously to a stateless *ingest tier*, which appends them to a partitioned *event log*. The *sessionize and validate* job consumes the log, consults its *dedup state* (local to the job, checkpointed) to drop already counted `viewId`s, and emits valid views to a *per-minute aggregate*, which writes idempotent totals to the *counter store* read by the *watch API*, and daily rollups to the *analytics warehouse* for creators. Everything left of the counter store is asynchronous; only the API’s read is synchronous. Storage boundaries: the log (replayable for days), the job state, the counter store and the warehouse. Failure points: a job crash (recover from checkpoint and replay the log; idempotent writes make replay safe) and a hot partition for a viral video (per-minute pre-aggregation bounds the write rate). Scaling: partition the log and the jobs by `videoId`.

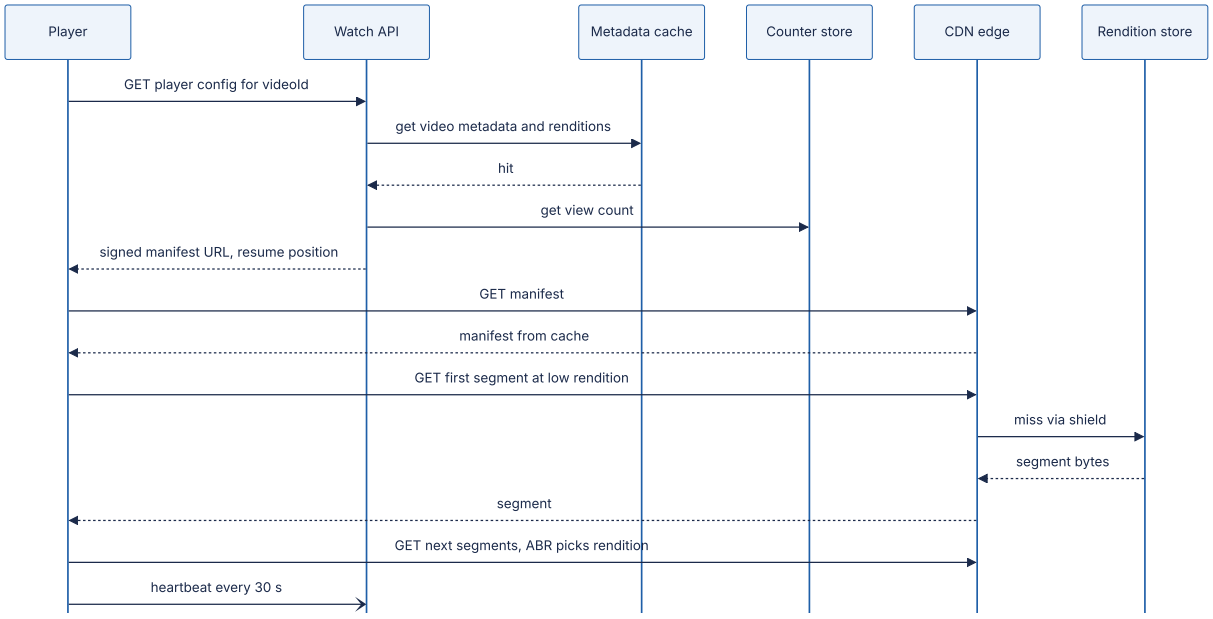
54.4.9 Data flow

Figure 54.4 — Write path: resumable upload to playable video.



Reading the diagram. Session creation is synchronous and records the video in the *metadata DB* before any bytes arrive, so a crash cannot leave orphaned objects without a record. The loop appends chunks; each acknowledgment follows a durable part write. Completion commits the state change and the outbox event in one transaction; the event reaches the *orchestrator* asynchronously (open arrowhead). The orchestrator leases tasks to *workers*, which read the source and report outputs; the video becomes playable when the policy check and the first rendition are done. Failure points: a dropped chunk (client re-queries the range), a front-end crash (any other front end continues the session), a worker crash (the lease expires and the task is re-run).

Figure 54.5 — Read path: starting playback.



Reading the diagram. The *player* makes one synchronous API call to authorize and locate the video; the API reads metadata from the *cache* and the count from the *counter store*, then returns a signed manifest URL. All later requests go to the *CDN edge*; a miss travels through the shield to the *rendition store*. The player starts at a low rendition to reach first frame quickly and lets the ABR algorithm climb (§21.8.3). Heartbeats are asynchronous and never block playback. Failure points: the watch API (playback cannot start, running sessions continue), the counter store (show a stale or missing count rather than fail), a cold segment in the warm tier (slower first segment).

54.4.10 Bottlenecks

- **Transcoding capacity** during upload surges (holidays, major events): the queue grows and time to playable rises. Priority classes keep the critical path moving; lazy codecs are deferred.
- **Original-store write bandwidth** at 600 Gb/s peak, concentrated in regions with many creators: spread uploads across regions and storage cells.
- **CDN shield and rendition store for viral videos:** a video going from zero to millions of views in an hour has cold caches; request collapsing at shields (§20.11) and proactive promotion to the hot tier on rising view velocity prevent a miss storm.
- **Hot counter keys:** handled by per-minute aggregation; never increment per view.
- **Metadata cache stampede** after a cache node fails: use request coalescing and staggered TTLs (§20.11, §20.13).

54.4.11 Failure scenarios

Table 54.2 — YouTube teaching design: failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Upload front end node	In-flight chunk fails	Client error; node health checks	Client re-queries range, continues on another node	Stateless nodes; session state in replicated DB
Orchestrator state store	No new tasks scheduled; uploads stuck in processing	Queue-age SLO alert	Fail over to replica; leases resume	Replicated store; idempotent tasks
Poison source file	Worker crashes repeatedly	Retry count per task	Quarantine after N attempts; notify creator	Probe step with sandboxed decoder
Encoder bug in new release	Corrupt renditions published	Automated quality checks (VMAF, decode test) on samples	Roll back encoder; re-encode affected videos from originals	Canary encoder releases (§43.6); originals immutable
Rendition store region loss	CDN misses fail for warm content	Shield error rates	Serve from another region; re-transcode if needed	Cross-region replication of hot tier
Counting job crash	Counts freeze	Consumer-lag alert	Restart from checkpoint, replay log	Idempotent writes; log retention longer than recovery time
Bot inflation	Fraudulent counts and payments	Anomaly detection on view velocity and sources	Retroactively discount views	Validation before publication

54.4.12 Scaling strategy

At 10× (5,000 hours per minute of upload, 10 billion watch-hours per day): eager-encoding compute grows to about 60,000 servers on the earlier assumptions, so hardware encoders and multi-output encoding become mandatory rather than optional; the break-even threshold for advanced codecs drops as their encoding cost falls, so more videos get them. Edge egress reaches petabits per second, which requires caches embedded in ISP networks rather than only at exchange points (§21.10). Counting moves to more log partitions and per-region aggregation with a global merge.

At 100×: the original archive grows by more than 100 EB a year, so the archive tier itself must be cheaper: denser erasure codes, cold media, and deleting originals of rejected or abandoned uploads aggressively. The orchestrator's state store becomes the coordination bottleneck and is split into independent cells by `video_id` range (§44.10), each with its own worker pool and a global scheduler that balances only capacity between cells.

54.4.13 Trade-offs

Table 54.3 — YouTube teaching design: key trade-offs.

Decision	Option chosen	Alternative	Why
Codecs	Eager H.264, lazy VP9/AV1 by popularity	Encode everything at upload	Most videos never reach break-even views
Segment length	Short (2–10 s) segments for parallelism and ABR	Whole-file encoding	Parallelism and switchability; small loss of compression efficiency at boundaries
Rendition durability	Regenerable, lower redundancy for cold	Same durability as originals	Saves storage; costs recompute on rare cold reads
View counts	Delayed, validated, deduplicated	Real-time raw increments	Correctness and fraud resistance over freshness
Upload path	Dedicated streaming front end	Through API servers	Bandwidth-bound tier scales independently

54.4.14 Alternative designs

- **Per-title or per-shot ladders** (as Netflix describes) instead of a fixed ladder: better quality per bit, worth it for popular videos where the extra analysis compute is amortized; apply it on the lazy, popularity-triggered branch.
- **Just-in-time packaging:** store one set of CMAF segments and generate HLS or DASH manifests on request at the edge or shield; saves storage and supports new manifest formats without reprocessing.
- **Live streaming** changes the problem: encoding must keep up in real time with a fixed latency budget, segments are produced continuously, and manifests change every few seconds (§21.8.1). The DAG becomes a streaming pipeline with no retry window.

54.4.15 Interview discussion

45-minute pacing plan. 0–5 min: clarify scope (UGC, upload and watch, counts; no live, no ads). 5–10 min: capacity, emphasizing bytes versus requests and that egress belongs to the CDN. 10–15 min: API (resumable upload, player config) and data model. 15–20 min: high-level diagram. 20–38 min: the transcoding DAG, scheduling, codec ladder by popularity and storage tiers. 38–43 min: view counting and failure scenarios. 43–45 min: scaling and trade-offs.

Likely follow-ups.

- *How do you make the upload resumable?* Server-side session with byte offset; client queries range after failure; chunks aligned to multipart parts.
- *Why split the video?* Parallelism (latency) and independent retry; segments must start at closed-GOP keyframes.

- *How would you reduce time to playable?* Prioritize the critical path; publish at the first rendition; faster split; hardware encoders.
- *How do you keep view counts accurate?* Player-generated view IDs, validation, deduplication window, idempotent window totals.

What distinguishes senior and staff answers. A senior candidate draws a working DAG with idempotent tasks and resumable upload. A staff candidate quantifies the cost structure (compute versus storage versus egress), derives the popularity-driven codec decision, recognizes renditions as a regenerable cache over immutable originals, and bounds latency by the critical path rather than adding workers.

54.4.16 Production considerations

- **Observability.** Per-stage queue age and task latency histograms; time to playable and time to complete per video; rendition quality scores on samples; player-side quality of experience (start time, rebuffer ratio, average bitrate) aggregated by CDN, ISP and device (§40.5).
- **Security.** Uploaded files are untrusted input to complex decoders: run probe and decode in sandboxes with resource limits. Sign manifest URLs with short expiry; private videos require the signature for every segment request. Encrypt originals at rest with per-tenant envelope keys (§10.9).
- **Cost.** Egress is the largest cost, then storage, then compute; the codec break-even and tiering decisions are recomputed quarterly from real prices. Preemptible capacity for lazy encodes.
- **Operations.** Encoder releases are canaried on a sample of uploads with automated quality comparison; a re-encode campaign (for a new codec or a fixed bug) is a scheduled batch over originals, rate-limited so that it never starves fresh uploads.

54.5 Netflix

54.5.1 Problem statement

Design a subscription video service in the style of Netflix: members browse a personalized catalog of licensed and original films and series on TVs, phones and browsers, press play, and watch in high quality within a couple of seconds, at evening peaks when the service carries a large share of a country’s Internet traffic.

Compared with YouTube, almost everything is inverted: the catalog is small, curated and known in advance, every title is protected by licensing contracts that demand digital rights management (DRM), and plays are enormous relative to titles. The distinctive hard problem is the **split between a control plane and a data plane**. Think of an airline: the booking system (a global software service that must always answer) decides who flies

where, and the aircraft (heavy physical infrastructure placed near passengers) carry them. A booking outage stops new trips but not flights already in the air. In the teaching design, the control plane (browsing, authorization, licenses, steering) runs in several cloud regions, and the video bytes come from caches inside or next to viewers' ISPs, as with Netflix's Open Connect (§21.10). The design questions are how a play request crosses from one plane to the other, and how the control plane survives the loss of a whole cloud region.

DEFINITION

Definition — Control plane and data plane. The **control plane** is the set of services that make decisions (who may watch, which file, from which server); the **data plane** is the set of components that move the bulk bytes once decided. They are scaled, deployed and failed independently: the data plane is sized for bandwidth, the control plane for request rate and availability.

DEFINITION

Definition — Digital rights management (DRM) license. A small, encrypted message issued by a license server that contains the content key (or keys) needed to decrypt an encrypted video, bound to a specific device and session and carrying usage rules (expiry, maximum resolution, offline permission). The video segments themselves are encrypted once and can be cached anywhere; only the license is personal.

54.5.2 Functional requirements

1. Sign in, select a profile, and browse a personalized home page of rows of titles; search the catalog.
2. Press play and watch with adaptive bitrate; select audio language and subtitles; resume across devices.
3. Enforce entitlement (active membership, plan limits such as resolution and concurrent streams) and content licensing (territory windows, DRM).
4. Download selected titles for offline viewing on mobile devices, within license limits.
5. Ingest new titles from studios: receive masters, encode, quality-check, and pre-position on caches before the release time.
6. Record viewing history and playback quality telemetry.
7. Out of scope: billing, studio production tools, the recommender model itself (Chapter 81).

54.5.3 Non-functional requirements

Table 54.4 — Netflix teaching design: non-functional targets.

Property	Target	Why
Play-start success	99.99% of play attempts start	The core metric; failures are visible immediately
Play-start latency	p50 < 1.5 s, p99 < 4 s from press to first frame	Members abandon slow starts
Running-stream survival	A control-plane outage must not stop streams already playing	Data plane independent of control plane
Rebuffer ratio	< 0.1% of play time	Long-form viewing magnifies stalls
Control-plane regional failure	Evacuate a whole cloud region in < 10 min with no loss of availability	Region failures happen
Viewing history	Durable; read-your-writes per member; cross-device resume within seconds	Resume is a product feature
Release readiness	A new title fully pre-positioned in caches before release time	Launch-night peaks
Content security	Studio-grade DRM; no clear-text content keys outside license servers and devices	Licensing contracts

54.5.4 Capacity estimation

Netflix reported more than 300 million paid memberships at the end of 2024 [Netflix 2025]. All numbers below are teaching assumptions built on that order of magnitude, not Netflix measurements.

WORKED EXAMPLE

Worked example — Peak egress and cache fleet. Assumptions: 300 million memberships; 50% stream on a given day (150 million daily viewers); 2 hours of viewing per viewer per day; average delivered bitrate 4 Mb/s (a mix of mobile and HD with efficient per-title encoding); evening peak is 2.5× the daily average; one cache appliance usefully serves 80 Gb/s (an illustrative figure for a 100 Gb/s-class server at 80% utilization).

1. Viewing hours per day: $150 \times 10^6 \times 2 = 3 \times 10^8$ h.
2. Average egress: $3 \times 10^8 \times 3,600 \times 4 \times 10^6 / 86,400 = 5 \times 10^{13}$ b/s $= 50$ Tb/s.
3. Peak egress: $2.5 \times 50 = 125$ Tb/s.
4. Minimum appliances at peak: $125 \times 10^{12} / (80 \times 10^9) \approx 1,563$; with geographic spread (every ISP needs its own), N+1 redundancy per site and room for growth, several thousand.

Interpretation. 125 Tb/s from a single cloud region would be impossible to buy at reasonable cost and would cross every ISP's transit links. **Engineering implication.** The data plane must be distributed to thousands of sites close to members, and the control plane must never sit on the per-byte path.

WORKED EXAMPLE

Worked example — Control-plane request rates. Assumptions: average viewing session 40 minutes; 60 control-plane API calls per daily viewer per day (home page, rows, artwork, title details, search, playback, license, telemetry batches); peak-to-average 3×.

1. Play starts per day: $3 \times 10^8 \times 60/40 = 4.5 \times 10^8$; average 5,200/s; peak about 15,600 play starts/s.
2. Each play start makes at least two critical calls (playback manifest, license): about 31,000 critical RPS at peak.
3. All API calls: $150 \times 10^6 \times 60 = 9 \times 10^9$ per day; average 104,000 RPS; peak about 312,000 RPS at the edge gateway, fanning out to several times that in internal service calls.

Interpretation. The control plane is a large but conventional microservice system, in the range that a few cloud regions handle comfortably. **Engineering implication.** Size each region to absorb an evacuated region's share (§44.11): with three regions, each must carry 1.5× its normal peak, about 156,000 RPS instead of 104,000.

WORKED EXAMPLE

Worked example — Catalog storage and daily fill. Assumptions: 50,000 hours of content in a territory's catalog; all encodes of a title (several codecs, ladders up to 4K, audio tracks, subtitles) sum to 40 Mb/s of stored bitrate; 100 hours of new content per day globally.

1. Catalog storage: $50,000 \times 3,600 \times 40 \times 10^6/8 = 9 \times 10^{14}$ B $= 900$ TB.
2. New content per day: $100 \times 3,600 \times 40 \times 10^6/8 = 1.8 \times 10^{12}$ B $= 1.8$ TB.
3. An appliance holding, say, 300 TB can hold a third of the whole catalog, enough for the popular part that serves almost all views.

Interpretation. The full catalog fits in roughly one rack of storage; the challenge is not capacity but choosing which files each appliance holds. **Engineering implication.** Pre-position by predicted popularity per region and fill during the off-peak window (§21.10); 1.8 TB/day of new content is small relative to the fill capacity.

54.5.5 API design

The device talks to one edge gateway; the gateway fans out to internal services over gRPC (§8.8). The critical playback calls are:

```
GET  /api/v1/home?profileId=p7&rows=20&cursor=...
     → { rows: [ { rowId, title, items: [ { titleId, artworkUrl, ... } ] } ], nextCursor
}

POST /api/v1/playback/manifest
     { profileId, titleId, deviceId, capabilities: { codecs: ["av1","hevc","avc"],
       maxHeight: 2160, hdr: ["hdr10","dv"], drm: "widevine-l1" }, network: "wifi" }
     → { playbackSessionId: "ps_91c...",
         streams: [ { type: "video", codec: "av1", height: 1080, kbps: 3100,
                      urls: [ "https://oca-1.isp-a.example/v/…?t=…", "https://oca-7.ix-
b.example/v/…?t=…" ] }, ... ],
         audio: [...], subtitles: [...], licenseUrl: "/api/v1/license",
         bookmarkSec: 1312, expiresAt: "2026-11-05T21:13:00Z" }

POST /api/v1/license
     { playbackSessionId, drmChallenge: "<opaque bytes from the device CDM>" }
     → { license: "<opaque bytes>", maxHeight: 2160, expiresAt: ... }

POST /api/v1/events      { playbackSessionId, events: [ {type:
"start"|"progress"|"stop"|"rebuffer", positionSec, ts} ] }
POST /api/v1/downloads   { profileId, titleId, deviceId }   → { downloadToken, license-
ExpiresAt }
```

What to notice:

- The manifest response is **personal and short-lived**: it reflects plan, device capabilities, territory and steering, and the URLs carry signed tokens. The segment files behind those URLs are shared and long-lived.
- Each stream carries a **ranked list of cache URLs**, so the client fails over between appliances without another control-plane call.
- The license request carries an opaque challenge from the device's content decryption module (CDM); the server never sends a content key in the clear.

54.5.6 Data model and database schema

The control plane holds several datasets with very different access patterns, so it is polyglot (§12.13):

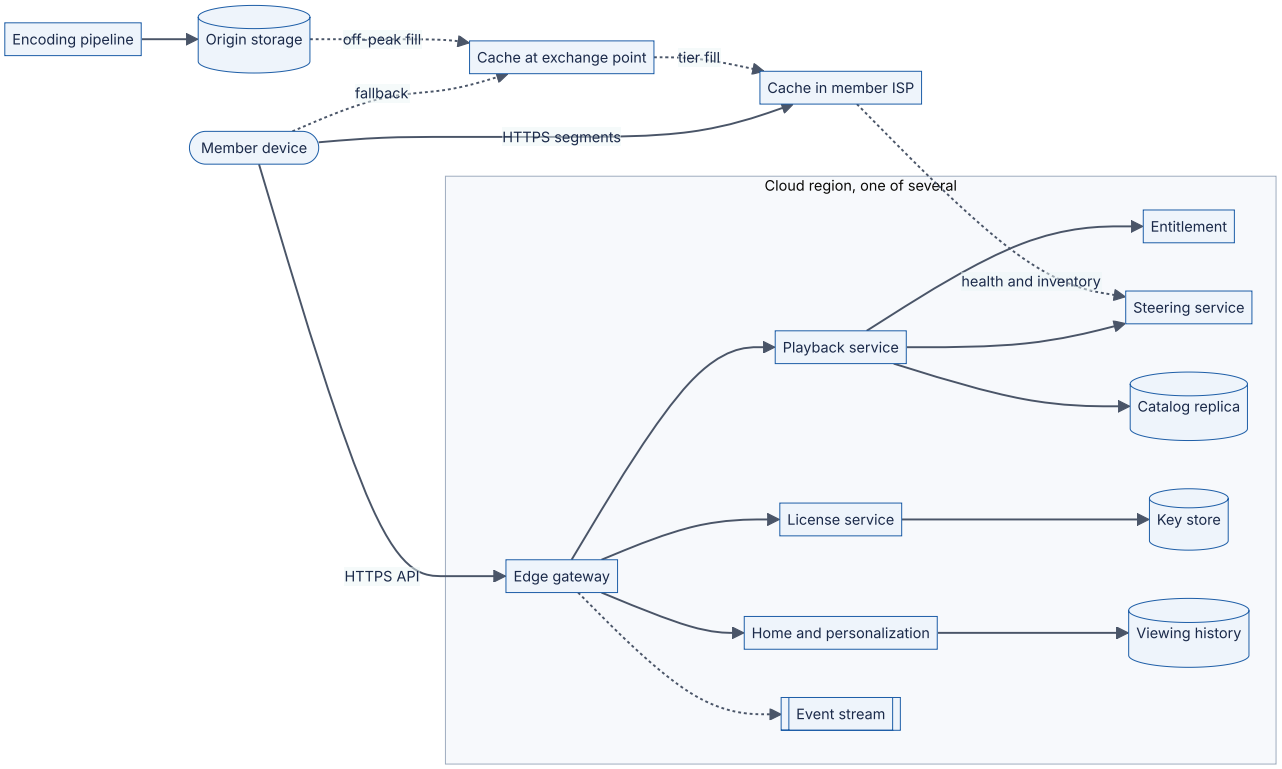
```
        -- Catalog: small, read-mostly, replicated to every region; changes are published, not edited in place.
        CREATE TABLE titles (
          title_id     BIGINT PRIMARY KEY,
          kind         VARCHAR(8),         -- movie | show | episode
          parent_id    BIGINT,             -- show for an episode
          runtime_s    INT,
          maturity     VARCHAR(8)
        );
        CREATE TABLE availability (        -- licensing windows per territory
          title_id BIGINT, country CHAR(2), starts_at TIMESTAMP, ends_at TIMESTAMP,
          offline_allowed BOOLEAN, max_downloads INT,
          PRIMARY KEY (title_id, country)
        );
        CREATE TABLE downloadables (       -- one row per encoded file
          file_id      BIGINT PRIMARY KEY,
          title_id     BIGINT,
          kind         VARCHAR(8),         -- video | audio | text
          codec        VARCHAR(8), height SMALLINT, kbps INT, language VARCHAR(8),
          key_id       BINARY(16),         -- DRM key identifier, the key itself is in the key store
          sha256       BINARY(32)
        );
```

- **Viewing history and bookmarks** are a per-member time series with very high write rates (progress events), read mostly as "latest position per title" and "recent titles". A wide-column store partitioned by `profile_id` with clustering by time, replicated across regions with eventual consistency, fits this (§12.6); the "latest bookmark" can be a separate compact row per `(profile_id, title_id)` overwritten with last-writer-wins, which is safe because each profile watches one stream at a time.
- **Steering state**: which files each appliance holds and how healthy and loaded it is, as a map `oca_id → {site, isp_prefixes, health, load, file_ids bitmap}`. It changes every few minutes and is held in memory by the steering service, rebuilt from appliance reports.

- **Content keys** live in a hardened key store, accessible only to license servers, never in the general catalog.
- **Playback sessions**: `{playbackSessionId → profile, device, title, issuedAt}` with a TTL, used to enforce concurrent-stream limits and to tie license requests to an authorized manifest.

54.5.7 High-level architecture

Figure 54.6 — Netflix teaching design: control plane in cloud regions, data plane in ISPs.



Reading the diagram. Inside a *cloud region* (one of several identical regions), the *edge gateway* receives all device API calls over HTTPS and routes them to services: *home and personalization* (reads *viewing history* and model outputs), the *playback service* (checks *entitlement*, reads the replicated *catalog* and asks the *steering service* for cache URLs) and the *license service* (reads the *key store*). Telemetry flows asynchronously into an *event stream*. Outside the region, the device fetches segments directly from a *cache in its ISP*, falling back to a cache at an Internet exchange point. Caches report health and inventory asynchronously to steering. The *encoding pipeline* writes to *origin storage*, from which caches are filled off-peak, tier by tier. The storage boundaries are the catalog and history stores, the key store, origin storage and each cache's disks. Failure points: a region (evacuated, §54.5.8), the gateway (fails the whole region's control plane), the license service (blocks starts, not running streams), a cache (client fails over to the next URL).

Scaling: control-plane services scale horizontally per region; data-plane capacity scales by adding appliances in ISPs.

> INDUSTRY EXAMPLE
>
> **Netflix's published split.** Netflix completed the migration of its streaming service's systems to AWS in early 2016, after a migration of about seven years [Izrailevsky 2016]. Its Open Connect documentation and engineering blog describe the complement: services in AWS handle everything up to pressing play, including choosing which Open Connect Appliances a client should use, and the appliances, embedded in ISPs or located at Internet exchange points and filled proactively during off-peak windows, serve the video bytes [Netflix Open Connect Overview; Netflix TechBlog 2016]. *Evidence: Primary* — [Izrailevsky 2016]; [Netflix Open Connect Overview]; [Netflix TechBlog 2016]

54.5.8 Detailed component design

Component 1 — The playback-start path

Pressing play triggers the most important request in the system. The playback service builds a **personalized manifest** in five steps:

1. **Authorize.** Validate the session token, check membership status and plan, and enforce the concurrent-stream limit by registering a playback session (a counter per account with TTL-based leases, so a crashed device's slot expires).
2. **Check availability.** Look up the title's licensing window for the member's country (`availability`); outside the window, refuse.
3. **Select files.** Filter the title's `downloadables` by device capabilities (codec, maximum resolution, HDR format, DRM security level) and plan (for example, a plan limited to 1080p). The result is a ladder per codec plus audio and subtitle tracks.
4. **Steer.** For each selected file, ask the steering service for a ranked list of caches that (a) hold the file, (b) are healthy and below a load threshold, and (c) are best placed for the client's network, judged by the client's IP prefix and the ISP routes each cache serves. Embedded caches in the client's ISP rank first, exchange-point caches next.
5. **Sign and return.** Embed short-lived tokens in the URLs and return the manifest with the license URL and the resume position.

The device then requests a **license**: its CDM generates a challenge; the license service verifies that the `playbackSessionId` is valid and matches the device, fetches the content key from the key store, and returns a license that encrypts the key for that device and carries rules (expiry, maximum resolution allowed for the device's security level). Streaming services commonly support several DRM systems (Widevine, PlayReady,

FairPlay) because each device platform supports one; with the common encryption scheme of CMAF, the same encrypted segments work with all of them, so only the license differs.

FORMULA

Play-start latency with overlapped license and first segments

$$T_{\text{start}} = T_{\text{manifest}} + \max\left(T_{\text{license}},\ T_{\text{conn}} + \frac{B_{\text{start}}}{C} + \text{RTT}_{\text{cache}}\right) + T_{\text{decode}}$$

Symbol	Meaning	Units
T_{start}	Time from pressing play to first frame	s
T_{manifest}, T_{license}	Round trip plus server time for each control-plane call	s
T_{conn}	Connection setup to the cache (TCP and TLS)	s
B_{start}	Bits the player buffers before starting	bits
C	Client's available bandwidth from the cache	bits/s
$\text{RTT}_{\text{cache}}$	Round trip to the cache	s
T_{decode}	Decoder initialization and first frame render	s

WORKED EXAMPLE

Worked example — Where the start time goes. Assumptions: 60 ms RTT to the cloud region; manifest server time 150 ms; license server time 50 ms; 12 ms RTT to the ISP cache and two round trips to connect; the player buffers two 4 s segments before starting; bandwidth 20 Mb/s; decoder start 100 ms.

1. Manifest: $0.06 + 0.15 = 0.21$ s. License: $0.06 + 0.05 = 0.11$ s.
2. Startup buffer at 1.5 Mb/s: $B_{\text{start}} = 2 \times 4 \times 1.5 = 12$ Mb; download $12/20 = 0.6$ s; with connect and one request RTT, $0.024 + 0.6 + 0.012 = 0.636$ s.
3. Fully sequential: $0.21 + 0.11 + 0.636 + 0.1 = 1.056$ s.
4. License in parallel with segment fetch: $0.21 + \max(0.11, 0.636) + 0.1 = 0.946$ s.
5. Manifest and license prefetched while the member hovers on the title: $0.636 + 0.1 = 0.736$ s.
6. Additionally start at 0.75 Mb/s: buffer download $6/20 = 0.3$ s, total $0.024 + 0.312 + 0.1 = 0.436$ s.

Interpretation. Once the control-plane calls are overlapped or prefetched, the startup buffer dominates. **Engineering implication.** Overlap the license with the first segment downloads (segments are encrypted, so fetching them before the key is safe), prefetch playback metadata for likely plays, and start at a modest rendition, letting ABR climb.

Component 2 — Steering and pre-positioning

Because the catalog is known, caches are filled ahead of demand rather than on a miss (§21.10). In the teaching design, a **placement service** runs nightly per cache site: it takes popularity predictions per region (for example, from recent viewing plus release schedules), ranks files by expected bytes served per byte stored, and fills each cache up to its capacity in that order, during the ISP-agreed off-peak window. Files a cache already holds stay; displaced files are evicted. New releases are pushed to every relevant site before the release time, so launch-night traffic finds full caches.

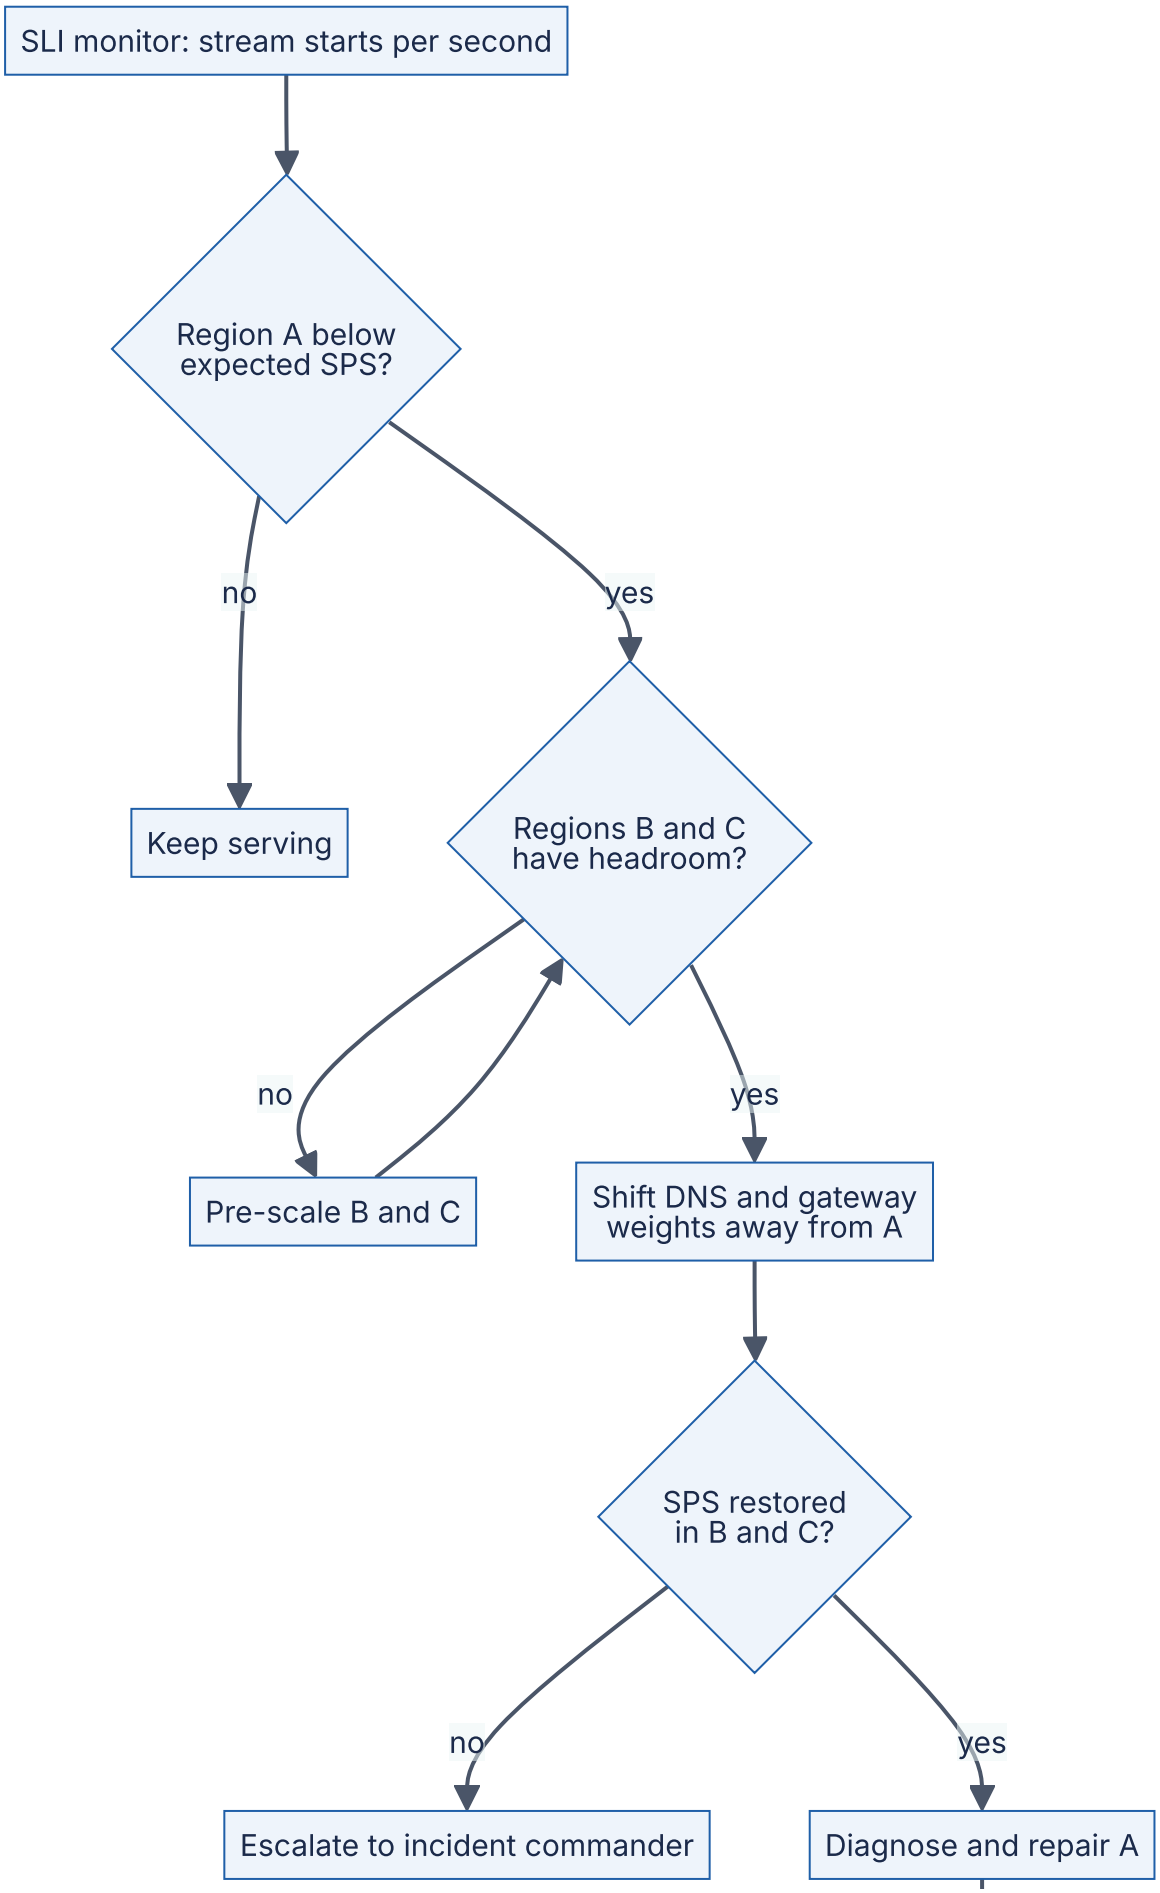
The **steering service** turns placement into per-request answers. It keeps an in-memory index of which caches hold which files, their health and load, and which client prefixes each cache should serve (learned from BGP sessions with ISPs). Steering decisions are cheap lookups, and because each manifest lists several caches, a cache failure is handled by the client moving to the next URL, with no control-plane call. Steering also sheds load: when a cache approaches its limit, it ranks lower in new manifests while existing sessions continue.

Component 3 — Resilience: static stability, chaos and regional evacuation

The control plane runs **active–active** in several cloud regions; any region can serve any member (§44.6). Three practices make that real:

- **Static stability and fallbacks.** Each request path degrades rather than fails: if personalization times out, the home page falls back to precomputed popular rows; if viewing history is unavailable, playback starts from the beginning; if steering's latest data is stale, it serves from its last snapshot. Running streams depend only on caches and an already-issued license, so they survive a full control-plane outage until the license or the manifest URLs expire (hours). Circuit breakers and timeouts on every dependency stop one slow service from exhausting threads in its callers (§39.5).
- **Chaos engineering.** Failures are injected deliberately in production to verify that fallbacks work, with stream starts per second as the steady-state metric (§39.11). Experiments run at increasing scope: kill an instance, add latency to one dependency for a small share of traffic, fail an availability zone, evacuate a region.
- **Regional evacuation.** When a region degrades, traffic is steered away from it: the device-facing DNS and gateway layer shift members to the remaining regions, which must already have headroom or scale up fast. The survivors then serve those members from their own replicas of catalog, entitlement and viewing history; replicas are eventually consistent across regions, so a member might lose a few seconds of bookmark progress, which is acceptable. Evacuation is rehearsed regularly so that the path stays warm (§44.11.3).

Figure 54.7 — Regional evacuation of the control plane.



SLI monitor: stream starts per second
Region A below expected SPS?
no
yes
Keep serving
Regions B and C have headroom?
no
yes
Pre-scale B and C
Shift DNS and gateway weights away from A
SPS restored in B and C?
no
yes
Escalate to incident commander
Diagnose and repair A

Reading the diagram. The *SLI monitor* compares stream starts per second (SPS) in each region with its expected daily pattern. If region A drops, the controller first checks that regions B and C have **headroom**; if not, it pre-scales them before moving traffic, because moving members to full regions would turn one regional incident into a global one. It then shifts DNS and gateway weights away from A, and verifies that SPS recovers in the survivors; if not, a human takes over. Repair and gradual return come last. All steps are control actions (synchronous decisions); the data plane is untouched throughout. Failure points: a false-positive signal evacuating a healthy region, and insufficient survivor capacity. Scaling: with N regions, each needs $N/(N-1)$ of its normal peak capacity, 1.5× for three regions (§44.11.2).

INDUSTRY EXAMPLE

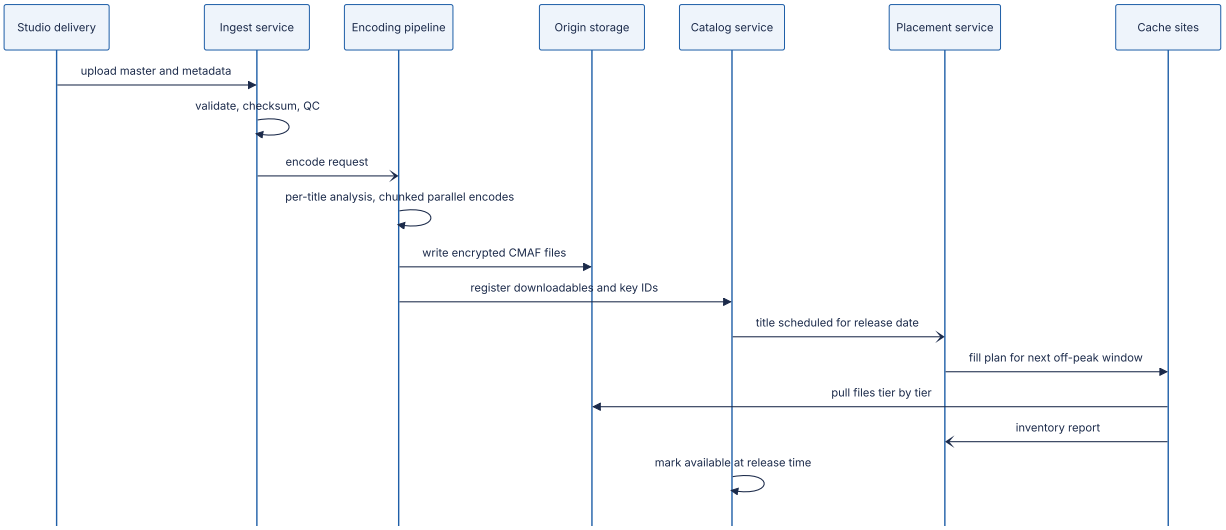
Netflix's resilience practices. Netflix introduced Chaos Monkey, which randomly terminates production instances, and a family of tools for larger failures [Izrailevsky and Tseitlin 2011]; Basiri et al. formalized chaos engineering as experimentation against a steady-state metric, using stream starts per second, and described exercises that simulate the failure of an entire AWS region [Basiri et al. 2016]. Netflix moved to active–active operation across AWS regions after a 2012 regional outage [Meshenberg et al. 2013] and later described re-engineering region evacuation so that it completes in minutes [Netflix TechBlog 2018]. *Evidence: Primary* — [Izrailevsky and Tseitlin 2011]; [Basiri et al. 2016]; [Meshenberg et al. 2013]; [Netflix TechBlog 2018]

Component 4 — The personalization hand-off

Personalization decides what appears on the home page and in which order, and even which artwork represents each title; the models are the subject of Chapter 81. From the system-design view, the boundary is clean: offline and near-line pipelines compute **candidate rows and rankings per profile** and store them in a fast key-value store keyed by `profile_id`; the home service reads them, applies business rules (availability in the member's country, maturity rating, de-duplication across rows), and renders the page. Live context (device, time of day, what was just watched) re-ranks a precomputed candidate set within the latency budget. If the store or the ranking call fails, the home service serves non-personalized popular rows for the territory, which keeps the product usable.

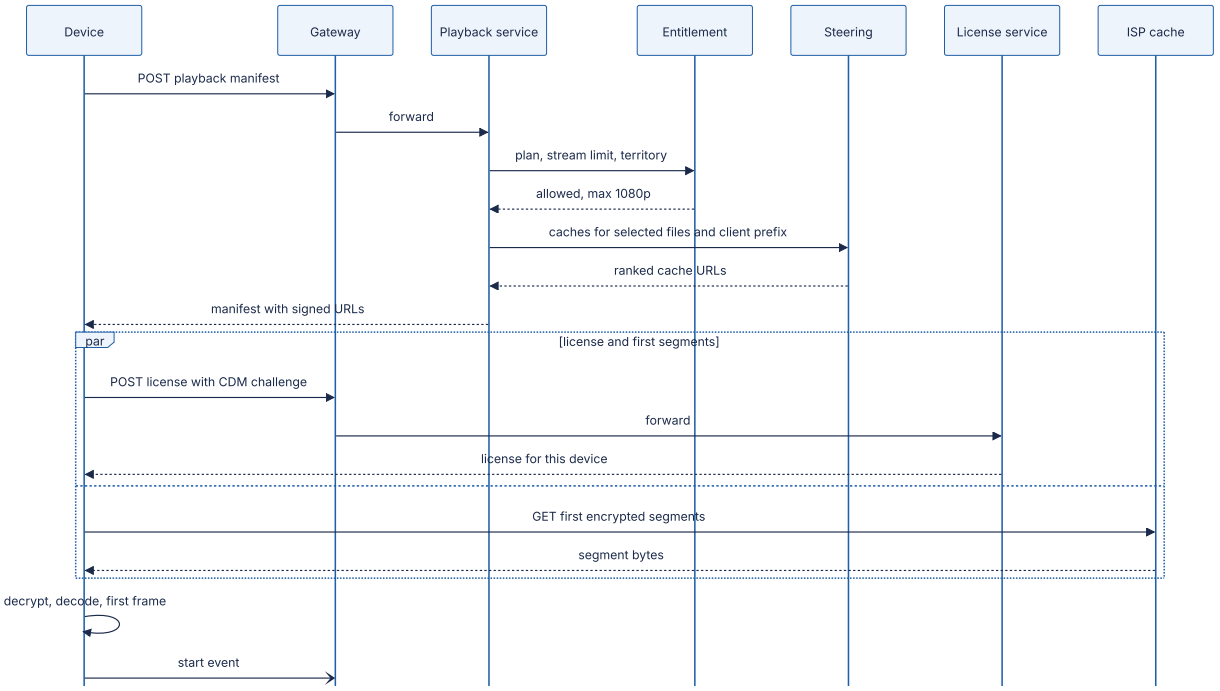
54.5.9 Data flow

Figure 54.8 — Write path: new title from studio to caches.



Reading the diagram. A studio delivers a master to the *ingest service*, which validates and quality-checks it and asynchronously requests encoding. The *encoding pipeline* analyzes the title, encodes chunks in parallel (the YouTube DAG of §54.4.8, without the popularity tiers), encrypts with content keys, writes files to *origin storage* and registers them with the *catalog*. The *placement service* includes the title in the next fill plans; *cache sites* pull files during the off-peak window and report inventory. The title becomes visible only at its release time, by which point every relevant cache holds it. Failure points: a failed QC (the studio redelivers), a missed fill window (the title is served from exchange-point caches or origin at higher cost). The path is asynchronous end to end: hours to days, not milliseconds.

Figure 54.9 — Read path: from pressing play to first frame.



Reading the diagram. The device makes one synchronous call through the *gateway* to the *playback service*, which consults *entitlement* and *steering* and returns a manifest of signed cache URLs. The device then fetches the license and the first encrypted segments in parallel (the `par` block): segments are useless without the key, so fetching them early is safe and saves the license round trip. Decryption and decoding happen on the device. The start event is asynchronous. Failure points: entitlement or license services (play cannot start; fallback to cached entitlement for short outages is a business decision), the first cache (the device tries the next URL), steering (serve from last snapshot).

54.5.10 Bottlenecks

- **Evening peak in the data plane:** an ISP site without enough appliances or with an under-filled cache pushes traffic to exchange points and transit; capacity planning per ISP site is the main lever.
- **Launch of a hit title:** millions of plays of the same files within minutes; caches handle it if pre-positioned, but the control plane sees a play-start spike, so playback and license services pre-scale for scheduled releases.
- **License service:** every start needs one; it touches the key store and must be both secure and highly available; caching keys inside license servers in hardware security modules or protected memory keeps the key store off the hot path.

54.5.11 Failure scenarios

Table 54.5 — Netflix teaching design: failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
One cloud region	Starts fail for members routed there	SPS drop versus prediction	Evacuate to other regions	Active–active, headroom, rehearsed evacuation
Personalization store	Home page cannot rank	Error and latency SLIs	Serve popular rows	Fallback path exercised by chaos tests
License service	No new plays	Start-failure rate by error code	Fail over; scale out	Multi-region, keys cached in protected memory
ISP cache appliance	Sessions on it stall	Client errors; health reports	Client uses next URL; steering removes it	N+1 per site; multiple URLs per manifest
Bad fill (corrupt file)	Playback errors for one title on one site	Client decode errors clustered by cache	Evict and refill; steer away	Checksums verified on fill
Steering data stale	Clients sent to caches without the file	Elevated cache misses and redirects	Rebuild from inventory reports	Snapshot plus incremental updates; caches redirect on miss
Bad deploy to playback service	Starts fail globally	Canary SPS comparison	Automatic rollback	Region-by-region staged rollout (§43.6)

54.5.12 Scaling strategy

At 10× members or viewing hours: the data plane scales almost linearly by adding appliances and sites, but the per-site fill window becomes a constraint, so caches must hold a larger share of the catalog (larger storage) and fill must be smarter (peer fill within a site). The control plane scales horizontally; the shared catalog and entitlement data stay small. The risk is the evacuation headroom: adding a fourth or fifth region lowers per-region overhead from 50% to 25–33%.

At 100×: live events (sports, shows) change the data-plane model, because content cannot be pre-positioned: caches must fill on demand from a live origin with shielding (§21.8), and the control plane must handle millions of simultaneous play starts at the moment an event begins, which calls for admission control and pre-issued licenses. The steering model also becomes multi-CDN for regions where appliances are not deployed.

54.5.13 Trade-offs

Table 54.6 — Netflix teaching design: key trade-offs.

Decision	Option chosen	Alternative	Why
Data plane	Own appliances in ISPs, pre-positioned	Commercial CDN, fill on miss	Known catalog and enormous volume make placement and embedding pay off
Control plane	Public cloud, multi-region active–active	Own data centers	Elasticity and speed; regions give failure isolation
Cross-region data	Eventually consistent replicas	Strongly consistent global store	Bookmarks and history tolerate seconds of lag; availability matters more
Start path	Overlap license with segment fetch	Sequential steps	Saves a round trip; segments are encrypted anyway
Degradation	Fallback rows, start without bookmark	Fail the request	Partial service beats an error page

54.5.14 Alternative designs

- **Commercial multi-CDN** instead of own appliances: the right choice below very large scale or for live, unpredictable content (§21.10.1).
- **Single-region control plane with standby:** simpler and cheaper but turns a region outage into a service outage, with an RTO of tens of minutes (§39.8).
- **Personalization computed fully online** per request: fresher but much more expensive and less robust than precomputed candidates with online re-ranking.

54.5.15 Interview discussion

45-minute pacing plan. 0–5 min: scope (subscription VOD, play start, offline, resilience; recommender out of scope). 5–10 min: capacity, showing that the 125 Tb/s peak forces a distributed data plane and the control plane is ordinary. 10–15 min: API and data model. 15–22 min: architecture with the two planes. 22–35 min: playback start (manifest, license, steering) with the latency arithmetic. 35–42 min: resilience (fallbacks, chaos, evacuation). 42–45 min: scaling and live events.

Likely follow-ups.

- *What happens to people watching when the control plane fails?* They keep watching; licenses and URLs are already issued.
- *How does the client find the best cache?* Steering ranks caches holding the file by client prefix, health and load; the manifest lists several.
- *How do you protect content?* Encrypted segments cached anywhere; per-device licenses from a hardened service; hardware-backed security levels gate resolution.
- *How do you prepare for a big release?* Pre-position files before release, pre-scale the control plane, and practice with load tests.

What distinguishes senior and staff answers. A senior candidate separates control and data planes and draws the play-start sequence. A staff candidate quantifies why (egress versus request rate), designs for running streams to survive control-plane failure, sizes evacuation headroom, and treats chaos experiments and rehearsed evacuations as part of the design rather than an afterthought.

54.5.16 Production considerations

- **Observability.** SPS per region, device type and ISP compared with its forecast is the top-level health signal; client-side quality-of-experience telemetry (start time, re-buffers, bitrate) by cache site detects data-plane problems that servers cannot see.
- **Security.** Content keys never leave the license service and the device's CDM; per-device security levels cap resolution; tokens in cache URLs prevent hot-linking; studio masters are stored with stricter access than encodes.
- **Cost.** The data plane is capital expenditure in ISPs, offset by eliminated transit; the control plane is cloud spend; encoding runs on spare capacity.
- **Operations.** Staged, region-by-region deployments with automated canary analysis; regular evacuation drills; fill-window coordination with ISPs; release-day runbooks.

54.6 Spotify

54.6.1 Problem statement

Design a music streaming service in the style of Spotify: a catalog of about a hundred million tracks, licensed from labels and distributors with per-country rules, playable instantly on phones, desktops, cars and speakers, including offline; user-created playlists that several people can edit together; search across artists, albums, tracks and playlists; and an accounting pipeline that counts every qualifying play so that rights holders are paid correctly.

A music track is small (about 4 MB at 160 kb/s) and people play the same tracks over and over, so the problem looks easy next to video. What makes it hard is that the service has to feel **local**: tapping a track must start sound in a fraction of a second, skipping must be instant, and playback must continue through a tunnel. That pushes intelligence into the client (prefetching and caching), which in turn means that licensing rules must be enforced on a device the service does not control, and that the plays it must count happen partly offline and arrive late. The distinctive hard problems are the **client-side cache and prefetch**, **offline licensing**, **collaborative playlists** and **exactly-once-ish play counting** for royalties.

DEFINITION

Definition — Qualifying stream. A play that counts toward royalty and chart calculations under the service's rules, typically a play that lasted at least a minimum duration (for example 30 seconds) and passed fraud checks. The definition is contractual: changing it changes who gets paid.

54.6.2 Functional requirements

1. Play any available track with near-instant start; skip, seek, shuffle, queue; gapless transitions.
2. Download playlists and albums for offline playback (premium tier), within licensing limits.
3. Create, edit, follow and share playlists; collaborative playlists editable by several users concurrently.
4. Search the catalog and public playlists with typeahead.
5. Ingest catalog metadata and audio from labels and distributors, with per-market availability, release dates and takedowns.
6. Count qualifying streams per track, market and month, and produce royalty statements.
7. Out of scope: podcasts and audiobooks, recommendations (Chapter 81), social features beyond playlist sharing.

54.6.3 Non-functional requirements

Table 54.7 — Spotify teaching design: non-functional targets.

Property	Target	Why
Playback start	p50 < 300 ms, p99 < 1 s from tap to sound (cached or prefetched: < 100 ms)	Music is browsed by skipping
Playback availability	99.99%; cached and downloaded tracks play with no connectivity	Users notice silence instantly
Playlist edits	Durable once acknowledged; visible to collaborators within 2 s; no lost concurrent edits	Collaboration
Search	p99 < 150 ms per keystroke	Typeahead
Catalog changes	Takedowns effective within 1 h worldwide, including on devices at next check-in	Licensing contracts
Stream counts	Each qualifying play counted exactly once in the monthly statement; off-line plays within 30 days	Royalties are money
Event loss	< 0.01% of play events	Under-counting is under-payment

54.6.4 Capacity estimation

Spotify reports monthly active users in the hundreds of millions; the teaching design assumes 600 million MAU.

WORKED EXAMPLE

Worked example — Plays, events and audio egress. Assumptions: 600 million MAU, 40% daily active (240 million DAU); 2 hours of listening per DAU per day; average track 3.5 minutes; average bitrate 160 kb/s; client cache serves 50% of bytes; peak is 2× average; five events per play (start, progress markers, end, plus a qualifying-stream marker).

1. Listening hours per day: $240 \times 10^6 \times 2 = 4.8 \times 10^8$ h.
2. Plays per day: $4.8 \times 10^8 \times 60/3.5 = 8.2 \times 10^9$; average 95,200 plays/s; peak about 190,000 plays/s.
3. Audio egress without cache: $4.8 \times 10^8 \times 3,600 \times 160,000/86,400 = 3.2 \times 10^{12}$ b/s $= 3.2$ Tb/s average, 6.4 Tb/s peak; with half the bytes from client caches, about 3.2 Tb/s at peak from CDNs.
4. Play events: $8.2 \times 10^9 \times 5 = 4.1 \times 10^{10}$ per day; average 476,000 events/s; peak about 950,000 events/s; at 500 B each, about 21 TB/day of raw events.

Interpretation. Audio egress is a few terabits per second, an order of magnitude below video, and fits commercial CDNs. Events approach a million per second and are the backbone of royalty accounting. **Engineering implication.** Buy delivery from CDNs; build the event pipeline as the critical, audited system.

WORKED EXAMPLE

Worked example — Catalog, playlists and client cache. Assumptions: 100 million tracks averaging 210 s; each stored in five encodings summing 960 kb/s (Ogg Vorbis at 96, 160 and 320 kb/s, AAC at 128 and 256 kb/s); 4 billion playlists with an average of 50 entries of about 40 B plus 200 B of attributes; a phone cache budget of 2 GB.

1. Audio catalog: $10^8 \times 210 \times 960,000/8 = 2.52 \times 10^{15}$ B ≈ 2.5 PB per copy; a lossless tier at roughly 1 Mb/s would add about as much again.
2. One track at 160 kb/s: $210 \times 160,000/8 = 4.2$ MB.
3. Playlists: $4 \times 10^9 \times (50 \times 40 + 200) = 8.8 \times 10^{12}$ B ≈ 8.8 TB, plus their operation logs.
4. Phone cache: $2 \times 10^9 / 4.2 \times 10^6 \approx 476$ tracks, more than most people's weekly rotation.

Interpretation. The catalog is modest by object-storage standards and the playlist data is small; the client cache can hold a user's habitual listening. **Engineering implication.** Design the client cache as a first-class tier with an eviction policy tuned to repeat listening; keep playlists in a strongly consistent, partitioned store.

54.6.5 API design

```
GET  /v1/tracks/{trackId}/playback?market=SE&quality=high
     → { fileId: "f_3a…", codec: "vorbis", kbps: 160,
         cdnUrls: ["https://audio-cdn-a.example/f_3a…?sig=…", "https://audio-cdn-
b.example/…"],
         keyHandle: "kh_…", gainDb: -6.2, expiresAt: … }

POST /v1/keys/{keyHandle}        { deviceId, deviceAttestation } → { wrappedKey }   (de-
vice-bound)

POST /v1/offline/grants          { deviceId, items: ["playlist:37i9…", "album:4aaw…"] }
     → { grantId, expiresAt: now+30d, maxTracks: 10000, items: [ { trackId, fileId,
wrappedKey } ] }

GET  /v1/playlists/{playlistId}?since=rev:1842
     → { revision: "rev:1846", ops: [ ... ] }        (or a full snapshot if too far be-
hind)

POST /v1/playlists/{playlistId}/ops
     { baseRevision: "rev:1846", clientOpId: "d1:op:771",
       ops: [ { op: "insert", itemId: "i_9f2", trackId: "t_88", after: "i_51c" },
              { op: "remove", itemId: "i_0aa" } ] }
     → { revision: "rev:1847", applied: [...], transformed: [...] }

GET  /v1/search?q=bohem&types=track,artist,playlist&market=GB&limit=10
POST /v1/events   [ { eventId, playId, type: "play_end", trackId, msPlayed, ts, offline:
false } ]
```

What to notice:

- Audio files are encrypted; the playback response returns CDN URLs and a **key handle**, and the decryption key is delivered wrapped for the specific device.
- An **offline grant** is a lease: it expires and must be renewed by checking in, which is when takedowns and subscription changes reach the device.
- Playlist edits are **operations against a base revision**, identified by `itemId`s rather than positions, with a client operation ID that makes retries idempotent.
- Every event carries a client-generated `eventId` and a `playId` shared by all events of one play; these are the deduplication keys of the counting pipeline.

54.6.6 Data model and database schema

```
        -- Catalog (read-mostly, replicated globally; written only by the ingest pipe-
line)
        CREATE TABLE tracks (
          track_id    CHAR(22) PRIMARY KEY,
          isrc        CHAR(12) NOT NULL,          -- International Standard Recording
Code
          album_id    CHAR(22), duration_ms INT, explicit BOOLEAN
        );
        CREATE TABLE track_availability (
          track_id CHAR(22), market CHAR(2), available_from TIMESTAMP, available_until
TIMESTAMP,
          rights_holder_id BIGINT,                -- who is paid for streams in this
market
          PRIMARY KEY (track_id, market)
        );
        CREATE TABLE audio_files (
          file_id CHAR(40) PRIMARY KEY,           -- content hash of the encrypted file
          track_id CHAR(22), codec VARCHAR(8), kbps INT, key_id BINARY(16)
        );

        -- Playlists (partitioned by playlist_id; each partition strongly consistent)
        CREATE TABLE playlists (
          playlist_id CHAR(22) PRIMARY KEY, owner_id BIGINT, name VARCHAR(200),
          collaborative BOOLEAN, revision BIGINT NOT NULL, snapshot_rev BIGINT
        );
        CREATE TABLE playlist_items (             -- materialized current state
          playlist_id CHAR(22), item_id CHAR(12), track_id CHAR(22),
          added_by BIGINT, added_at TIMESTAMP,
          sort_key VARBINARY(64),                 -- fractional index: order without
renumbering
          PRIMARY KEY (playlist_id, item_id)
        );
        CREATE TABLE playlist_ops (               -- append-only operation log
          playlist_id CHAR(22), revision BIGINT, client_op_id VARCHAR(40), author_id
BIGINT,
          op JSON, PRIMARY KEY (playlist_id, revision),
          UNIQUE (playlist_id, client_op_id)      -- idempotent retries
        );

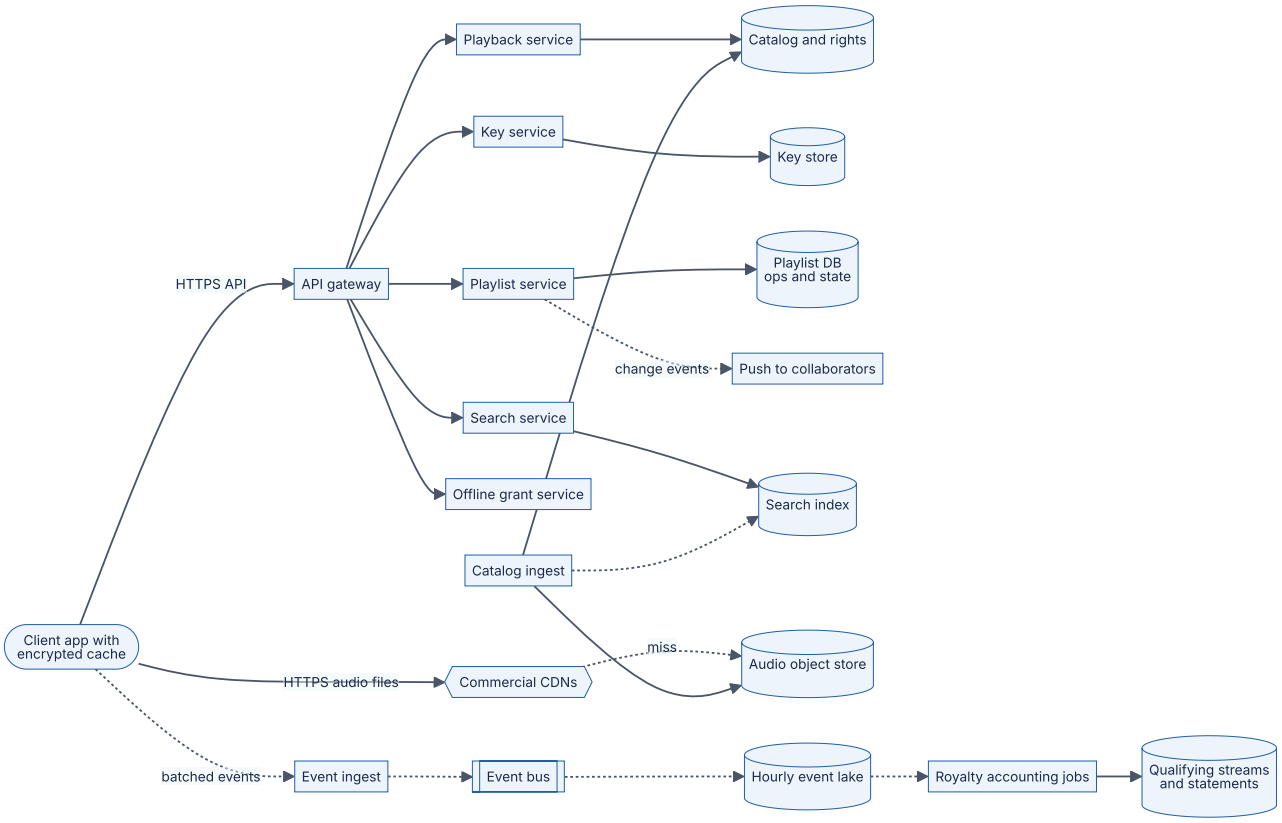
        -- Accounting (append-only, partitioned by month and market)
        CREATE TABLE qualifying_streams (
          month CHAR(7), market CHAR(2), track_id CHAR(22), play_id CHAR(32),
          user_id BIGINT, ms_played INT, offline BOOLEAN,
          PRIMARY KEY (month, market, play_id)    -- uniqueness enforces exactly-once
counting
        );
```

The catalog is read-mostly and fits a relational store replicated to every region, fronted by caches. Playlists need per-playlist serializable updates and an operation log, so a partitioned relational or NewSQL store keyed by `playlist_id` fits (§12.11, §14.7). Raw events

go to an object-store data lake partitioned by hour; `qualifying_streams` is a warehouse table whose primary key is the deduplication guarantee.

54.6.7 High-level architecture

Figure 54.10 — Spotify teaching design.



Reading the diagram. The *client* holds an encrypted cache of audio files and talks to the *API gateway* over HTTPS. The *playback service* checks rights in the *catalog* and returns CDN URLs; the *key service* releases device-bound keys from the *key store*; the *playlist service* stores operations and state in the *playlist DB* and pushes changes to collaborators asynchronously; the *search service* queries the *search index*; the *offline grant service* issues download leases. Audio bytes come from *commercial CDNs* backed by the *audio object store*. Events flow asynchronously from clients through *event ingest* and an *event bus* into an *hourly event lake*, from which *royalty accounting jobs* produce *qualifying streams and statements*. *Catalog ingest* writes metadata, audio and index updates. Storage boundaries: catalog, key store, playlist DB, audio store, event lake and warehouse. Failure points: the key service (cached tracks still need keys, so clients cache wrapped keys too), the event pipeline (events are buffered on the device and in the bus), the playlist DB partition for a very popular collaborative playlist. Scaling: stateless services scale horizontally; playlists partition by ID; events partition by hour and user.

54.6.8 Detailed component design

Component 1 — Client prefetch and cache

The client is the fastest tier of the delivery system. Three mechanisms make playback feel local:

1. **Cache.** Every played track is stored, encrypted, in a local cache with a size budget, evicted by a policy that favors tracks played repeatedly (LFU-like with recency, §20.9). Starting a cached track needs no network at all, provided the wrapped key is also cached.
2. **Prefetch the next track.** When the current track nears its end (say 20 s left), the client fetches the beginning of the next track in the queue, and the key for it. When the user is likely to skip (for example on a freshly opened playlist), prefetch the first few seconds of the next several tracks: a 5 s header at 160 kb/s is only 100 KB.
3. **Fast start.** For an uncached track, fetch the first seconds at a lower bitrate or with a small first range request, start playback, and continue with the full file in larger ranges.

Prefetch costs bandwidth and battery when the user does not play the prefetched track, so the client tunes the depth of prefetch to network type and observed skip behavior.

> INDUSTRY EXAMPLE
>
> **Spotify's original client-centric design.** Kreitz and Niemelä described Spotify's early streaming protocol, in which clients combined a local cache, a peer-to-peer network among clients and Spotify's servers; at the time of the measurements only 8.8% of music data played came from Spotify's servers, and the median playback latency was 265 ms. Clients began prefetching the next track before the current one ended, so that the transition was gapless [Kreitz and Niemelä 2010]. *Evidence: Primary* — [Kreitz and Niemelä 2010]

Component 2 — Offline downloads under licensing constraints

Labels license music for streaming to subscribers, not for permanent copies, so offline playback is a **time-limited lease** enforced on the device:

1. The client requests an **offline grant** for the items; the server checks the subscription, per-device and per-account download limits, and per-track offline permission (`track_availability`), and returns the files' identifiers and their content keys wrapped for this device, with an expiry (for example 30 days).
2. Files are downloaded from the CDN and stored encrypted; keys are stored in the device's secure storage.

3. Before the grant expires, the client must **check in**: the server renews the grant, removes tracks that were taken down or are no longer licensed in the user's market, and the client deletes them. If the client never checks in (the subscription lapsed, the device is lost), keys expire and the files become unplayable.
4. **Offline plays are logged locally** with their `playId`s and uploaded at the next check-in, up to 30 days late. The accounting pipeline must accept them into the month in which they occurred, before statements close (Component 4).

> WARNING / TRADE-OFF
>
> **Device enforcement is best effort.** A rooted device can extract keys. Licensing contracts accept this with layered defenses: per-device key wrapping, hardware-backed key storage where available, download caps, mandatory check-ins and anomaly detection on download volume. Never design as though device-side checks are a security boundary against a determined attacker.

Component 3 — Playlists as collaborative documents

A collaborative playlist is a small shared document: an ordered list edited by several people at once, sometimes offline. A naive design that sends the whole list on every save loses edits: Ann adds a track while Bo deletes another, and whoever saves second overwrites the other's change (a lost update, §11.13). The teaching design treats a playlist like a tiny collaborative editor:

1. **Stable item IDs.** Each entry has a unique `itemId`, so "remove item i_0aa" means the same thing regardless of what others inserted, and two people can add the same track twice without confusion.
2. **Position by neighbor, order by fractional index.** Inserts and moves say "after item X"; the server assigns a `sort_key` between X's key and its successor's (a fractional index), so no other rows are renumbered and concurrent inserts at different positions commute.
3. **Server-ordered operation log.** The playlist service serializes operations per playlist: it appends each batch to `playlist_ops` at the next revision, inside a transaction on that playlist's partition. A client sends its operations with its `baseRevision`; if other operations were applied since, the server **transforms** the client's operations against them (an insert after a deleted item goes after that item's nearest surviving predecessor; a remove of an already removed item becomes a no-op; two concurrent moves of the same item resolve by revision order). This is the server-centric form of operational transformation that §54.7 develops for text.
4. **Idempotency.** `client_op_id` is unique per playlist, so a retried batch returns the original result instead of applying twice.
5. **Propagation.** After commit, a change event notifies connected collaborators, who fetch operations since their revision; a client too far behind fetches a snapshot.

The partition key is `playlist_id`, so all operations on one playlist are serialized on one partition. That is the right trade: even a popular collaborative playlist sees a few edits per second, while followers only read, from caches.

Component 4 — Royalty and play-count accounting

Royalties under a **pro-rata** model divide a pool of revenue in a market and month among rights holders in proportion to their share of qualifying streams. Counting errors therefore do not just misreport a number; they move money from one rights holder to another.

FORMULA

Pro-rata stream share

$$\text{Payout}_h = P \times \frac{s_h}{\sum_k s_k}$$

Symbol	Meaning	Units
Payout_h	Amount allocated to rights holder h in a market and month	$
P	Royalty pool for that market and month	$
s_h	Qualifying streams of tracks controlled by h	streams
$\sum_k s_k$	All qualifying streams in the market and month	streams

WORKED EXAMPLE

Worked example — What a 0.5% double count costs. Assumptions (illustrative): pool $P = \$400$ million; 80 billion qualifying streams in the month; label A has 20 billion, label B 10 billion.

1. Per-stream value: $400 \times 10^6 / 80 \times 10^9 = \$0.005$. A receives \$100 million, B \$50 million.
2. A bug double-counts 0.5% of B's streams: $s_B = 10.05 \times 10^9$, total 80.05×10^9.
3. B now receives $400 \times 10^6 \times 10.05/80.05 = \$50.219$ million, \$218,600 too much.
4. A now receives $400 \times 10^6 \times 20/80.05 = \$99.938$ million, \$62,500 too little; the rest of the \$218,600 is taken from every other rights holder.

Interpretation. In a fixed pool, over-counting one party is under-paying everyone else. **Engineering implication.** The counting pipeline must be exactly-once at the level of a qualifying play, auditable (every counted stream traceable to its events) and reproducible (re-running a month yields the same totals).

The pipeline is batch-oriented because payment is monthly, but it is fed by a streaming event system:

1. **Client buffering.** Clients write events to a local durable queue and upload them in batches with retries; each event has a unique `eventId`, and all events of one play share a `playId`. Retries create duplicates; offline listening creates lateness.
2. **Durable ingest.** Ingest acknowledges a batch only after the event bus has persisted it; the bus writes events into **hourly partitions** of the event lake. Producers cannot be made exactly-once end to end (§32.9), so the system is at-least-once on delivery and deduplicates downstream.
3. **Deduplicate and qualify.** A job groups events by `playId`, keeps the maximum `msPlayed` per play, applies the qualifying rule (threshold, fraud filters) and emits at most one qualifying stream per `playId`. Uniqueness is enforced by the warehouse key `(month, market, play_id)`: writing the same play twice is a no-op upsert.
4. **Late data.** Each month stays open for corrections until a close date (say 35 days after month end), long enough for 30-day offline grants. Late events for a closed month go into an adjustments table applied to the next statement, never silently into the wrong month.
5. **Reconcile and close.** Before statements are issued, totals are reconciled against independent counts (client-side counters, CDN file-access logs by `fileId`) to detect loss or duplication; the month is then frozen and statements are generated.

The code below shows the deduplication rule in miniature.

```
        # Idempotent stream counting: events may be duplicated (client retries),
        # reordered, or arrive days late (offline listening). A play counts once,
        # when its maximum observed ms_played first reaches the 30 s threshold.
        from collections import defaultdict

        THRESHOLD_MS = 30_000

        class StreamCounter:
            def __init__(self):
                self.max_played = {}                # play_id -> max ms_played seen
                self.counted = set()                # play_ids already emitted
                self.streams = defaultdict(int)     # (track_id, month) -> qualifying
streams

            def ingest(self, event):
                pid = event["play_id"]
                best = max(self.max_played.get(pid, 0), event["ms_played"])
                self.max_played[pid] = best
                if best >= THRESHOLD_MS and pid not in self.counted:
                    self.counted.add(pid)           # in production: same transaction
as the count
                    self.streams[(event["track_id"], event["month"])] += 1

        events = [
            {"play_id": "a1", "track_id": "T1", "month": "2026-10", "ms_played":
12_000},
            {"play_id": "a1", "track_id": "T1", "month": "2026-10", "ms_played":
41_000},
            {"play_id": "a1", "track_id": "T1", "month": "2026-10", "ms_played":
41_000},  # retry
            {"play_id": "b7", "track_id": "T1", "month": "2026-10", "ms_played":
25_000},  # skipped
            {"play_id": "c3", "track_id": "T2", "month": "2026-10", "ms_played":
180_000},
            {"play_id": "a1", "track_id": "T1", "month": "2026-10", "ms_played":
35_000},  # late, smaller
        ]
        c = StreamCounter()
        for e in events:
            c.ingest(e)
        print(dict(c.streams))     # {('T1', '2026-10'): 1, ('T2', '2026-10'): 1}
```

What to notice:

- The key is the play, not the event: the retried event and the late, smaller progress event for `a1` do not change the count.
- The month comes from the event's occurrence time, not its arrival time, so a late offline play lands in the right statement.
- In production, `counted` is the warehouse primary key or a transactional state store, and "add to counted" and "increment" must commit together, which is exactly what upserting `(month, market, play_id)` achieves.

INDUSTRY EXAMPLE

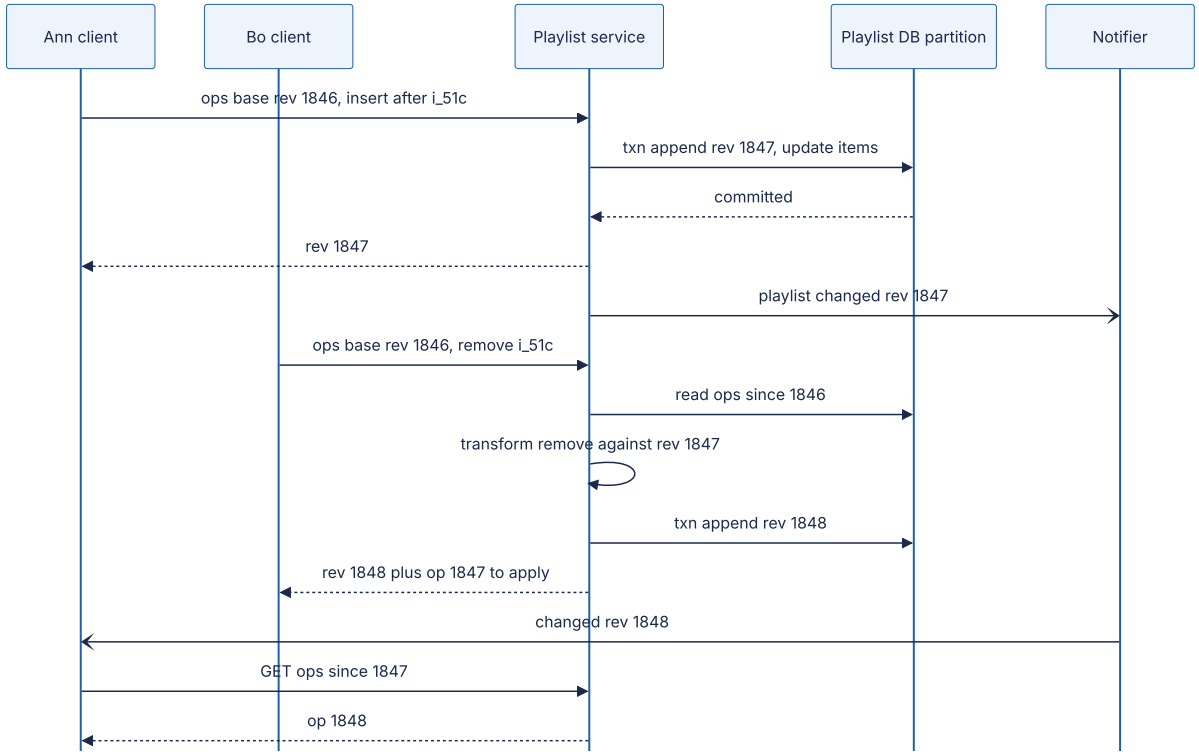
Spotify's event delivery. Spotify has described its event delivery system in a series of engineering posts: client events were originally transported with Kafka into Hadoop, and during its move to Google Cloud Platform the company redesigned the pipeline around Cloud Pub/Sub and Dataflow, writing delivered events into hourly partitions for downstream consumers [Maravić 2016; Spotify Engineering 2019]. Spotify also publishes that a stream counts toward royalties once it has been listened to for at least 30 seconds [Spotify Loud & Clear]. *Evidence: Primary* — [Maravić 2016]; [Spotify Engineering 2019]; [Spotify Loud & Clear]

Search, briefly

Search is an inverted index over tracks, artists, albums and public playlists (Chapter 16) with typeahead on prefixes (§16.9), ranked by text match combined with popularity, and **filtered by market availability** at query time so that users never see tracks they cannot play. The index is rebuilt from the catalog with near-real-time updates for new releases and takedowns (§16.10).

54.6.9 Data flow

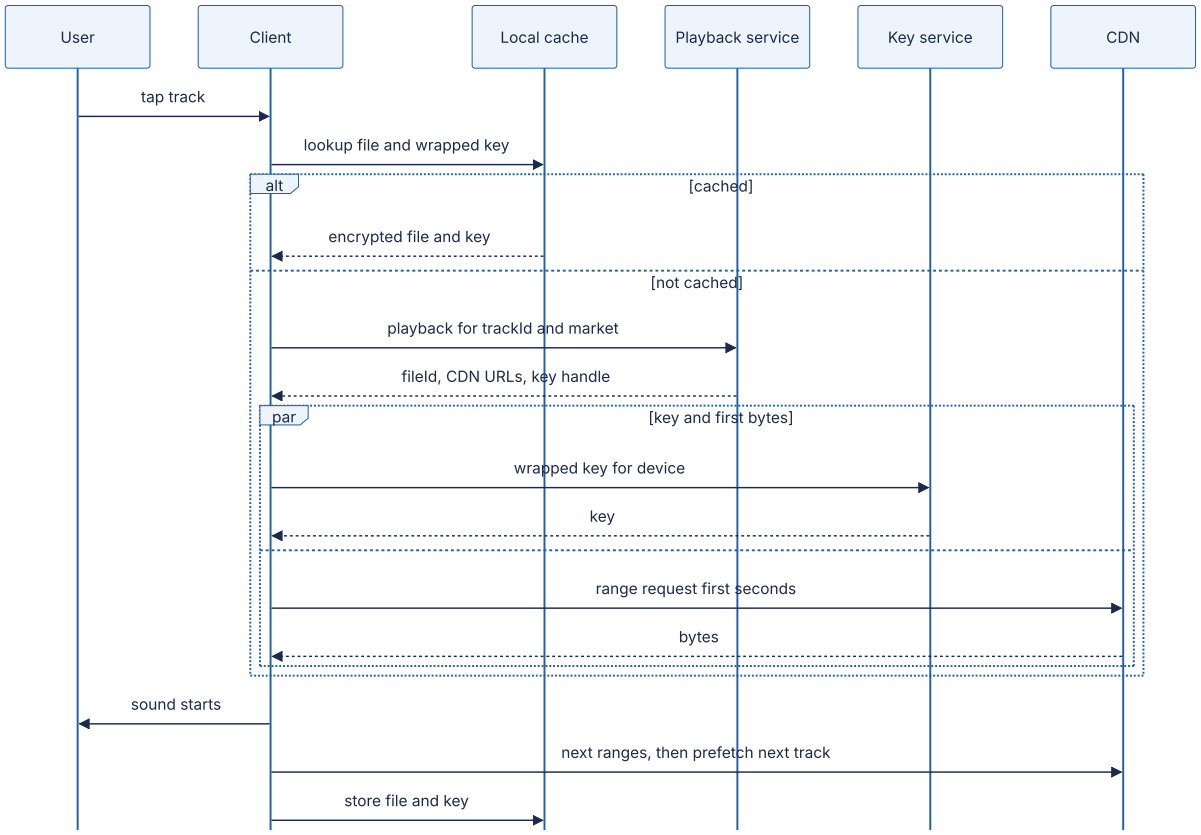
Figure 54.11 — Write path: concurrent edits to a collaborative playlist.



Reading the diagram. Ann and Bo both edit from revision 1846. Ann's insert commits first as revision 1847 in one transaction on the playlist's partition, and a change notifica-

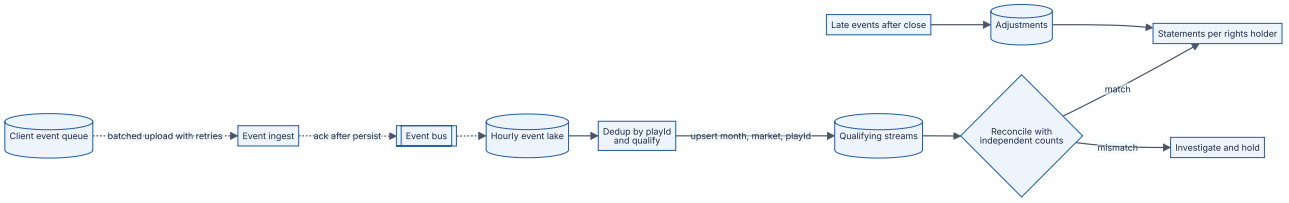
tion goes out asynchronously. Bo's remove arrives with base 1846, so the service reads the operations he has not seen, transforms his operation against them (removing `i_51c` is still valid; Ann's new item now follows `i_51c`'s predecessor), commits revision 1848 and returns both the new revision and Ann's operation so that Bo's client converges. Ann is notified and fetches the missing operation. Failure points: the partition leader (writes pause until failover; clients queue operations locally), the notifier (clients poll as a fallback). No edit is lost because every operation is applied in a single serialized log.

Figure 54.12 — Read path: playing a track with cache and prefetch.



Reading the diagram. The *client* first checks its *local cache*; a hit plays with no network at all. On a miss it makes one synchronous call to the *playback service* for rights and URLs, then fetches the key and the first bytes in parallel (`par`), starting sound as soon as both arrive. Remaining ranges and the next track's prefetch proceed in the background, and the file and key are cached. Failure points: the playback or key service (cached tracks still play; uncached tracks fail), a CDN (the client tries the second URL). Scaling: the more the cache serves, the less every server tier sees.

Figure 54.13 — Play-count and royalty accounting pipeline.



Reading the diagram. Each *client* keeps a durable *event queue* and uploads batches asynchronously; *ingest* acknowledges only after the *event bus* has persisted the batch, so a retry after a lost acknowledgment creates duplicates rather than loss. The bus writes *hourly partitions* to the *event lake*. A batch job *deduplicates by playId and qualifies* plays, upserting into *qualifying streams* keyed by month, market and play. Before statements, totals are *reconciled* with independent counts; mismatches block the close. Late events after a month closes go to *adjustments* applied to the next statement. Failure points: client queue loss (uninstall before upload), a bus outage (clients keep queuing), a bad qualifying rule (re-run the month from the lake, which is the immutable source of truth).

54.6.10 Bottlenecks

- **New release spikes:** a major album release makes millions of clients request the same few files and keys at midnight; CDN pre-warming and key-service caching handle it.
- **Event ingest at peak** (about a million events/s): batching on the client and horizontally scaled ingest keep request rates far lower than event rates.
- **Month-end close:** deduplication over a month of plays (about 250 billion) is a large shuffle; partition by `playId` hash and process incrementally per day, leaving only late events for the close.
- **Hot collaborative playlist:** a playlist edited live by thousands (a public party playlist) saturates one partition; cap collaborators or switch to append-only suggestion queues.

54.6.11 Failure scenarios

Table 54.8 — Spotify teaching design: failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Key service	Uncached tracks cannot start	Start-failure rate	Fail over; clients use cached keys	Multi-region; long-lived wrapped keys for cache
CDN provider	Slow or failed fetches in a region	Client QoE telemetry by CDN	Shift traffic to second CDN	Multi-CDN URLs in every response
Event bus outage	Events delayed	Ingest errors, consumer lag	Clients retry from local queue	Durable client queue; multi-zone bus
Duplicate events	Over-count, overpayment	Reconciliation mismatch	Dedup by playId; rerun month	Warehouse uniqueness key
Takedown not applied	Unlicensed playback	Audit of served filelds against rights	Revoke keys; force grant refresh	Rights checked at playback and check-in
Playlist partition leader loss	Edits pause seconds	Write errors	Leader election; clients queue ops	Replicated partitions (§26)

54.6.12 Scaling strategy

At 10×: delivery grows to tens of terabits per second at peak, still within multi-CDN capacity, but commercial terms motivate deeper caching (larger client caches, ISP-embedded caches for the most popular tracks). Events reach ten million per second: ingest becomes regional with regional lakes and a global merge. Month-end deduplication must be fully incremental.

At 100×: the catalog itself grows (user uploads, AI-generated music), so ingest needs automated fraud and duplicate detection, and per-track overhead (indexes, rights rows) dominates; the rights database becomes a large partitioned system rather than a replicated small one. Royalty accounting needs streaming qualification with exactly-once state (§31.11) so that statements are near-real-time and month-end is a formality.

54.6.13 Trade-offs

Table 54.9 — Spotify teaching design: key trade-offs.

Decision	Option chosen	Alternative	Why
Delivery	Client cache plus commercial CDNs	Own CDN	Bitrates are low; CDNs suffice
Offline	30-day leases with check-in	Permanent downloads	Licensing requires revocability
Playlists	Server-ordered op log with transformation	Last-writer-wins on whole list	No lost concurrent edits
Counting	At-least-once delivery, dedup by playId	Exactly-once end to end	End-to-end exactly-once across devices is impossible; idempotent keys are not
Month close	Fixed close with adjustments	Keep months open forever	Statements must be final and auditable

54.6.14 Alternative designs

- **CRDT playlists** (a sequence CRDT, §27.14) instead of a server-ordered log: better for long offline editing and peer sync, at the cost of metadata per element and harder auditing of who did what.
- **Streaming royalty computation** (Flink-style, §29.9) with exactly-once state instead of daily batch: fresher dashboards for artists; statements still need a close.
- **User-centric payment model** (each subscriber's fee is split among the artists that subscriber played): changes the formula, not the pipeline; counting must then be per user, which increases state.
- **Peer-to-peer delivery** as in Spotify's early design: reduces server egress but complicates mobile clients and battery use.

54.6.15 Interview discussion

45-minute pacing plan. 0–5 min: scope. 5–10 min: capacity (plays, events, egress, catalog). 10–15 min: API and data model. 15–20 min: architecture. 20–28 min: client cache, prefetch and offline leases. 28–36 min: collaborative playlists. 36–42 min: counting and royalties with late data. 42–45 min: scaling and trade-offs.

Likely follow-ups.

- *How do you start playback in 100 ms?* Cache hits and prefetched headers; on a miss, parallel key and first-range fetch.
- *How are offline downloads revoked?* Expiring grants renewed at check-in; keys expire.
- *Two users edit a playlist at once?* Item IDs, neighbor-relative positions, serialized log per playlist with transformation; idempotent op IDs.

- *How do you avoid double counting?* `playId` dedup key with a uniqueness constraint; month by occurrence time; reconciliation before close.

What distinguishes senior and staff answers. A senior candidate designs caching, playlists without lost updates and a deduplicated counter. A staff candidate shows that counting errors redistribute a fixed pool, designs for auditability and reproducibility, handles lateness with explicit close semantics, and treats the device as an untrusted but necessary enforcement point.

54.6.16 Production considerations

- **Observability.** Start latency split by cache hit or miss; skip-to-sound latency; event loss estimated from sequence gaps per client; reconciliation deltas per market.
- **Security.** Device-bound key wrapping; key service isolated; rate limits on offline grants; fraud detection on streaming patterns (bot farms inflating streams).
- **Cost.** CDN egress is the main delivery cost; client caching is the cheapest capacity available. The event lake grows by about 21 TB/day of raw events, so tier it after statements close.
- **Operations.** Catalog ingest is a contractual pipeline with SLAs for takedowns; statement generation is a monthly release with sign-off; rule changes to qualification are versioned and applied only from a future month.

54.7 Google Drive

54.7.1 Problem statement

Design a cloud file service in the style of Google Drive: users store files and folders, share them with people, groups or anyone with a link, open them from any device, and edit documents together in real time, with full version history and a storage quota.

Picture a library where each reader’s card lists the rooms they may enter, permissions can cover one shelf or a whole wing, and some books are being written by several authors at the same desk at once. Two hard problems dominate: deciding **who may see what** on every one of about a million requests per second, with permissions inherited through folders and groups, and letting several people **edit the same document concurrently** without anyone’s keystrokes being lost or the copies diverging.

DEFINITION

Definition — Operational transformation (OT). A technique for real-time collaborative editing in which each user applies their own edits immediately, and edits received from others are **transformed** (their positions adjusted) against concurrent edits already applied, so that all copies converge to the same document while each edit keeps its intended effect [Ellis and Gibbs 1989].

54.7.2 Functional requirements

1. Upload, download, create, rename, move, copy, trash and restore files and folders; files up to terabytes.
2. Share an item with users, groups, a domain or anyone with the link, at roles owner, editor, commenter or viewer; sharing a folder shares its contents.
3. List folders, “Shared with me”, recent files; search by name and content among items the user can access.
4. Real-time collaborative editing of native documents with presence (cursors) and comments.
5. Version history: restore earlier versions of files and documents.
6. Per-user storage quota covering everything the user owns.
7. Change feed for sync clients and third-party apps.
8. Out of scope: the document layout engine, Office format conversion, malware scanning internals.

54.7.3 Non-functional requirements

Table 54.10 — Google Drive teaching design: non-functional targets.

Property	Target	Why
Availability	99.99% for metadata reads and opens; 99.95% for uploads	Work tool used all day
Metadata latency	p99 < 200 ms for list and open	Interactive browsing
Authorization check	p99 < 10 ms, millions per second	On every read path
ACL consistency	No access granted after revocation is acknowledged (“new enemy” safe)	Security
Editing latency	Own keystrokes local (0 ms); others’ edits visible p95 < 500 ms	Collaboration feel
Edit durability	No acknowledged edit lost; all replicas converge	Users trust the document
File durability	11 nines per object per year	Users’ only copy
Quota	Never exceeded by more than one in-flight upload	Billing and fairness

54.7.4 Capacity estimation

Google has reported that Drive has more than a billion users; the teaching assumptions follow that order of magnitude.

WORKED EXAMPLE

Worked example — Metadata, storage and request rates. Assumptions: 1 billion users, 300 million daily active; 1,000 items (files and folders) per user; 1 KB of metadata per item; 5 GB stored per user; each DAU adds 10 MB/day of new content, performs 100 metadata operations and 10 writes per day; peak 3× average.

1. Items: $10^9 \times 1,000 = 10^{12}$; metadata $10^{12} \times 1$ KB $= 1$ PB, before replication and indexes.
2. Logical file data: $10^9 \times 5$ GB $= 5$ EB; growth $300 \times 10^6 \times 10$ MB $= 3$ PB/day ≈ 1.1 EB/yr; average ingest $3 \times 10^{15} \times 8/86,400 \approx 278$ Gb/s.
3. Metadata reads: $300 \times 10^6 \times 100/86,400 = 347,000$/s; peak about 1 million/s, each needing an authorization check.
4. Metadata writes: $300 \times 10^6 \times 10/86,400 = 34,700$/s; peak about 104,000/s.

Interpretation. A petabyte of metadata with a million reads per second is too large for one database and too relational (folders, moves, sharing) for a plain key-value store. **Engineering implication.** Use a horizontally partitioned, transactional store (§28.8, §28.10) with a dedicated authorization service and aggressive caching.

WORKED EXAMPLE

Worked example — Collaborative editing load. Assumptions: 5 million documents open for editing at peak; in 20% of them someone is typing; clients batch keystrokes and send at most 2 operation batches per second per active document.

1. Active documents: $5 \times 10^6 \times 0.2 = 10^6$.
2. Operation batches: $10^6 \times 2 = 2 \times 10^6$ commits/s, each fanned out to the other editors of that document.
3. If each document's session is owned by one server handling 5,000 active documents, about 200 servers carry the typing load, plus headroom.

Interpretation. The aggregate rate is large, but each document's rate is tiny and independent. **Engineering implication.** Partition by document and serialize each document's operations on one owner (a session server), so ordering is local and cheap.

54.7.5 API design

Uploads use the same resumable protocol as §54.4.5. The other main calls:

```
POST  /drive/v1/files                       { name, parentId, mimeType }      → {
fileId, ... }
GET   /drive/v1/files/{fileId}?fields=...    → { fileId, name, parents, owners, size,
version, capabilities }
GET   /drive/v1/files?q=parentId='f_1' and trashed=false&pageToken=...     → { files[],
nextPageToken }
PATCH /drive/v1/files/{fileId}?addParents=f_9&removeParents=f_1   If-Match: "v42"   →
200 | 412
GET   /drive/v1/files/{fileId}/content       → 302 to signed chunk-server URL
POST  /drive/v1/files/{fileId}/permissions   { role: "editor", type: "group", email:
"eng@example.com" }
DELETE /drive/v1/files/{fileId}/permissions/{permissionId}  → { consistencyToken }
GET   /drive/v1/files/{fileId}/revisions     → { revisions: [ { revisionId, modified-
Time, keepForever } ] }
GET   /drive/v1/changes?pageToken=...        → { changes[], newStartPageToken }
GET   /drive/v1/about?fields=storageQuota     → { limit, usage, usageInTrash }

WebSocket /docs/v1/{docId}/session
  client → { type: "ops", baseRevision: 812, ops: [ {ins: 14, text: "h"} ], clientSeq:
33 }
  server → { type: "ack", clientSeq: 33, revision: 815 }
  server → { type: "remote", revision: 816, author: "u_7", ops: [ ... ] }
  both   → { type: "presence", cursor: 92 }
```

What to notice:

- Moves use `If-Match` on the item's version (optimistic concurrency), so two concurrent moves of the same folder cannot both win silently.

- Revoking a permission returns a **consistency token**; later content reads carry it so that the check is evaluated at least as fresh as the revocation (the Zanzibar zookie, §8.12.2).
- The editing session is a WebSocket (§9.6) carrying operations against a base revision, acknowledgments, remote operations and presence.
- The changes feed returns a page token, which sync clients store as their cursor.

54.7.6 Data model and database schema

```
        -- Metadata store: transactional, partitioned. Interleave children with their
namespace.
        CREATE TABLE items (
          namespace_id BIGINT,                -- a user's My Drive or a shared drive
          item_id      BIGINT,
          parent_id    BIGINT,                -- folder within the same namespace
          name         VARCHAR(255),
          kind         VARCHAR(8),            -- folder | blob | doc
          owner_id     BIGINT,                -- charged for quota
          size_bytes   BIGINT,
          head_version BIGINT,                -- current version number
          trashed_at   TIMESTAMP,
          PRIMARY KEY (namespace_id, item_id)
        );
        CREATE UNIQUE INDEX by_parent ON items (namespace_id, parent_id, name, item_id);

        CREATE TABLE versions (
          namespace_id BIGINT, item_id BIGINT, version BIGINT,
          chunk_list   BINARY,                -- ordered list of (chunk_id, length,
sha256)
          created_by BIGINT, created_at TIMESTAMP, keep_forever BOOLEAN,
          PRIMARY KEY (namespace_id, item_id, version)
        );

        CREATE TABLE quota (
          user_id BIGINT PRIMARY KEY, limit_bytes BIGINT, used_bytes BIGINT,
reserved_bytes BIGINT
        );

        -- Authorization tuples (Zanzibar-style), partitioned by object
        --   item:123#owner@user:9    item:123#viewer@group:eng#member
item:123#parent@item:77
        CREATE TABLE acl_tuples (
          object VARCHAR(64), relation VARCHAR(16), subject VARCHAR(80), commit_ts
TIMESTAMP,
          PRIMARY KEY (object, relation, subject)
        );

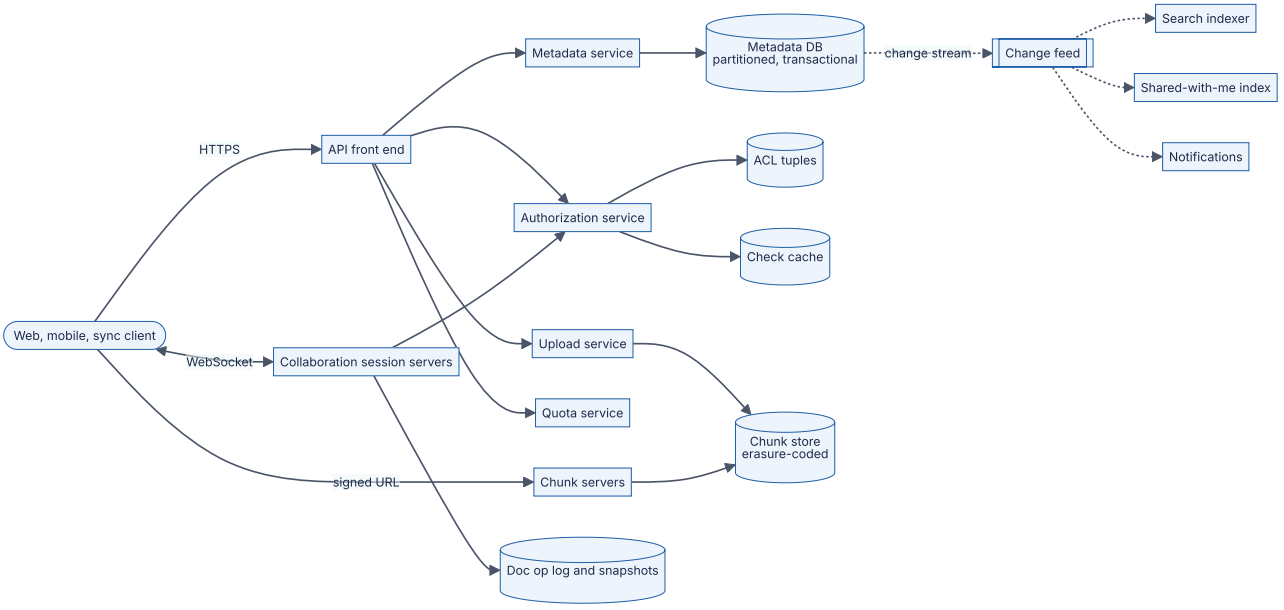
        -- Collaborative documents: operation log plus periodic snapshots
        CREATE TABLE doc_ops (
          doc_id BIGINT, revision BIGINT, author BIGINT, ops BINARY, ts TIMESTAMP,
          PRIMARY KEY (doc_id, revision)
        );
        CREATE TABLE doc_snapshots (doc_id BIGINT, revision BIGINT, body BINARY,
PRIMARY KEY (doc_id, revision));
```

File bytes are split into chunks (say 8 MB) stored in a distributed file system or object store (§15.5) and referenced by `chunk_list`; versions share unchanged chunks. Metadata is partitioned by `namespace_id`, so listing a folder and moving items within a namespace are single-partition transactions; moving between namespaces is a cross-partition transaction, which a store with distributed transactions handles (§28.8). Choosing a Spanner-

like store also gives externally consistent timestamps, which the authorization design uses.

54.7.7 High-level architecture

Figure 54.14 — Google Drive teaching design.



Reading the diagram. All clients reach the *API front end* over HTTPS; editors also hold a *WebSocket* to a *collaboration session server* (bidirectional arrow). The front end calls the *metadata service* (backed by the partitioned, transactional *metadata DB*), the *authorization service* (tuples plus a check cache), the *upload service* and the *quota service*. File bytes go to and from *chunk servers* via signed URLs, so the front end never relays bulk data; chunks live in an erasure-coded *chunk store*. Session servers persist the *op log and snapshots* and check authorization when a user joins. Committed metadata changes flow asynchronously through a *change feed* to the *search indexer*, the *shared-with-me index* and *notifications*. Failure points: the authorization service (on every path; must fail closed), the metadata partition for a huge shared drive, a session server (clients reconnect to a new owner). Scaling: metadata by namespace, authorization by object, sessions by document.

54.7.8 Detailed component design

Component 1 — Metadata service and chunked storage

The metadata service owns the file tree. Each operation is a transaction on the namespace's partition: create inserts an item and its first version; rename and move update `parent_id` / `name` with a check that the destination has no sibling of the same name and that the move does not create a cycle (a folder cannot become its own descendant;

check by walking ancestors in the same transaction). Delete moves an item to the trash; a purge job deletes trashed items after a retention period and decrements quota.

File content is written as **chunks** before the metadata commit: the upload service writes chunks to the chunk store, verifies checksums, and only then commits a new version row pointing at the chunk list and advances `head_version`. A crash between the two leaves orphan chunks, which a garbage collector removes after a grace period by comparing chunk references with stored chunks (mark and sweep). An edit to a large file that changes only part of it creates a version that reuses the unchanged chunks; Dropbox takes this further with content-defined deduplication (§54.8).

Quota is enforced with reservations: an upload reserves its declared size (`reserved_bytes += size`) if `used + reserved + size <= limit`; on commit, the reservation becomes usage; on abort or expiry, it is released. Because the quota row for a user is a hot key during a bulk upload, it lives in the user's home partition and is updated in the same transaction as the version commit.

Component 2 — Sharing and the authorization model

Sharing is **relationship-based access control** (§8.12): permissions are tuples such as `item:123#editor@user:ann` and `item:123#viewer@group:eng#member`, and **rewrite rules** derive effective permissions: an owner is an editor, an editor is a commenter, a commenter is a viewer, and a viewer of a folder is a viewer of every item whose `parent` is that folder. A **check** ("may Ann view item 123?") is a graph search over tuples and rules: direct tuples on the item, then group membership, then the parent chain.

Three design points matter at a million checks per second:

1. **Caching and request deduplication.** Popular items (a company handbook) and large groups are checked constantly; cache check results and sub-results (group memberships), and collapse identical concurrent checks.
2. **Freshness without a global lock.** Every ACL change commits at a timestamp; the content write that follows carries a consistency token. A check evaluated at a snapshot at least as recent as the token cannot use an ACL older than the change, which closes the **new enemy** window: remove Bo, then add a confidential section, and Bo cannot read the section through a stale cache (§8.12.2).
3. **Listing what a user can see.** "Shared with me" and search need the reverse question, "which items may Ann view?". Checking every item is impossible, so a reverse index `user → items shared directly with the user or the user's groups` is maintained asynchronously from the change feed, and search results are post-filtered by batched checks.

> INDUSTRY EXAMPLE
>
> **Zanzibar and Drive.** Google's Zanzibar paper describes one authorization system serving many Google products, listing Drive among its clients, storing more than two trillion relation tuples, serving millions of checks per second with 95th-percentile latency below 10 ms, and using consistency tokens ("zookies") to avoid the new-enemy problem [Pang et al. 2019]. *Evidence: Primary* — [Pang et al. 2019]

Link sharing is a tuple with a special subject (`anyone-with-link`) plus an unguessable item ID; organization policies can forbid it. Every permission change is written to an audit log (§10.12).

Component 3 — Real-time collaborative editing

Each open document has one **session owner**, a collaboration server chosen by consistent hashing on `doc_id` (§14.8). The owner holds the document state in memory, appends every accepted operation to `doc_ops` at the next revision, and broadcasts it to all connected clients. This is the client–server form of OT pioneered by the Jupiter system [Nichols et al. 1995]:

1. A client applies its own edit to its local copy immediately (zero-latency typing) and sends it with the server revision it was based on.
2. The server transforms the incoming operation against every operation committed since that base revision, appends the transformed operation, and broadcasts it.
3. A client receiving a remote operation transforms it against its own sent-but-unacknowledged and unsent operations before applying it.
4. Each client has at most one batch in flight; it waits for the acknowledgment before sending the next, which keeps transformation to two parties (client and server) and makes the algorithm much simpler than peer-to-peer OT.

The heart of OT is the **transform function**. For two concurrent edits a and b to the same state, it must satisfy the convergence property $b \circ T(a, b) = a \circ T(b, a)$: applying b then the transformed a gives the same document as applying a then the transformed b. For character inserts and deletes:

```
        # Operational transformation for single-character insert and delete.
        # transform(a, b) rewrites a so that it can be applied after b has been applied.
        # Ties between inserts at the same position are broken by site ID.
        import random

        def apply(doc, op):
            kind, pos = op[0], op[1]
            return doc[:pos] + op[2] + doc[pos:] if kind == "ins" else doc[:pos] +
doc[pos + 1:]

        def transform(a, b):
            if a is None or b is None:
                return a
            ka, pa, kb, pb = a[0], a[1], b[0], b[1]
            if ka == "ins" and kb == "ins":
                if pa < pb or (pa == pb and a[3] < b[3]):
                    return a
                return ("ins", pa + 1, a[2], a[3])
            if ka == "ins" and kb == "del":
                return a if pa <= pb else ("ins", pa - 1, a[2], a[3])
            if ka == "del" and kb == "ins":
                return a if pa < pb else ("del", pa + 1)
            if pa == pb:                        # both deleted the same character
                return None                     # a becomes a no-op
            return a if pa < pb else ("del", pa - 1)

        def apply_maybe(doc, op):
            return doc if op is None else apply(doc, op)

        def random_op(doc, site):
            if doc and random.random() < 0.5:
                return ("del", random.randrange(len(doc)))
            return ("ins", random.randrange(len(doc) + 1), random.choice("xyz"), site)

        random.seed(7)
        for _ in range(10_000):
            doc = "".join(random.choice("abc") for _ in range(random.randrange(0, 6)))
            a, b = random_op(doc, site=1), random_op(doc, site=2)
            left = apply_maybe(apply(doc, a), transform(b, a))     # site 1: a, then b'
            right = apply_maybe(apply(doc, b), transform(a, b))    # site 2: b, then a'
            assert left == right, (doc, a, b, left, right)
        print("converged in 10,000 random concurrent pairs")
        print(apply_maybe(apply("cat", ("ins", 1, "h", 1)), transform(("del", 2),
("ins", 1, "h", 1))))
```

What to notice:

- An insert at or before a concurrent delete keeps its position; after it, it shifts left by one. A delete after a concurrent insert shifts right.

- Two inserts at the same position need a deterministic tie-breaker (site ID); without it, the copies diverge.
- Two deletes of the same character become one: the second is a no-op.
- The last line merges “insert h at 1” and “delete the t” on `cat` into `cha` on both sides. Real editors transform richer operations (ranges, formatting, tables), which is where most of OT’s complexity lives.

OT or CRDT? A **sequence CRDT** (§27.14) gives every character a unique, ordered identifier, so concurrent inserts and deletes commute without transformation and replicas converge without a central server, which suits offline-first and peer-to-peer editing. The costs are per-character metadata (identifiers and tombstones for deleted characters, which need garbage collection) and less natural support for operations such as “move this range” or schema-rich documents. Server-centric OT needs a single ordering point per document, which a cloud editor has anyway, and keeps the stored document compact. The teaching design uses OT with a session owner; §54.7.14 discusses the CRDT alternative.

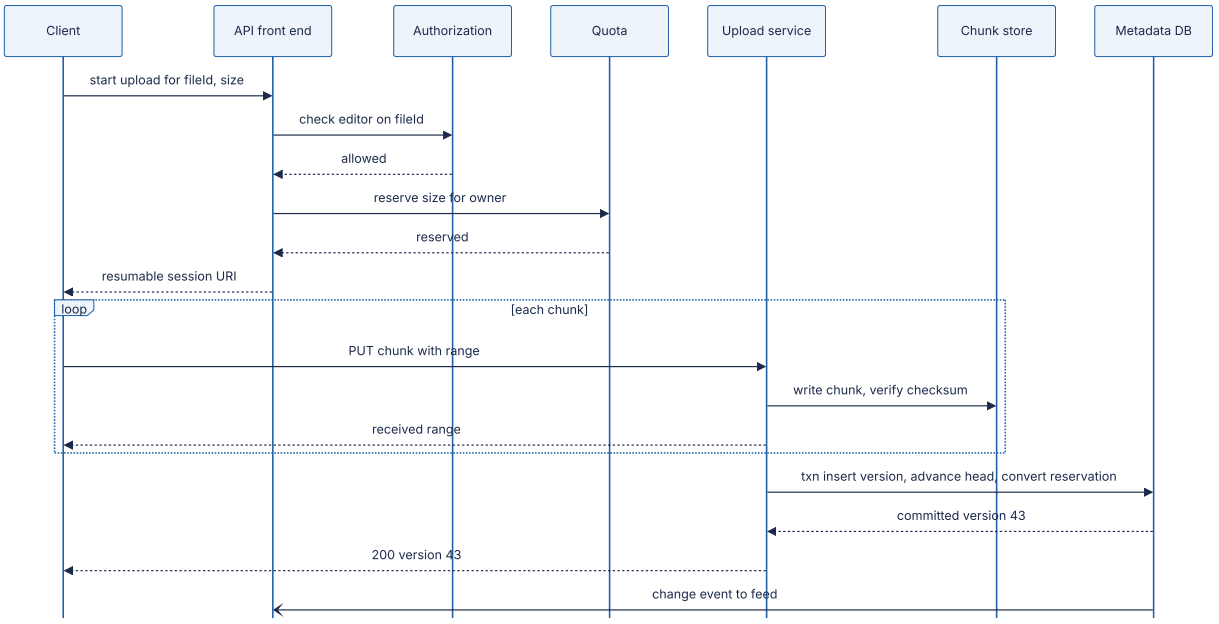
> INDUSTRY EXAMPLE
>
> **Google Docs and OT.** Google described the collaboration model of the rebuilt Google Docs editor in a 2010 blog series: each change is represented as an operation, concurrent operations are reconciled with operational transformation, and a collaboration protocol between clients and Google’s servers keeps all editors’ copies consistent [Day-Richter 2010]. *Evidence: Primary* — [Day-Richter 2010]

Component 4 — Versioning

Versions take two forms. For uploaded files, each content change creates a `versions` row with its chunk list; older versions are kept for a retention period or count and then garbage-collected unless pinned (`keep_forever`), and their unique chunks are deleted. For collaborative documents, the operation log *is* the version history: any revision can be reconstructed by loading the nearest earlier snapshot and replaying operations. Snapshots are taken every few hundred operations so that opening a document never replays more than that; named versions are pinned snapshots. Old operations can be compacted into coarser revisions (for example, per editing session) after a period, which keeps the log bounded while preserving a useful history.

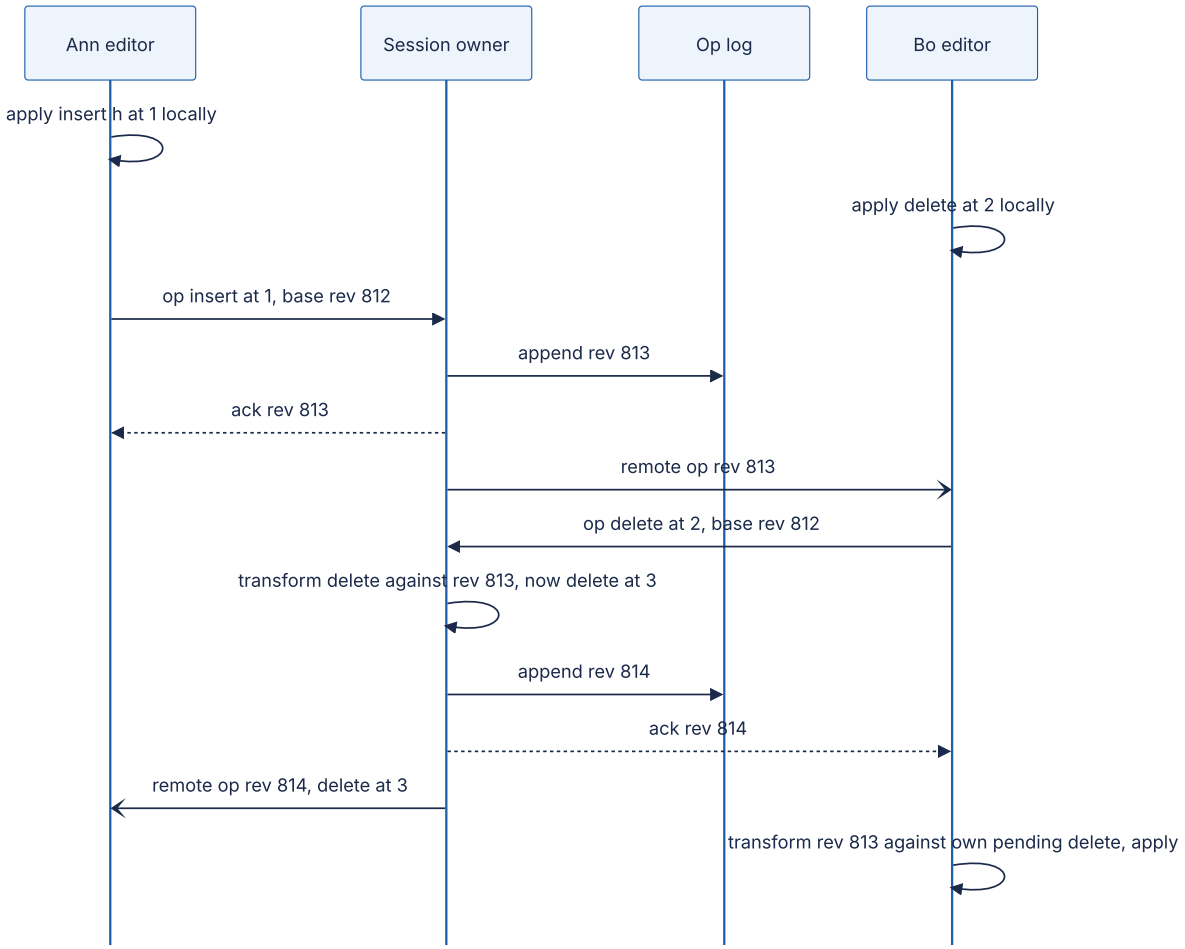
54.7.9 Data flow

Figure 54.15 — Write path: uploading a new version.



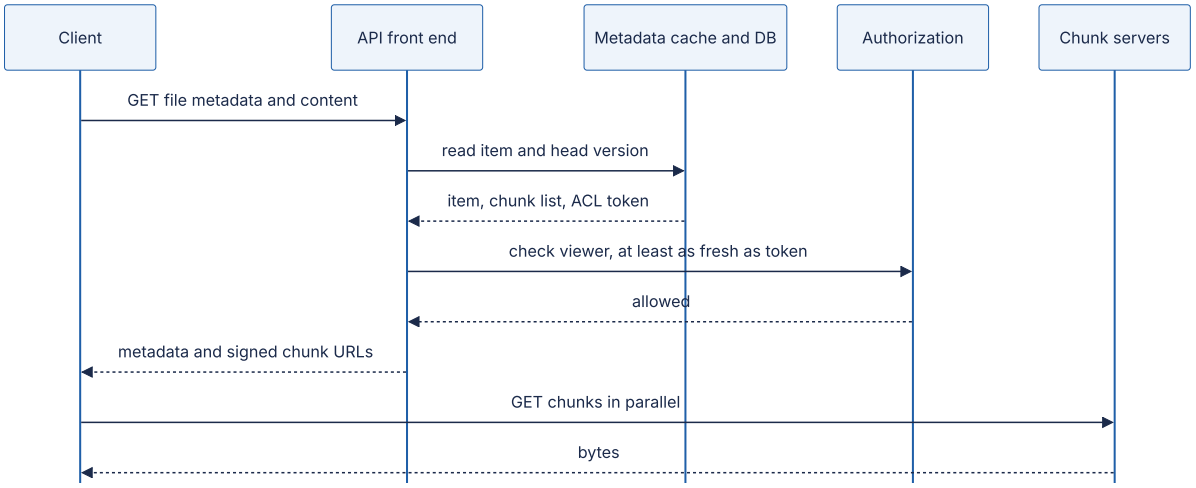
Reading the diagram. The front end checks authorization and reserves quota before any bytes arrive, so an upload that would exceed quota fails fast. Chunks stream to the *upload service* and the *chunk store*; only after all are durable does one transaction insert the version, move the head and convert the reservation into usage. The change event propagates asynchronously to search, sync clients and notifications. Failure points: a crash mid-upload (resume from the received range; reservation expires if abandoned), a crash before commit (orphan chunks, garbage-collected).

Figure 54.16 — Collaborative editing session with concurrent operations.



Reading the diagram. Both editors apply their own edits locally at once. Ann’s insert reaches the *session owner* first and becomes revision 813 in the *op log*; it is acknowledged to Ann and broadcast to Bo asynchronously. Bo’s delete arrives based on revision 812, so the owner transforms it against 813 (the deleted character moved one place right), appends it as 814 and broadcasts it to Ann. Bo, who receives 813 while his delete is in flight, transforms 813 against his pending operation before applying it. Both end with the same text. Failure points: the session owner crashing (clients reconnect to the new owner, which rebuilds state from snapshot plus log and asks clients to resend unacknowledged operations, deduplicated by client sequence numbers).

Figure 54.17 — Read path: opening a shared file.



Reading the diagram. The front end reads metadata (usually from cache), then asks the *authorization service* to evaluate the check at a snapshot at least as fresh as the item's stored consistency token, and returns short-lived signed URLs for chunks, which the client fetches in parallel from *chunk servers*. If authorization is unavailable, the request fails closed. Failure points: a stale cache entry (harmless, because the check uses the token), the authorization service (fail closed, so its availability bounds Drive's).

54.7.10 Bottlenecks

- **Authorization fan-out** for deeply nested groups and folders: precompute group membership indexes and cache sub-results.
- **Huge shared drives:** a namespace with millions of items and thousands of writers makes one partition hot; split large namespaces into sub-partitions by folder subtree.
- **Folder moves and permission changes on large trees:** inheritance through `parent` avoids rewriting every child, but the reverse indexes (shared-with-me, search ACLs) must be updated asynchronously, which can take minutes for very large trees.
- **Very popular documents** (a company-wide doc with thousands of simultaneous viewers): separate viewers from editors, broadcasting to viewers through a fan-out tier rather than the session owner.

54.7.11 Failure scenarios

Table 54.11 — Google Drive teaching design: failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Authorization service	All opens fail (closed)	Check error rate and latency SLO	Fail over; serve from caches only within freshness bound	Multi-region, replicated; capacity headroom
Session owner crash	Editors pause briefly	WebSocket disconnects	Reassign owner; rebuild from snapshot plus log; clients resend	Ops durable before ack
Metadata partition hot	Slow lists and writes in one namespace	Per-partition latency	Split partition	Load-based splitting
Reverse index lag	New shares missing from Shared with me	Feed consumer lag	Catch up; direct link still works	Monitor lag; backfill
Orphan chunks	Wasted storage	GC metrics	Mark-and-sweep GC	Commit protocol with grace period
Accidental mass deletion	Data appears lost	User reports; anomaly on delete rate	Restore from trash and versions	Trash retention; versioning

54.7.12 Scaling strategy

At 10×: metadata reaches 10 PB and 10 million reads/s; partition counts grow, and cross-partition moves become more frequent and more expensive, so the API discourages cross-namespace moves of huge folders (copy-then-delete in the background). Authorization becomes the critical shared service, regionally replicated with snapshot reads near users.

At 100×: the change feed and reverse indexes become the bottleneck; partition them by user and accept seconds of lag. Storage growth (100 EB/yr) pushes cold versions and rarely opened files to colder, denser erasure codes, with transparent recall.

54.7.13 Trade-offs

Table 54.12 — Google Drive teaching design: key trade-offs.

Decision	Option chosen	Alternative	Why
Metadata store	Partitioned transactional (NewSQL)	Key-value plus application locking	Moves, uniqueness and quotas need transactions
Permissions	Inherited via parent tuples	Copy ACLs to every child	Sharing a folder of a million files is one write
Editing	Server-centric OT with session owner	CRDT, peer-to-peer	Single ordering point exists; compact storage
Revocation	Consistency tokens	Synchronous cache invalidation everywhere	Correctness without global coordination
Reverse indexes	Asynchronous	Synchronous with every share	Write latency; lag is visible but not unsafe

54.7.14 Alternative designs

- **CRDT-based editor** (for example, in the style of the JSON CRDT [Kleppmann and Beresford 2017]): strong for offline-first and end-to-end encrypted collaboration, where the server cannot read operations and therefore cannot transform them.
- **Per-user storage partition with no shared namespaces:** simpler partitioning, but shared drives and organization ownership become awkward.
- **ACL lists on each item, evaluated locally:** fast for direct shares, but inheritance and group changes require rewriting many items; acceptable only for small trees.
- **Locking instead of concurrent editing** (check-out/check-in): trivial consistency, unacceptable collaboration experience.

54.7.15 Interview discussion

45-minute pacing plan. 0–5 min: scope (storage, sharing, collaborative editing). 5–10 min: capacity (metadata size, checks per second, editing load). 10–15 min: API and schema. 15–20 min: architecture. 20–30 min: sharing and authorization, including inheritance and the new-enemy problem. 30–40 min: collaborative editing with OT, a worked transform, OT versus CRDT. 40–45 min: versioning, quota, scaling.

Likely follow-ups.

- *How do you list "Shared with me"?* An asynchronously maintained reverse index from user (and groups) to items; checks still applied on open.
- *Revoked user still sees content?* Consistency tokens force checks at a fresh enough snapshot.
- *Two people type at the same spot?* Deterministic tie-break in the transform; both copies converge.
- *How do you open a document with a million operations quickly?* Snapshots every few hundred operations.

What distinguishes senior and staff answers. A senior candidate uses ReBAC with inheritance and draws the OT session. A staff candidate explains why the check service bounds availability and must fail closed, handles the reverse-listing problem, quantifies per-document versus aggregate editing load, and chooses between OT and CRDT from requirements (central server, offline, encryption) rather than fashion.

54.7.16 Production considerations

- **Observability.** Check latency and cache hit ratio; reverse-index lag; editing round-trip latency (local op to remote visibility); session-owner reassignment rate.
- **Security.** Fail closed on authorization errors; audit log of every share and access by administrators; link-sharing policies; data-loss-prevention scanning on the change feed; encryption at rest with per-customer keys for enterprise tiers (§10.9).

- **Cost.** Storage dominates; versions and trash are a large hidden share, so retention limits matter; the authorization service is small in bytes but large in CPU.
- **Operations.** Transform functions are versioned with the client; any change ships behind a document-schema version and is tested with randomized convergence tests like the one above, at much larger scale.

54.8 Dropbox

54.8.1 Problem statement

Design a file-synchronization service in the style of Dropbox: a user's folder on a laptop, a desktop and a phone, and the folders other people share with them, are kept identical automatically. Edit a file on one device and the change appears on the others within seconds; work offline and the changes sync when the device reconnects; two people edit the same file and neither edit is lost.

Google Drive (§54.7) is a cloud service that devices browse. Dropbox, in this teaching framing, is a **replication system** whose replicas are ordinary folders on many devices, each of which can change at any time, crash at any point, run out of disk, or stay offline for weeks. The hard problem is the **sync engine**: detecting changes, uploading only new bytes, committing changes to a per-namespace journal on the server, telling other devices promptly, and reconciling concurrent changes without ever losing a user's edit. Think of clerks in different towns keeping copies of one ledger, posting each other only new lines, with a rule for when two write different lines on the same page.

> DEFINITION
>
> **Definition — Namespace and journal.** A **namespace** is a unit of sharing and synchronization: a user's root folder or a shared folder, mounted into each member's tree. Each namespace has an append-only **journal** on the server: every committed change (add, modify, delete, move) gets the next journal ID. A device's sync position in a namespace is simply the last journal ID it has applied, its **cursor**.

54.8.2 Functional requirements

1. Desktop clients sync a local folder with the server in both directions; mobile and web clients browse and fetch on demand.
2. Upload only changed data; never upload the same block twice if the server has it.
3. Share folders with other users; changes in a shared folder sync to all members.
4. Notify devices of remote changes within seconds.
5. Handle concurrent edits by producing a conflicted copy rather than discarding data; handle concurrent moves and deletes predictably.

6. Version history and restoration of deleted files.
7. Out of scope: document previews, collaborative editing (§54.7), enterprise administration.

54.8.3 Non-functional requirements

Table 54.13 — Dropbox teaching design: non-functional targets.

Property	Target	Why
Data safety	No acknowledged change ever lost; no silent overwrite	The product promise
Durability	11–12 nines per block per year	Many users' only copy
Sync latency	p95 < 5 s from commit to other on-line devices starting download	Feels instant
Commit availability	99.95%; clients queue changes off-line indefinitely	Offline is normal
Bandwidth efficiency	Upload ≤ 1.1× the truly new bytes for typical edits	User networks are slow
Metadata consistency	Per-namespace linearizable journal	Devices must agree on order
Notification scale	100 million concurrently connected devices	Every device waits for changes

54.8.4 Capacity estimation

Dropbox has reported hundreds of millions of registered users; the assumptions below are illustrative.

WORKED EXAMPLE

Worked example — Commits, uploads and notifications. Assumptions: 50 million daily active users with 2 connected devices each; 20 file changes committed per DAU per day; 1 MB of genuinely new data per change after deduplication; each commit notifies 3 other devices on average; peak 3× average.

1. Connected devices: $50 \times 10^6 \times 2 = 10^8$ long-lived notification connections.
2. Commits: $50 \times 10^6 \times 20 = 10^9$ per day; average 11,600/s; peak about 34,700/s.
3. New data: $10^9 \times 1$ MB $= 1$ PB/day; average upload bandwidth $10^{15} \times 8/86,400 \approx 93$ Gb/s.
4. Notifications: $34,700 \times 3 \approx 104,000$ wake-ups/s at peak, each followed by a delta-list request.
5. Notification servers at 250,000 idle connections each: $10^8/2.5 \times 10^5 = 400$ servers.

Interpretation. The commit rate is moderate; the connection count is the unusual number. **Engineering implication.** Notification servers are a specialized tier optimized for idle connections and must carry no state that cannot be rebuilt; commits go to a partitioned metadata store.

WORKED EXAMPLE

Worked example — Block index size. Assumptions: 1 EB of unique stored data; average block 2 MB (most files are smaller than the 4 MiB maximum block); 64 B per index entry (32-byte SHA-256 plus location and reference count).

1. Blocks: $10^{18}/2 \times 10^6 = 5 \times 10^{11}$.
2. Index: $5 \times 10^{11} \times 64 = 3.2 \times 10^{13}$ B $= 32$ TB.

Interpretation. The block index is far too large for memory on one machine but modest for a partitioned database. **Engineering implication.** Partition the index by hash prefix (§14.8); lookups are uniform by construction because SHA-256 output is uniform.

54.8.5 API design

```
POST /2/sync/commit
  { namespaceId: 881, path: "/Reports/q3.xlsx", parentRev: "rev_04f",
    blockList: ["sha256:9a1…", "sha256:77c…", "sha256:e02…"], size: 9437184, mtime: … }
  → 200 { rev: "rev_051", journalId: 1201447 }
  → 409 { needBlocks: ["sha256:77c…"] }                 (upload these, then retry)
  → 409 { conflict: true, serverRev: "rev_050" }          (parentRev is stale)

PUT  /2/blocks/{sha256}            <bytes ≤ 4 MiB>  → 200   (server verifies the hash)
POST /2/blocks/has                 { hashes: [...] } → { missing: [...] }
GET  /2/blocks/{sha256}            → bytes (from a block server or CDN, signed)

POST /2/sync/list                  { cursors: { "881": 1201440, "902": 77310 } }
  → { entries: [ { namespaceId, journalId, path, op: "modify"|"delete"|"move", rev,
blockList } ],
      cursors: { "881": 1201447, "902": 77310 }, hasMore: false }

POST /2/notify/longpoll            { cursors: { "881": 1201447, "902": 77310 }, timeout:
90 }
  → { changes: true }  |  { changes: false, backoff: 30 }
```

What to notice:

- A commit names content by **block hashes**, not bytes; the server replies with the blocks it lacks, so unchanged and already-known blocks are never uploaded.
- `parentRev` is the revision the client edited from; the server commits only if it is still current (compare-and-set), which is how conflicts are detected.
- The long poll carries the client's cursors and returns only a boolean; the client then calls `list` to fetch the changes. Dropbox's public API has the same shape: a long-poll endpoint that reports whether a folder cursor is stale, followed by a list-continue call with the cursor [Dropbox API v2 docs].

54.8.6 Data model and database schema

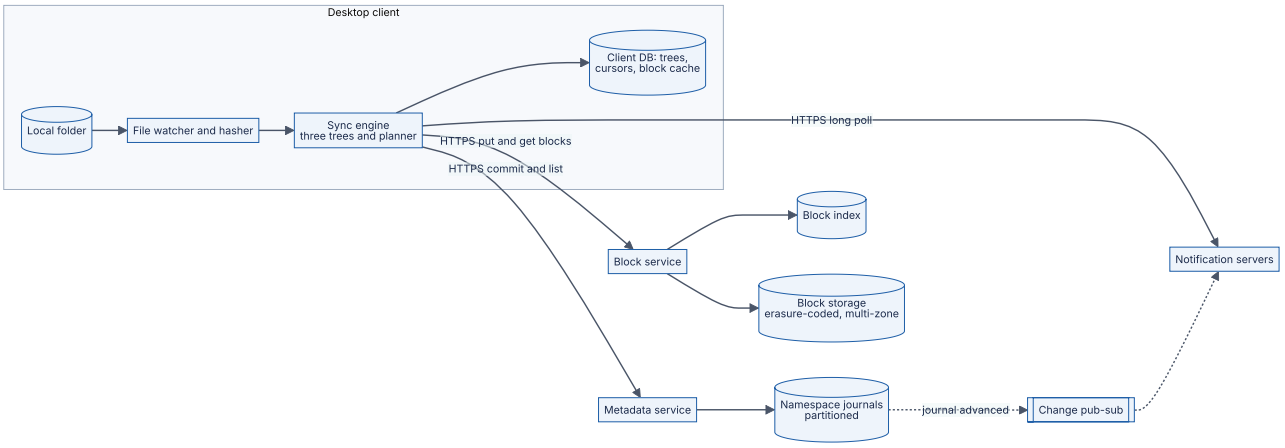
```
        -- Metadata, partitioned by namespace_id: every namespace's journal lives on one
partition.
        CREATE TABLE namespaces (
          namespace_id BIGINT PRIMARY KEY, owner_id BIGINT, kind VARCHAR(8),  -- root |
shared
          latest_journal_id BIGINT NOT NULL
        );
        CREATE TABLE journal (
          namespace_id BIGINT, journal_id BIGINT,
          path VARCHAR(1024), op VARCHAR(8),          -- add | modify | delete | move
          rev CHAR(12), parent_rev CHAR(12), block_list BINARY, size BIGINT,
          device_id BIGINT, committed_at TIMESTAMP,
          PRIMARY KEY (namespace_id, journal_id)
        );
        CREATE TABLE files_latest (                 -- current state, derived from the
journal
          namespace_id BIGINT, path VARCHAR(1024), rev CHAR(12), journal_id BIGINT,
          block_list BINARY, size BIGINT, deleted BOOLEAN,
          PRIMARY KEY (namespace_id, path)
        );
        CREATE TABLE mounts (                       -- shared folders mounted into
users' trees
          user_id BIGINT, namespace_id BIGINT, mount_path VARCHAR(1024),
          PRIMARY KEY (user_id, namespace_id)
        );

        -- Block index, partitioned by hash prefix
        CREATE TABLE blocks (
          hash BINARY(32) PRIMARY KEY, size INT, storage_cell INT, extent_id BIGINT, re-
fcount BIGINT
        );
```

The journal and `files_latest` are updated in one transaction per commit on the namespace's partition, so each namespace's history is linearizable and a cursor is a precise point in it (§25.3). Partitioning by namespace keeps commits single-partition, except when a move crosses namespaces (rare, handled as delete plus add with the same blocks). Blocks are content-addressed and immutable; deleting a file decrements reference counts, and a block is reclaimed only when no version in retention references it.

54.8.7 High-level architecture

Figure 54.18 — Dropbox teaching design.



Reading the diagram. On the *desktop client*, a *file watcher* notices changes in the *local folder* and hashes content into blocks; the *sync engine* keeps three trees and a planner (Component 3) and persists them, with cursors and a block cache, in a *client DB*. The client talks HTTPS to three server tiers: the *metadata service* for commits and change lists, the *block service* for block uploads and downloads, and the *notification servers* for long polls. Metadata lives in *namespace journals*, partitioned by namespace. The block service consults the *block index* and stores blocks in erasure-coded, multi-zone *block storage*. When a journal advances, an event is published asynchronously through *change pub-sub* to the notification servers holding long polls for that namespace. Storage boundaries: the local folder and client DB on each device, the journals, the block index and block storage. Failure points: a metadata partition (commits for its namespaces pause; clients queue), a notification server (its clients reconnect elsewhere and re-list from their cursors, so no change is missed). Scaling: metadata by namespace, blocks by hash, notifications by connection.

54.8.8 Detailed component design

Component 1 — Client-side chunking, deduplication and delta sync

When a file changes, the client splits it into blocks, hashes each block with SHA-256, and asks the server which hashes it lacks. Only missing blocks are uploaded. This gives three kinds of savings at once: an unchanged block of an edited file is not re-sent; a file copied or renamed within the account costs nothing; and a block the server already holds is not re-sent.

How to cut blocks. Fixed-size blocks (every 4 MiB) are simple and make block boundaries predictable, but an insertion near the start of a file shifts every later boundary, so every later block looks new. **Content-defined chunking** (CDC, §15.8.3) places boundaries where a rolling hash of the content matches a pattern, so boundaries move with the content and an insertion changes only the chunk that contains it.

FORMULA

Upload size after a small insertion: fixed blocks versus CDC

$$U_{\text{fixed}} \approx \lceil \frac{S - o}{B} \rceil B \qquad U_{\text{CDC}} \approx k \times E[\text{chunk}] + \Delta, \quad k \in \{1, 2\}$$

Symbol	Meaning	Units
S	File size	bytes
o	Offset of the insertion	bytes
B	Fixed block size	bytes
Δ	Inserted bytes	bytes
$E[\text{chunk}]$	Expected CDC chunk size (§15.8.3)	bytes
k	Chunks touched by the edit (two if it straddles a boundary)	count

WORKED EXAMPLE

Worked example — Inserting 100 bytes into a 1 GB file. $S = 10^9$ B, $o = 10^8$ B (10% into the file), $B = E[\text{chunk}] = 4$ MiB $= 4,194,304$ B, $\Delta = 100$ B.

1. Fixed blocks: $\lceil 9 \times 10^8 / 4,194,304 \rceil = 215$ blocks; $215 \times 4,194,304 \approx 902$ MB uploaded.
2. CDC: one or two chunks, about 4.2–8.4 MB uploaded.
3. Ratio: roughly 100–200× less upload with CDC for this edit.

Interpretation. For append-only or in-place edits (logs, most office files rewritten in place, images), fixed blocks lose nothing; for insertions into large files (archives, databases, video project files), they waste almost the whole file. **Engineering implication.** Use CDC for large files, or keep fixed blocks and add an rsync-style delta step within a block: the rolling-checksum algorithm finds shifted matches against the previous version at any byte offset [Tridgell and Mackerras 1996], at the cost of client CPU and the need to keep the previous version.

INDUSTRY EXAMPLE

Dropbox's published block design. Measurements of the Dropbox client by Drago et al. found that it split files into chunks of up to 4 MB (4 MiB; the papers and Dropbox posts write "4 MB"), deduplicated chunks already on the server, applied delta encoding to modified content and bundled small chunks into fewer requests, with separate servers for metadata, storage and change notification [Drago et al. 2012]. Dropbox's own description of Magic Pocket, its in-house block store, describes blocks of up to 4 MB, identified by their SHA-256 hash [Cowling 2016]. Dropbox's public API documents a file `content_hash` computed by hashing each 4 MB block with SHA-256 and hashing the concatenation [Dropbox API v2 docs]. *Evidence: Primary* — [Drago et al. 2012]; [Cowling 2016]; [Dropbox API v2 docs]

Cross-user deduplication saves more space but creates a side channel: if uploading a block is skipped because someone else has it, an attacker can test whether any user holds a given file, and a client that claims a hash without proving possession could download content it never had. A safe design either deduplicates only within an account or requires proof that the client holds the bytes (for example, the server asks for a hash of the block combined with a server-chosen nonce) before granting access to a block.

Component 2 — The metadata journal and commit protocol

A commit is a **compare-and-set on a path** inside the namespace's partition:

1. The client sends `commit(namespace, path, parentRev, blockList)`.
2. The server checks that every block in the list exists in the block index (and that the client may reference it). If some are missing, it returns `needBlocks`; the client uploads them (each upload verified by hashing the bytes) and retries. Blocks are always durable *before* the metadata that references them, so no committed file can point at missing data.
3. In one transaction: if `files_latest[path].rev == parentRev` (or the path does not exist and `parentRev` is null), append a journal entry with the next `journal_id`, update `files_latest`, and increment block reference counts. Otherwise return a conflict.
4. After commit, publish "namespace 881 advanced to journal ID 1201447" to the notification tier.

The journal is the system's source of truth and its replication log: any device can reconstruct the namespace by replaying it from its cursor, and `files_latest` is a materialized view of it (§32.3). Retries are safe: a commit whose response was lost is retried with the same `parentRev`; if the first attempt succeeded, the server sees that `files_latest` already holds the same block list from the same device and returns the existing revision rather than a conflict.

Component 3 — The client sync engine: three trees and a planner

The client's hardest job is deciding what to do when both sides may have changed. The teaching design keeps three trees in the client database:

- **Remote tree:** the latest server state the client has observed (from `list`).
- **Local tree:** the latest state of the disk the client has observed (from the watcher and hashing).
- **Synced tree:** the last state on which both sides agreed: the **merge base**.

A **planner** compares the three for each path, exactly like a three-way merge in version control: if only the remote side differs from the synced tree, download; if only the local side differs, upload (commit); if both differ and agree, record agreement; if both differ and disagree, produce a conflicted copy. After each action succeeds, the synced tree is updated. Because the synced tree records what was agreed, a client that crashes mid-way restarts by re-observing disk and server and re-planning: actions are idempotent and the plan is always derived from observations, not from a queue of half-done work.

```
        # Three-way sync planning: compare each path's state on the server (remote),
        # on disk (local) and at the last point both agreed (synced, the merge base).
        # States are content hashes; None means the path does not exist.

        def plan(remote, local, synced):
            actions = []
            for path in sorted(set(remote) | set(local) | set(synced)):
                r, l, s = remote.get(path), local.get(path), synced.get(path)
                if r == l:
                    if r != s:
                        actions.append(("record_synced", path))       # both sides al-
ready agree
                elif l == s:
                    actions.append(("download" if r else "delete_local", path))
                elif r == s:
                    actions.append(("upload" if l else "delete_remote", path))
                elif l is None:
                    actions.append(("download", path))                # local delete
loses to remote edit
                elif r is None:
                    actions.append(("upload", path))                  # remote delete
loses to local edit
                else:
                    actions.append(("conflicted_copy", path))         # both edited:
keep both
            return actions

        synced = {"a.txt": "h1", "b.txt": "h2", "c.txt": "h3", "d.txt": "h4"}
        remote = {"a.txt": "h1", "b.txt": "h9", "c.txt": "h3", "d.txt": "h7"}
        local  = {"a.txt": "h5", "b.txt": "h2",                "d.txt": "h8", "e.txt":
"h6"}
        for action in plan(remote, local, synced):
            print(action)
        # ('upload', 'a.txt') ('download', 'b.txt') ('delete_remote', 'c.txt')
        # ('conflicted_copy', 'd.txt') ('upload', 'e.txt')
```

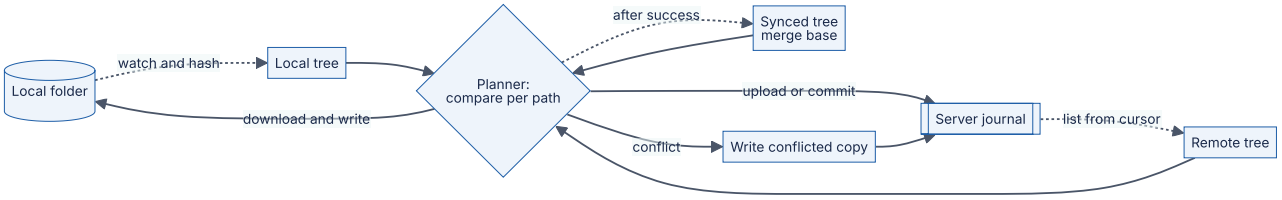
What to notice:

- Without the synced tree, `c.txt` (deleted locally) would look like a new remote file to download, and `e.txt` (new locally) like a remote deletion: two-way comparison cannot tell “I deleted it” from “they created it”.
- An edit always beats a concurrent delete, because silently discarding an edit is the one unforgivable outcome.
- Two different edits of `d.txt` produce a **conflicted copy**: the server version keeps the name, and the local version is committed as a new file such as `d (Ann's conflicted copy 2026-11-05).txt`. Nothing is lost, and the user resolves it.
- Directory moves need more care than this per-path sketch: two devices moving the same folder to different places, or moving a folder into its own descendant on another device, must be resolved so that the tree stays a tree.

INDUSTRY EXAMPLE

Dropbox Nucleus. Dropbox rewrote its desktop sync engine over about four years, releasing the new engine, Nucleus, written in Rust, to all users by 2020. Dropbox describes Nucleus as persisting observations rather than pending work, and representing state as three trees (remote, local and synced, the last being the merge base), from which a planner derives operations; nearly all of its logic runs on a single control thread for determinism, with I/O and hashing offloaded to background threads, and the engine was tested heavily with randomized testing [Jayakar 2020; Goldberg 2020]. *Evidence: Primary* — [Jayakar 2020]; [Goldberg 2020]

Figure 54.19 — The three-tree sync loop.



Reading the diagram. Observations flow asynchronously (dotted) from the *local folder* into the *local tree* and from the *server journal* into the *remote tree*. The *planner* compares both with the *synced tree* and issues synchronous actions: commits to the server, downloads to disk, or a conflicted copy committed as a new file. After each action succeeds, the synced tree advances. Storage boundaries: the disk, the client DB holding the three trees, and the server journal. Failure points: a crash between an action and the synced-tree update (the next observation shows both sides agree, so the planner just records it); a disk full (downloads pause, uploads continue). Scaling: the planner's work is proportional to changed paths, not folder size, because trees are diffed incrementally.

Component 4 — Change notification by long polling

Every connected device needs to learn of changes within seconds, but almost all devices are idle almost all the time. A long poll (§9.4) fits: the client sends its cursors and the server holds the request open until a namespace advances or a timeout (about 90 s) passes; the response says only "changes" or "no changes", and the client then lists from its cursors. Because the notification server holds no state that matters (the cursor travels with the request), a server crash costs nothing but a reconnect, and a missed notification is impossible to turn into a missed change: the next long poll or periodic list catches up from the cursor. A **backoff** field lets the server shed load by telling clients to wait before polling again. WebSockets (§9.6) would also work; long polling passes through restrictive proxies and keeps the server side trivially stateless.

Notification servers subscribe to the namespaces of their connected clients on a pub-sub tier; when a commit advances a namespace, every server with a waiting client for that

namespace completes the request. Shared folders with many members create fan-out: a commit to a namespace mounted by 10,000 users wakes 10,000 or more devices, so wake-ups are jittered over a few seconds to avoid a thundering herd of `list` calls.

Component 5 — Block storage and the migration to Magic Pocket

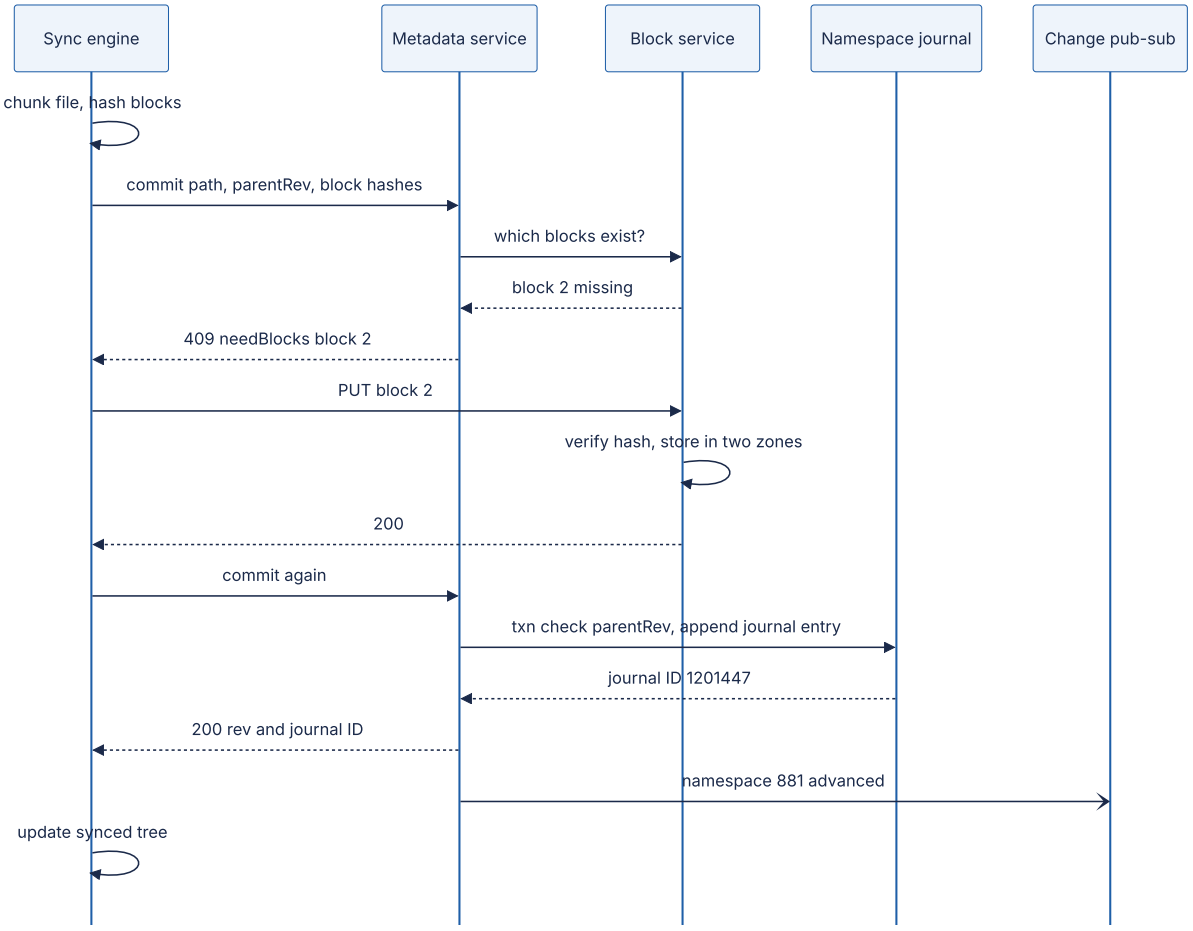
Blocks are immutable, content-addressed and up to 4 MiB, which makes the storage layer simple in principle: a key-value store from hash to bytes, with a block index locating each block in a storage **cell**; blocks are packed into large append-only extents, erasure-coded within a zone for cheap durability, and replicated to another zone so that the loss of a whole site loses nothing (§15.6). Immutability makes caching trivial and repairs verifiable: the hash checks the bytes.

> INDUSTRY EXAMPLE
>
> **Magic Pocket.** Dropbox originally stored file blocks in Amazon S3 and in 2016 described moving the large majority of user data into Magic Pocket, its own exabyte-scale block storage system, built on custom hardware in its own data centers; the system stores immutable blocks keyed by SHA-256 hashes, replicates them across geographic zones and uses erasure coding [Gupta 2016; Cowling 2016]. Dropbox's 2018 registration statement attributed tens of millions of dollars of annual operating cost reductions to this infrastructure migration (§51.3) [Dropbox 2018]. *Evidence: Primary* — [Gupta 2016]; [Cowling 2016]; [Dropbox 2018]

The migration itself is a lesson in moving an exabyte without downtime: because blocks are immutable and addressed by hash, both stores can hold the same block, so the block service writes new blocks to both, copies old blocks in the background with hash verification, flips reads per cell once a cell is fully copied and verified, and deletes from the old store only after a long period of dual operation. The same pattern applies to any immutable, content-addressed data.

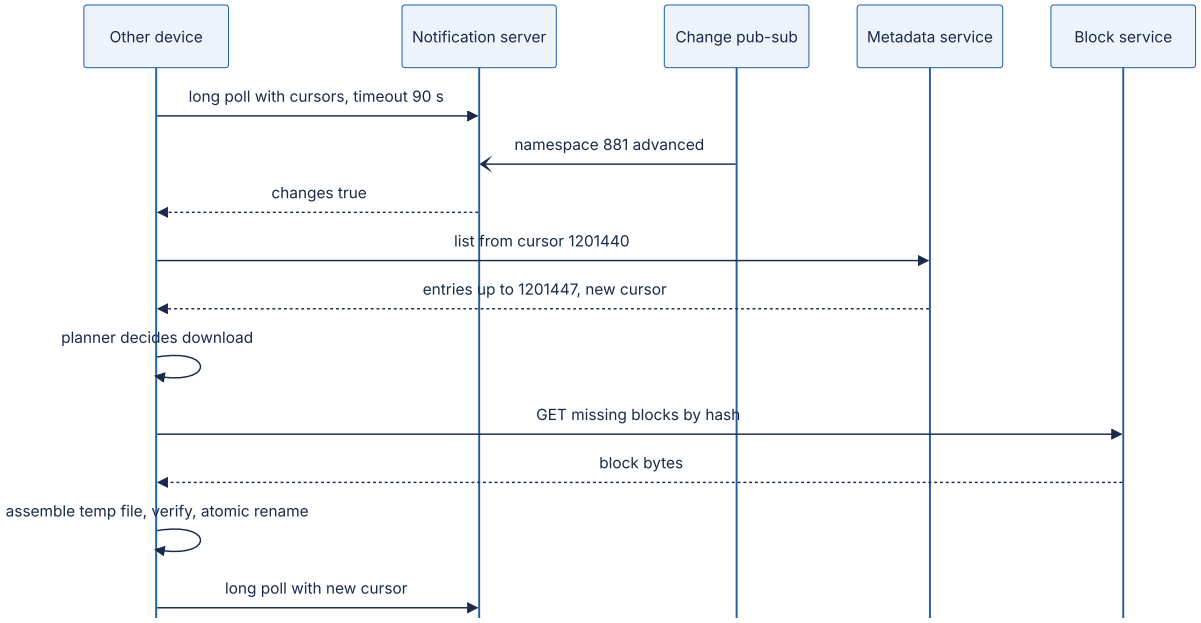
54.8.9 Data flow

Figure 54.20 — Write path: committing an edited file.



Reading the diagram. The client hashes blocks locally and offers a commit by hashes. The *metadata service* asks the *block service* which blocks exist and returns the missing list; the client uploads only those, each verified by hash and stored durably in two zones. The retried commit performs the compare-and-set on `parentRev` and appends to the *namespace journal* in one transaction. The change notification is asynchronous. If `parentRev` were stale, the server would return a conflict and the planner would create a conflicted copy. Failure points: a lost commit response (retry is recognized as already applied), a crash between block upload and commit (orphan blocks with zero references are garbage-collected).

Figure 54.21 — Read path: another device learns of the change.



Reading the diagram. The device holds a *long poll* on a *notification server*, which completes it when *pub-sub* reports that one of its namespaces advanced. The device lists changes from its cursor via the *metadata service*, plans, and fetches only the blocks it lacks (blocks already in its cache or elsewhere on disk are reused). It assembles the file in a temporary location, verifies the hashes and renames it into place atomically so that applications never see a half-written file, then polls again. Failure points: a notification server crash (reconnect, cursor unchanged), a lost notification (the next poll or periodic list catches up), a block fetch failure (retry from another replica).

54.8.10 Bottlenecks

- **Connection count:** 100 million idle long polls; tune servers for memory per connection and spread reconnect storms after deploys with jitter.
- **Large shared namespaces:** a company-wide shared folder concentrates commits on one partition and fans out to tens of thousands of devices; split very large namespaces and rate-limit wake-ups.
- **Initial sync of a new device:** downloading hundreds of gigabytes; prioritize recently used files, fetch on demand for the rest (placeholder files), and use LAN sync between devices on the same network.
- **Client hashing CPU** for large files: hash incrementally and only regions the file system reports as changed, where available.

54.8.11 Failure scenarios

Table 54.14 — Dropbox teaching design: failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Concurrent edits	Two versions of one file	`parentRev` mismatch	Conflicted copy; user resolves	Compare-and-set commits
Metadata partition down	Commits stall for its namespaces	Commit error rate per partition	Fail over to replica	Replicated partitions; client offline queue
Notification server crash	Clients disconnected	Connection drops	Reconnect; list from cursor	Stateless servers; cursor in request
Client crash mid-download	Partial file	On restart, local tree differs	Re-plan from observations	Temp file plus atomic rename
Corrupt block on disk	Wrong bytes	Hash mismatch on read or scrub	Repair from other zone or parity	Content addressing; background scrubbing
Buggy client release deletes files	Mass deletion propagates	Anomalous delete-rate alarms	Restore from version history	Staged client rollout; delete-rate circuit breaker

54.8.12 Scaling strategy

At 10×: a billion connected devices need about 4,000 notification servers and a sharded pub-sub layer; the block index grows to hundreds of terabytes and stays partitioned by hash; metadata partitions multiply, and namespace placement is rebalanced by load. Smarter clients (on-demand placeholders, LAN sync, CDC for large files) reduce bytes per change.

At 100×: storage, not metadata, dominates cost; colder data moves to denser erasure codes and archival media, and storage cells grow. Global users require regional metadata homes, with each namespace's journal living in its home region and cross-region shared folders paying a latency cost on commit (§44.6).

54.8.13 Trade-offs

Table 54.15 — Dropbox teaching design: key trade-offs.

Decision	Option chosen	Alternative	Why
Conflict policy	Conflicted copies	Last-writer-wins	Never lose data; users resolve rarely
Chunking	4 MiB blocks, CDC for large files	Whole-file upload	Dedup and resumable transfers
Notification	Long poll, stateless	Stateful push protocol	Proxy-friendly, crash-proof
Sync state	Three trees from observations	Queue of pending operations	Restartable and testable
Dedup scope	Within account or with proof of possession	Global blind dedup	Avoid side channels

54.8.14 Alternative designs

- **Operation-based sync** (record every local operation and replay it remotely): preserves intent for moves and renames but is fragile when the operation log and disk disagree; observation-based planning is more robust.
- **CRDT-based file tree** (§27.14): handles concurrent moves without central ordering, but a tree CRDT must still prevent cycles and gives users surprising merges; a central journal is simpler for a client–server product.
- **Full-file versioning with no block layer:** simpler, but every edit to a large file re-uploads and re-stores it.

54.8.15 Interview discussion

45-minute pacing plan. 0–5 min: scope (desktop sync, sharing, conflicts). 5–10 min: capacity, highlighting connection count and bytes per change. 10–15 min: API (commit by hashes, list by cursor, long poll). 15–20 min: architecture. 20–30 min: chunking, deduplication and delta sync with the fixed-versus-CDC arithmetic. 30–40 min: journal, commit compare-and-set, three-tree planner and conflicts. 40–45 min: notifications and storage migration.

Likely follow-ups.

- *How do you avoid re-uploading a renamed 10 GB file?* Same block hashes; the commit references existing blocks.
- *What if two devices edit offline and reconnect?* The second commit's `parentRev` is stale; it becomes a conflicted copy.
- *How do you guarantee no missed change?* Cursors on a linearizable journal; notifications are hints, lists are truth.
- *What if a client bug deletes everything?* Deletes are journal entries; versions and trash restore; delete-rate circuit breakers stop propagation.

What distinguishes senior and staff answers. A senior candidate designs block-level dedup, a commit protocol and long-poll notification. A staff candidate explains why a merge base is required, makes every step idempotent and restartable, treats notifications as hints over a cursor, discusses dedup side channels and plans a live storage migration.

54.8.16 Production considerations

- **Observability.** Time from commit to download start on other devices; client-reported sync health (“up to date” share of clients); conflict rate per million commits; block-scrub repair rate.
- **Security.** Hash-verified uploads; proof of possession for cross-account block references; encryption at rest per block with keys in a KMS (§10.9); shared-link scoping and audit logs.
- **Cost.** Storage dominates; dedup ratio and erasure-code overhead are the levers; the build-versus-buy decision for storage is the Magic Pocket story (§51.9).
- **Operations.** Client releases are staged with kill switches, because a client bug can corrupt data on millions of devices that the service does not control; randomized and fault-injection testing of the sync engine before release.

54.9 Summary and revision notes

SUMMARY

- **YouTube:** bytes, not requests, dominate. Resumable sessions with byte offsets; a DAG of idempotent tasks over closed-GOP segments; latency bounded by the critical path, $\max(W/w, T_{cp}) \le T_w \le W/w + T_{cp}$; publish at the first rendition; eager H.264, lazy advanced codecs above break-even views $V^* = (C_{enc} + C_{store})/(t_w \Delta b p_{egress})$; renditions are a regenerable cache over immutable originals; views counted by a validated, deduplicated stream pipeline.
- **Netflix:** control plane in cloud regions, data plane in ISP-embedded caches filled off-peak. Play start = personalized manifest, device-bound license, ranked cache URLs; overlap license with first segments. Running streams survive control-plane loss. Fallbacks, chaos experiments on stream starts per second, and rehearsed regional evacuation with $N/(N-1)$ headroom.
- **Spotify:** the client cache is the fastest tier; prefetch the next track; offline downloads are expiring leases renewed at check-in; playlists are op logs with stable item IDs and server-side transformation; royalties split a fixed pool, so count each qualifying play exactly once by `playId`, by occurrence month, with a close and adjustments.
- **Google Drive:** transactional metadata partitioned by namespace; chunked versions; ReBAC with inheritance, cached checks, consistency tokens against the new-enemy problem, asynchronous reverse indexes; OT with one session owner per document; quota by reservation.
- **Dropbox:** commit by block hashes, upload only missing blocks; CDC beats fixed blocks for insertions; per-namespace linearizable journal with compare-and-set commits; three-tree planner with a merge base; conflicted copies, never silent loss; long polls as hints over cursors; live migration of immutable blocks by dual write and verified copy.

Table 54.16 — The distinctive problem of each case.

Case	Dominant load	Hard problem	Key technique
YouTube	Ingest bytes and egress	Transcoding at low cost	Segment DAG, popularity-driven codecs and tiers
Netflix	Peak egress	Fast, resilient play start	Control/data-plane split, evacuation
Spotify	Play events	Local feel and exact royalties	Client cache, leases, dedup by playId
Google Drive	Metadata reads with checks	Sharing and co-editing	ReBAC with tokens, OT session owner
Dropbox	Idle connections, changed bytes	Multi-device sync without loss	Block hashes, journal cursors, three trees

54.10 Knowledge checkpoint

1. Why are YouTube renditions stored with lower durability than originals?
2. A DAG has 3,000 s of total work and a 50 s critical path. What is the best possible makespan on 100 workers, and the list-scheduling upper bound?
3. Why must transcoding segments start at closed-GOP keyframes?
4. Recompute the VP9 break-even if delivery costs $0.01/GB, other assumptions as in §54.4.8.
5. Why does view counting write “total as of window end” rather than increments?
6. What keeps Netflix streams playing when the control plane fails?
7. Why can segments be fetched before the license arrives?
8. With four control-plane regions, how much capacity must each have relative to its normal peak to survive the loss of one?
9. Why is a Spotify offline download a lease rather than a file?
10. In a fixed royalty pool, who pays for one label’s over-count?
11. Why do playlist operations reference item IDs rather than positions?
12. What is the new-enemy problem and how do consistency tokens prevent it?
13. Apply the transform: on `abc`, site 1 inserts `x` at 0 and site 2 deletes position 1. What do both sites end with?
14. Why does a sync engine need a synced tree in addition to local and remote trees?
15. Why is a missed long-poll notification harmless?
16. Upload size for a 100-byte insertion at 500 MB into a 2 GB file with 4 MiB fixed blocks?

Answers

1. A rendition is a deterministic function of the original and a recipe; it can be regenerated, so losing it costs compute, not data.
2. Lower bound $\max(30, 50) = 50$ s; upper bound $30 + 50 = 80$ s.

3. A closed GOP references no frames outside itself, so each segment encodes and decodes independently and players can switch renditions at boundaries.
4. Saving per view doubles to $\$0.000197$; $V^* = 0.0925/0.000197 \approx 470$ views.
5. Replaying a window after a crash must give the same result; a set is idempotent, an increment is not.
6. Video bytes come from ISP caches using already-issued manifests and licenses, which remain valid for hours.
7. Segments are encrypted; without the key they are useless, so prefetching them leaks nothing and hides the license round trip.
8. $4/3 \approx 1.33\times$.
9. Licensing requires revocation; expiring keys renewed at check-in enforce takedowns and lapsed subscriptions.
10. Every other rights holder in the same pool, in proportion to their share.
11. Item IDs keep their meaning under concurrent inserts and deletes; positions shift.
12. Evaluating access with an ACL older than the content (for example, after removing a user and then adding secrets); a token from the ACL change forces later checks to use a snapshot at least that fresh.
13. Site 1: `xabc`, then the delete transformed to position 2 → `xac`. Site 2: `ac`, then insert at 0 → `xac`.
14. To distinguish “deleted here” from “created there” and to detect true conflicts; it is the merge base of a three-way merge.
15. Notifications are hints; the cursor-based list on the next poll returns every change after the cursor.
16. $\lceil 1.5\times10^9/4,194,304\rceil = 358$ blocks, about 1.5 GB; CDC would upload about 4–8 MB.

54.11 Interview questions

Basic

Q1. How would you let users resume a 5 GB upload over a flaky network? Answer. A resumable session: create it with total length, get a session URI, send chunks with byte ranges, and after any failure ask the server for the received range and continue. The server writes chunks as multipart parts and acknowledges only durable bytes; completion commits metadata and emits a processing event through an outbox.

Q2. Why do Netflix-style services separate control and data planes? Answer. They scale on different axes: the data plane on bandwidth (over 100 Tb/s at peak in our estimate), best placed in ISPs; the control plane on request rate and availability, best run in multi-region cloud. Separation also isolates failures: control-plane outages stop new plays, not running ones.

Intermediate

Q3. Design view counting for a video that gets 50,000 views per second. Answer. Heartbeats to a partitioned log; a stream job sessionizes by player-generated view ID, validates, deduplicates within a window, pre-aggregates per minute and writes idempotent totals to a counter store. Never update a row per view; use HyperLogLog for approximate uniques.

Q4. How do you prevent lost updates when two users edit a collaborative playlist? Answer. Stable item IDs; inserts relative to neighbors with fractional sort keys; a per-playlist serialized op log with base revisions; server-side transformation of stale operations; idempotent client op IDs; notify collaborators to fetch missing ops.

Advanced

Q5. Compare OT and CRDTs for a document editor that must support end-to-end encryption. Answer. Server-centric OT requires the server to read and transform operations, which encryption forbids; a CRDT converges without server understanding, so the server only relays and stores ciphertext. The cost is per-element metadata, tombstones and harder rich-text semantics. Without encryption and with a central server, OT is simpler and more compact.

Q6. A sync-client release has a bug that deletes files locally. How should the system limit damage? Answer. Deletes are journal entries, so history and trash allow restoration; staged rollout with kill switches limits exposure; a server-side circuit breaker rejects or holds commits with anomalous delete rates per account; the planner treats mass local disappearance (for example, an unmounted disk) as suspicious and asks the user. Recovery is a bulk restore from journal positions before the bug.

54.12 Practical exercises

1. Extend the transcoding simulation in §54.4.8 with speculative re-execution of stragglers (one segment task takes 10× longer) and measure time to full ladder with and without it.
2. Modify the Spotify counter to read events from a file in random order with 20% duplicates and verify that totals are unchanged across ten shuffles.
3. Add range deletions to the OT transform of §54.7.8 and extend the randomized convergence test.
4. Implement content-defined chunking (reuse §15.8.3) and measure bytes re-uploaded after random insertions into a 100 MB file, versus fixed 4 MiB blocks.
5. Extend the three-tree planner to handle directory moves and detect a move that would create a cycle.

54.13 Design challenges

1. **Live sports streaming.** Adapt the Netflix design for a live match with 20 million concurrent viewers starting within five minutes: what changes in fill, steering, licensing and admission control?
2. **Podcast platform.** Design hosting, transcoding and download analytics for 5 million podcasts, where advertisers pay per verified download.
3. **End-to-end encrypted Dropbox.** Keep block deduplication, sharing and version history while the server never sees plaintext or file names.

Chapter 55 — Case Studies IV: Location, Commerce and Payments

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 9 h

The six systems in this chapter all touch the physical or financial world, and that changes what “correct” means. A news feed that shows a post twice is untidy; a dispatch system that sends two drivers to one rider wastes two people’s time, a ticketing system that sells seat 14C twice puts two fans in one seat, and a payment system that charges a card twice takes real money from a real person. Each design therefore has one problem where an approximate, eventually consistent answer is not good enough, sitting inside a much larger system where it is.

The cases come in three pairs. Uber (§55.4) and its ride-matching core (§55.5) are about **moving things on a map**: ingesting hundreds of thousands of GPS points per second, finding nearby supply with a cell index, and promising one driver to exactly one rider. Google Maps (§55.6) is about **the map itself**: serving tiles to a billion screens and finding shortest paths on a graph with hundreds of millions of intersections. Amazon (§55.7) and the ticket-booking system (§55.8) are about **scarce inventory under a crowd**: not selling what you do not have when a hundred thousand people want the same item in the same minute. The payment system (§55.9) is about **money that must add up**: a double-entry ledger, idempotency from the button to the bank, and reconciliation with an outside world you do not control.

Every company fact is labeled with its evidence; every architecture is a teaching design (*Evidence: Illustrative*), not a claim about how the named company builds its systems. Every number in a capacity estimate is an assumption chosen to be plausible and is stated as such.

55.1 Learning objectives

After this chapter you should be able to:

- Model a ride’s lifecycle as a persisted state machine and size a location-ingestion pipeline from driver count and update interval.
- Find nearby drivers with a hexagonal or square cell index and ring expansion, and estimate candidate counts from driver density.

- Compare greedy and batched (bipartite) matching on pickup time, and guarantee one driver per ride with leases and fencing tokens.
- Size a map-tile pyramid, explain why vector tiles replaced raster tiles, and explain how Dijkstra, A* and contraction hierarchies trade preprocessing for query speed.
- Design an e-commerce checkout as a saga with inventory reservations, and shard a hot inventory counter for a flash sale.
- Compare row locks, optimistic concurrency and in-memory holds for seat inventory, and size a virtual waiting room with Little's Law.
- Design a payment system around an immutable double-entry ledger, end-to-end idempotency keys, signed webhooks and daily reconciliation, while keeping card data out of PCI scope.
- Pace each design in a 45-minute interview and name what distinguishes a staff-level answer.

55.2 Prerequisites

The case studies apply these concept chapters and do not re-teach them.

- **All cases.** Capacity estimation habits — §2.11, Chapter 4 (decimal units throughout; Little's Law, §4.11); caching — §20.7, §20.15 (hot keys); partitioning and shard keys — §14.6, §14.7; message brokers and delivery guarantees — §30.8, Chapter 31; SLOs — §39.6.
- **Uber (§55.4).** Geospatial indexing (geohash, S2, H3) — §17.9; WebSockets and server push — §9.6; Kafka — Chapter 31; multi-region and cell-based architecture — §44.10, §33.12; state machines in event-driven systems — §32.3.
- **Ride matching (§55.5).** H3 k-rings — §17.9.5; distributed locks, leases and fencing tokens — §26.10–§26.13; timeouts and retries — §22.11, §22.12.
- **Google Maps (§55.6).** CDNs and cache keys — §21.3, §21.6; object storage — §15.4; search, tokenization and typeahead — §16.3, §16.9; graph data — §12.7.
- **Amazon (§55.7).** Sagas — §32.7 (the deep treatment); transactional outbox — §32.5; search systems — Chapter 16; load shedding — §22.9; Dynamo-style stores — §27.7.
- **Ticket booking (§55.8).** Isolation levels, MVCC and locking — §11.13–§11.15; rate limiting — §22.3, §52.6; Redis — §20.6; TTL — §20.8.
- **Payments (§55.9).** Idempotency keys — §22.15 (the deep treatment); idempotent consumers — §32.10; sagas — §32.7; tokenization and PCI scope — §50.10; audit logging — §10.12; encryption and KMS — §10.9.

55.3 How to use these case studies

Work each case as §52.3 describes: read the problem statement, close the book and sketch your own requirements, estimate and architecture before reading ours, then compare section by section. Every case uses the same sixteen subsections in the same order, so you can also read “across” the chapter, for example all six failure-scenario tables in a row. Capacity numbers are assumptions stated in `example` callouts and recomputed with Python; change one and rerun the arithmetic yourself. The cases are written to be read in order: §55.5 zooms into one component of §55.4, and §55.9 is the payment step that §55.7 and §55.8 call at checkout, so later cases refer back rather than repeat.

55.4 Uber: a ride-hailing platform

55.4.1 Problem statement

Design the backend of a global ride-hailing platform. A rider opens the app, sees cars moving on a map around them and an upfront price, taps “Request”, and within seconds is told which driver is coming and when. The rider watches the car approach, rides, pays automatically and rates the driver. Drivers go online, stream their location while working, receive trip offers they can accept or decline, and are guided through pickup and drop-off.

Think of it as an air-traffic control room for cars. Thousands of moving dots report their position every few seconds; a controller assigns each new request to one dot and then follows that pair until the trip ends. Three things make this hard. First, **write volume**: location updates outnumber trips by roughly a thousand to one, so the platform is a write-heavy telemetry system with a small transactional core attached. Second, **space**: “who is near this rider?” is a two-dimensional question that ordinary indexes answer badly (§17.9). Third, **the physical world does not wait**: a trip that is half-recorded during a failover still has a rider sitting in a car.

This section designs the platform as a whole: the trip lifecycle, location ingestion, the supply index, the pricing hand-off, trip storage and the regional layout. The matching algorithm and dispatch consistency get their own case in §55.5; pricing models and ETA prediction are machine-learning problems treated in Chapter 83; charging the rider is the payment system of §55.9.

55.4.2 Functional requirements

Rider

1. See nearby available cars on a live map and an upfront fare estimate for a pickup and destination.

2. Request a ride for a product (economy, premium, shared); cancel before or after a driver is assigned.
3. Track the assigned driver’s position and arrival time in real time; share the trip with a contact.
4. Pay automatically at trip end; receive a receipt; rate the driver.

Driver

5. Go online and offline; stream location while online.
6. Receive a trip offer with pickup location and estimated earnings; accept or decline within a time limit.
7. Mark arrival, start trip and end trip; see trip history and earnings.

Platform

8. Compute a price per trip, including a demand-based multiplier (“surge”) per area.
9. Keep a durable trip record for receipts, support, safety investigations, tax and analytics.
10. Serve many cities in many countries with local regulations (data residency, airport queues, product availability).

Out of scope here: the matching algorithm (§55.5), the pricing and ETA models (Chapter 83), card processing (§55.9), food delivery, and fraud detection (Chapter 82).

55.4.3 Non-functional requirements

Table 55.1 — Non-functional requirements for the ride-hailing platform.

Property	Target	Why
Availability of ride request and trip state	99.99% per region (about 4.3 min of downtime per 30 days)	A failed request is a lost trip and a stranded rider
Location freshness	Driver position in the supply index at most 5 s old at p99	Matching on stale positions sends the wrong driver
Nearby-cars and fare-estimate latency	p99 < 300 ms server-side	Shown on app open; slow screens lose riders
Ride request to driver offer	p99 < 2 s (excluding batching delay, §55.5)	Riders abandon after a few seconds of "finding your driver"
Trip-state durability	No acknowledged trip transition lost (RPO = 0 within a region)	Trips are financial and safety records
Trip-state consistency	Linearizable per trip; one driver per trip, one trip per driver	Double assignment is a visible failure (§55.5.8)
Location history	At-least-once into the data lake; loss of a few points tolerated	Used for analytics, fare disputes and safety, not for correctness
Regional isolation	A failure in one region does not affect trips in another	Cities are independent markets

Notice the split: a small amount of data (trip state) needs strong guarantees, and a large amount (positions) needs only freshness. The architecture follows that split.

55.4.4 Capacity estimation

FORMULA

Location ingestion rate

$$U = \frac{N_{\text{online}}}{\Delta t}, \qquad B_{\text{in}} = U \times s$$

Symbol	Meaning	Units
U	Location updates arriving per second	updates/s
N_{online}	Drivers online at the same time	drivers
Δt	Interval between updates from one driver	s
B_{in}	Ingress bandwidth for location updates	bytes/s
s	Size of one update on the wire	bytes

WORKED EXAMPLE

Worked example — trips, locations and reads. Assumptions (teaching numbers, decimal units): 30 million trips per day; peak hour at 3× the daily average; 2 million drivers online at the global peak and 1 million on average; one location update every 4 s, 200 bytes on the wire; 5 million riders with the app open at peak, refreshing nearby cars every 5 s; 5 fare estimates per completed trip.

1. **Trips.** $30 \times 10^6 / 86,400 = 347$ trips/s on average; peak $3 \times 347 = 1,042 \approx 1,000$ trip requests/s.
2. **Fare estimates.** $5 \times 1,042 = 5,208 \approx 5,200$ estimates/s at peak.
3. **Location updates at peak.** $U = 2 \times 10^6 / 4 = 500,000$ updates/s.
4. **Ingress bandwidth.** $B_{\text{in}} = 500,000 \times 200 = 100$ MB/s $= 0.8$ Gb/s before TLS and framing overhead.
5. **Nearby-car reads.** $5 \times 10^6 / 5 = 1,000,000$ reads/s at peak: more than the writes.
6. **Ratio.** Location writes to trip requests: $500,000 / 1,042 \approx 480$ at peak; over a day, $(1 \times 10^6 / 4) \times 86,400 / (30 \times 10^6) = 720$ updates per trip.

Interpretation. The transactional core handles about a thousand writes per second; the telemetry path handles half a million. *Engineering implication.* Location updates must never touch the trip database. They go to an in-memory index and an append-only log, and nearby-car reads must be cached per cell rather than computed per rider.

WORKED EXAMPLE

Worked example — storage, memory and servers.

1. **Location history.** Average $U = 1 \times 10^6/4 = 250,000$ updates/s; per day $250,000 \times 86,400 = 2.16 \times 10^{10}$ points. At 100 bytes per point after columnar compression: $2.16 \times 10^{10} \times 100 = 2.16$ TB/day, $\times 365 = 788$ TB/year before replication.
2. **Trip records.** 5 KB per trip (states, timestamps, fare breakdown, IDs): $30 \times 10^6 \times 5,000 = 150$ GB/day, 54.75 TB/year.
3. **Trip trails.** A 20-minute trip at one point per 4 s is $1,200/4 = 300$ points; at 50 bytes each, 15 KB per trip, $30 \times 10^6 \times 15,000 = 450$ GB/day, 164 TB/year.
4. **Supply index memory.** 2 million drivers × 200 bytes (ID, position, cell, status, vehicle class, timestamp) = 400 MB. Even with 3× index overhead this fits in one machine's memory.
5. **Ingestion servers.** If one location-service node handles 20,000 updates/s (parse, validate, map to a cell, update index, append to log), then $500,000/20,000 = 25$ nodes, 50 with 2× headroom.
6. **Persistent connections.** 2×10^6 drivers $+5 \times 10^6$ riders $= 7 \times 10^6$ connections. At a blast-radius cap of 200,000 connections per gateway node (§9.9.2 sizes memory per connection), $7 \times 10^6/200,000 = 35$ nodes; to survive the loss of one zone of three, the §9.9.2 formula gives $3 \times \lceil 7 \times 10^6/(2 \times 200,000) \rceil = 3 \times 18 = 54$.

Interpretation. Memory is not the problem: 400 MB of driver state is tiny. Throughput, blast radius and locality are. *Engineering implication.* Partition the supply index by city (or region cell) for isolation and throughput, not for capacity; history goes to cheap columnar storage through a log.

Table 55.2 — Capacity summary (peak unless stated).

Quantity	Value
Trip requests	~1,000/s
Fare estimates	~5,200/s
Location updates	500,000/s (0.8 Gb/s)
Nearby-car reads	1,000,000/s before per-cell caching
Location history	2.16 TB/day, ~788 TB/year raw
Trip records and trails	150 GB + 450 GB per day
Supply index	~400 MB of state
Persistent connections	7 million

55.4.5 API design

Riders and drivers use two channels: request–response HTTPS for commands, and one long-lived bidirectional stream (WebSocket, §9.6, or gRPC streaming) per app for location uploads and server push. All mutating requests carry an idempotency key (§22.15), because mobile networks drop responses constantly.

```
# Rider: commands over HTTPS (JSON)
POST /v1/estimates
  { "pickup": {"lat": 37.7749, "lng": -122.4194},
    "dropoff": {"lat": 37.7937, "lng": -122.3965}, "product": "economy" }
  -> 200 { "quote_id": "q_8f2", "fare": {"amount": 1840, "currency": "USD"},
           "surge_multiplier": 1.3, "pickup_eta_s": 240, "expires_at": "2026-11-
05T18:04:00Z" }

POST /v1/rides                        Idempotency-Key: 6b1e...
  { "quote_id": "q_8f2", "payment_method_id": "pm_77", "pickup": {...}, "dropoff": {...}
}
  -> 202 { "ride_id": "r_91c", "state": "REQUESTED" }

GET  /v1/rides/{ride_id}              -> 200 { "ride_id", "state", "driver", "vehicle",
"eta_s", "version" }
POST /v1/rides/{ride_id}/cancel       Idempotency-Key: ...   -> 200 { "state":
"CANCELED", "fee": {...} }

# Driver: commands over HTTPS
POST /v1/drivers/me/status             { "status": "ONLINE", "vehicle_id": "v_12" }
POST /v1/offers/{offer_id}/accept      Idempotency-Key: ...   -> 200 { "ride_id":
"r_91c", "state": "DRIVER_ASSIGNED" }
POST /v1/offers/{offer_id}/decline
POST /v1/rides/{ride_id}/arrived | /start | /complete   { "version": 7, "odometer_m":
... }

# Stream frames (one connection per app session)
driver -> server  LocationBatch { driver_id, points: [{lat, lng, heading, speed_mps,
                                  accuracy_m, ts_ms}], seq }
server -> driver  Offer { offer_id, ride_id, pickup, expires_at_ms, fencing_token }
server -> rider   RideUpdate { ride_id, state, driver_location, eta_s, version }
server -> rider   NearbyCars { cell, cars: [{lat, lng, heading, product}] }
```

What to notice:

- `quote_id` binds the request to the fare the rider saw. The price is computed once, signed and stored with an expiry, so the trip uses exactly the price on screen even if the surge multiplier changes a second later.
- `POST /v1/rides` returns `202 Accepted`: matching is asynchronous, and the result arrives over the stream.
- Driver state transitions carry the trip's `version`, so a retried or reordered "start trip" cannot overwrite a newer state (optimistic concurrency, §11.14).

- Location frames are batched (several points per frame) and sequence-numbered, so the server can drop duplicates and out-of-order points cheaply.

55.4.6 Data model and database schema

Three kinds of data live in three kinds of store.

Trips are the system of record: relational, transactional per trip, partitioned by city and trip. Any sharded relational store or distributed SQL database (§28.10) fits; the key properties are single-row compare-and-set and secondary indexes for "trips of this rider".

```
        CREATE TABLE trips (
          trip_id          BIGINT       NOT NULL,      -- time-ordered ID (§17.10)
          city_id          INT          NOT NULL,
          rider_id         BIGINT       NOT NULL,
          driver_id        BIGINT,                     -- NULL until assigned
          product          VARCHAR(16)  NOT NULL,
          state            VARCHAR(20)  NOT NULL,      -- see Figure 55.2
          version          INT          NOT NULL DEFAULT 0,
          quote_id         VARCHAR(32)  NOT NULL,
          fare_minor       BIGINT,                     -- integer minor units, never
floats
          currency         CHAR(3)      NOT NULL,
          pickup_lat       DOUBLE PRECISION NOT NULL,
          pickup_lng       DOUBLE PRECISION NOT NULL,
          dropoff_lat      DOUBLE PRECISION,
          dropoff_lng      DOUBLE PRECISION,
          requested_at     TIMESTAMPTZ  NOT NULL,
          updated_at       TIMESTAMPTZ  NOT NULL,
          PRIMARY KEY (city_id, trip_id)
        );
        CREATE INDEX trips_by_rider  ON trips (rider_id, requested_at DESC);
        CREATE INDEX trips_by_driver ON trips (driver_id, requested_at DESC);

        -- Every transition is also appended here, in the same transaction (audit, out-
box).
        CREATE TABLE trip_events (
          city_id     INT          NOT NULL,
          trip_id     BIGINT       NOT NULL,
          version     INT          NOT NULL,
          from_state  VARCHAR(20)  NOT NULL,
          to_state    VARCHAR(20)  NOT NULL,
          actor       VARCHAR(32)  NOT NULL,         -- rider, driver, dispatcher, time-
out
          payload     JSONB,
          created_at  TIMESTAMPTZ  NOT NULL,
          published   BOOLEAN      NOT NULL DEFAULT FALSE,   -- transactional outbox
(§32.5)
          PRIMARY KEY (city_id, trip_id, version)
        );
```

Live driver state is in memory, partitioned by city. Two structures, updated together by the location service:

```
driver:{driver_id}  -> { lat, lng, heading, cell_r9, status:
IDLE|OFFERED|ON_TRIP|OFFLINE,
                        product_mask, trip_id, last_seen_ms, lease_epoch }
cell:{h3_r9_index}  -> set of driver_ids currently inside this hexagon (with status
IDLE)
```

Location history is an append-only stream (Kafka, Chapter 31) partitioned by driver ID, compacted into columnar files in object storage (§15.4, §13.13) for analytics, map matching and disputes.

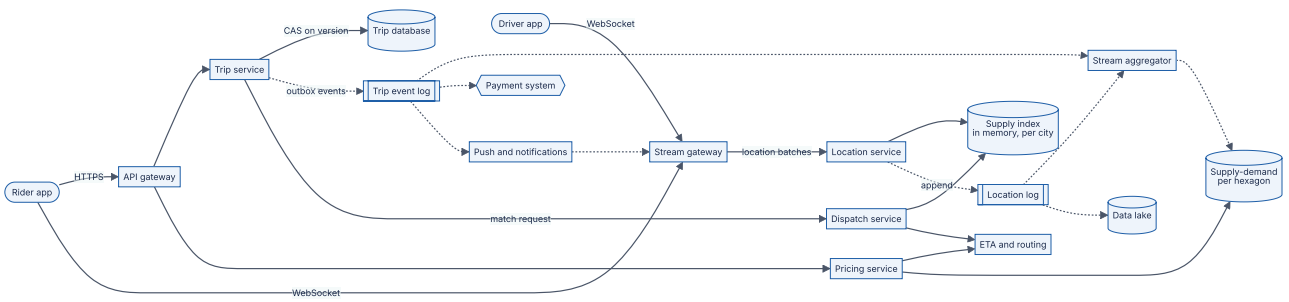
Why not one database? A trip row changes about ten times in its life; a driver's position changes 720 times per trip. Putting both in the same store would size the expensive transactional database for telemetry. Why a relational schema for trips? Trips need conditional updates (`UPDATE ... WHERE version = ?`), secondary indexes and ad hoc queries by support staff; nothing here needs a schemaless document model, although Uber itself chose one (below).

INDUSTRY EXAMPLE

Uber's trip storage. Uber described Schemaless, an append-only, sharded datastore built on MySQL, which it designed in 2014 when it projected that its existing Postgres database could not store trip data growth by year end. Schemaless stores immutable cells in a sparse three-dimensional map (row key, column name, ref key) in the style of Bigtable, buffers writes to survive a failed MySQL primary, and offers change notifications ("triggers") to downstream consumers. Trip data fits because parts of a trip, such as ratings, arrive asynchronously long after the trip ends [Thomsen 2016]. *Evidence: Primary* — [Thomsen 2016]

55.4.7 High-level architecture

Figure 55.1 — High-level architecture of the ride-hailing platform (one region).



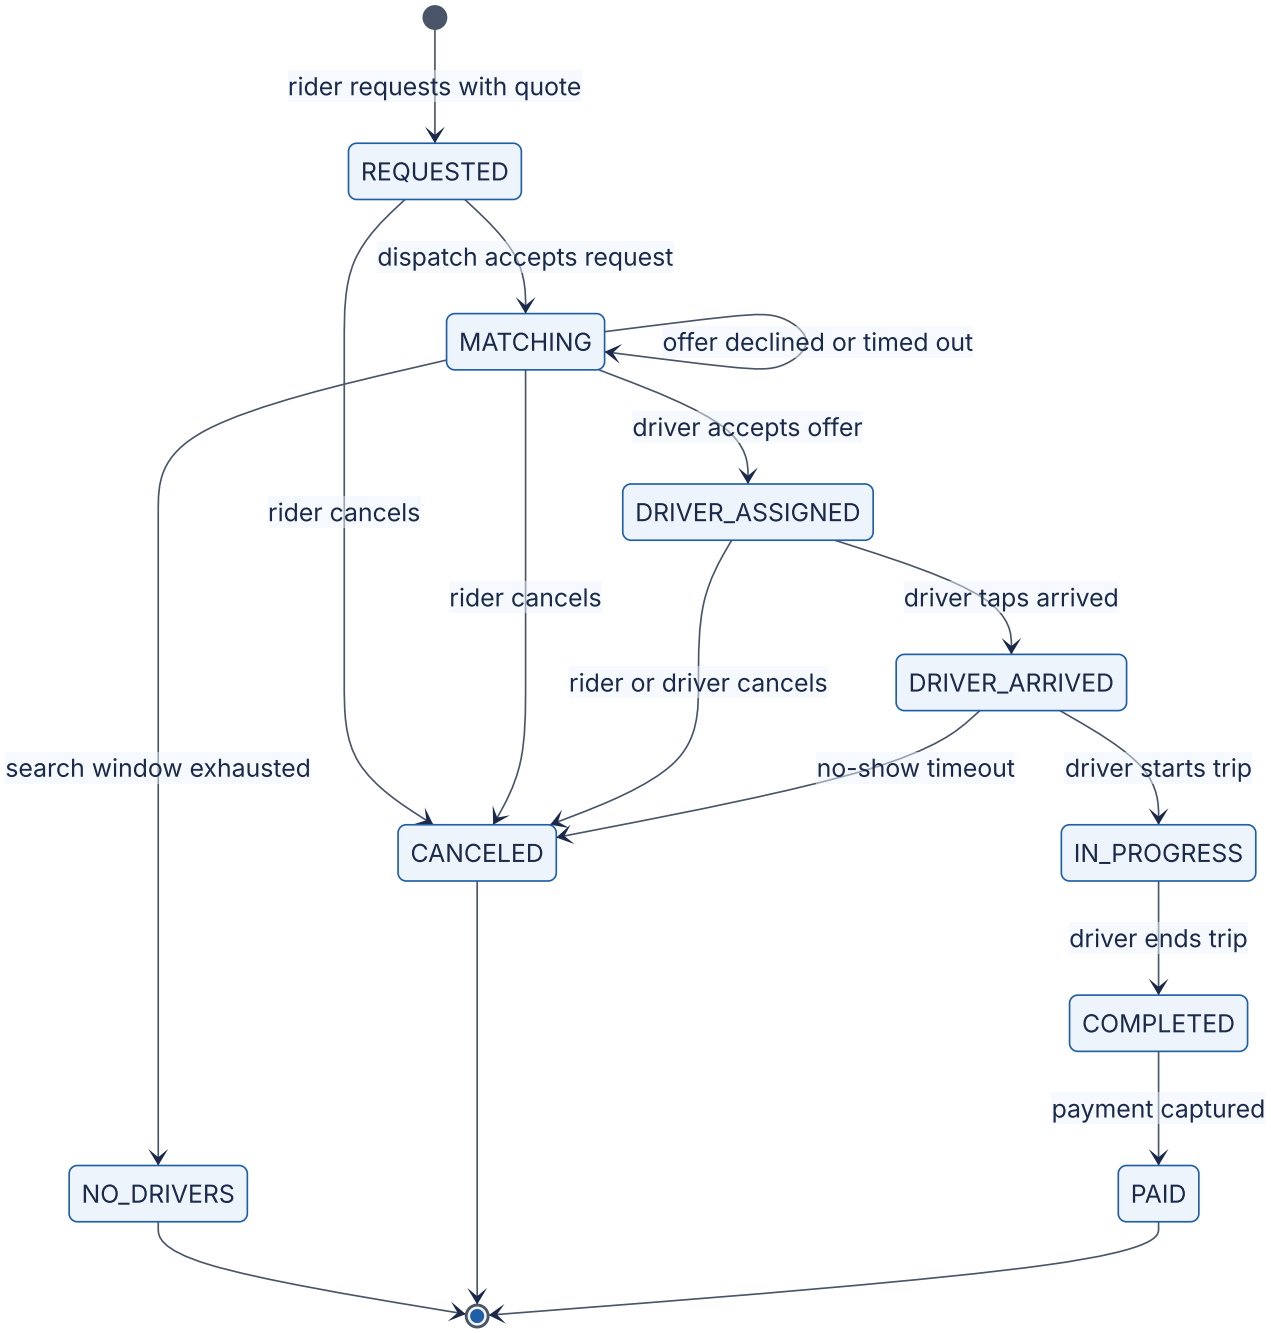
Reading the diagram. Riders send commands (estimate, request, cancel) over HTTPS through the API gateway; both apps also hold a WebSocket to the stream gateway, which is a thin connection-terminating tier. Driver location batches flow synchronously from the stream gateway to the location service, which updates the in-memory supply index and appends to the location log asynchronously (dotted). The trip service owns trip state: it performs compare-and-set updates on the trip database and, in the same transaction, writes outbox events that are relayed to the trip event log. It asks the dispatch service (§55.5) to match a request; dispatch reads candidates from the supply index and pickup times from the ETA service. The pricing service reads ETA and the per-hexagon supply–demand table that a stream aggregator computes from both logs. Downstream consumers — payments (§55.9), push notifications and the data lake — are asynchronous, so their failure never blocks a trip transition. Storage boundaries: trip database (durable, strongly consistent), supply index (volatile, rebuilt from the log), logs (durable, replayable). Failure points: the stream gateway (millions of reconnects after a deploy), the supply index of a hot city, and the trip database primary of a city. Scaling: every box except the gateways is partitioned by city.

55.4.8 Detailed component design

Component 1: the trip lifecycle as a state machine

A trip is a long-running process with a handful of well-defined states, several actors (rider, driver, dispatcher, timers) and real-world side effects. Model it explicitly as a state machine whose current state and version live in one row.

Figure 55.2 — Trip lifecycle state machine.



Reading the diagram. Each arrow is one transition, triggered by an actor (rider, driver, dispatcher) or a timer, and each is applied as a single conditional write to the trip row. `MATCHING` loops on itself while offers are declined or time out (§55.5.8). Cancellation is allowed from every pre-trip state, but the fee depends on the state: free before assignment, chargeable after a grace period once a driver is driving. `IN_PROGRESS` cannot be canceled by the rider; the trip must be ended. `COMPLETED` hands off to payment asynchronously, so a payment outage delays `PAID` but never prevents a trip from ending. Failure points: two actors racing on the same transition (a rider canceling while the driver accepts) and lost timers; the next paragraphs handle both.

How it works:

1. **One owner per trip.** The trip service is the only writer of the trip row. Other services request transitions; they never write state directly.
2. **Compare-and-set.** A transition is `UPDATE trips SET state = :to, version = version + 1, ... WHERE city_id = :c AND trip_id = :t AND state = :from AND version = :v`. If zero rows change, someone else won the race; reload and decide. When a rider cancels at the same moment the driver accepts, exactly one of the two updates succeeds, and the loser is told the true state.
3. **Transition table, not if-statements.** Valid `(from, event) → to` pairs live in a table checked before every write; an invalid event (start a canceled trip) is rejected with 409 Conflict and logged.
4. **Events in the same transaction.** Each transition inserts a `trip_events` row in the same database transaction; a relay publishes unpublished rows to the trip event log (transactional outbox, §32.5). Downstream consumers — payment, notifications, receipts, analytics — are therefore never told about a transition that did not commit, and never miss one that did.
5. **Durable timers.** "Offer expires in 15 s" and "no-show after 5 minutes" are rows in a timer table (or a delayed-message queue) keyed by trip and version, not in-process sleeps. When a timer fires it requests a transition with the version it was created for; if the trip has moved on, the compare-and-set fails harmlessly.

> COMMON MISTAKE
>
> **"Trip state can live in the dispatcher's memory and be written to the database at the end."** Then a dispatcher crash forgets every in-flight trip, and a rider in a moving car has no record. Persist each transition before acknowledging it; keep only derived, rebuildable state (the supply index) in memory.

Component 2: location ingestion

At 500,000 updates per second, every microsecond per update counts. The path is designed so that the common case touches memory and a log, nothing else.

1. **Client side.** The driver app samples GPS every second but uploads a batch every 4 s, compressing the points. When the network drops it buffers and uploads later, flagged as late; late points go to history but not to the live index.
2. **Stream gateway.** Terminates TLS and the WebSocket, authenticates once per connection (not per frame), and forwards frames to the location service partition for the driver's city (consistent hashing on city and driver, §14.8).
3. **Validation and smoothing.** Reject impossible jumps (300 km/h in a city), clamp poor-accuracy fixes, and optionally **map-match** the point onto the road network so that a car on a highway is not shown in the river beside it.
4. **Cell assignment.** Compute the H3 index at resolution 9 (average hexagon about 0.105 km², §17.9.5). If the cell changed, move the driver from the old cell's set to

the new one; otherwise update the position only.

5. **Supply index update.** Write the driver record with `last_seen_ms`. A sweeper removes drivers not heard from for 15 s from cell sets (they are probably in a tunnel or have lost signal) without marking them offline.
6. **Log append.** Append the raw batch to the location log, asynchronously and in batches. The live path does not wait for the log's acknowledgment; the log is for history and for rebuilding the index after a crash.

A crashed supply-index node loses nothing that matters: within one update interval (4 s) every online driver in its cities has reported again. Rebuilding from the log is needed only for faster warm-up.

Component 3: the supply index and the pricing hand-off

The supply index answers two questions: "which idle drivers are near this point?" (dispatch, §55.5) and "how many cars should this rider see on the map?" (the nearby-cars display). The second one is the 1 million reads per second of the estimate above, and it does not need per-rider precision. Compute, once per second per occupied resolution-9 hexagon, a small snapshot of cars in its k-ring; every rider whose position falls in that hexagon receives the same snapshot. A dense city with 20,000 occupied hexagons then costs 20,000 snapshot computations per second, independent of how many riders are watching, and each snapshot is cached and pushed over the riders' streams.

Pricing needs a coarser view: supply (idle drivers) and demand (requests and app opens) per hexagon per minute. A stream aggregator consumes the location log and the trip event log, counts both per resolution-7 or resolution-8 hexagon (5.16 km² and 0.737 km², §17.9.5) in one-minute windows, and writes the table to a key-value store. The pricing service reads it when it builds a quote. How the multiplier is computed from supply, demand and forecasts is a machine-learning and economics problem (Chapter 83, §83.6); the system-design contract is only this: **the price is fixed in a signed quote with an expiry**, the request references the quote, and the trip stores the quote. Riders never pay a price they did not see.

> INDUSTRY EXAMPLE
>
> **H3 and surge at Uber.** Uber built H3, a hexagonal hierarchical grid, to analyze and optimize marketplace dynamics such as supply, demand and pricing by area, and open-sourced it in 2018; hexagons were chosen because all six neighbors are equidistant, which simplifies smoothing across adjacent areas [Brodsky 2018; H3 Docs]. Uber's SIGMOD paper on its real-time data infrastructure names dynamic pricing (surge) as a mission-critical use of that stack, computing demand and supply ratios per geofence from streaming data built on Kafka and Flink [Fu and Soman 2021]. *Evidence: Primary* — [Brodsky 2018; H3 Docs; Fu and Soman 2021]

Component 4: regional architecture

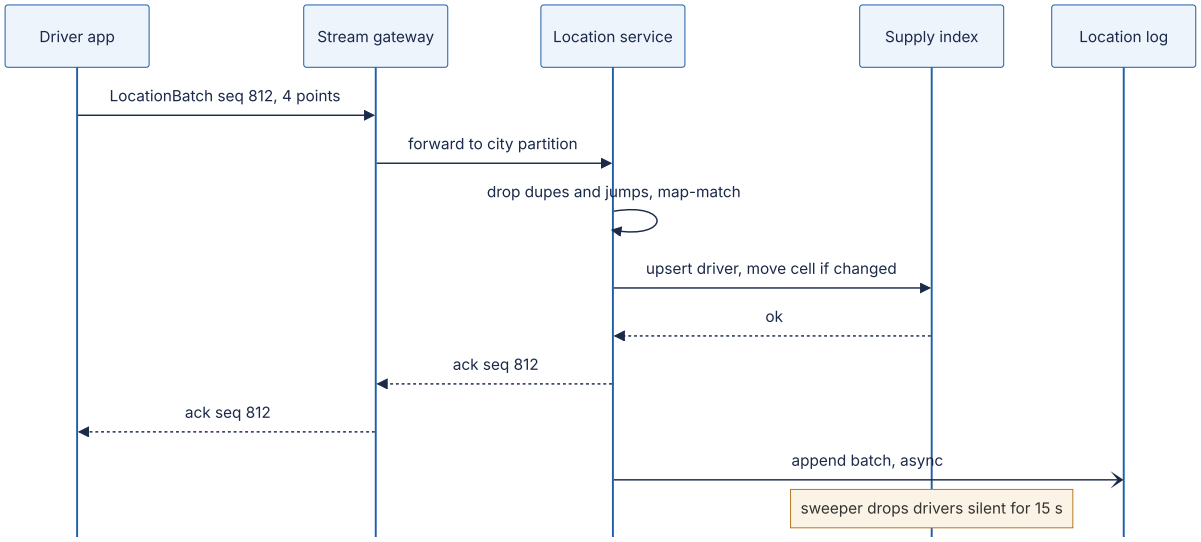
Cities are almost perfect partitions: a rider in Lagos is never matched with a driver in Lima. Exploit that.

- **City-to-region mapping.** Each city is homed in one region (a cloud region or data-center pair). All of its trip rows, supply index partitions, dispatch workers and timers live there. The edge routes a request by the city of its pickup point; a traveler's app follows the city, not the home country.
- **Cells inside a region.** Within a region, group cities into cells (§33.12, §44.10) with their own service instances, so a bad deploy or a hot city damages one cell, not the whole region.
- **Failover.** Trip databases replicate synchronously within the region (across availability zones) for RPO = 0 and asynchronously to a paired region for disaster recovery. On regional failure, the city's home moves to the pair; in-flight trips continue from the replicated state, and anything lost in the asynchronous gap is reconstructed from the apps, which hold the current trip ID, state and version locally and resubmit them.
- **Global data.** Rider and driver accounts, payment methods and ratings are global but read-mostly; replicate them to every region with a home region per user for writes (§44.6).

> INDUSTRY EXAMPLE
>
> **Uber's dispatch rewrite, as presented in 2015.** In a QCon London talk, Uber's Matt Ranney described a rewrite of the dispatch system ("DISCO") that sharded supply by Google S2 cells, used Ringpop (a library combining SWIM-style membership, consistent hashing and request forwarding) to spread that state across Node.js processes, and could consider drivers still on a trip whose route would end near a new rider. He also described using driver phones as a backup store of trip state during datacenter failover [Ranney 2015; Hoff 2015; Ringpop]. *Evidence: Secondary* — [Ranney 2015; Hoff 2015]; Ringpop's design is *Primary* — [Ringpop]

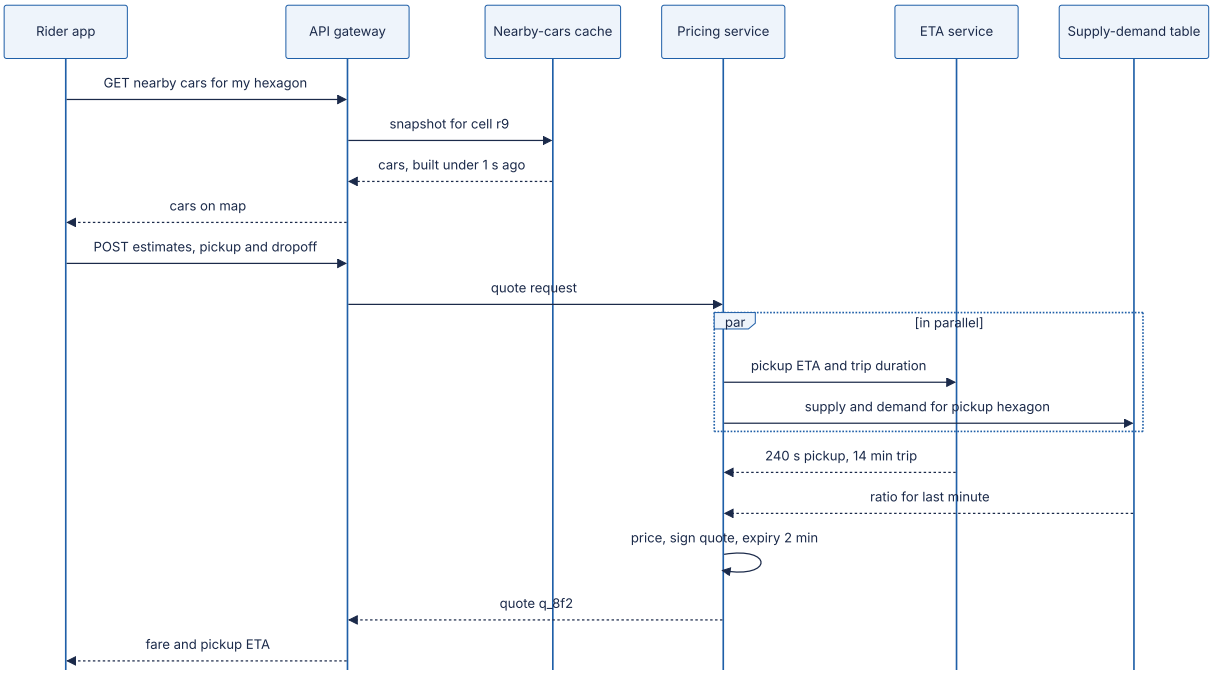
55.4.9 Data flow

Figure 55.3 — Write path: a driver location update.



Reading the diagram. The app sends a sequence-numbered batch over its WebSocket; the gateway forwards it to the location-service partition that owns the driver's city. The service validates and map-matches the points, updates the in-memory supply index (moving the driver between hexagon sets if the cell changed) and acknowledges; the app discards acknowledged points. The log append is asynchronous (open arrowhead), so a slow log never slows the live path. Storage boundaries: memory (supply index) and the durable log. Failure points: a crashed location node loses its partition's index until drivers report again (at most 4 s); a lost acknowledgment makes the app resend, and the sequence number turns the retry into a no-op. Scaling: add partitions per city; split a city by hexagon ranges if one city exceeds a node.

Figure 55.4 — Read path: a rider opens the app and gets a quote.



Reading the diagram. The nearby-cars call reads a per-hexagon snapshot that is rebuilt once a second and shared by every rider in the hexagon, so the 1 million reads per second become cache hits. The estimate fans out in parallel to the ETA service and the supply–demand table, then the pricing service signs a quote with an expiry and stores it (a key-value write keyed by `quote_id`) so the later request can reference it. All calls are synchronous; the slowest dependency (ETA) sets the latency, so it gets a tight timeout with a fallback (straight-line distance at the city's average speed) rather than failing the screen. Failure points: an ETA outage (degrade to fallback ETAs and widen the fare range) and a stale supply–demand table (fall back to multiplier 1.0 after a staleness threshold). The ride request itself, which starts matching, is the write path of §55.5.9.

55.4.10 Bottlenecks

1. **Hot cells.** A stadium emptying or an airport at 06:00 concentrates thousands of drivers and riders in a few hexagons; the partition that owns them saturates. Split hot cities into sub-partitions by hexagon ranges, and for airports use a separate first-in-first-out queue model rather than nearest-driver search.
2. **The connection tier.** Seven million persistent connections reconnecting after a gateway deploy can overload authentication and the location service. Drain slowly, reconnect with jittered backoff, and validate session tokens locally (§9.6).
3. **The ETA service.** Every quote and every dispatch candidate needs a road-network ETA (§55.6). Dispatch alone may ask for 20 candidates per request (§55.5.4). Cache ETAs between hexagon pairs for short horizons and batch requests.
4. **The trip database of one city.** About a thousand trips per second globally is small, but a single mega-city at 200 trips/s with ten transitions each is 2,000 conditional writes per second on one partition. Partition by `(city_id, trip_id)` and let large cities span several shards.
5. **The location log.** 500,000 records per second must be spread over enough log partitions; partition by driver, not by city, so one city's spike spreads across brokers.

55.4.11 Failure scenarios

Table 55.3 — Failure scenarios for the ride-hailing platform.

What fails	Impact	Detection	Recovery	Prevention
Location-service node	Drivers in its partitions invisible to dispatch for up to one update interval	Partition heartbeat; drop in updates/s per city	Reassign partition; drivers re-report within 4 s; optional warm-up from log	Replicated partitions or fast reassignment; per-city alarms
Stream gateway fleet restart	Mass reconnect storm; stale maps; missed offers	Connection count cliff; handshake error rate	Jittered reconnect; offers re-sent on reconnect from trip service state	Slow drain; local token validation; admission control
Trip database primary	Trip transitions fail for that shard	Write errors; failover monitor	Promote synchronous replica (seconds); apps retry with same idempotency key and version	Synchronous replication across zones; small shards
Outbox relay stalls	Payments, notifications and receipts delayed	Age of oldest unpublished event	Restart relay; it resumes from `published = FALSE` rows	Alert on outbox age; multiple relay workers with leases
ETA service slow	Quotes and dispatch slow; timeouts	p99 latency SLO burn	Fallback ETA; shed quote traffic before dispatch traffic	Per-caller timeouts and bulkheads (§22.14)
GPS spoofing by a driver	Wrong matches; fraudulent fares	Impossible speed; mismatch with network cell or accelerometer	Suspend account; reprice trips from map-matched trail	Server-side plausibility checks; device attestation
Region outage	All cities homed there stop	Health checks; synthetic trips	Rehome cities to paired region; apps resubmit trip state	Regular evacuation drills (§44.11)

55.4.12 Scaling strategy

At 10× (300 million trips per day, 5 million updates per second): the per-city partitioning holds, but the largest cities exceed one partition, so split cities by hexagon ranges with a directory that maps resolution-5 or resolution-6 parents to partitions; boundary queries fan out to two partitions. The location log grows to about 21.6 TB per day: keep raw points for days, not years, and keep map-matched, downsampled trails for longer. The connection tier grows to about 350 nodes; this is the point where a dedicated edge connection service with its own release cadence pays off.

At 100×: update frequency, not driver count, becomes the cost to attack. Adaptive reporting — every 1–2 s when a driver is near a pickup or in a dense, high-demand area, every 10–15 s when idle in a quiet suburb — cuts the average rate several-fold with no matching loss. Regions become cells of a few cities each, and global services (accounts, payment methods) must be read locally with no synchronous cross-region call on the trip path.

55.4.13 Trade-offs

- **Freshness versus battery and bandwidth.** Halving Δt doubles ingestion and drains phones faster; adaptive intervals spend updates where matching quality depends on them.
- **Strong trip state versus availability.** Trip transitions need a primary; during a partition the minority side cannot accept transitions. Accept it: the app keeps showing the last known state and retries, which is better than two conflicting histories.
- **Exact versus snapshot nearby cars.** Per-hexagon snapshots are up to a second old and identical for nearby riders; nobody notices, and the read load drops by orders of magnitude.
- **City partitioning versus global optimization.** Cross-city effects (a driver crossing a city boundary) are handled as rare exceptions instead of making every query global.

55.4.14 Alternative designs

Table 55.4 — Alternative designs for the supply index.

Option	How it works	Advantages	Disadvantages	Choose when
In-memory H3 cell sets (this design)	Hexagon ID → driver set, partitioned by city	Uniform rings; fast; pricing uses the same cells	Custom service to build and operate	High update rate, ring-based search and pricing
Redis GEO	Sorted set scored by 52-bit geohash; `GEOSEARCH`	Off the shelf; simple	Square cells; one key per area gets hot; manual partitioning	Smaller fleets, one region, fast start
PostGIS with a GiST index	Spatial index in the database	Rich queries; transactional	Updates at 500,000/s far exceed one database	Low update rates (stores, venues)
Quadtree in memory	Adaptive tree splits dense areas	Adapts to density	Constant splits and merges as cars move	Mostly static points
S2 cell sharding	Hilbert-ordered 64-bit cells	Range scans; good coverer	Square-ish cells; rings less uniform	Range-partitioned stores; polygons

A different overall shape is **polling instead of push**: apps poll every few seconds for trip state and nearby cars. It is simpler and stateless but multiplies request volume and adds up to one poll interval of delay to offers, which hurts acceptance rates. Push for offers and trip updates, pull for everything else, is the usual compromise.

55.4.15 Interview discussion

Table 55.5 — A 45-minute pacing plan for “design Uber”.

Minutes	Focus	Output
0–5	Scope: rider, driver, platform; exclude ML pricing and payments internals	Functional list; NFR split between trip state and telemetry
5–10	Estimate: trips/s, location updates/s, connections	1,000 trips/s vs 500,000 updates/s; "telemetry system with a transactional core"
10–20	High-level architecture	Figure 55.1 shape; city partitioning
20–35	Deep dives: trip state machine and location ingestion; then nearby search (§55.5)	Compare-and-set, outbox, H3 index, rings
35–42	Failures and scaling	Region failover; hot cells; reconnect storms
42–45	Trade-offs and what you would build next	Adaptive intervals; quote locking

Likely follow-ups. *How do you stop two drivers being assigned?* Compare-and-set on the trip row and a lease on the driver (§55.5.8). *Why not store positions in the database?* 500,000 writes per second of data that is obsolete in 4 s. *How is surge applied fairly?* A signed quote with expiry; the request references it. *What happens when a region dies mid-trip?* Rehome the city; apps resubmit trip ID, state and version; the trip service reconciles.

What distinguishes senior and staff answers. A senior candidate separates telemetry from transactional state and names the cell index. A staff candidate also designs the failure behavior (what the rider sees during failover), turns the 1 million reads per second into per-cell snapshots, adapts update frequency to cost, and treats cities as isolation boundaries for deploys and incidents.

55.4.16 Production considerations

- **Observability.** Service-level indicators that matter to riders: request-to-offer latency, offer acceptance rate, pickup-ETA error (promised versus actual), and **location freshness** (age of the newest point per driver, p99 per city). Per-city dashboards, because a global average hides a dead city.
- **Security and privacy.** Precise location histories are sensitive personal data: restrict access by role, log every access (§10.12), mask rider and driver phone numbers through a proxy, coarsen locations in analytics, and delete or aggregate raw trails on a retention schedule (§50.9). Defend against GPS spoofing and emulator farms with plausibility checks.
- **Cost.** The largest variable costs are connection gateways, ETA computations and location-history storage; adaptive reporting and downsampled trails reduce all three.

- **Operations.** Launching a city is configuration (products, regulations, geofences, airport queues), not code. Deploy by cell, one city group at a time, and run regular region-evacuation drills.

55.5 Ride matching system

55.5.1 Problem statement

Zoom into the dispatch box of Figure 55.1. A ride request arrives with a pickup point and a product. Within about two seconds the system must choose one driver, offer the trip, and either confirm the match or move on to another driver if the first declines or does not answer. Two promises must hold under every failure: **a driver is never committed to two rides at once, and a ride is never committed to two drivers.**

An analogy: a taxi rank dispatcher with a radio. The naive dispatcher gives each caller the nearest free cab the moment they call. A better one waits a moment, looks at all callers and all free cabs together, and pairs them so that the *total* waiting is smallest; sometimes the nearest cab goes to the second caller because the first caller has another cab almost as close. Both dispatchers must also never say “cab 7, take this job” to two callers, even if the radio crackles and the dispatcher repeats themselves.

The distinctive hard problems are therefore three: finding candidates fast with geospatial cells (§17.9), choosing the *assignment* well (ETA rather than distance, batched rather than greedy), and making the commitment safe in a distributed system with leases and fencing tokens (§26.10–§26.13).

55.5.2 Functional requirements

1. Given a ride request (pickup, product, rider constraints), find candidate drivers who are idle, eligible for the product and close in **driving time**.
2. Include drivers about to finish a trip near the pickup (“in-flight supply”) when they would arrive sooner than idle drivers.
3. Assign drivers to requests, individually or in batches, minimizing total pickup time subject to business constraints (maximum pickup ETA, product eligibility, driver preferences).
4. Offer the trip to the chosen driver with a deadline; on decline or timeout, re-offer to the next best driver; stop after a search window and report “no drivers”.
5. Guarantee one driver per ride and one ride per driver across retries, crashes and network partitions.
6. Emit every decision (candidates, scores, outcome) for analysis and offline replay.

55.5.3 Non-functional requirements

Table 55.6 — Non-functional requirements for ride matching.

Property	Target
Request to first offer	p50 < 1 s, p99 < 3 s including a batching window of up to 2 s
Offer deadline	15 s for the driver to respond
Double assignment	Zero: a correctness invariant, not a percentage
Availability	99.99% per city; a matching outage stops the business
Candidate search	p99 < 20 ms in memory
ETA computation for candidates	p99 < 100 ms for a batch of 20
Decision log	At-least-once, complete enough to replay any decision

55.5.4 Capacity estimation

FORMULA

Expected candidates in a hexagonal k-ring

$$C(k) = \rho \times (1 + 3k(k+1)) \times A_{\text{cell}}$$

Symbol	Meaning	Units
$C(k)$	Expected idle drivers inside the k-ring around the pickup hexagon	drivers
ρ	Density of idle, eligible drivers	drivers/km²
k	Ring radius in hexagon steps	—
$1 + 3k(k+1)$	Number of hexagons in the k-ring (§17.9.5)	cells
A_{cell}	Average hexagon area at the chosen resolution (0.105 km² at H3 resolution 9)	km²

WORKED EXAMPLE

Worked example — how far must the search expand? Goal: at least 5 idle candidates before ranking by ETA. Index resolution 9, $A_{\text{cell}} = 0.105$ km².

1. **Downtown, $\rho = 8$ drivers/km².** $k = 1$: $7 \times 0.105 = 0.735$ km², $C = 8 \times 0.735 = 5.9$. One ring is enough; $k = 2$ gives $19 \times 0.105 \times 8 = 16.0$.
2. **Suburb, $\rho = 0.3$ drivers/km².** $k = 6$: $127 \times 0.105 = 13.3$ km², $C = 4.0$, not enough. $k = 7$: $169 \times 0.105 = 17.7$ km², $C = 5.3$.
3. **Equivalent radius.** A 7-ring covers 17.7 km², the area of a circle of radius $\sqrt{17.7/\pi} = 2.38$ km; a 1-ring covers 0.735 km², radius 0.48 km.

Interpretation. A fixed search radius is wrong everywhere: too large downtown (hundreds of candidates to rank) and too small in the suburbs (none). *Engineering implication.* Expand rings until enough candidates are found, then expand one more ring because a driver in the next ring may be closer by road (§55.5.8); in sparse areas jump to a coarser resolution (resolution 8 hexagons are seven times larger) instead of walking 169 cells.

WORKED EXAMPLE

Worked example — matching load. Assumptions: 1,000 requests/s at the global peak (§55.4.4); the largest city 100 requests/s; 20 candidates per request are scored by road ETA; batching window 2 s.

1. **Candidate searches.** 1,000/s globally, each touching tens of in-memory sets: trivial CPU.
2. **ETA computations.** $1,000 \times 20 = 20,000$ point-to-point ETAs per second globally; in the largest city $100 \times 20 = 2,000$/s.
3. **Batch size.** Largest city: $100 \times 2 = 200$ requests per window. If 300 idle drivers are within reach, the cost matrix has $200 \times 300 = 60,000$ cells; only the 20 nearest per request are real edges, so $200 \times 20 = 4,000$ ETAs per batch.
4. **Assignment cost.** A dense Hungarian solve is $O(n^2 m) = 200^2 \times 300 = 1.2 \times 10^7$ steps, milliseconds in compiled code; sparse solvers or splitting the city into zones keep it well under the window.

Interpretation. The solver is cheap; the ETA computations are the dominant cost. *Engineering implication.* Batch the ETA requests, cache ETAs between hexagon pairs for a few seconds, and partition the batch by zone so each solver instance handles a few hundred requests at most.

FORMULA

Offers needed to place a ride

$$\mathbb{E}[N] = \frac{1}{p}, \qquad P(N > n) = (1 - p)^n$$

Symbol	Meaning	Units
N	Number of offers sent until one driver accepts	offers
p	Probability that a given offer is accepted (assumed independent)	—
n	A number of offers already sent	offers

WORKED EXAMPLE

Worked example — re-offers and the search window. Assume acceptance $p = 0.7$; a declined offer takes 5 s on average and an ignored one the full 15 s deadline; one-third of non-acceptances are ignores.

1. **Expected offers.** $\mathbb{E}[N] = 1/0.7 = 1.43$.
2. **Tail.** $P(N > 3) = 0.3^3 = 0.027$: 2.7% of rides need a fourth offer.
3. **Time per failed offer.** $\frac{2}{3} \times 5 + \frac{1}{3} \times 15 = 3.33 + 5 = 8.33$ s.
4. **Delay for a ride needing four offers.** $3 \times 8.33 = 25$ s of failed offers before the fourth.

Interpretation. Most rides are placed on the first offer, but the tail is dominated by ignored offers. *Engineering implication.* Shorten the deadline for drivers who habitually ignore offers, track acceptance probability per driver and use it in the score, and cap the search window (say 60 s) before telling the rider “no drivers available”.

55.5.5 API design

Matching is internal, so its interfaces are RPCs, plus the driver-facing offer frames of §55.4.5.

```
        service Dispatch {
          // Called by the trip service when a trip enters MATCHING. Idempotent on
trip_id + trip_version.
          rpc RequestMatch(MatchRequest) returns (MatchAccepted);
          // Called by the trip service when the rider cancels; stops offers in flight.
          rpc CancelMatch(CancelMatchRequest) returns (CancelMatchResponse);
        }

        message MatchRequest {
          int64  trip_id = 1;
          int32  trip_version = 2;
          int32  city_id = 3;
          double pickup_lat = 4;
          double pickup_lng = 5;
          string product = 6;              // economy, premium, xl ...
          int32  max_pickup_eta_s = 7;     // business constraint, e.g. 900
          int64  search_deadline_ms = 8;   // give up and report NO_DRIVERS after this
        }

        service Supply {
          // Candidate search: rings around a hexagon, filtered by status and product.
          rpc Candidates(CandidateQuery) returns (CandidateList);
          // Atomically claim a driver for an offer; returns a fencing token or
ALREADY_CLAIMED.
          rpc Claim(ClaimRequest) returns (ClaimResult);
        }

        message ClaimResult {
          bool   ok = 1;
          int64  fencing_token = 2;        // strictly increasing per driver
          int64  lease_expires_ms = 3;
        }
```

What to notice: `RequestMatch` is idempotent on `(trip_id, trip_version)`, so a retried call does not start a second search. `Claim` is the only operation that commits a driver, and it returns a **fencing token** that every later step must present (§55.5.8).

55.5.6 Data model and database schema

```
        -- One row per driver, in the same per-city shard as the trips table (§55.4.6),
        -- so a trip transition and a driver claim can commit in one local transaction.
        CREATE TABLE driver_dispatch (
          city_id           INT          NOT NULL,
          driver_id         BIGINT       NOT NULL,

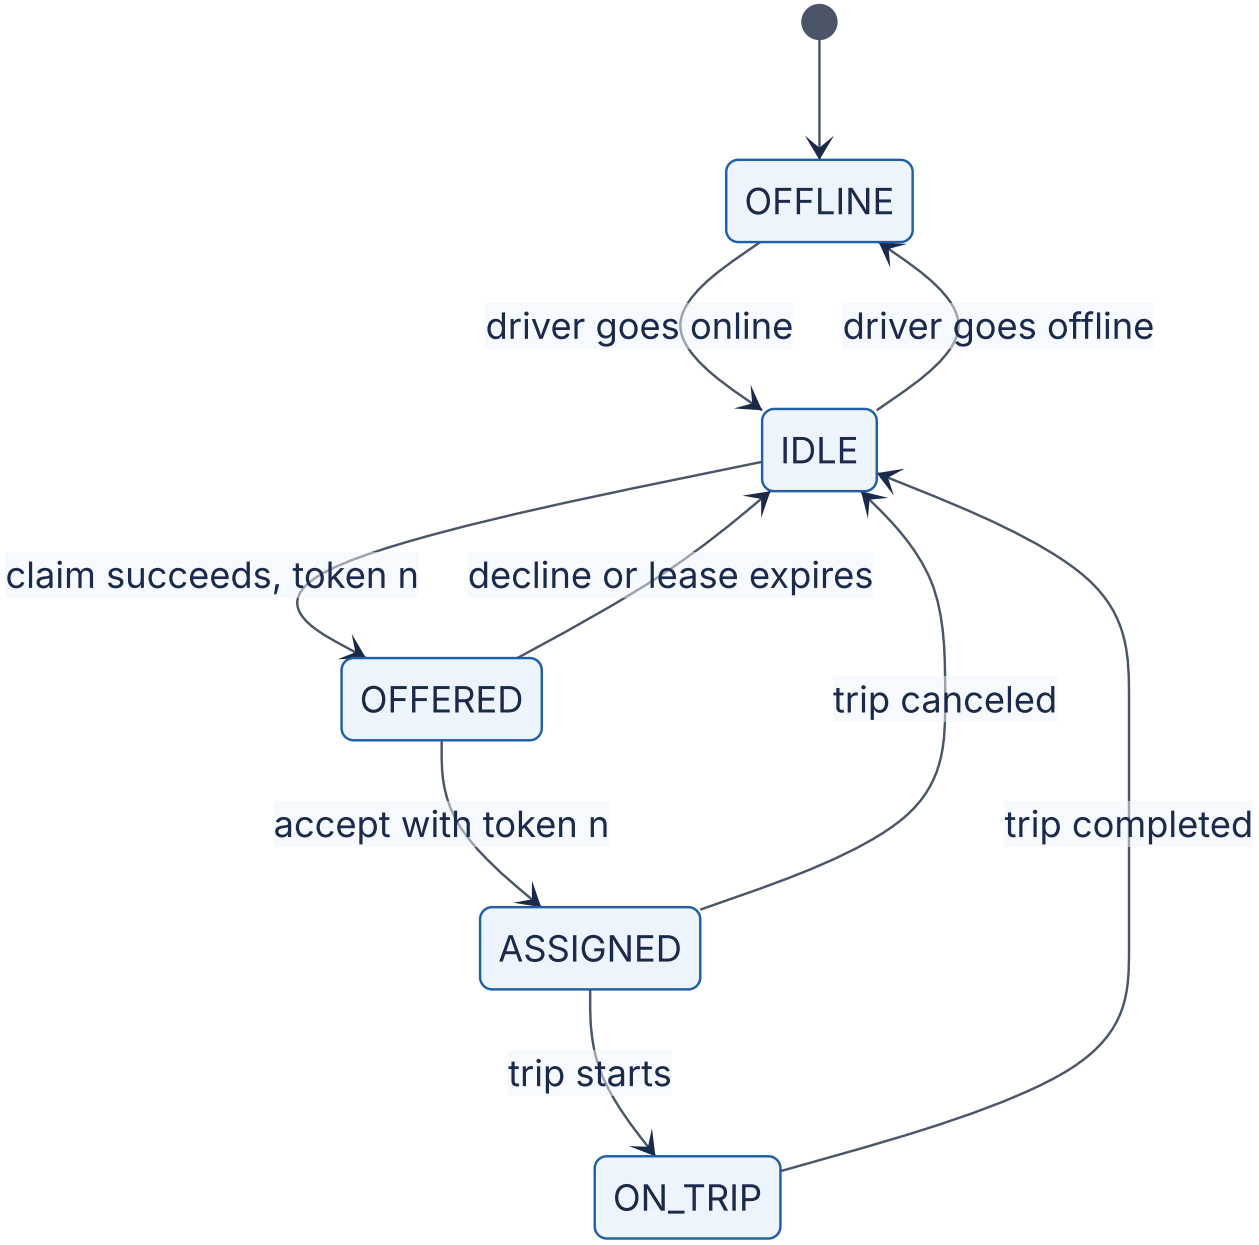
```

The in-memory supply index (§55.4.6) holds positions and a *hint* of each driver's state, so that candidate search skips busy drivers. The `driver_dispatch` row is the *truth*. The design deliberately tolerates a stale hint (a driver who just accepted elsewhere may still look idle in memory for a fraction of a second) because the claim against the row will fail and the matcher will move on.

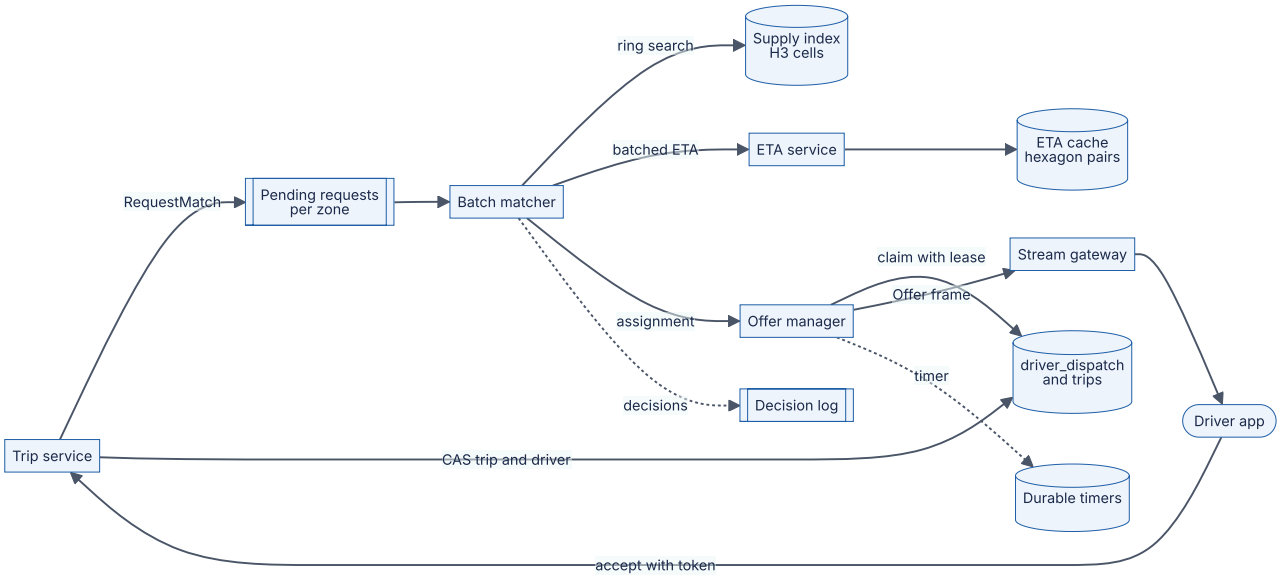
Figure 55.5 — Driver dispatch state, owned by the claim row.



Reading the diagram. Each transition is a conditional update on the driver's `driver_dispatch` row. `IDLE → OFFERED` increments the fencing token and sets a lease (15 s plus a grace period); only an accept carrying that token can move the row to `ASSIGNED`. If the lease expires the row returns to `IDLE` and the next claim gets token $n+1$, so a late accept with token n is rejected. The failure point is a matcher that crashes after claiming: nothing needs cleaning up, because the lease expiry releases the driver.

55.5.7 High-level architecture

Figure 55.6 — Ride-matching architecture within one city partition.



Reading the diagram. The trip service enqueues a request for the pickup's zone (a group of resolution-6 hexagons inside the city). Every batching window, the batch matcher drains the zone's queue, searches the supply index ring by ring, asks the ETA service for road ETAs in one batched call (backed by a short-lived cache keyed by hexagon pairs) and solves the assignment. The offer manager claims each chosen driver with a conditional write on `driver_dispatch`, which returns a fencing token, pushes the offer to the driver's app and arms a durable timer. The driver's accept goes to the trip service, which commits the trip and driver transitions together in one local transaction (both rows live in the city shard). Solid arrows are synchronous; the timer and the decision log are asynchronous. Storage boundaries: memory (supply index, ETA cache) versus the durable city shard (truth). Failure points: a matcher crash (requests stay in the queue and are re-batched), an offer manager crash (leases expire), the ETA service (fallback to distance-based estimates). Scaling: one matcher per zone; more zones for bigger cities.

55.5.8 Detailed component design

Component 1: nearest-driver search with ring expansion

1. Convert the pickup to its resolution-9 hexagon h.
2. For $k = 0, 1, 2, \ldots$ read the idle-driver sets of the cells exactly k steps away (a **hex ring**; the union up to k is a **k-ring** or disk) and filter by product eligibility and the state hint.
3. Stop when at least K candidates are found (for example $K = 8$) **plus one further ring**, or when k reaches a ceiling; in sparse areas restart at resolution 8 or 7 rather than walking hundreds of fine cells.
4. Compute the straight-line (haversine) distance for each candidate and keep the nearest $K' = 20$ as the shortlist for ETA scoring.

Why the extra ring? The first ring that contains *K* candidates bounds the *count*, not the *distance*: a driver just outside it can be closer than one in a far corner of the ring, because a k-ring is a jagged hexagon, not a circle. The extra ring makes it very unlikely that the true nearest few are missed; the haversine sort removes the excess.

Component 2: ETA-based versus distance-based scoring

Straight-line distance is a poor proxy for pickup time. A driver 400 m away across a river or on the other carriageway of a divided highway may need 8 minutes; a driver 1.2 km away on the same arterial road may need 2. So the shortlist is scored with **road-network ETAs** from the routing engine (§55.6) using live traffic, plus correction terms:

```
score(driver, request) = road_eta_seconds(driver -> pickup)
                       + a * (1 - predicted_acceptance(driver))
                       + b * heading_penalty(driver, pickup)
                       - c * fairness_bonus(driver)          # lower is better; a, b, c
tuned by experiment
```

The weights are business decisions, tuned by experiments; the learned acceptance probability and ETA corrections are Chapter 83 material. The system-design point is the two-stage funnel: a cheap geometric filter to about 20 candidates, then an expensive but accurate road ETA only for those. In-flight drivers enter the same funnel with
ETA = remaining trip time + ETA from drop-off to pickup.

Component 3: greedy versus batched assignment

Greedy matching handles each request on arrival: take the best-scoring free driver. It is simple and adds no delay, but it is myopic. **Batched matching** collects requests for a short window (1–2 s), builds a bipartite graph — requests on one side, drivers on the other, an edge weighted by the score where the ETA is under the cap — and solves the minimum-cost **assignment problem**, for example with the Hungarian algorithm [Kuhn 1955] or a min-cost-flow solver. The program below shows the classic trap for greedy matching, ring expansion over a cell index, and a comparison on random batches.

```
        import math
        import random
        from collections import defaultdict

        CELL_KM = 0.5                                   # square cells stand in for H3
hexagons

        def cell_of(x, y):
            return (math.floor(x / CELL_KM), math.floor(y / CELL_KM))

        def ring(cx, cy, k):
            """Cells exactly k steps away (Chebyshev ring); k = 0 is the center cell."""
            if k == 0:
                return [(cx, cy)]
            out = []
            for dx in range(-k, k + 1):
                out += [(cx + dx, cy - k), (cx + dx, cy + k)]
            for dy in range(-k + 1, k):
                out += [(cx - k, cy + dy), (cx + k, cy + dy)]
            return out

        def nearby(index, x, y, want, max_k=6):
            """Expand rings until `want` candidates are found, plus one safety ring."""
            cx, cy = cell_of(x, y)
            found, k, extra = [], 0, None
            while k <= max_k:
                for c in ring(cx, cy, k):
                    found += index.get(c, [])
                if extra is None and len(found) >= want:
                    extra = k + 1                       # a nearer driver may sit one ring
further out
                if extra is not None and k >= extra:
                    break
                k += 1
            return found, k

        def eta_min(d, r, speed_kmh=24.0):
            """Manhattan distance at city speed: a stand-in for a road-network ETA."""
            return (abs(d[0] - r[0]) + abs(d[1] - r[1])) / speed_kmh * 60

        def greedy(riders, drivers):
            """Each rider, in arrival order, takes the nearest free driver."""
            free, total, pairs = set(range(len(drivers))), 0.0, []
            for i, r in enumerate(riders):
                j = min(free, key=lambda j: eta_min(drivers[j], r))
                free.remove(j)
                total += eta_min(drivers[j], r)
                pairs.append((i, j))
            return total, pairs

        def hungarian(cost):

                            if cur < minv[j]:
                                minv[j], way[j] = cur, j0
                            if minv[j] < delta:
                                delta, j1 = minv[j], j
                    for j in range(m + 1):
                        if used[j]:
                            u[p[j]] += delta
                            v[j] -= delta
                        else:
                            minv[j] -= delta
                    j0 = j1
                    if p[j0] == 0:
                        break
                while j0:
                    j1 = way[j0]
                    p[j0] = p[j1]
                    j0 = j1
            pairs = [(p[j] - 1, j - 1) for j in range(1, m + 1) if p[j]]
            return sum(cost[i][j] for i, j in pairs), sorted(pairs)

        def batched(riders, drivers):
            return hungarian([[eta_min(d, r) for d in drivers] for r in riders])

        # 1. The textbook trap: two riders, two drivers on a line (km).
        riders, drivers = [(1.0, 0.0), (2.2, 0.0)], [(1.8, 0.0), (0.0, 0.0)]
        print("toy greedy :", round(greedy(riders, drivers)[0], 1), "min",
greedy(riders, drivers)[1])
        print("toy batched:", round(batched(riders, drivers)[0], 1), "min",
batched(riders, drivers)[1])

        # 2. Ring expansion over a cell index.
        random.seed(7)
        drivers = [(random.uniform(0, 10), random.uniform(0, 10)) for _ in range(400)]
        index = defaultdict(list)
        for j, d in enumerate(drivers):
            index[cell_of(*d)].append(j)
        cands, k = nearby(index, 5.0, 5.0, want=8)
        print(f"ring search: {len(cands)} candidates after k = {k} rings")

        # 3. One 2-second batch in a busy area: 30 riders, 40 idle drivers in 10 x 10
km.
        g_tot = b_tot = 0.0
        for trial in range(200):
            rs = [(random.uniform(0, 10), random.uniform(0, 10)) for _ in range(30)]
            ds = [(random.uniform(0, 10), random.uniform(0, 10)) for _ in range(40)]
            g_tot += greedy(rs, ds)[0] / 30
            b_tot += batched(rs, ds)[0] / 30
```

```
        print(f"mean pickup ETA over 200 batches: greedy {g_tot / 200:.2f} min, "
              f"batched {b_tot / 200:.2f} min ({100 * (1 - b_tot / g_tot):.0f}% lower)")
```

Output:

```
toy greedy : 7.5 min [(0, 0), (1, 1)]
toy batched: 3.5 min [(0, 1), (1, 0)]
ring search: 18 candidates after k = 2 rings
mean pickup ETA over 200 batches: greedy 4.05 min, batched 3.48 min (14% lower)
```

What to notice:

- In the toy case, rider 0 (at 1.0 km) grabs driver 0 (at 1.8 km, 2.0 min away), leaving rider 1 (at 2.2 km) with driver 1 at the origin, 5.5 min away: 7.5 min in total. Swapping gives 2.5 + 1.0 = 3.5 min. Greedy is not wrong for rider 0; it is wrong for the system.
- `nearby` stops one ring *after* reaching the target count. With 400 drivers on 100 km² (4 per km², 1 per 0.25 km² cell) eight candidates appear within the 3 × 3 block and the safety ring brings the count to 18.
- `hungarian` is the standard $O(n^2 m)$ potential-based algorithm; its result was checked against brute force on 300 random small instances. Production systems use sparse min-cost-flow or auction solvers with an ETA cap so that impossible pairs have no edge.
- The 14% gain is for a dense random batch with Manhattan ETAs; real gains depend on density and window length. The price is up to one window of added latency for every rider, so the window must stay short (1–2 s) and can shrink when supply is plentiful (greedy is near-optimal when every rider has many close drivers).

INDUSTRY EXAMPLE

Batched dispatch in the literature. Researchers at DiDi described order dispatch on their platform as repeated matching of the orders and drivers collected in short decision windows, combining a bipartite assignment in each window with learned estimates of each driver's future value, and reported improvements over myopic dispatch in A/B tests [Xu et al. 2018]. The assignment step itself is the classical assignment problem solved by the Hungarian method [Kuhn 1955]. *Evidence: Primary* — [Xu et al. 2018; Kuhn 1955]

Component 4: dispatch consistency — one driver, one ride

The race to prevent: two matcher instances (after a failover, or two zones whose search rings overlap at a border) both pick driver *d* for different rides; or a matcher pauses for a garbage-collection cycle after sending an offer, the offer's lease expires, *d* is offered a new ride, and then the old offer's acceptance arrives.

1. **Claim with a lease.** Before sending an offer, the offer manager runs one conditional update:

```
        UPDATE driver_dispatch
           SET state = 'OFFERED', trip_id = :trip, fencing_token = fencing_token
+ 1,
               lease_expires_at = now() + interval '20 seconds', updated_at =
now()
         WHERE city_id = :city AND driver_id = :driver
           AND (state = 'IDLE' OR (state = 'OFFERED' AND lease_expires_at <
now()))
        RETURNING fencing_token;
```

   Zero rows means someone else holds the driver: take the next candidate. This is a **lease** (§26.11): a lock that releases itself, so a crashed matcher cannot strand a driver. The lease (20 s) is longer than the offer deadline shown to the driver (15 s) to absorb clock skew and network delay.

2. **Fencing token on every later step.** The offer frame carries the token. The driver's accept is applied by the trip service in **one local transaction** on the city shard:

```
        BEGIN;
        UPDATE trips SET state = 'DRIVER_ASSIGNED', driver_id = :driver, version
= version + 1
         WHERE city_id = :city AND trip_id = :trip AND state = 'MATCHING' AND ver-
sion = :v;
        UPDATE driver_dispatch SET state = 'ASSIGNED', lease_expires_at = NULL
         WHERE city_id = :city AND driver_id = :driver AND trip_id = :trip
           AND state = 'OFFERED' AND fencing_token = :token;
        -- application: if either UPDATE touched 0 rows, ROLLBACK and reply "offer
no longer valid"
        COMMIT;
```

   The first statement guarantees one driver per ride (only one accept can move the trip out of `MATCHING`); the second guarantees one ride per driver (only the holder of the current token can assign the driver). A late accept from an expired offer carries an old token and fails, exactly as a stale lock holder is fenced off at the storage layer in §26.13.

3. **Why the same shard?** If trips and drivers lived in different databases, assigning would need a distributed transaction (§28.4) or a saga with compensation ("unassign the driver"). Co-locating both by city turns it into one local transaction. Drivers who cross into a neighboring city are re-homed when they go idle there.

4. **Rider cancellation during an offer.** `CancelMatch` moves the trip to `CANCELED` with a compare-and-set; the driver's accept then fails on the first `UPDATE`, the app shows "rider canceled", and the claim row is released.

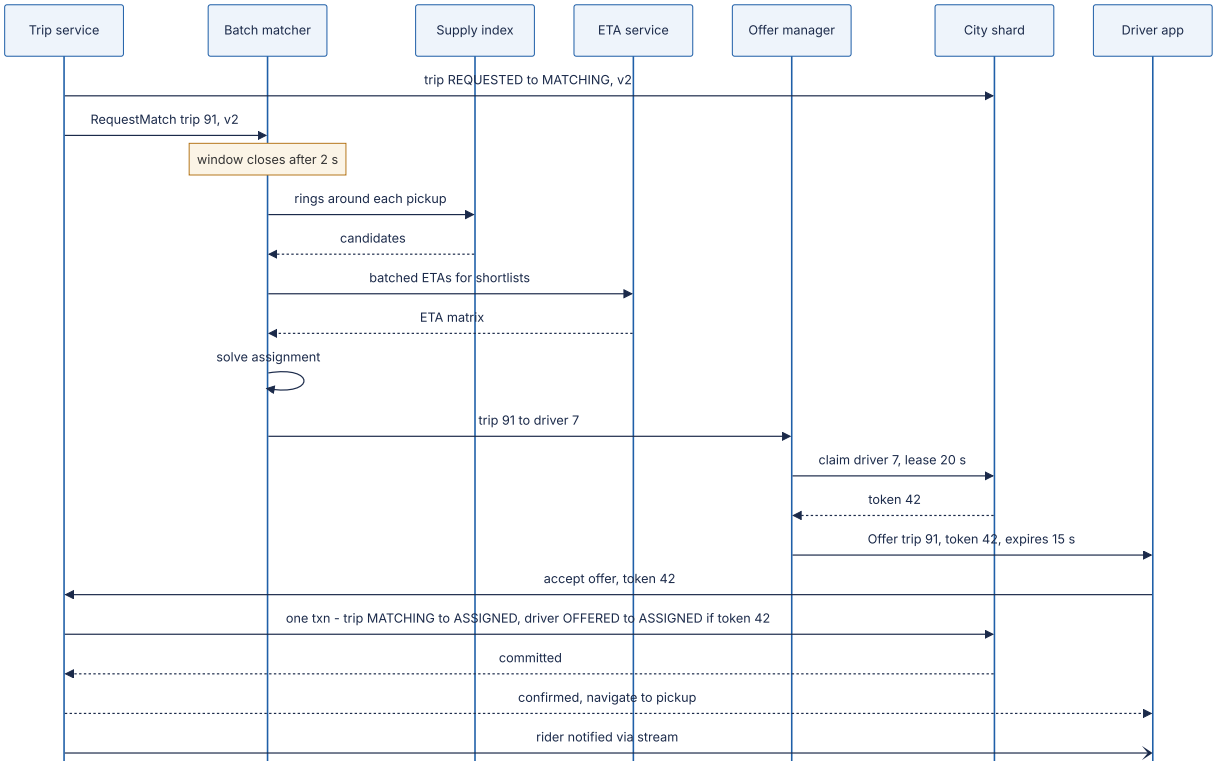
> COMMON MISTAKE
>
> **“A Redis lock with a TTL on the driver is enough.”** A TTL lock prevents most double offers but not a paused or partitioned holder acting after expiry, and a Redis failover can lose an acknowledged lock. Use the lock (or lease) only to *reduce* contention; make the commit itself conditional on a fencing token checked by the database that stores the assignment (§26.10, §26.13).

Component 5: timeouts and re-offers

Each offer arms a durable timer at `lease_expires_at`. On decline or expiry the offer row records the outcome, the driver returns to `IDLE` (and is excluded from this trip’s later rounds), and the trip goes back into the next batch with its accumulated exclusion list. The search widens on each round: larger rings, a higher ETA cap, other eligible products if the rider allowed upgrades. When `search_deadline_ms` passes, the trip moves to `NO_DRIVERS`. Offers are sent to **one driver at a time**; broadcasting to several and letting the first acceptor win is faster in sparse areas but trains drivers to tap without reading and shows “trip taken” to the losers, so use it only where acceptance rates are low.

55.5.9 Data flow

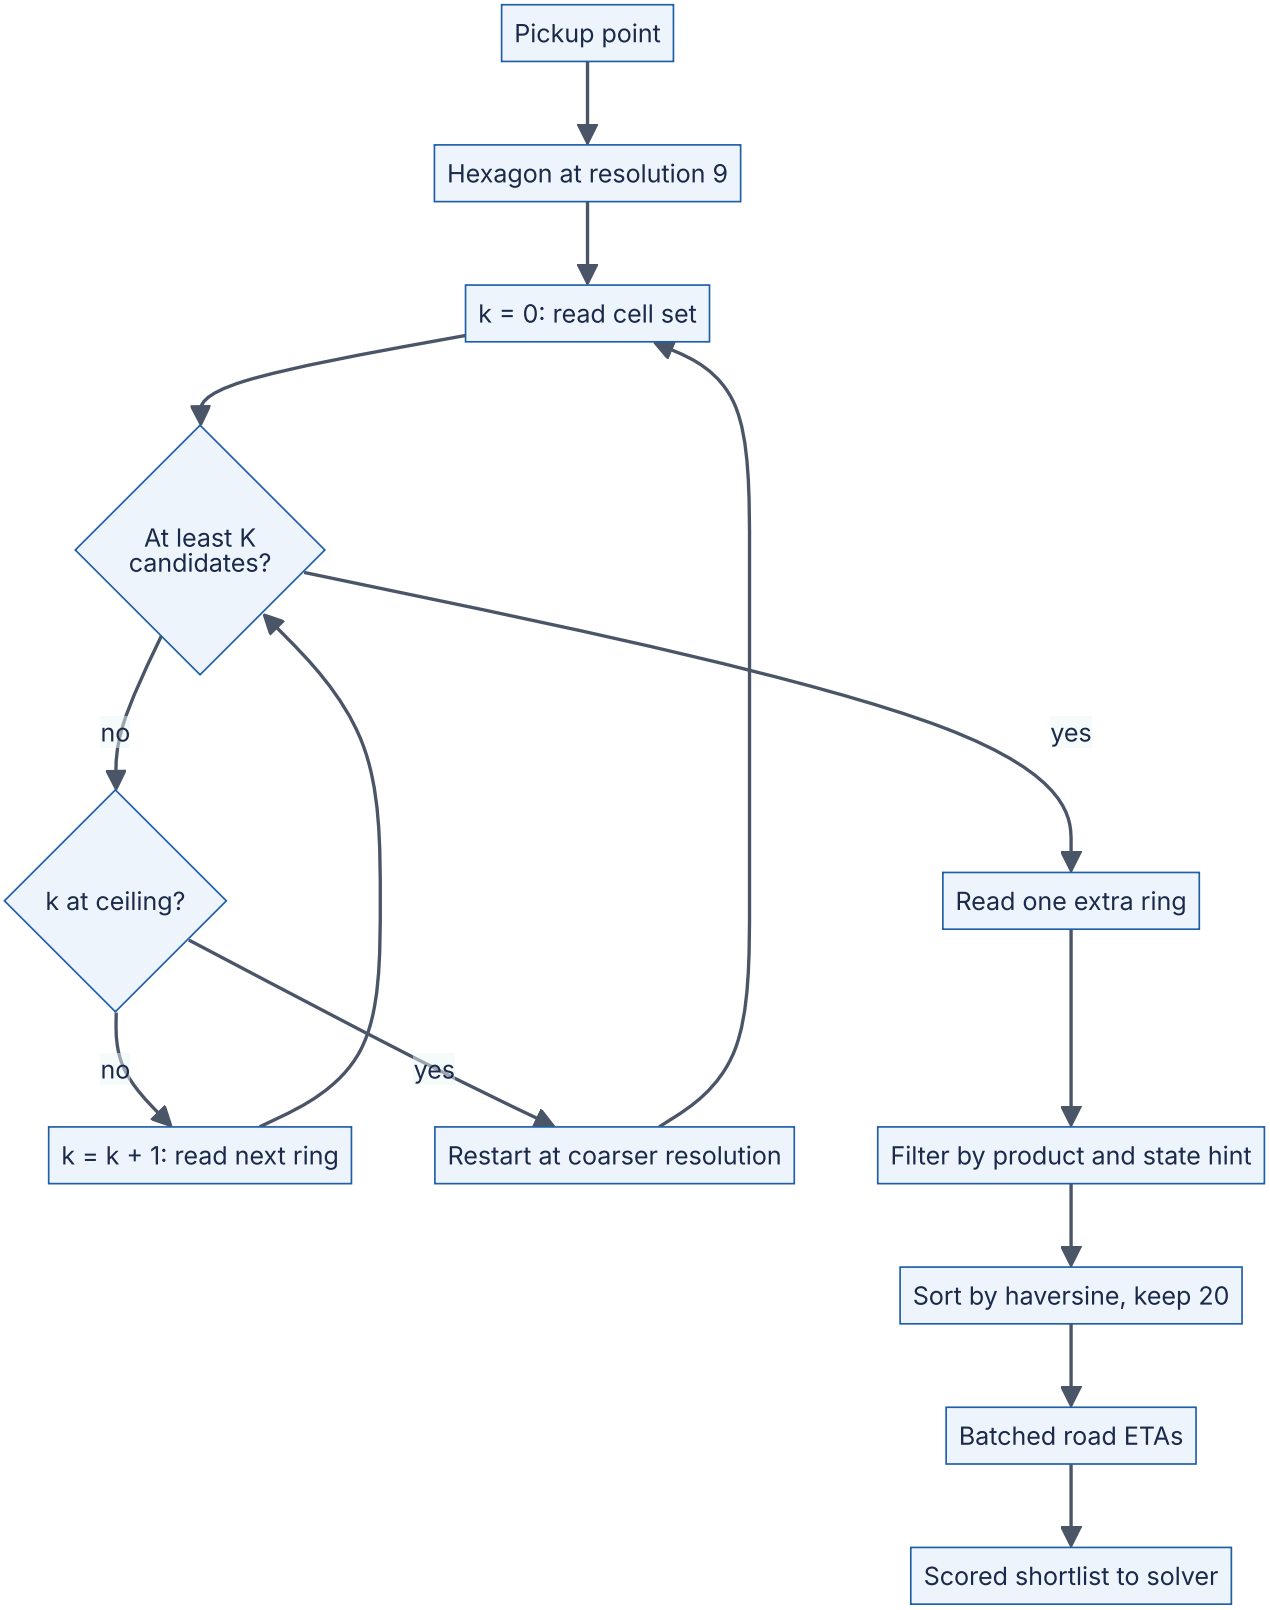
Figure 55.7 — Write path: request, batch, claim, offer and accept.



Reading the diagram. The trip service persists `MATCHING` before asking dispatch, so a crash anywhere later can be recovered by re-requesting the match with the same version.

The matcher batches, searches, scores with batched ETAs and solves; the offer manager claims the driver (the first durable step on the driver’s side) and receives fencing token 42; the offer is pushed over the stream gateway (omitted). The accept goes straight to the trip service, which commits both rows in one transaction guarded by the trip version and the token. All steps are synchronous except the final notifications. Failure points: the driver’s accept is lost in the network (the app retries with the same offer ID; the transaction is idempotent because the second attempt finds the trip already assigned to this driver and returns success), and a matcher crash after the claim (the lease expires in 20 s and the trip is re-batched).

Figure 55.8 — Read path: candidate search with ring expansion.



Reading the diagram. All steps run in memory inside the matcher and the supply-index partition, synchronously. The loop reads one ring of cell sets at a time until the candidate count reaches *K*, then reads one safety ring; if the ring ceiling is hit first (a sparse suburb), the search restarts at a coarser resolution whose hexagons are seven times larger. Filtering uses the in-memory state hint, which may be slightly stale; the claim in Figure

55.7 is the authoritative check. Only the final shortlist pays for road ETAs. Failure points: a partition boundary inside the ring (query both partitions in parallel) and an ETA timeout (fall back to haversine distance divided by the zone's average speed). Scaling: cell reads are independent and parallelizable; the ETA step is the cost driver.

55.5.10 Bottlenecks

1. **ETA computations**, 20,000 per second at peak: batch, cache by hexagon pair for 30–60 s, and use a cheaper model for the first filter.
2. **Zone boundaries.** Requests near a zone edge see candidates owned by a neighboring matcher; both may pick the same driver. The claim resolves it safely, but frequent claim failures waste a round. Overlap zones slightly and let the claim arbitrate, or assign border cells to one owner per window.
3. **Hot events.** At a concert's end, 5,000 requests in 10 minutes in a few hexagons create a large, dense batch: use a pickup-zone queue (first come, first served) instead of nearest matching, which is fairer and cheaper.
4. **Offer round-trips.** Every non-accepted offer adds 5–15 s; acceptance prediction and shorter deadlines matter more than solver speed.

55.5.11 Failure scenarios

Table 55.7 — Failure scenarios for ride matching.

What fails	Impact	Detection	Recovery	Prevention
Matcher crashes mid-batch	Requests in the batch delayed	Missing heartbeat; queue age	Another instance takes the zone; trips still `MATCHING` are re-batched	Requests persisted before matching; zone leases
Two matchers pick the same driver	One claim fails	Claim-conflict rate	Loser takes next candidate	Conditional claim; zone ownership
Matcher pauses after offer, lease expires	Driver re-offered elsewhere; stale accept arrives	Accept with old token	Accept rejected by token check	Fencing token in the commit transaction
Driver accept lost in network	Driver unsure; rider waiting	App retry with same offer ID	Idempotent commit returns success	Retries with idempotent transaction
ETA service down	Matches by distance; worse pickups	ETA error rate	Fallback to haversine at zone average speed	Bulkheads; cached ETA matrix
Supply index stale	Offers to drivers who went offline	Rising offer-expiry rate	Exclude after expiry; re-offer	15 s silence eviction; app heartbeat
City shard primary fails	No claims or commits for seconds	Failover monitor	Promote replica; re-batch	Synchronous replicas; small shards

55.5.12 Scaling strategy

At 10×, the largest city reaches 1,000 requests per second: split it into more zones, with one matcher per zone and overlap arbitration by claims, and precompute ETA matrices between busy hexagon pairs. **At 100×**, the global-optimum assignment per city is no longer tractable each window; the system becomes hierarchical: a coarse rebalancer moves idle supply between zones (by incentives or suggestions) every few minutes, while fine-grained matching stays local. Pooled rides add a vehicle-routing problem with capacity and detour constraints, which is far harder than one-to-one assignment and usually solved by insertion heuristics.

55.5.13 Trade-offs

- **Batch window versus latency.** Longer windows find better assignments but every rider waits up to one window longer; adapt the window to the supply-to-demand ratio.
- **Global optimum versus fairness and predictability.** Minimizing total ETA can leave one rider repeatedly unmatched; add an aging term to the score.
- **Strong commitment versus availability.** Claims require the city shard; if it is unavailable, matching stops. The alternative — optimistic assignments reconciled later — produces double-dispatched drivers, which is worse.
- **One offer at a time versus broadcast.** Sequential offers are slower but respectful of drivers; broadcast trades driver experience for speed.

55.5.14 Alternative designs

Table 55.8 — Matching strategies compared.

Strategy	How it works	Advantages	Disadvantages	Choose when
Greedy nearest (distance)	Nearest idle driver by straight line	Simplest; no extra latency	Ignores roads; myopic	Prototypes; very low volume
Greedy by ETA	Best road ETA on arrival	Correct notion of “near”	Still myopic	Low density, where batches are tiny
Batched assignment	Window, bipartite graph, min-cost solver	Lower total ETA; handles contention	Adds up to one window of latency	Dense cities, high demand
Batched with future value	Assignment weights include learned driver value	Accounts for where drivers end up	Needs ML, offline replay to tune	Mature marketplaces (Chapter 83)
Broadcast, first to accept	Offer to N drivers at once	Fast in low-acceptance areas	Driver frustration; more claim conflicts	Sparse supply, long-distance trips
Pickup queue (FIFO)	Drivers queue at a venue; riders take the head	Fair; trivial to compute	Only for fixed pickup points	Airports, stadiums

55.5.15 Interview discussion

Pacing (45 minutes). Requirements and invariants (5 min: one driver per ride, one ride per driver); estimates (5 min: candidates per ring, ETA load); architecture (10 min: Figure 55.6); deep dives (20 min: ring search, greedy versus batched with the two-rider counterexample, claim with lease and fencing token in one transaction); failures and scaling (5 min).

Likely follow-ups. *Why not a distributed lock service?* It would work, but a conditional update in the database that stores the assignment gives the same guarantee with fewer moving parts, and the fencing check must happen there anyway. *How do you choose the window?* By experiment: measure total ETA and request-to-offer latency at 0, 1, 2 and 3 s. *How do you match riders to drivers on another partition?* Query both partitions; the claim arbitrates. *How do you test matching changes?* Replay the decision log offline against the new algorithm, then A/B test by city and time slice (switchback experiments, because riders and drivers in one city interact).

What distinguishes senior and staff answers. A senior candidate uses a cell index, ETA scoring and a lock with expiry. A staff candidate produces the greedy counterexample unprompted, explains why the lock alone is unsafe and puts the fencing check inside the commit transaction, co-locates trips and drivers to avoid a distributed transaction, and talks about measuring matching quality with replay and switchback experiments.

55.5.16 Production considerations

- **Observability.** Per city and zone: request-to-offer latency, offers per match, acceptance rate, claim-conflict rate, lease expiries, ETA prediction error, and the fraction of matches made at each ring radius. A sudden rise in claim conflicts means overlapping zones or a stale supply index.
- **Security and abuse.** Drivers may decline strategically or spoof location to wait in better zones; acceptance-rate features and location plausibility checks feed into fairness and fraud systems (Chapter 82).
- **Cost.** ETA computations dominate; caching and two-stage funnels keep them proportional to requests, not to candidates squared.
- **Operations.** Every matching change ships behind a flag per city, with the decision log enabling exact replay of any incident (“why did this rider wait 12 minutes?”).

55.6 Google Maps: tiles, routing and live traffic

55.6.1 Problem statement

Design a global mapping service: a map you can pan and zoom smoothly on any device, search for places and addresses, and turn-by-turn directions with arrival times that ac-

count for current traffic. Think of an atlas, a gazetteer and a road-trip planner in one book, except that the book is redrawn for each reader's screen, the index answers misspelled questions, and the road-trip planner listens to millions of drivers reporting how fast traffic is moving right now.

The distinctive hard problems are two very different ones. **Tile serving** is a read-scaling problem: hundreds of thousands of small, cacheable objects per second, most of them identical across users, so the answer is a pyramid of precomputed tiles behind a CDN (§21.3). **Routing** is an algorithmic problem: Dijkstra's algorithm is correct but far too slow on a road graph of hundreds of millions of intersections, so the answer is preprocessing — A* with good lower bounds and, above all, **contraction hierarchies**. Live traffic and ETA prediction are covered briefly; the machine-learning ETA model is Chapter 83 (§83.5).

Evidence: Illustrative — this is a teaching design for a Maps-like product, not a description of Google's internal architecture; published Google sources are cited where used.

55.6.2 Functional requirements

1. **Map display.** Render the map at any location and zoom level (0 = whole world to about 20 = individual buildings), in several styles (default, satellite, terrain, dark) and the viewer's language.
2. **Search and geocoding.** Find places and addresses by text with autocomplete; convert addresses to coordinates (geocoding) and coordinates to addresses (reverse geocoding).
3. **Directions.** Compute routes for driving, walking, cycling and transit between two or more points, with alternatives and turn-by-turn instructions.
4. **ETA with live traffic.** Predict arrival time from current and historical speeds; show traffic colors on the map.
5. **Navigation.** Follow the user, detect deviation and reroute; update ETA en route.
6. **Map updates.** Apply new roads, closures and business changes from data pipelines and user reports.

Out of scope: Street View imagery capture, transit-schedule ingestion details, reviews and photos, and the ML ETA model.

55.6.3 Non-functional requirements

Table 55.9 — Non-functional requirements for the mapping service.

Property	Target
Tile latency	p99 < 100 ms at the edge for cached tiles; < 300 ms on a miss
Route latency	p99 < 500 ms for a city route, < 1.5 s for a cross-continent route
Search and autocomplete	p99 < 150 ms per keystroke
Availability	99.99% for tiles and routing (navigation users are driving)
Traffic freshness	Segment speeds at most 2–3 minutes old
Map data consistency	Tiles and routing graph from the same published map version
ETA accuracy	Tracked as error distribution against actual arrival (Chapter 83)

55.6.4 Capacity estimation

FORMULA

Tile pyramid size and ground resolution

$$T(z) = 4^z, \qquad T_{\le Z} = \sum_{z=0}^{Z} 4^z = \frac{4^{Z+1} - 1}{3}, \qquad r(z, \varphi) = \frac{C_{\text{eq}} \cos \varphi}{256 \times 2^z}$$

Symbol	Meaning	Units
$T(z)$	Number of tiles at zoom level z	tiles
$T_{\le Z}$	Tiles in all levels from 0 to Z	tiles
z, Z	Zoom level; maximum zoom level	—
$r(z, \varphi)$	Ground distance covered by one pixel of a 256-pixel tile	m/pixel
C_{eq}	Earth's equatorial circumference, 40,075,016.686 m	m
φ	Latitude	degrees

WORKED EXAMPLE

Worked example — how big is the pyramid?

1. **Tiles to zoom 14.** $T_{\le 14} = (4^{15} - 1)/3 = 357,913,941$ tiles. About 70% of Earth is ocean, so assume 30% carry land detail: $0.3 \times 3.58 \times 10^8 = 1.07 \times 10^8$ tiles. At 20 KB per vector tile: $1.07 \times 10^8 \times 20,000 = 2.15$ TB per map version.
2. **Raster to zoom 18.** $T_{\le 18} = (4^{19} - 1)/3 = 9.16 \times 10^{10}$; 30% land is 2.75×10^{10} tiles; at 15 KB per PNG, 412 TB — for *one* style, one language and one pixel density.
3. **Ground resolution.** $C_{\text{eq}}/256 = 156,543$ m/pixel at zoom 0. In San Francisco ($\varphi = 37.77^\circ$, $\cos\varphi = 0.7905$) at zoom 15: $156,543 \times 0.7905/32,768 = 3.78$ m/pixel; at zoom 18, 0.47 m/pixel.

Interpretation. Each zoom level has four times the tiles of the one above, so the deepest levels dominate everything. *Engineering implication.* Precompute vector tiles only to about zoom 14–16 and let clients **overzoom** (render deeper zooms from the same geometry), and keep styles and labels on the client. One 2 TB vector pyramid replaces hundreds of terabytes of raster tiles per style and language.

WORKED EXAMPLE

Worked example — traffic. Assumptions: 300 million daily users; 100 tile requests per user per day; peak 2× average for tiles, 3× for routing and search; CDN hit ratio 95%; 1.5 route requests per user per day (including reroutes); 2 searches per user per day, each with 5 autocomplete keystrokes; 20 million concurrent navigation sessions at peak, each reporting a probe point every 10 s.

1. **Tiles.** $300 \times 10^6 \times 100 = 3 \times 10^{10}$ per day; $/86,400 = 347,222$/s average; peak 694,444/s. Origin (5% misses): 34,722/s. Edge egress at 20 KB: $694,444 \times 20,000 = 13.9$ GB/s ≈ 111 Gb/s.
2. **Routes.** 4.5×10^8 per day $= 5,208$/s average, 15,625/s at peak.
3. **Search.** 6×10^8 per day $= 6,944$/s average, 20,833/s peak; autocomplete $5 \times 20,833 = 104,167$ keystroke queries/s at peak.
4. **Probe ingestion.** $2 \times 10^7/10 = 2 \times 10^6$ points/s; at 100 bytes, 200 MB/s.
5. **Road graph in memory.** Assume 500 million nodes and 1.2 billion directed edges at 16 bytes each: $8 + 19.2 = 27.2$ GB; contraction-hierarchy shortcuts add an amount assumed equal to the edge count, so about 46 GB per full copy.

Interpretation. Tiles are the largest request volume, but almost all of it is served by the CDN; probe ingestion is the largest *write* volume; routing is modest in request count but expensive per request. *Engineering implication.* Three separate subsystems with different scaling levers: cache hierarchy for tiles, a streaming pipeline for traffic, and memory-resident, regionally partitioned graphs for routing.

55.6.5 API design

```
GET /tiles/v3/{layer}/{z}/{x}/{y}.mvt?mapver=2026-11-01.3
  -> 200 application/vnd.mapbox-vector-tile   (protobuf; Cache-Control: public, max-
age=86400, immutable)

GET /v1/geocode?q=1600+Amphitheatre+Parkway&bias=37.42,-122.08
  -> 200 { "results": [ { "place_id": "p_9a", "formatted": "...", "location":
{"lat":..., "lng":...},
                          "precision": "ROOFTOP", "score": 0.97 } ] }
GET /v1/reverse-geocode?lat=37.4220&lng=-122.0841   -> 200 { "results": [ ... ] }
GET /v1/autocomplete?q=blue+bot&session=s_51&near=37.77,-122.42   -> 200 { "predic-
tions": [ ... ] }

POST /v1/routes
  { "origin": {"lat":..., "lng":...}, "destination": {...}, "waypoints": [],
    "mode": "DRIVE", "depart_at": "now", "alternatives": true, "avoid": ["TOLLS"] }
  -> 200 { "routes": [ { "route_id": "rt_4c", "duration_s": 1260,
"duration_in_traffic_s": 1490,
            "distance_m": 18400, "polyline": "encoded...", "steps": [ ... ], "mapver":
"2026-11-01.3" } ] }

POST /v1/probes            (batched, from navigating clients that opted in)
  { "session": "anon_7f", "points": [ {"lat":..., "lng":..., "speed_mps": 13.2, "head-
ing": 90, "ts_ms": ...} ] }
  -> 204
```

What to notice: tile URLs include the **map version**, so tiles are immutable and can be cached for a long time and invalidated by changing the version rather than purging the CDN (§21.6). Routes return the map version they were computed on, so navigation can request tiles of the same version. Probe uploads use a rotating anonymous session ID, not a user ID.

55.6.6 Data model and database schema

Four stores, each matched to its access pattern.

1. **Map feature database (source of truth).** Roads, buildings, places, boundaries, each a versioned feature with geometry and attributes, keyed by feature ID and spatially indexed by S2 cell (§17.9.4). Edits from data pipelines and moderators append new versions; a *published map version* is a consistent snapshot.

2. **Tile store.** Object storage (§15.4) with key `layer/mapver/z/x/y`, filled by a batch tile-build pipeline from a published version; the CDN fronts it.

3. **Routing graph.** Built from the same version into compact binary files, partitioned by region (for example per S2 level-4 or level-5 cell group plus the cross-border long-distance network), loaded into the memory of routing servers:

```
nodes:    node_id -> (lat_e7, lng_e7, ch_level)                # 16 bytes packed
edges:    CSR arrays: first_edge[node], target[e], weight_ds[e],  # deciseconds
free-flow
          segment_id[e], flags[e] (toll, ferry, turn restrictions)
shortcuts: same CSR layout, plus middle_node[e] to unpack paths
```

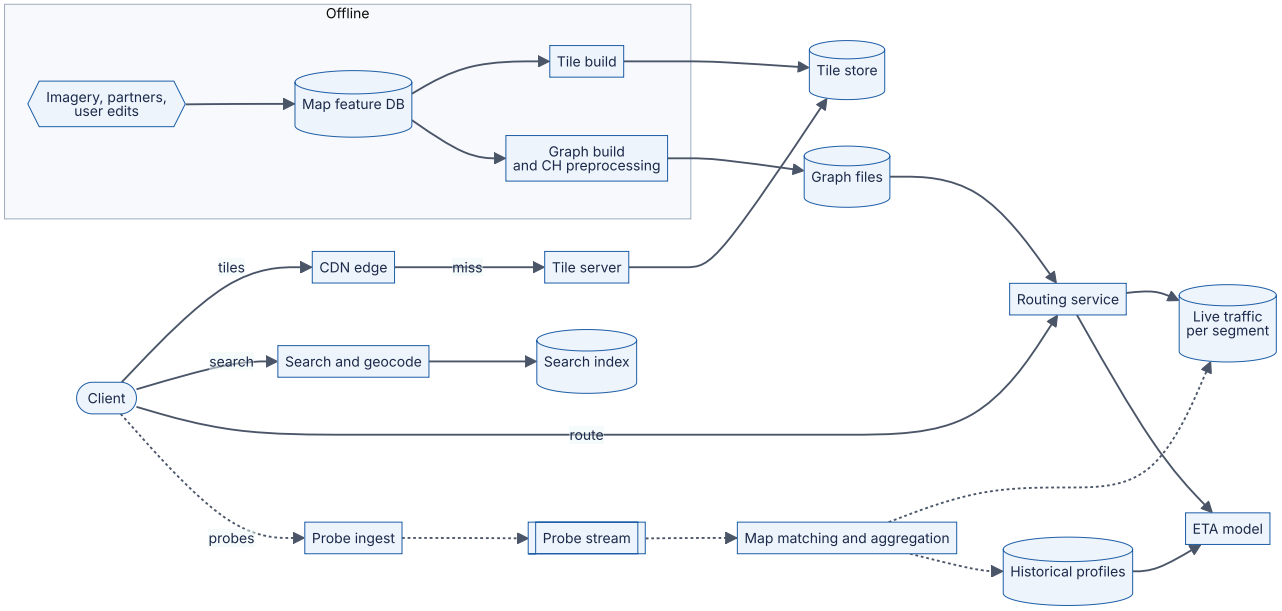
4. **Traffic store.** In-memory, per region: `segment_id -> (speed_kmh, confidence, updated_ms)` for live speeds, plus historical speed profiles per segment per 15-minute slot of the week in a key-value store.

5. **Search index.** An inverted index over place names, addresses and categories (Chapter 16), with per-document geographic cells for location bias and a prominence score.

Why not a graph database for routing? General graph databases (§12.7) traverse with pointer chasing over pages; routing needs a fixed, read-only, cache-friendly array layout and custom algorithms. Why not compute tiles on demand? Popular tiles would be recomputed millions of times; precomputation plus CDN makes the common case a cache hit.

55.6.7 High-level architecture

Figure 55.9 — Mapping service: data pipeline, tiles, routing and traffic.



Reading the diagram. The offline subgraph turns source data into a published map version, then builds two artifacts from it: tiles (to the tile store) and the routing graph with contraction-hierarchy shortcuts (to graph files). Clients fetch tiles from the CDN; misses go to stateless tile servers that read object storage. Search and geocoding query an inverted index. Route requests go to routing servers, which hold graph partitions in memory and read live segment speeds; an ETA model combines route, live and historical

speeds. Navigating clients upload probes asynchronously (dotted) into a stream; map matching snaps them to road segments and aggregates speeds per segment per minute into the live traffic store and, over time, the historical profiles. Storage boundaries: the feature database (source of truth), object storage, in-memory graphs and traffic. Failure points: a bad map version (roll back by pointing to the previous version), tile-server overload after a style change (pre-warm), and a stalled traffic pipeline (fall back to historical profiles). Scaling: tiles by CDN capacity, routing by region partitions and replicas, traffic by stream partitions keyed by region.

55.6.8 Detailed component design

Component 1: tile serving and vector tiles

The world is projected with **Web Mercator** onto a square and cut into a quadtree: at zoom z there are $2^z \times 2^z$ tiles addressed `z/x/y` (the "slippy map" scheme) [OpenStreetMap Wiki: Slippy map tilenames]. Early web maps served **raster tiles**: 256 × 256 pixel images rendered on the server. **Vector tiles** instead carry geometry and attributes for one tile, encoded with integer coordinates in a tile-local grid (commonly 4,096 units across) as protocol buffers [Mapbox Vector Tile Specification 2.1]; the client renders them with the GPU.

Why vector tiles won:

1. **Size and count.** One vector pyramid serves every style, language, pixel density and rotation; raster needs a pyramid per combination (412 TB versus 2 TB in the worked example).
2. **Overzoom.** Geometry from zoom 14 renders crisply at zoom 18, so the pyramid stops early.
3. **Smooth interaction.** Fractional zoom, 3D tilt and label rotation happen on the client without new downloads.
4. **Cheaper updates.** A changed road invalidates a few vector tiles per zoom; the client restyles locally.

The cost is client CPU and GPU for rendering, and a more complex build pipeline: **generalization** (simplifying geometry and dropping minor features at low zooms so a zoom-5 tile does not contain every footpath in a country) and **label placement** consistent across tile edges.

Serving is a three-level cache: device cache (tiles are immutable per map version), CDN edges with an origin shield (§21.5), then tile servers over object storage. Tile requests are extremely skewed — popular cities at common zooms — so the CDN hit ratio is high; the long tail (rural zoom-16 tiles) is served from object storage on a miss. For a new map version, pre-warm the CDN with the top few million tiles before switching clients to it.

INDUSTRY EXAMPLE

Open tile standards. The `z/x/y` addressing of Web Mercator tiles used by OpenStreetMap and most web maps is documented by the OpenStreetMap project [OpenStreetMap Wiki: Slippy map tilenames]. The Mapbox Vector Tile specification (version 2.1) defines vector tiles as protocol buffers containing named layers of features whose geometry uses integer coordinates within an extent, commonly 4,096 [Mapbox Vector Tile Specification 2.1]. *Evidence: Primary* — [OpenStreetMap Wiki; Mapbox Vector Tile Specification 2.1]

Component 2: routing from Dijkstra to contraction hierarchies

Model roads as a directed graph: intersections are nodes, road segments are edges weighted by travel time. A route is a shortest path.

Dijkstra's algorithm [Dijkstra 1959] grows a ball of settled nodes around the origin in order of distance, using a priority queue; it is exact but settles every node closer than the destination. For a 500 km trip that is a large fraction of a country's road graph: millions of nodes, seconds of CPU per query, far too slow at 15,000 routes per second.

A* [Hart, Nilsson and Raphael 1968] adds a heuristic $h(v)$, a lower bound on the remaining cost, and orders the queue by $g(v) + h(v)$. If h never overestimates (it is **admissible**), A* is still exact; the better the bound, the narrower the search. For travel time, the straight-line distance divided by the fastest speed limit is admissible but weak, because most roads are much slower than the fastest. The program below measures the effect.

```
        import heapq
        import math
        import random

        def build_grid(n, seed=3):
            """n x n street grid, 100 m blocks; each edge's travel time is >= distance /
max speed."""
            random.seed(seed)
            pos, adj = {}, {}
            for r in range(n):
                for c in range(n):
                    pos[(r, c)] = (c * 0.1, r * 0.1)            # km
                    adj[(r, c)] = []
            for r in range(n):
                for c in range(n):
                    for dr, dc in ((0, 1), (1, 0)):
                        if r + dr < n and c + dc < n:
                            speed = random.choice([30, 50, 50, 50, 80])    # km/h per
segment
                            t = 0.1 / speed * 3600                         # seconds
                            adj[(r, c)].append(((r + dr, c + dc), t))
                            adj[(r + dr, c + dc)].append(((r, c), t))
            return pos, adj

        def shortest(adj, src, dst, h=lambda v: 0.0):
            """A* search; with h = 0 it is exactly Dijkstra's algorithm."""
            dist, prev, settled = {src: 0.0}, {}, 0
            pq = [(h(src), src)]
            done = set()
            while pq:
                _, u = heapq.heappop(pq)
                if u in done:
                    continue                                    # stale queue entry
                done.add(u)
                settled += 1
                if u == dst:
                    break
                for v, w in adj[u]:
                    nd = dist[u] + w
                    if nd < dist.get(v, math.inf):
                        dist[v], prev[v] = nd, u
                        heapq.heappush(pq, (nd + h(v), v))
            path, v = [dst], dst
            while v != src:
                v = prev[v]
                path.append(v)
            return dist[dst], path[::-1], settled

        pos, adj = build_grid(120)                              # 14,400 intersections
        src, dst = (10, 10), (100, 90)
        V_MAX = 80 / 3600                                       # km per second, fastest
road

        def h_time(v):
            """Straight-line distance at top speed: never overestimates, so A* stays ex-
act."""
```

```
            (x1, y1), (x2, y2) = pos[v], pos[dst]
            return math.hypot(x1 - x2, y1 - y2) / V_MAX

        d_cost, d_path, d_settled = shortest(adj, src, dst)
        a_cost, a_path, a_settled = shortest(adj, src, dst, h_time)
        print(f"Dijkstra: {d_cost / 60:.2f} min, {d_settled:,} nodes settled")
        print(f"A*      : {a_cost / 60:.2f} min, {a_settled:,} nodes settled")
        print("same optimum:", abs(d_cost - a_cost) < 1e-9, "| path hops:", len(a_path)
- 1)
```

Output:

```
Dijkstra: 16.24 min, 13,132 nodes settled
A*      : 16.24 min, 9,582 nodes settled
same optimum: True | path hops: 170
```

What to notice:

- One function implements both algorithms: Dijkstra is A* with $h = 0$. Both return the same 16.24-minute optimum, as admissibility guarantees.
- Dijkstra settled 13,132 of 14,400 nodes to cross most of the grid; A* with the top-speed bound settled 9,582, only 27% fewer, because a bound based on 80 km/h is loose when most roads allow 30–50 km/h.
- Better lower bounds exist: **landmarks** (ALT) precompute distances to a few dozen landmark nodes and use the triangle inequality to bound remaining cost [Goldberg and Harrelson 2005]. But the large wins come from preprocessing the graph itself.

Contraction hierarchies (CH) [Geisberger et al. 2008] exploit the fact that road networks have a natural hierarchy: long trips use a small set of important roads.

1. **Order the nodes by importance.** Heuristics rank nodes so that minor residential intersections come first and motorway junctions last.
2. **Contract nodes in that order.** Removing node v may destroy a shortest path $u \to v \to w$; if no other path ("witness") between u and w is as short, add a **shortcut** edge $u \to w$ with the combined weight, remembering v as its middle node. Continue until every node is contracted.
3. **Query bidirectionally, upward only.** Run Dijkstra from the origin forward and from the destination backward, but each search relaxes only edges leading to *more important* nodes. The two searches meet near the top of the hierarchy; the best meeting node gives the shortest distance.
4. **Unpack.** Replace each shortcut recursively by its middle node to recover the full turn-by-turn path.

Because each search climbs only upward, it settles a few hundred to a few thousand nodes instead of millions. The original paper reported query times well under a millisecond on a European road network of millions of nodes, after a preprocessing step of min-

utes [Geisberger et al. 2008]. The price is **static weights**: CH bakes travel times into shortcuts. Live traffic changes weights every minute, so production systems either re-customize quickly using variants designed for it — **customizable route planning** (CRP) separates metric-independent partitioning from a fast per-metric customization step [Delling et al. 2011] — or compute routes with CH on typical weights and then re-score the top candidate routes with live and predicted segment speeds.

> KEY CONCEPT
>
> **The trade you are making.** Dijkstra: no preprocessing, slow queries. A*: no preprocessing, faster queries if the bound is good. CH and CRP: minutes to hours of preprocessing and extra memory for shortcuts, in exchange for queries that are orders of magnitude faster. At 15,000 route requests per second, preprocessing once per map version is cheap.

Component 3: live traffic ingestion and ETA

1. **Collect.** Navigating clients that have opted in upload batched probe points (position, speed, heading, timestamp) under a rotating anonymous identifier.
2. **Map-match.** A streaming job snaps each probe sequence to the most likely road segments (a hidden-Markov-model style matcher over candidate segments), which is essential where roads are parallel or stacked.
3. **Aggregate.** Per segment and one-minute window, compute robust speed statistics (median, trimmed mean) and a confidence based on probe count; discard stationary outliers (a parked delivery van is not a traffic jam).
4. **Publish.** Write `segment → speed` into the in-memory traffic store of the region; render traffic-color overlay tiles (small, short-TTL tiles) from it.
5. **Predict.** The ETA for a route combines live speeds near the departure time with historical profiles further along the route (traffic 40 minutes ahead is better predicted by “Tuesdays at 18:00” than by now), corrected by a learned model.
6. **Privacy.** Trim the first and last few hundred meters of each trip, aggregate only segments with enough distinct contributors, and discard raw probes after aggregation (§50.10).

INDUSTRY EXAMPLE

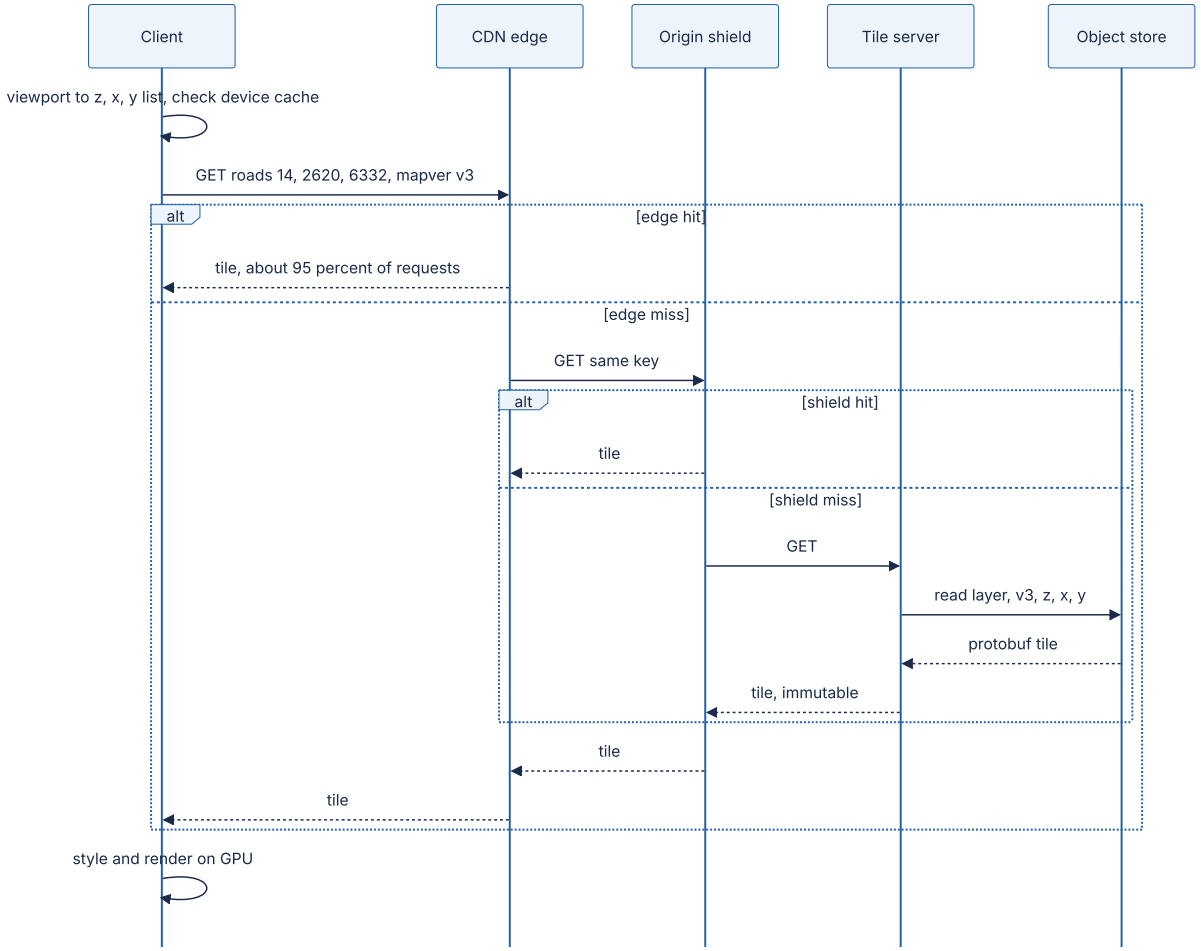
Graph neural networks for ETA in Google Maps. Google DeepMind and Google Maps researchers described an ETA model that represents the road network around a route as a graph of "supersegments" and predicts travel times with a graph neural network; they report that it was deployed in production and reduced negative ETA outcomes compared with the previous production approach, by more than 40% in some cities such as Sydney [Derrow-Pinion et al. 2021]. Chapter 83 treats the modeling. *Evidence: Primary* — [Derrow-Pinion et al. 2021]

Component 4: geocoding and place search

Forward geocoding parses free text ("1600 amphitheatre pkwy mtn view") into components (house number, street, locality), normalizes abbreviations and spelling per country, and searches an inverted index of addresses (§16.3) constrained by the administrative hierarchy; candidates are ranked by text match, component agreement and precision (rooftop beats street-interpolated). **Reverse geocoding** looks up the point's S2 cell and its neighbors in a spatial index of address points and street segments and returns the nearest plausible address. **Place search and autocomplete** query a prefix index (§16.9) with location bias — the same prefix ranks "Blue Bottle Coffee" first in San Francisco and something else in Tokyo — and a session token groups the keystrokes of one search for billing and quality analysis.

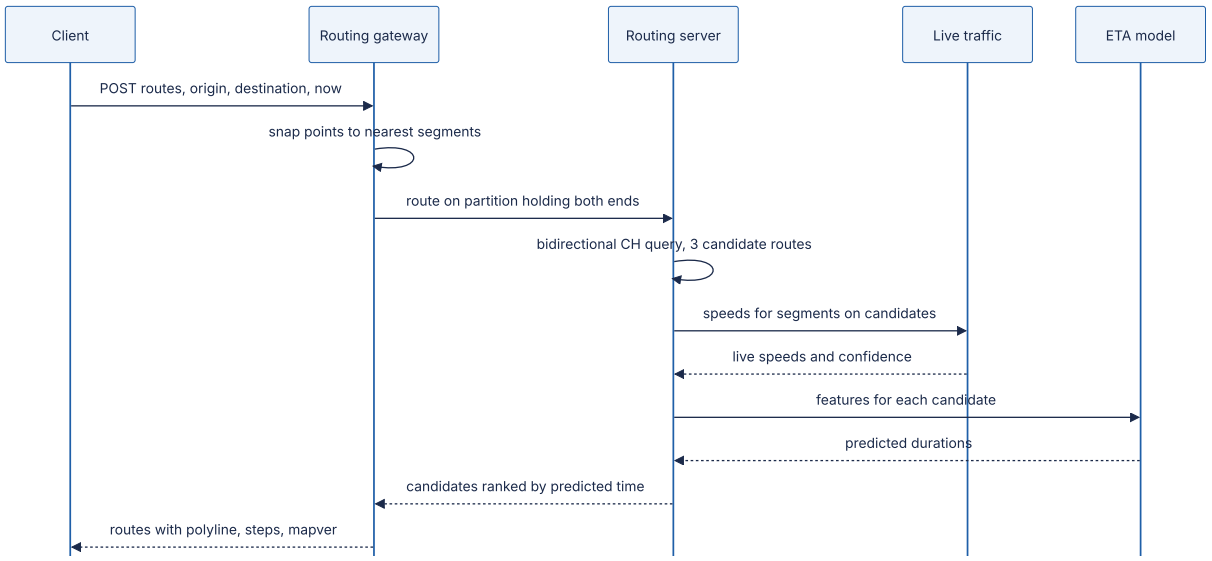
55.6.9 Data flow

Figure 55.10 — Read path: loading map tiles.



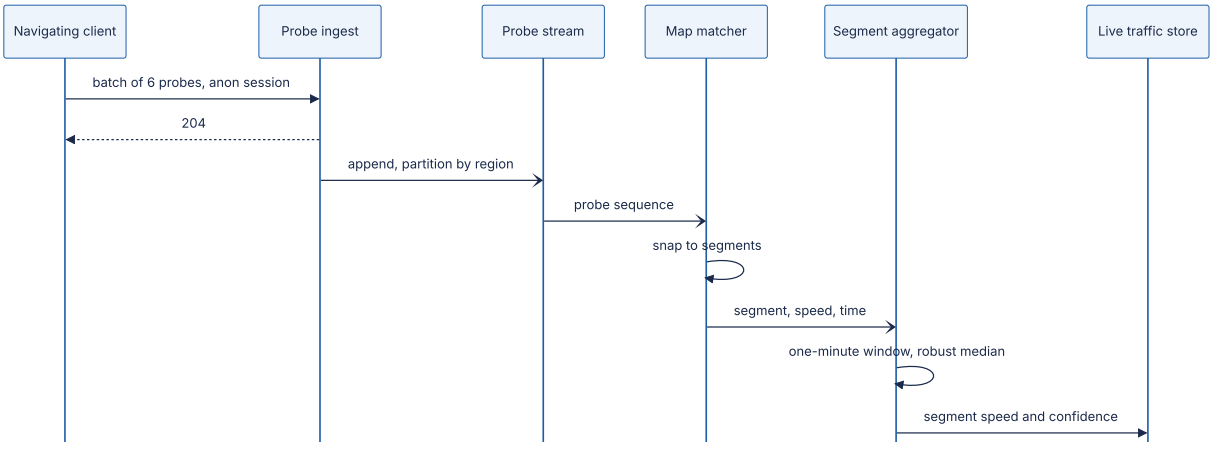
Reading the diagram. The client converts its viewport into a list of tile coordinates and fetches only those missing from its device cache, usually a dozen or two in parallel over HTTP/2 or HTTP/3. Most requests end at the CDN edge; misses go to a regional origin shield, which collapses concurrent misses for the same tile into one origin request (§21.5), and only then to a stateless tile server reading object storage. Every response is immutable for its map version, so caches never serve stale data across versions. All calls are synchronous. Failure points: an origin outage is masked for popular tiles by the caches; a style or version change that invalidates everything at once creates a miss storm, prevented by pre-warming and staggered rollout. Scaling: add edge capacity; tile servers are stateless.

Figure 55.11 — Read path: a route request.



Reading the diagram. The gateway snaps origin and destination to road segments and selects the routing partition (a cross-region trip goes to servers holding the long-distance overlay graph). The routing server runs a contraction-hierarchy query to find a few good candidate routes on typical weights, then re-scores them with live segment speeds and the ETA model; the client receives the best route and alternatives. All calls are synchronous with tight timeouts: if traffic or the model times out, the route is returned with historical-profile ETAs. Failure points: a routing replica that loaded a different map version than the tiles (prevented by version pinning) and a partition with no healthy replica (route via a neighboring partition's overlay with degraded detail). Scaling: replicate each partition; route requests are independent.

Figure 55.12 — Write path: probe ingestion to live traffic.



Reading the diagram. Clients upload batches and receive an immediate acknowledgment; everything after the stream append is asynchronous. The stream is partitioned by region so map matching and aggregation scale with regional volume (2 million probes per second at peak). The aggregator emits one speed per segment per minute, so the live traffic store receives far fewer writes than probes arrive (about 333,000 segment updates

per second if 20 million segments carry traffic). Failure points: a lagging aggregator makes traffic stale (detect by the age of the newest update and fall back to historical profiles beyond a threshold); a sudden drop in probes in a region can mean an app bug rather than empty roads, so low-confidence segments revert to historical speeds.

55.6.10 Bottlenecks

1. **Tile miss storms** on a new map version or style: pre-warm the top tiles, roll out by region, and keep the previous version serving until the new one is warm.
2. **Graph preprocessing time**: a full contraction of a continent takes long enough that map updates are batched; urgent closures are applied as live weight overrides (infinite weight) without rebuilding.
3. **Cross-partition routes**: long trips must cross partition boundaries; keep an overlay graph of boundary nodes and important roads that every routing server can use.
4. **Autocomplete fan-out**: 100,000 keystroke queries per second, each latency-critical; cache popular prefixes per region and debounce on the client.
5. **Map matching CPU** for 2 million probes per second: run matching per region, sample in dense areas where hundreds of probes per segment add no information.

55.6.11 Failure scenarios

Table 55.10 — Failure scenarios for the mapping service.

What fails	Impact	Detection	Recovery	Prevention
Bad map version (missing bridge)	Wrong routes; visible errors	Route-quality canaries; user reports spike	Roll back the version pointer	Automated diff checks; staged rollout
Tiles and graph on different versions	Route drawn through roads not on the map	Version mismatch metrics	Pin route and tile versions per session	Build both from one snapshot
CDN region degraded	Slow map loads	Edge error rate, real-user monitoring	Steer to other edges	Multi-CDN or multiple edge tiers
Traffic pipeline stalls	Stale traffic colors and ETAs	Age of newest segment update	Fall back to historical profiles	Lag alarms; replicated aggregators
Routing server OOM on graph load	Partition capacity lost	Health checks	Shift to replicas; load next version gradually	Memory headroom; canary loads
Probe spoofing (fake jam)	Traffic falsely shown; reroutes	Many probes from few devices, impossible patterns	Drop low-diversity aggregates	Require distinct contributors per segment

55.6.12 Scaling strategy

At 10× (3 billion tile requests per hour at peak), the design holds by adding CDN capacity; origin load grows only with the miss ratio, so improve hit ratio further with larger tiles (512 px) and longer device caching. Routing at 156,000 requests per second needs more replicas per partition and a precomputed cache for frequent origin–destination hexagon pairs. **At 100×**, probe ingestion (20 million per second) becomes the dominant cost: aggregate on the device (send segment-level summaries rather than raw points) and sample in congested areas. Map updates must move from periodic full rebuilds to incremental tile and graph updates per region.

55.6.13 Trade-offs

- **Vector versus raster:** smaller, restylable, overzoomable, but needs capable clients and a more complex build.
- **Preprocessing versus freshness:** CH gives the fastest queries on static weights; CRP or re-scoring candidates handles live traffic at some cost in optimality or speed.
- **Live versus historical speeds:** live is accurate now and noisy; historical is stable and wrong during incidents; blend by horizon and confidence.
- **Privacy versus coverage:** stricter aggregation thresholds hide traffic on quiet roads.

55.6.14 Alternative designs

Table 55.11 — Shortest-path approaches compared.

Approach	Preprocessing	Query work	Live traffic	Choose when
Dijkstra	None	Settles all nodes closer than the target	Trivial (weights read at query time)	Small graphs; correctness baselines
Bidirectional Dijkstra	None	About half of Dijkstra’s	Trivial	Medium graphs
A* (straight-line bound)	None	Somewhat fewer nodes	Trivial	Games, grids, walking
ALT (landmarks)	Distances to landmarks	Several times fewer nodes	Bounds stay valid only if weights do not drop below preprocessing values	Moderate scale with changing weights
Contraction hierarchies	Minutes per continent	Hundreds to thousands of nodes	Requires recontraction or re-scoring	Very high query rates on fixed metrics
Customizable route planning	Metric-independent partition, plus fast customization	Small, partition-based	Re-customize in seconds	Live traffic at scale

55.6.15 Interview discussion

Pacing (45 minutes). Scope (5 min: tiles, search, directions with traffic; exclude Street View); estimates (5 min: tile pyramid and request rates); architecture (10 min: Figure 55.9, offline versus online); deep dives (20 min: vector tiles and CDN versioning; Dijkstra → A* → CH and the live-traffic problem; probe pipeline); failures and scaling (5 min).

Likely follow-ups. *Why not render tiles on demand?* Popular tiles repeat millions of times; precompute and cache. *How do you update one road?* Rebuild affected tiles at all zooms for a new version; apply closures as live weight overrides in routing until the next graph build. *Why does A* need an admissible heuristic?* Otherwise it may stop with a non-optimal path. *How do you route across continents?* Partition plus an overlay graph of boundary nodes and major roads. *How do you keep tiles and routes consistent?* Version both artifacts from one snapshot and pin the version per session.

What distinguishes senior and staff answers. A senior candidate designs the tile pyramid with a CDN and explains A*. A staff candidate computes the pyramid size and argues for vector tiles with overzoom, explains why CH does not tolerate changing weights and how CRP or candidate re-scoring fixes it, versions every artifact, and designs the probe pipeline with privacy thresholds.

55.6.16 Production considerations

- **Observability.** Tile hit ratio per zoom and region; time-to-first-render on clients; route latency per partition; ETA error distribution (p50, p90 of actual minus predicted) per city; traffic freshness; map-version skew between fleets.
- **Security and privacy.** Probe data reveals home and work locations: anonymous rotating IDs, trip-end trimming, minimum contributor counts and short raw-data retention (§50.10). API keys and quotas protect paid APIs from scraping (§22.3).
- **Cost.** CDN egress dominates; vector tiles, compression and device caching are the main levers. Routing servers are memory-bound; compact graph layouts save fleets.
- **Operations.** Map releases are deployments: canary a new version in one region, compare route quality metrics against the previous version, then roll forward; keep rollback to the previous version one pointer change away.

55.7 Amazon: an e-commerce platform

55.7.1 Problem statement

Design a large online store: customers browse and search a catalog of hundreds of millions of products, add items to a cart, check out with a saved address and card, and track the order until delivery. Third-party sellers list products and stock. A few times a year a

sales event multiplies traffic, and some items (“lightning deals”) have a few thousand units that a hundred thousand people try to buy in the same minute.

A department store is a fair analogy: a huge, mostly static catalog on the shelves (read-heavy, cacheable), shopping baskets that customers carry around (must never be lost or refused), and a checkout counter that must never sell the last television twice. The distinctive hard problem is **inventory correctness under contention** — reserve versus oversell — wrapped in a checkout that spans services which cannot share a transaction, so it runs as a **saga** (§32.7). Everything else is a read-scaling problem.

Evidence: Illustrative — a teaching design for an Amazon-scale store; published Amazon sources are cited where used.

55.7.2 Functional requirements

1. Browse product pages (title, images, price, availability, delivery estimate, reviews, recommendations).
2. Search and filter the catalog with ranking and facets.
3. Add, update and remove cart items; the cart persists across devices and sessions.
4. Check out: choose address and payment, see final price with tax and shipping, place the order.
5. Reserve inventory at checkout; never confirm an order that cannot be fulfilled for strictly stocked items.
6. Process orders through fulfillment (warehouse allocation, picking, shipping) with status updates.
7. Support flash sales on limited stock with fair, bounded load.
8. Sellers update listings, prices and stock.

Out of scope: payment processing internals (§55.9), recommendation models (§56.5, Chapter 81), warehouse robotics, and seller payouts.

55.7.3 Non-functional requirements

Table 55.12 — Non-functional requirements for the e-commerce platform.

Property	Target
Product page latency	p99 < 300 ms server-side, assembled from many services
Search latency	p99 < 200 ms
Cart availability	“Add to cart” never refused: 99.99% plus always-writable design
Checkout availability	99.99%; checkout is revenue
Inventory correctness	Zero oversell for strictly stocked items; bounded, compensated oversell allowed for replenishable items
Order durability	No acknowledged order lost (RPO = 0)
Availability shown on product page	Eventually consistent, at most seconds stale
Flash-sale behavior	Graceful: excess demand queued or told “sold out”, never errors

55.7.4 Capacity estimation

WORKED EXAMPLE

Worked example — traffic and storage. Assumptions: 100 million daily active customers; 20 product page views, 5 searches and 2 cart writes per customer per day; 10 million orders per day; sales-event peak 5× the daily average for browsing and 10× for orders; 500 million products at 10 KB of structured data each; 100 million active carts at 2 KB; 5 KB per order.

1. **Product pages.** $100 \times 10^6 \times 20 = 2 \times 10^9$/day; $/86,400 = 23,148$/s; peak $\times 5 = 115,741 \approx 116,000$/s.
2. **Searches.** 5×10^8/day $= 5,787$/s; peak 28,935/s.
3. **Cart writes.** 2×10^8/day $= 2,315$/s; peak 11,574/s.
4. **Orders.** $10^7/86,400 = 116$/s; peak $\times 10 = 1,157$/s.
5. **Catalog.** $5 \times 10^8 \times 10,000 = 5$ TB (images separately in object storage behind the CDN).
6. **Carts.** $10^8 \times 2,000 = 200$ GB.
7. **Orders.** $10^7 \times 5,000 = 50$ GB/day, 18.25 TB/year.
8. **Product-page fan-out.** If one page calls 50 backend services, 116,000 pages/s become 5.8 million internal calls/s.

Interpretation. Reads outnumber orders by about 100 to 1, and the catalog fits comfortably in a distributed cache. *Engineering implication.* The product page is a caching and aggregation problem; checkout is a correctness problem at only about a thousand per second, except for hot items.

FORMULA

Partitioned inventory counter for a hot item

$$N \geq \lceil \frac{\lambda_w \, t_h}{u} \rceil$$

Symbol	Meaning	Units
N	Number of sub-counters (partitions) for one item's stock	—
λ_w	Reservation attempts per second that reach the inventory store for that item	attempts/s
t_h	Time each reservation holds the row lock (read, check, write, commit)	s
u	Target utilization of each sub-counter, below 1 to keep queueing delay low (§4.10)	—

WORKED EXAMPLE

Worked example — a lightning deal. 1 million customers open the deal page in the first minute: $10^6/60 = 16,667$ page views per second, served from cache. Suppose a gate (§55.7.8) lets $\lambda_w = 5,000$ reservation attempts per second through to the inventory store, each holding the row lock for $t_h = 2$ ms (a replicated commit), and we target $u = 0.7$.

1. **One row's ceiling.** $1/0.002 = 500$ reservations/s.
2. **Load.** $\lambda_w t_h = 5,000 \times 0.002 = 10$: ten rows' worth of lock time per second.
3. **Partitions.** $N \geq \lceil 10/0.7 \rceil = \lceil 14.3 \rceil = 15$ sub-counters.
4. **Without the gate.** All 16,667 attempts/s would need $\lceil 16,667 \times 0.002/0.7 \rceil = \lceil 47.6 \rceil = 48$ sub-counters.

Interpretation. A single inventory row serializes at about 500 reservations per second however powerful the database is. *Engineering implication.* Split a hot item's stock across sub-counters, route attempts to a random sub-counter, and gate demand so the inventory store sees only attempts that could plausibly succeed.

55.7.5 API design

```
GET  /v1/products/{asin}?zip=98109           -> 200 { product, offers: [{seller_id,
price, availability, delivery_by}], ... }
GET  /v1/search?q=usb+c+charger&facets=brand,price&page=1

PUT  /v1/cart/items/{asin}                   { "quantity": 2, "offer_id": "o_31" }   ->
200 { cart }
DELETE /v1/cart/items/{asin}
GET  /v1/cart

POST /v1/checkout/preview                    { "address_id": "a_2", "payment_method_id":
"pm_7" }
  -> 200 { "lines": [...], "tax": ..., "shipping": ..., "total": {"amount": 4598, "cur-
rency": "USD"},
           "price_token": "pt_c1", "expires_at": "..." }
POST /v1/orders                              Idempotency-Key: 0c6f...
  { "cart_version": 14, "price_token": "pt_c1", "address_id": "a_2",
"payment_method_id": "pm_7" }
  -> 202 { "order_id": "o-113-55", "status": "PENDING" }
GET  /v1/orders/{order_id}                   -> 200 { "status": "CONFIRMED", "items":
[...], "shipments": [...] }
POST /v1/orders/{order_id}/cancel            Idempotency-Key: ...
```

What to notice: placing an order returns `202 Accepted` with a `PENDING` order because the checkout saga runs asynchronously; the client polls or receives a push. The `Idempotency-Key` turns a double-tapped “Place order” into one order (§22.15). The `price_token` pins the total shown at preview, and `cart_version` makes the order reflect exactly the cart the customer reviewed.

55.7.6 Data model and database schema

Each service owns its data (§34.11).

- **Catalog**: a document per product in a key-value or document store (§12.5), cached aggressively; changes flow by change data capture (§32.6) to the search index.
- **Cart**: a key-value item keyed by customer ID, always writable, replicated across zones; a Dynamo-style store (§27.7) is the classic choice.
- **Orders**: relational, partitioned by customer ID, since nearly every query is “this customer’s orders”.
- **Inventory**: relational with strong consistency per row, partitioned by SKU, because reservations are conditional updates.

```
        CREATE TABLE inventory (
          sku            BIGINT   NOT NULL,
          fc_id          INT      NOT NULL,        -- fulfillment center
          bucket         SMALLINT NOT NULL DEFAULT 0,   -- sub-counter for hot items (0
for normal ones)
          on_hand        INT      NOT NULL CHECK (on_hand >= 0),
          reserved       INT      NOT NULL DEFAULT 0 CHECK (reserved >= 0),
          version        BIGINT   NOT NULL DEFAULT 0,
          PRIMARY KEY (sku, fc_id, bucket),
          CHECK (reserved <= on_hand)
        );

        CREATE TABLE reservations (
          reservation_id BIGINT      PRIMARY KEY,
          order_id       VARCHAR(32) NOT NULL,
          sku            BIGINT      NOT NULL,
          fc_id          INT         NOT NULL,
          bucket         SMALLINT    NOT NULL,
          quantity       INT         NOT NULL,
          state          VARCHAR(10) NOT NULL,     -- HELD | COMMITTED | RELEASED |
EXPIRED
          expires_at     TIMESTAMPTZ NOT NULL,
          UNIQUE (order_id, sku, fc_id, bucket)    -- a retried reserve step cannot hold
twice
        );

        CREATE TABLE orders (
          customer_id    BIGINT      NOT NULL,
          order_id       VARCHAR(32) NOT NULL,
          status         VARCHAR(16) NOT NULL,     -- PENDING | CONFIRMED | SHIPPED |
DELIVERED | CANCELED | REJECTED
          total_minor    BIGINT      NOT NULL,
          currency       CHAR(3)     NOT NULL,
          idem_key       VARCHAR(64) NOT NULL,
          created_at     TIMESTAMPTZ NOT NULL,
          PRIMARY KEY (customer_id, order_id),
          UNIQUE (customer_id, idem_key)
        );
```

The reservation is one conditional statement in one transaction with the reservation insert, so the check and the decrement cannot be separated by a concurrent buyer:

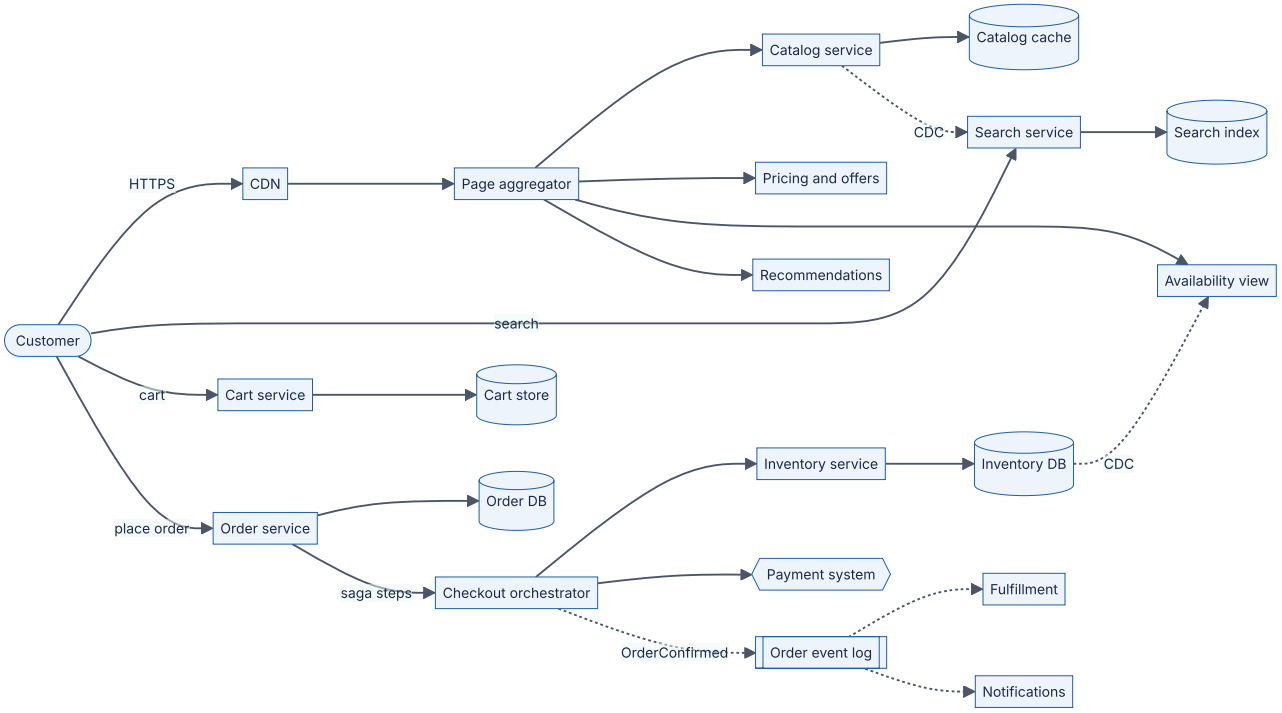
```
        UPDATE inventory SET reserved = reserved + :qty, version = version + 1
         WHERE sku = :sku AND fc_id = :fc AND bucket = :b AND on_hand - reserved >=
:qty;
        -- 1 row: insert the reservation row (state HELD, expires_at = now() + 15 min)
and commit.
        -- 0 rows: try another bucket or fulfillment center, or report out of stock.
```

INDUSTRY EXAMPLE

The shopping cart that motivated Dynamo. Amazon's Dynamo paper uses the shopping cart as its motivating example: customers must be able to add items even during failures, so the store is always writable and replicas may diverge; divergent cart versions are reconciled by the application, which merges them, with the documented consequence that a deleted item can reappear [DeCandia et al. 2007]. Amazon's CTO also described a single page request calling many internal services — more than a hundred — to assemble the page [Gray 2006]. *Evidence: Primary* — [DeCandia et al. 2007; Gray 2006]

55.7.7 High-level architecture

Figure 55.13 — E-commerce platform: browse, cart, checkout and fulfillment.



Reading the diagram. Product pages are assembled by a page aggregator that calls catalog, pricing, availability and recommendations in parallel, with per-call timeouts and fallbacks. Search is a separate service over an index fed asynchronously by change data capture from the catalog. The cart service writes to an always-available key-value store. Placing an order creates a `PENDING` order and hands it to the checkout orchestrator, which runs the saga: reserve inventory, authorize payment (§55.9), confirm. Confirmed orders are published to the order event log for fulfillment and notifications. The availability view used on product pages is a cached, eventually consistent projection of the inventory database; the inventory service itself is the strongly consistent source. Failure points: a slow dependency of the page aggregator (bulkheads and fallbacks), a hot inventory row

(sub-counters), the payment provider (saga retries and compensation). Scaling: catalog and pages by caching; cart and orders by customer partitioning; inventory by SKU partitioning.

55.7.8 Detailed component design

Component 1: inventory — reserve versus oversell

There are two counts that customers care about and they need different consistency.

1. **"In stock" on the product page** is a *display* value. It may be seconds stale; it comes from a cached projection updated by change data capture. Being wrong here costs an annoyed customer, not an oversell.
2. **The reservation at checkout** is a *commitment*. It runs against the inventory row with the conditional update of §55.7.6; it either succeeds atomically or tells the saga to stop.

When to reserve? **At add-to-cart** is wrong at this scale: carts are abandoned at high rates, so stock would sit locked in carts for days (undersell). **At order placement** is the standard choice: reserve with a TTL (for example 15 minutes) that covers payment authorization; commit the reservation when the order is confirmed; release it on payment failure or expiry. A sweeper expires `HELD` reservations past `expires_at`, returning stock.

How much is held at once? By Little's Law (§4.11), held units ≈ reservation rate × hold time. At 1,157 orders/s with an average of 1.5 units per order and a typical hold of 30 s from reserve to confirm: $1,157 \times 1.5 \times 30 \approx 52,000$ units held at any moment across the catalog — negligible overall but significant for a single hot item, which is why holds must be short and expired promptly.

Oversell policy is a business decision per item. For a replenishable item, a small oversell (sell 101 when 100 are on hand because a returned unit is in transit) is often cheaper than refusing orders; the order is confirmed and fulfilled late, with an apology if needed. For a strictly limited item (a lightning deal, a collectible), the `CHECK (reserved <= on_hand)` constraint makes oversell impossible. Physical reality adds a third case: the warehouse discovers a damaged unit after confirmation. The order pipeline must therefore support **post-confirmation compensation** (reallocate from another fulfillment center, or cancel and refund) no matter how good the reservation logic is.

Component 2: checkout as a saga

The order, inventory and payment services each own their database, and the payment provider is external, so no single ACID transaction can span the checkout. Use an orchestrated saga [Garcia-Molina and Salem 1987] exactly as developed in §32.7.2, where this

very example — order, inventory, payment — is worked through; here we only add the e-commerce specifics.

1. T_1 **Create order** `PENDING` (idempotent on `(customer_id, idem_key)`); compensation: mark `REJECTED`.
2. T_2 **Reserve inventory** for each line, choosing fulfillment centers by delivery promise and stock; compensation: release reservations.
3. T_3 **Authorize payment** for the total (the pivot, §32.7.1): the card is authorized, not captured; compensation before the pivot passes is not needed because a failed authorization has no effect.
4. T_4 **Confirm order**: commit reservations, set `CONFIRMED`, emit `OrderConfirmed` through the outbox (§32.5). Retriable, never compensated.
5. **Capture payment at shipment**, not at order time. This matches common card-network practice of capturing when goods ship, and it means a cancellation before shipment only voids an authorization rather than refunding a charge.

Every step is sent with the saga ID as its idempotency key, so the orchestrator can crash and resend; every compensation is itself idempotent and retried until it succeeds (§32.7). A saga stuck in a compensation alerts a human.

Component 3: flash sales and hot items

A lightning deal combines three loads: a page view storm (cacheable), a reservation storm on one SKU (not cacheable) and bot traffic. Defenses, in order from the edge inward:

1. **Static deal page from the CDN**, with the countdown computed on the client; availability fetched as a small, cached JSON blob refreshed every second.
2. **Admission gate.** Before the sale, mint exactly as many *purchase tokens* as there are units plus a small overbooking margin (for example 5,000 units → 5,500 tokens to account for abandonment), stored as an atomic counter in an in-memory store. Each “Buy” attempt decrements the counter; attempts after it reaches zero get “sold out — join the waitlist” immediately without touching inventory. For very large crowds, put a virtual waiting room in front (§55.8.8).
3. **Sub-counters.** Spread the item’s stock across N buckets (15 in the worked example); a reservation picks a random bucket and, if empty, tries others. When most buckets are empty, consolidate the remainder into one.
4. **Per-customer limits and bot defenses.** One unit per account, rate limits per account and device (§22.3), and challenges for suspicious clients.
5. **Short holds.** Deal reservations get a short TTL (for example 5 minutes) so that abandoned holds return to the pool quickly; released units re-mint tokens.

The gate is allowed to be approximate (an in-memory counter can lose a few decrements on failover), because the inventory row remains the authority: the worst case is a few

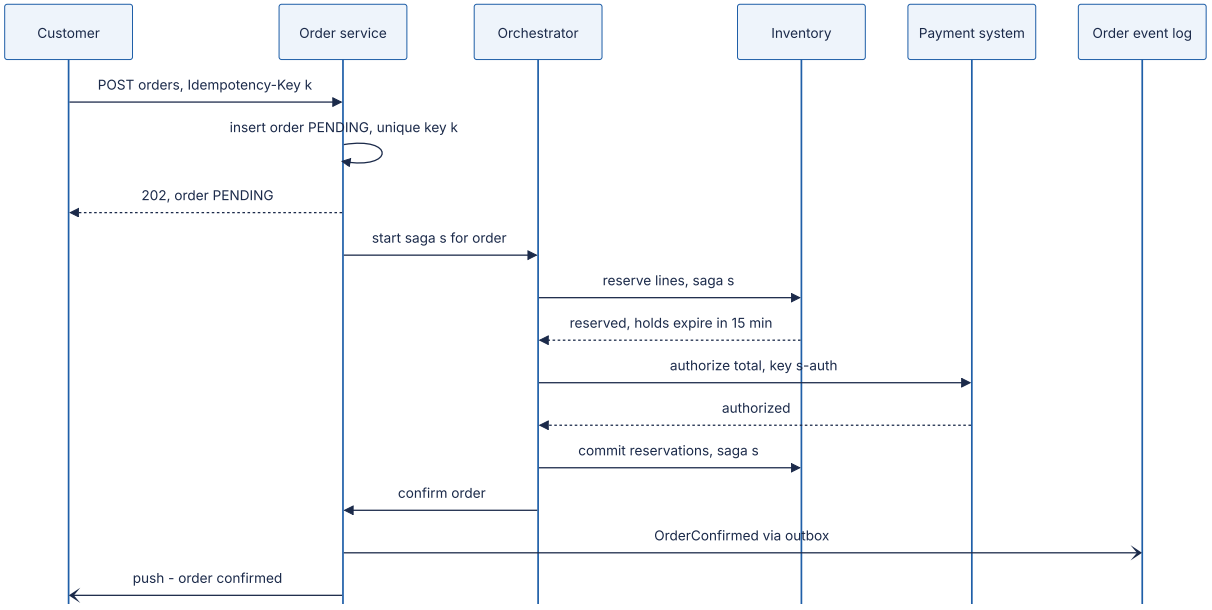
more attempts than units, which the conditional update rejects.

Component 4: the product page and the recommendations hand-off

A product page is assembled from tens of services. Its latency is the slowest required call, and its tail latency compounds with fan-out (§23.6). Classify each widget: **required** (title, price, buy box) or **optional** (recommendations, reviews summary, "frequently bought together"). Required calls get retries within a deadline; optional calls get a strict timeout and a fallback (cached or popular items), and the page renders without them if needed. Recommendations are computed by a separate system (§56.5 for the systems view, §81.8 for the model) and exposed as a low-latency lookup keyed by product and customer; the commerce platform only consumes them.

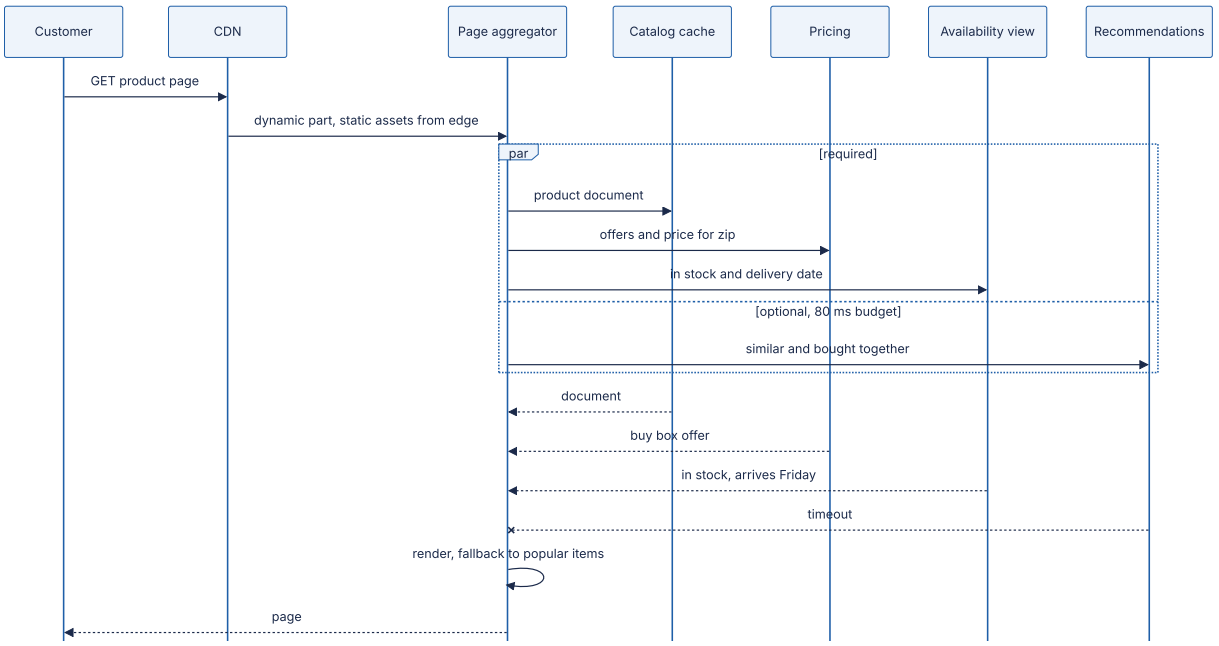
55.7.9 Data flow

Figure 55.14 — Write path: placing an order (orchestrated saga, success case).



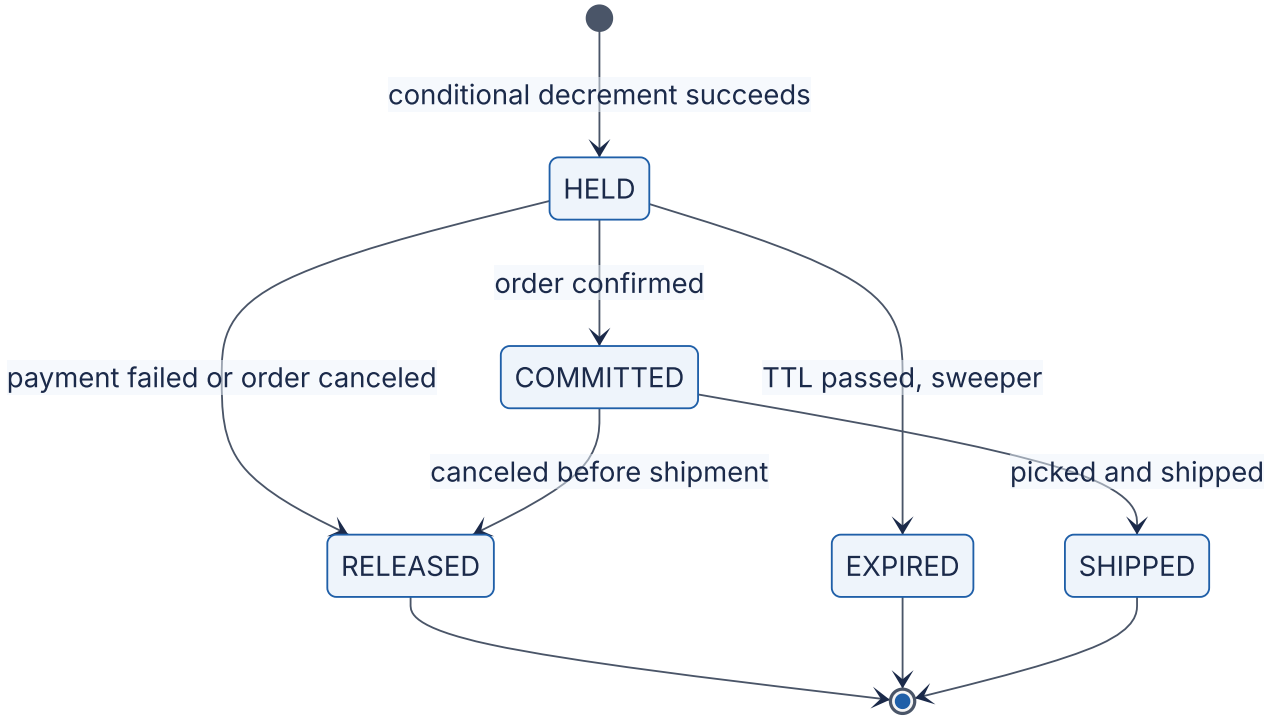
Reading the diagram. The order is persisted as `PENDING` with a unique idempotency key before anything else, so a retried request returns the same order. The orchestrator persists each saga state before sending the next command (§32.7) and uses keys derived from the saga ID, so every step is safe to resend. Inventory reservations carry a TTL in case the saga stalls. Payment is authorized, not captured. Confirmation commits reservations and publishes `OrderConfirmed` through the outbox for fulfillment. Synchronous: each saga command and reply; asynchronous: the event log and the customer push. Failure paths: an out-of-stock reservation ends the saga with the order `REJECTED`; a declined authorization releases reservations and rejects the order (compensation in reverse order, as in Figure 32.10).

Figure 55.15 — Read path: rendering a product page.



Reading the diagram. Static assets (images, scripts) come from the CDN edge; the dynamic shell goes to the page aggregator, which calls required services in parallel with the optional recommendations call under its own small budget. Here the recommendations call times out, so the page uses a cached list of popular items instead of failing. The availability call reads the cached projection, not the inventory database, which keeps 116,000 page views per second away from the strongly consistent store. All calls are synchronous with deadlines propagated from the edge. Failure points: a slow required service (retry once within the deadline, then show a degraded page without the buy box rather than an error) and cache stampedes on a newly hot product (request coalescing, §20.11).

Figure 55.16 — Reservation lifecycle.



Reading the diagram. A reservation exists only after the conditional update succeeded. It ends in exactly one terminal state. `RELEASED` and `EXPIRED` return the units to `on_hand - reserved`; `SHIPPED` decrements `on_hand` and `reserved` together. Every transition is a conditional update on the reservation row (`WHERE state = 'HELD'`), so a confirmation racing the expiry sweeper resolves to one winner; if the sweeper wins, the orchestrator sees the failed commit and re-reserves or rejects the order.

55.7.10 Bottlenecks

1. **Hot SKUs** during deals: sub-counters, gating and short holds.
2. **Page fan-out tail latency**: parallel calls, deadlines, optional widgets with fallbacks, and caching of the assembled fragments.
3. **Search index freshness** after price changes: price and availability are looked up at query time for the top results rather than trusted from the index.
4. **The order database for one huge customer** (a business account placing thousands of orders): partition by customer, but split large accounts further by order ID.
5. **Payment provider limits** during peaks: authorization calls are rate limited by the provider; queue and smooth them, and use multiple providers (§55.9.8).

55.7.11 Failure scenarios

Table 55.13 — Failure scenarios for the e-commerce platform.

What fails	Impact	Detection	Recovery	Prevention
Inventory DB partition down	Checkouts for its SKUs fail	Reservation error rate	Failover to replica; saga retries with same keys	Synchronous replicas; small partitions
Orchestrator crashes mid-saga	Orders stuck `PENDING`	Age of oldest pending saga	Resume from persisted saga state; resend idempotent step	Saga log; multiple orchestrator instances
Payment provider timeout	Unknown authorization outcome	Timeout metric	Retry with same idempotency key; query provider status	Provider idempotency; second provider
Compensation keeps failing	Stock stuck held or order stuck	Saga in compensating state > N min	TTL expiry frees stock; human queue	Idempotent, retried compensations
Availability projection lags	Page says in stock; checkout fails	CDC lag metric	Clear message at checkout; suggest alternatives	Lag alarms; short projection TTL
Cart store replica divergence	Deleted item reappears	Merge counts	Customer removes item; merged at read	Accept as a trade-off of always-writable carts
Bot storm on a deal	Real customers locked out	Request rate per account and device	Challenges; block lists	Per-account limits; gate; waiting room

55.7.12 Scaling strategy

At 10× (1.16 million page views per second, 11,570 orders per second), page rendering scales by caching and adding aggregators; carts and orders scale linearly by customer partitioning. Inventory needs sub-counters for many more items at once, so make bucket count dynamic per SKU based on observed contention. **At 100×**, run regional deployments with regional inventory (each fulfillment network's stock owned in its region), so a reservation never crosses an ocean, and replicate the catalog globally as read-only data. Sales events become a capacity-planning exercise with pre-scaled fleets, load tests at expected peak, and feature flags that switch optional widgets off (§39.5).

55.7.13 Trade-offs

- **Always-writable carts versus exact carts.** Availability wins; occasional resurrected items are accepted.
- **Reserve at order time versus at cart time.** Order time avoids undersell from abandoned carts, at the cost of some checkouts failing "out of stock" after the item looked available.
- **Strict versus allowed oversell.** Strict for limited items, allowed and compensated for replenishable items.

- **Authorize now, capture at shipment.** Cancellations become cheap voids; authorizations can expire for slow shipments and must be re-authorized.
- **Saga versus distributed transaction.** Sagas keep services independent and the payment provider outside any lock, at the cost of visible intermediate states (`PENDING`).

55.7.14 Alternative designs

Table 55.14 — Ways to prevent oversell.

Approach	How it works	Advantages	Disadvantages	Choose when
Conditional update on one row	`WHERE on_hand - reserved >= qty`	Simple; exact	About 500/s per row	Normal items
Sub-counters	Stock split across *N* rows	Scales a hot item	Fragmented remainders; more complex	Deals, launches
In-memory token gate plus database	Atomic counter admits buyers; DB stays authoritative	Absorbs crowds	Gate may over-admit slightly	Flash sales
Queue per SKU	Serialize reservations through one consumer	Ordered, fair	Adds queueing latency	Very hot single items
Allow oversell, reconcile later	Accept orders, cancel or backorder	Highest availability	Unhappy customers	Replenishable goods

55.7.15 Interview discussion

Pacing (45 minutes). Scope and requirements (5 min); estimates (5 min: 116,000 page views/s versus 1,157 orders/s); architecture (10 min: Figure 55.13); deep dives (20 min: inventory reservation and oversell policy, the checkout saga with authorize-then-capture, flash sale with gate and sub-counters); failures and scaling (5 min).

Likely follow-ups. *Why not reserve on add to cart?* Abandoned carts would lock stock. *What if payment succeeds but the confirm step crashes?* The orchestrator resumes from its log and resends confirm; inventory and order steps are idempotent. *How do you show accurate stock on the page?* You do not need to; show an eventually consistent value and be exact at reservation. *How do you handle a single item with 100,000 buyers?* Gate, sub-counters, per-customer limits, waiting room.

What distinguishes senior and staff answers. A senior candidate separates display availability from reservation, writes the conditional update and uses a saga. A staff candidate quantifies the per-row ceiling and sizes sub-counters, distinguishes oversell policies per item type, places authorization and capture deliberately, and designs post-confirmation compensation because warehouses are imperfect.

55.7.16 Production considerations

- **Observability.** Business SLIs: checkout success rate, out-of-stock-at-checkout rate (the gap between display and reservation), oversell incidents, saga duration and stuck sagas, page latency per widget.
- **Security.** Payment data never touches commerce services (tokens only, §55.9.8); account takeover protection; bot management for deals; price-manipulation checks for seller updates.
- **Cost.** Product-page caching and image delivery dominate; pre-scaling for events is cheaper than incidents.
- **Operations.** Game days before sales events; kill switches for optional widgets; a runbook for “deal sold out in two seconds and customers are angry”, which is a communication problem as much as a technical one.

55.8 Ticket booking system

55.8.1 Problem statement

Design a ticketing platform for concerts, sports and theater: fans browse events, pick specific seats on a seat map (or a quantity for general admission), hold them for a few minutes while paying, and receive tickets. Most of the year the load is modest. Then a stadium tour goes on sale at 10:00 and two million people arrive for fifty thousand seats.

Picture a theater box office with a seating chart on the counter. When you point at 14C, the clerk pencils your initials on it; if you walk away without paying, the clerk erases it after a few minutes; and the clerk never sells 14C to two people. Now imagine two million people at the counter at once. The distinctive hard problems are **seat inventory with strong consistency** (every seat is unique, unlike a pile of identical phone chargers), **temporary holds with TTLs**, **double-booking prevention under extreme contention**, and **fair admission** through a virtual waiting room when demand exceeds supply by a factor of forty.

Evidence: Illustrative — a teaching design, not the architecture of any named ticketing company.

55.8.2 Functional requirements

1. Browse and search events; view a venue’s seat map with live availability by section and seat.
2. Select specific seats (reserved seating) or a quantity (general admission, best available) and place a **hold** for a fixed time.
3. Pay within the hold; on success issue tickets (barcodes or mobile tickets); on failure or expiry release the seats.

4. Never sell the same seat twice; never sell more general-admission tickets than capacity.
5. For high-demand on-sales, admit buyers through a virtual waiting room in a fair order, with per-account purchase limits.
6. Organizers configure events, price levels, holds for production and resale rules.

Out of scope: the resale marketplace, ticket transfer, entry scanning and pricing optimization.

55.8.3 Non-functional requirements

Table 55.15 — Non-functional requirements for ticket booking.

Property	Target
Double booking	Zero: invariant enforced by the database of record
Hold correctness	A held seat is not offered to anyone else until released or expired
Seat map freshness	Availability at most 1–2 s stale during on-sales
Hold latency	p99 < 500 ms for a hold request admitted to the purchase flow
Availability during on-sale	Waiting room never errors; purchase flow degrades by admitting fewer, not by failing
Fairness	Arrival order (or a published lottery) decides admission; bots and multi-account abuse limited
Durability	No issued ticket lost; RPO = 0 for orders and tickets

55.8.4 Capacity estimation

WORKED EXAMPLE

Worked example — normal days are small. Assumptions: 300 million tickets per year, 2.5 tickets per order; 50,000 reserved-seating events on sale at once with 10,000 seats on average; 100 bytes per seat row; 3 KB per order.

1. **Orders.** $3 \times 10^8 / 2.5 = 1.2 \times 10^8$ orders/year $= 328,767$/day $= 3.8$/s on average.
2. **Seat inventory.** $5 \times 10^4 \times 10^4 = 5 \times 10^8$ seat rows $\times 100$ bytes $= 50$ GB.
3. **Orders storage.** $1.2 \times 10^8 \times 3,000 = 360$ GB/year.

Interpretation. Averages are tiny; one ordinary relational database cluster could hold everything. *Engineering implication.* The design is driven entirely by on-sale spikes concentrated on one event: contention on a few thousand rows, not data volume.

FORMULA

Waiting-room sell-out position and admission time

$$q^* = \frac{S}{bc}, \qquad a = \frac{L_{\max}}{W}, \qquad T^* = \frac{q^*}{a}$$

Symbol	Meaning	Units
q^*	Queue position at which inventory is expected to sell out	positions
S	Seats (or tickets) on sale	tickets
b	Average tickets per order	tickets/order
c	Fraction of admitted buyers who complete a purchase	—
a	Admission rate from the waiting room into the purchase flow	buyers/s
$L_{\max}$	Concurrent buyers the purchase flow can serve (Little's Law, §4.11)	buyers
W	Average time a buyer spends in the purchase flow	s
T^*	Time to admit buyers up to the sell-out position	s

WORKED EXAMPLE

Worked example — a stadium on-sale. $S = 50,000$ seats; $b = 2.5$; $c = 0.8$; 2 million people in the queue; the purchase flow can serve $L_{\max} = 30,000$ concurrent buyers, each spending $W = 360$ s (choose seats, pay); hold TTL equal to W.

1. **Sell-out position.** $q^* = 50,000/(2.5 \times 0.8) = 25,000$. Only the first 25,000 of 2,000,000 can expect tickets: $1 - 25,000/2,000,000 = 98.75\%$ of the queue will not.
2. **Admission rate.** $a = 30,000/360 = 83.3$ buyers/s.
3. **Time to admit position 25,000.** $T^* = 25,000/83.3 = 300$ s, five minutes.
4. **Holds.** Admitted buyers create holds at $83.3 \times 2.5 = 208$ seats/s, so all 50,000 seats are held after $50,000/208 = 240$ s, while some buyers are still choosing. Concurrently held seats would reach $208 \times 360 = 75,000$, more than exist: buyers admitted after minute four see an empty seat map while 20% of holds are still going to expire unpaid.
5. **Waiting-room polling.** 2 million waiting clients checking status every 30 s: $2 \times 10^6/30 = 66,667$ requests/s.

Interpretation. The backend's capacity is not the only limit on admission: inventory is. *Engineering implication.* Make admission **inventory-aware** — admit only while unheld seats remain, and tell queue positions far beyond q^* honestly that the event is likely to sell out — and serve the waiting room from a cheap, stateless edge tier because it carries the largest request rate.

55.8.5 API design

```
GET  /v1/events/{event_id}                          -> 200 { event, venue, price_levels,
on_sale_at }
GET  /v1/events/{event_id}/availability?section=112
  -> 200 { "section": "112", "version": 88412, "seats": "base64 bitmap", "price_level":
"P2" }

POST /v1/queue/{event_id}/join                      -> 200 { "queue_token": "qt_...",
"position_hint": null }
GET  /v1/queue/{event_id}/status   (Authorization: queue token)
  -> 200 { "state": "WAITING", "position": 41203, "est_wait_s": 540 }
  -> 200 { "state": "ADMITTED", "access_token": "at_...", "expires_at": "..." }

POST /v1/holds                     (Authorization: access token)   Idempotency-Key:
9d2e...
  { "event_id": "e_77", "seats": ["112-K-14", "112-K-15"] }          # or {"section":
"GA", "quantity": 2}
  -> 201 { "hold_id": "h_5c", "seats": [...], "expires_at": "...10:08:00Z" }
  -> 409 { "error": "SEATS_UNAVAILABLE", "unavailable": ["112-K-15"] }

POST /v1/holds/{hold_id}/purchase   Idempotency-Key: ...
  { "payment_method_token": "tok_...", "price_token": "pt_..." }
  -> 202 { "order_id": "o_3a", "status": "PAYMENT_PENDING" }
GET  /v1/orders/{order_id}         -> 200 { "status": "CONFIRMED", "tickets": [ ... ] }
DELETE /v1/holds/{hold_id}         -> 204   (release early)
```

What to notice: availability is served as a **per-section bitmap with a version**, so clients fetch a few hundred bytes per section and the server can cache one copy for everyone. Hold and purchase require an **access token** issued by the waiting room, so nobody can skip the queue by calling the API directly. Holds are all-or-nothing for the requested seats: two adjacent seats are useless if only one is held.

55.8.6 Data model and database schema

Seat inventory lives in a relational database with row-level locking and unique constraints, partitioned by event. Every seat of a reserved-seating event is a row, created when the event is published.

```
        CREATE TABLE seats (
          event_id        BIGINT      NOT NULL,
          seat_id         VARCHAR(16) NOT NULL,          -- "112-K-14": section-row-num-
ber
          section         VARCHAR(8)  NOT NULL,
          price_level     VARCHAR(4)  NOT NULL,
          status          VARCHAR(10) NOT NULL,          -- AVAILABLE | HELD | SOLD |
KILLED
          hold_id         BIGINT,
          hold_expires_at TIMESTAMPTZ,
          version         BIGINT      NOT NULL DEFAULT 0,
          PRIMARY KEY (event_id, seat_id)
        );
        CREATE INDEX seats_free ON seats (event_id, section) WHERE status = 'AVAILABLE';

        CREATE TABLE holds (
          hold_id     BIGINT      PRIMARY KEY,
          event_id    BIGINT      NOT NULL,
          account_id  BIGINT      NOT NULL,
          status      VARCHAR(16) NOT NULL,            -- ACTIVE | PAYMENT_PENDING |
CONVERTED | EXPIRED | RELEASED
          expires_at  TIMESTAMPTZ NOT NULL,
          idem_key    VARCHAR(64) NOT NULL,
          UNIQUE (account_id, idem_key)
        );

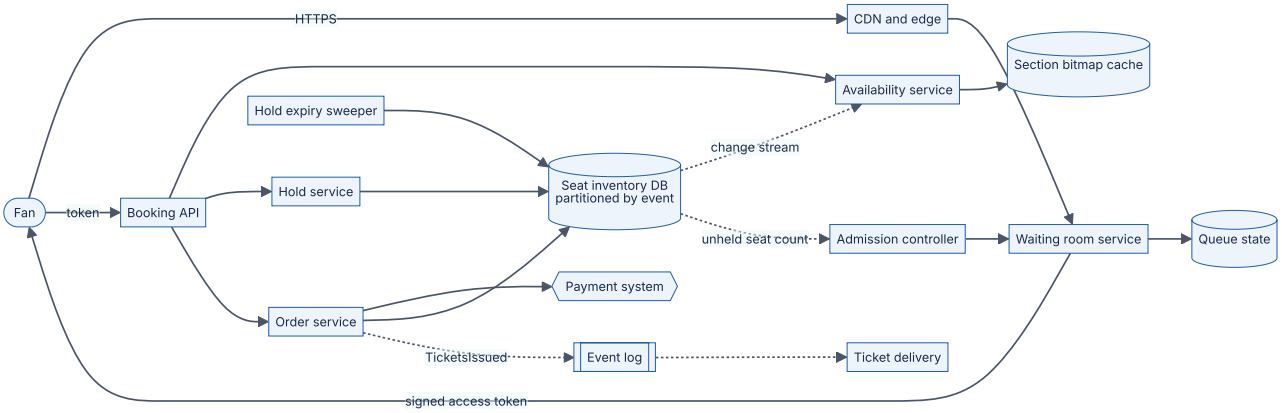
        -- The last line of defense: a seat can appear in at most one issued ticket per
event.
        CREATE TABLE tickets (
          ticket_id   BIGINT      PRIMARY KEY,
          event_id    BIGINT      NOT NULL,
          seat_id     VARCHAR(16) NOT NULL,
          order_id    VARCHAR(32) NOT NULL,
          barcode     VARCHAR(64) NOT NULL UNIQUE,
          UNIQUE (event_id, seat_id)
        );

        -- General admission: a counter per event and price level.
        CREATE TABLE ga_inventory (
          event_id BIGINT, price_level VARCHAR(4), capacity INT NOT NULL, held INT NOT
NULL DEFAULT 0,
          sold INT NOT NULL DEFAULT 0, PRIMARY KEY (event_id, price_level),
          CHECK (held + sold <= capacity)
        );
```

Why relational? Seats are a small, hot, highly contended data set that needs multi-row atomicity (hold two adjacent seats or none) and constraints the database enforces for you. The `UNIQUE (event_id, seat_id)` on `tickets` makes double booking impossible at the storage layer even if every application-level check had a bug.

55.8.7 High-level architecture

Figure 55.17 — Ticket booking with a virtual waiting room.



Reading the diagram. During an on-sale, every fan first reaches the waiting room through the CDN edge; the waiting room records arrival (or lottery order) in its queue state and, when an admission controller says so, issues a short-lived signed access token. Only token holders reach the booking API. Seat maps come from the availability service, which keeps per-section bitmaps in a cache fed asynchronously by the seat database's change stream. Holds are conditional updates in the seat inventory database; purchases go through the order service, which calls the payment system (§55.9) and converts holds to tickets. A sweeper expires holds. The admission controller watches both backend health and the number of unheld seats, closing the gate when inventory runs out. Storage boundaries: queue state (in memory, replicated), seat database (authoritative), bitmap cache (derived). Failure points: the seat database partition of the hot event, and the waiting room itself, which must survive millions of clients. Scaling: the waiting room scales at the edge; the seat database is partitioned by event, and a mega-event further by section.

55.8.8 Detailed component design

Component 1: preventing double booking — three approaches

All three approaches below are correct if implemented carefully; they differ in throughput under contention and in operational risk.

(a) Pessimistic row locks. Lock the requested seat rows, check, update, commit.

```
        BEGIN;
        SELECT seat_id, status, hold_expires_at FROM seats
         WHERE event_id = :e AND seat_id IN (:s1, :s2)
         ORDER BY seat_id                              -- fixed order prevents dead-
locks
         FOR UPDATE;
        -- application: abort unless every row is AVAILABLE, or HELD with
hold_expires_at < now()
        UPDATE seats SET status = 'HELD', hold_id = :h, hold_expires_at = now() + inter-
val '8 minutes',
                         version = version + 1
         WHERE event_id = :e AND seat_id IN (:s1, :s2);
        INSERT INTO holds (...) VALUES (...);
        COMMIT;
```

For “best available” requests, `SELECT ... WHERE status = 'AVAILABLE' ... LIMIT :n FOR UPDATE SKIP LOCKED` lets concurrent buyers take *different* free seats instead of queueing behind the same rows.

(b) Optimistic concurrency. No explicit lock; one conditional update that succeeds only if nothing changed (§11.14).

```
        UPDATE seats SET status = 'HELD', hold_id = :h, hold_expires_at = now() + inter-
val '8 minutes',
                         version = version + 1
         WHERE event_id = :e AND seat_id IN (:s1, :s2)
           AND (status = 'AVAILABLE' OR (status = 'HELD' AND hold_expires_at < now()));
        -- application: if rows updated != 2, ROLLBACK (all or nothing) and return 409
with fresh availability
```

(c) In-memory holds with TTL. Keep holds in Redis: one key per seat, set only if absent, with an expiry; a Lua script makes a multi-seat hold atomic on one Redis node (put all of an event section’s keys in one hash slot). The database records only sold seats.

```
EVAL hold.lua  keys: seat:{e77:112}:K-14  seat:{e77:112}:K-15   args: h_5c  480000
  -- for every key: if EXISTS -> return 0;  then for every key: SET key h_5c PX 480000;
return 1
```

Table 55.16 — Preventing double booking: three approaches compared.

	Row locks (pessimistic)	Optimistic conditional update	Redis holds with TTL
How it works	`SELECT ... FOR UPDATE`, check, update	`UPDATE ... WHERE status = 'AVAILABLE'`, check row count	`SET NX PX` per seat via an atomic script; DB on purchase
Correctness source	Database locks	Database row-level atomicity	Redis atomicity, plus DB unique constraint at purchase
Behavior under contention	Waiters queue on locks; deadlock risk without ordering	Losers fail fast and retry with fresh data	Losers fail fast in microseconds
Throughput on a hot section	Lowest: lock hold time includes round trips	Higher: one statement, short lock	Highest: in memory
Expiry	Lazy (`hold_expires_at < now()`) plus sweeper	Same	Native key TTL
Failure risk	Long transactions hold locks	Retry storms if many collide	Failover can lose holds (asynchronous replication): two buyers think they hold one seat
Operational complexity	Low	Low	Higher: two stores to keep consistent
Choose when	Low contention; best-available with `SKIP LOCKED`	Default for reserved seating	Mega on-sales where the database cannot absorb hold churn

The recommended design uses **(b) as the default** and adds **(c) only for mega on-sales**, with the database's `UNIQUE (event_id, seat_id)` on tickets as the final guard in every case. If Redis loses a hold during failover and two buyers reach purchase for the same seat, the second ticket insert fails, the second buyer's payment authorization is voided, and they are offered alternative seats — an unhappy but bounded outcome, never a double booking.

> COMMON MISTAKE
>
> **"Check availability, then book."** Reading `status = 'AVAILABLE'` in one statement and updating in another, without a lock or a condition on the update, is the classic time-of-check-to-time-of-use race: two buyers both see the seat free and both write `HELD`. The check and the write must be one atomic step.

Component 2: holds, TTLs and payment timeouts

A hold is a lease on seats (§26.11). Its TTL balances two harms: too short and buyers lose seats while typing card details; too long and abandoned holds keep seats away from other

buyers (the worked example showed 75,000 seats' worth of holds competing for 50,000 seats).

1. **Hold** with TTL W_h (for example 8 minutes); the seat map shows held seats as unavailable.
2. **Purchase** moves the hold to `PAYMENT_PENDING` and *extends* its expiry by a bounded payment window (for example 3 minutes), so a slow card authorization is not cut off mid-flight. The extension happens once.
3. **Authorize** the card through the payment system with an idempotency key derived from the hold ID.
4. **Convert**: in one transaction, insert tickets (unique per seat), set seats `SOLD`, hold `CONVERTED`. Then **capture** the payment.
5. **Late success.** If the authorization succeeds after the hold expired and the seat was resold, the ticket insert fails on the unique constraint; the order service voids the authorization and tells the buyer. This compensation path must exist even though it is rare.
6. **Expiry.** A sweeper sets expired holds to `EXPIRED` and seats back to `AVAILABLE`; the conditional updates already treat expired holds as free, so the sweeper only tidies up and publishes availability changes.

Component 3: the virtual waiting room and fairness

A virtual waiting room is a queue in front of the site that admits visitors at a controlled rate.

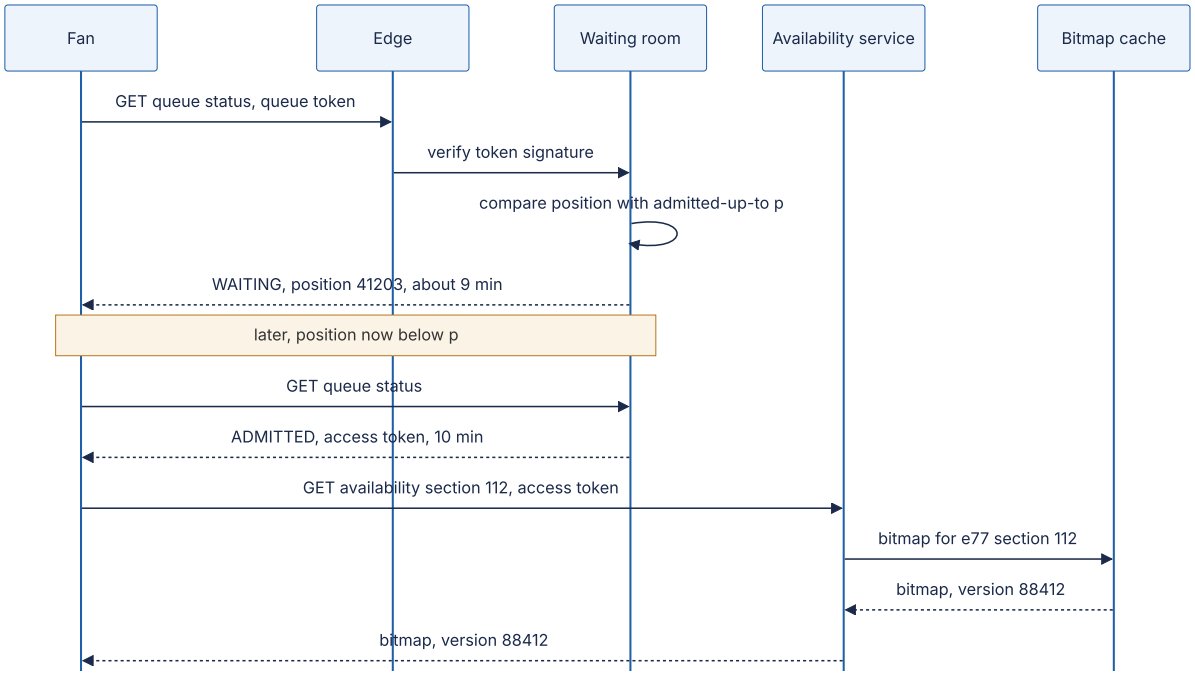
1. **Pre-queue.** Visitors who arrive before the on-sale time wait on a static page. At the start, they are assigned **random** positions (a lottery), so refreshing at 09:59:59.9 gives no advantage; later arrivals join at the back in arrival order.
2. **Queue token.** Each visitor receives a signed token containing the event, a queue position and an identity binding (account and device). Status polls are answered from the token and a small, replicated "admitted up to position p" counter, so the waiting room is almost stateless and served at the edge.
3. **Admission.** The admission controller raises p at rate a, computed from backend health ($L_{\max}$, §55.8.4) and **unheld inventory**. When unheld seats reach zero, it stops admitting and tells waiting visitors so, reopening if holds expire.
4. **Access token.** An admitted visitor exchanges the queue token for a short-lived access token that the booking API requires; tokens are single-use per account, preventing one admitted visitor from passing the token to a bot farm.
5. **Fairness controls.** Pre-registration and identity verification for the largest on-sales, one queue position per verified account, purchase limits per account and payment card, and bot detection on join. Publish the rules: perceived fairness depends on understanding the process as much as on the algorithm.

INDUSTRY EXAMPLE

Waiting rooms in practice. Queue-it, a commercial virtual-waiting-room service, documents a pre-queue in which early arrivals wait for a scheduled start, after which their positions are randomized, while later arrivals are queued first in, first out [Queue-it Docs]. In November 2022, Ticketmaster attributed problems during the presale for Taylor Swift's Eras Tour to unprecedented demand, stating that the event generated 3.5 billion total system requests, four times its previous peak, and that over 2 million tickets were sold that day [Ticketmaster 2022]. *Evidence: Primary* — [Queue-it Docs; Ticketmaster 2022]

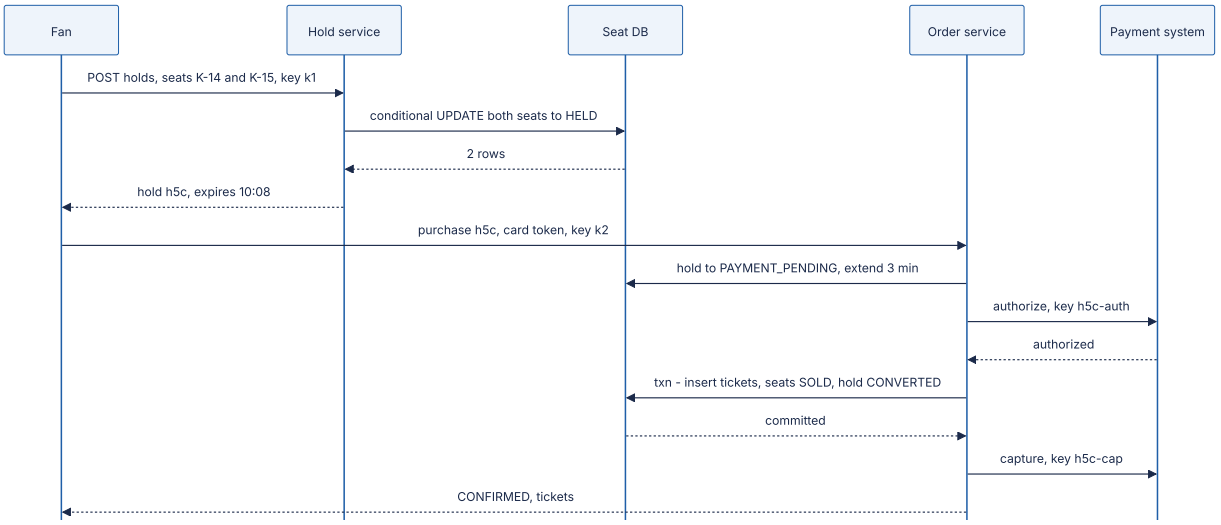
55.8.9 Data flow

Figure 55.18 — Read path: queue status and seat map.



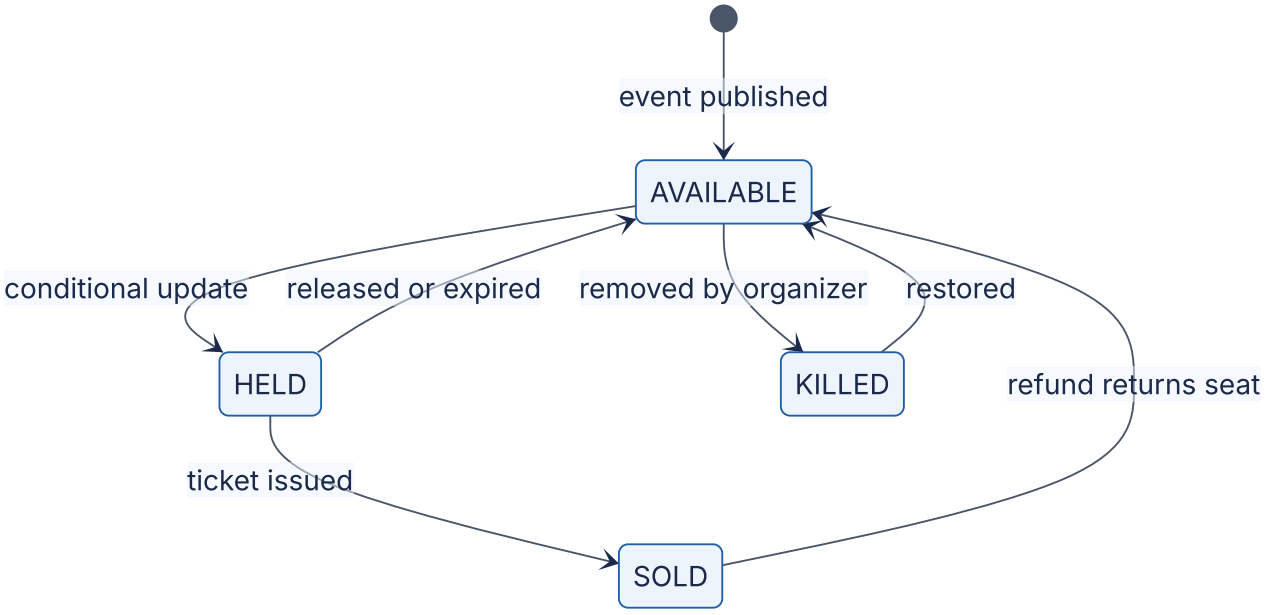
Reading the diagram. Queue status checks verify a signed token and compare its position with one replicated counter, so 66,667 polls per second cost almost nothing and need no database. Once admitted, the fan receives an access token and loads per-section bitmaps from a cache that the seat database's change stream keeps within a second or two of the truth. All calls are synchronous. Failure points: if the waiting room's counter store is unavailable, status checks keep answering "waiting" (fail closed for admission, never open the gates); if the bitmap cache lags, fans may click seats that are already held and receive a 409 with fresh availability, which is acceptable.

Figure 55.19 — Write path: hold, pay and issue tickets.



Reading the diagram. The hold is one conditional update on both seat rows: two rows changed means both seats are held; anything else rolls back. Purchase first extends the hold so payment cannot race the expiry, then authorizes the card with an idempotency key derived from the hold, converts the hold to tickets in one transaction whose unique constraint prevents double booking, and finally captures. Every call carries an idempotency key, so a fan who taps “Pay” twice or retries after a timeout creates one order and one charge. Failure points: authorization declined (hold returns to `ACTIVE` until expiry so the fan can try another card), authorization succeeds after expiry (ticket insert fails, authorization voided), capture fails (retried asynchronously; the tickets are already issued because the authorization guarantees funds).

Figure 55.20 — Seat state machine.



Reading the diagram. A seat moves only through conditional updates on its row. `HELD` carries a hold ID and expiry, and an expired hold counts as available to the next condi-

tional update even before the sweeper runs. `SOLD` can return to `AVAILABLE` only through a refund flow that first invalidates the ticket's barcode. `KILLED` covers seats removed for camera positions or stage changes.

55.8.10 Bottlenecks

1. **One event's seat partition** during an on-sale: sub-partition by section; route all holds for a section to the same database node to keep multi-seat holds local.
2. **Popular sections**: everyone wants the floor; the best-available path with `SKIP LOCKED` spreads buyers across free seats instead of colliding on the same ones.
3. **Seat-map refreshes**: bitmaps per section, pushed or cached for one second, never queried from the database per fan.
4. **Payment provider throughput** at the moment thousands of holds convert: admission rate bounds it; agree on capacity with the provider in advance.
5. **Waiting-room polling**: long poll intervals with jitter, served from edge compute.

55.8.11 Failure scenarios

Table 55.17 — Failure scenarios for ticket booking.

What fails	Impact	Detection	Recovery	Prevention
Seat DB primary for the hot event	Holds and purchases stop	Error rate; failover monitor	Promote synchronous replica; admission pauses meanwhile	Synchronous replication; admission tied to health
Redis failover loses holds	Two buyers believe they hold one seat	Unique-violation count at ticket insert	Void second authorization; offer alternatives	DB unique constraint; use Redis holds only when needed
Sweeper stops	Expired holds still shown as held	Count of expired-but-held seats	Restart; conditional updates already treat them as free	Lazy expiry in the update predicate
Payment slow at hold expiry	Seat released mid-payment	Late-authorization count	Payment-pending extension; void if lost	Bounded extension; idempotent authorization
Waiting room overloaded	Fans see errors, refresh, amplify load	Edge error rate	Serve static queue page from CDN; slower polls	Edge-hosted, token-based, stateless design
Bots join the queue at scale	Real fans lose positions	Join rate per IP, device, account	Purge suspicious tokens before admission	Verified registration; one position per account
Admission too fast	Purchase flow overloaded or seats over-held	Hold latency; unheld seat count	Admission controller backs off	Admission by health and inventory

55.8.12 Scaling strategy

At 10× (20 million fans for one tour), the waiting room scales at the edge without change, since its state is a counter and signed tokens; the purchase flow does not need to grow, because inventory, not demand, bounds it. What grows is the number of simultaneous on-sales: partition seat inventory by event across many database clusters, and run a separate admission controller per event. **At 100×**, the honest answer is that a first-come mechanism stops being meaningful when demand exceeds supply by a factor of hundreds; product changes — registration with a lottery for the right to buy, staggered on-sales by region, dynamic pricing — scale better than infrastructure.

55.8.13 Trade-offs

- **Hold TTL length:** buyer comfort versus inventory recycling.
- **Lottery versus first in, first out:** lotteries remove the advantage of speed and bots; first in, first out rewards those who wait, which some fans find fairer.
- **Database holds versus in-memory holds:** simplicity and guaranteed durability versus raw throughput during mega on-sales.
- **Strict seat selection versus best available:** choice is popular but creates hot spots on the same seats; best available spreads load.
- **Honesty about sell-out:** telling position 300,000 that tickets are unlikely reduces load and anger but must be phrased carefully because cancellations happen.

55.8.14 Alternative designs

Table 55.18 — Alternative architectures for hot inventory.

Option	How it works	Advantages	Disadvantages	Choose when
Relational database with conditional updates (this design)	Seat rows, constraints, holds as columns	Simple, correct, constraint-enforced	Throughput bounded by the hot partition	Nearly all events
Single-writer actor per event section	All requests for a section go to one in-memory owner that serializes them and logs to durable storage	Very high throughput; no lock contention	Needs routing, failover and log replay	Mega on-sales built in-house
Redis holds plus database purchases	Holds in memory; tickets in the database	Fast holds	Two sources of truth during holds	Large on-sales with an existing Redis tier
Pre-assigned inventory per sales channel	Allocate seat blocks to channels or regions	Removes global contention	Stranded inventory in one channel	Multi-channel distribution
Lottery instead of on-sale	Registration, random draw, then purchase windows	Removes the spike entirely	Not real time; product change	Demand far above supply

55.8.15 Interview discussion

Pacing (45 minutes). Requirements (5 min: reserved seats, holds, on-sale spike); estimates (5 min: averages are tiny, the spike is everything; compute q^*); architecture (10 min: Figure 55.17); deep dives (20 min: double booking three ways with SQL, holds with TTL and payment extension, waiting room and fairness); failures and scaling (5 min).

Likely follow-ups. *How do you hold two adjacent seats atomically?* One conditional update over both rows, all or nothing, in one transaction (or one Lua script). *What if the hold expires during payment?* Extend once on purchase; if still lost, void the authorization. *How do you stop bots?* Verified registration, one position per account, signed single-use access tokens, purchase limits. *Why not just scale the database?* The contention is on a few thousand rows of one event; more machines do not help a single hot row.

What distinguishes senior and staff answers. A senior candidate writes an atomic hold and adds a waiting room. A staff candidate compares row locks, optimistic updates and Redis holds with their failure modes, keeps a database constraint as the final guard, handles the late-payment race explicitly, and makes admission inventory-aware rather than purely capacity-based.

55.8.16 Production considerations

- **Observability.** For each on-sale: queue length, admission rate, unheld seats, hold success rate, 409 rate on holds (stale maps), hold-to-purchase conversion, unique-vi-

olation count (should be zero outside Redis failovers), payment authorization latency.
- **Security.** Signed and identity-bound tokens; rate limits per account, device and card; anomaly detection on queue joins; barcodes that rotate on mobile tickets to defeat screenshots.
- **Cost.** On-sales are short; pre-scale the edge and purchase flow for the scheduled time and scale down afterwards, rather than running peak capacity all year.
- **Operations.** Every major on-sale is a planned event with a rehearsal (load test against a copy of the venue), a war room, and pre-agreed decisions such as when to pause admission.

55.9 Payment system

55.9.1 Problem statement

Design the payment system behind a marketplace such as the ones in this chapter: riders pay for trips (§55.4), shoppers for orders (§55.7), fans for tickets (§55.8); the platform keeps a commission and pays out drivers, sellers and organizers. Card processing is done by external **payment service providers** (PSPs) that talk to card networks and banks; our system decides what to charge, calls PSPs, records every movement of money, pays out balances and proves, every day, that its records agree with the PSPs' and the bank's.

An old-fashioned bookkeeper is the right analogy. Every movement of money is written twice — once where it came from, once where it went — in ink, in a book whose pages are never torn out; mistakes are corrected by writing a new, opposite entry. At the end of each day the bookkeeper compares the book with the bank statement, line by line. The distinctive hard problem is **exactly-once money movement**: networks lose responses, PSPs time out, webhooks arrive twice or out of order, and yet each customer must be charged exactly once and each seller paid exactly once. No component can deliver exactly once on its own; the system achieves it as **at-least-once delivery plus idempotent processing at every hop** (§32.9), with a **double-entry ledger** that makes errors detectable and **reconciliation** that catches what everything else missed.

Evidence: Illustrative — a teaching design; published practices of Stripe and Airbnb are cited where used.

55.9.2 Functional requirements

1. Create a payment for an amount and currency, authorize it on a stored or new payment method, capture it fully or partially later, void an uncaptured authorization, and refund captured funds fully or partially.
2. Store payment methods without storing card numbers (tokenization).

3. Route each payment to one of several PSPs; process their asynchronous notifications (webhooks).
4. Record every money movement in a double-entry ledger: customer payments, PSP fees, platform commission, seller balances, refunds, chargebacks, payouts, currency conversion.
5. Pay out seller balances to bank accounts on a schedule.
6. Reconcile daily against PSP settlement reports and bank statements, surfacing every unexplained difference.
7. Support many currencies.

Out of scope: fraud scoring (Chapter 82), tax calculation, invoicing, and card network internals.

55.9.3 Non-functional requirements

Table 55.19 — Non-functional requirements for the payment system.

Property	Target
Double charge	Zero caused by our retries; every client-visible operation idempotent
Ledger correctness	Every transaction balances per currency; ledger is append-only and immutable
Durability	RPO = 0 for payments and ledger; retention of financial records for years (jurisdiction-dependent, often 7 or more)
Availability	99.99% for the payment API (the PSP's availability is a separate dependency)
Latency	p99 < 2 s for authorization, dominated by the PSP and the card network
Consistency	Linearizable per payment; balances derived from the ledger, never edited directly
Reconciliation	100% of transactions matched or explained within two business days
Compliance	PCI DSS scope minimized: no raw card numbers in our systems
Auditability	Every change attributable to an actor and time; tamper-evident logs (§10.12)

55.9.4 Capacity estimation

FORMULA

Duplicate charges from blind retries

$$D = n \times p_t \times p_s$$

Symbol	Meaning	Units
D	Duplicate charges per day if timed-out requests are retried without idempotency	charges/day
n	Payment requests per day	requests/day
p_t	Fraction of requests whose response is lost or times out at the client	—
p_s	Fraction of those timed-out requests that had actually succeeded	—

WORKED EXAMPLE

Worked example — volume, storage and why idempotency is not optional. Assumptions: 50 million payments per day; peak 5× average; on average 6 ledger lines per payment over its life (authorization, capture, fee, commission, payout share, occasional refund); 200 bytes per ledger line; 2 inbound webhooks per payment; 1 KB per idempotency record kept 24 hours or more; 0.1% of requests time out at the client, half of them after succeeding.

1. **Payments.** $5 \times 10^7 / 86,400 = 579$/s average; peak $2,894 \approx 2,900$/s.
2. **Ledger lines.** $5 \times 10^7 \times 6 = 3 \times 10^8$/day; $\times 200$ bytes $= 60$ GB/day; $\times 365 = 21.9$ TB/year; seven years $= 153$ TB before replication.
3. **Webhooks.** 10^8/day $= 1,157$/s average.
4. **Idempotency store.** $5 \times 10^7 \times 1,000 = 50$ GB per day of retention.
5. **Duplicates without idempotency.** $D = 5 \times 10^7 \times 0.001 \times 0.5 = 25,000$ double charges per day.

Interpretation. The request rate is modest — a few thousand per second — but the ledger grows forever, and even a 0.1% timeout rate would double-charge tens of thousands of people a day. *Engineering implication.* Throughput is not the challenge; correctness under retries and long-term storage are. Design the ledger for append-only growth with partitioning by time and account, and make every hop idempotent.

55.9.5 API design

```
POST /v1/payments                          Idempotency-Key: 3f6c...   (required)
  { "amount": 1840, "currency": "USD", "customer_id": "c_9",
    "payment_method": "pm_tok_7f",          # a token from the vault, never a card num-
ber
    "capture": "manual", "order_ref": "o-113-55",
    "splits": [ {"account": "seller:s42", "amount": 1564}, {"account":
"platform:commission", "amount": 276} ] }
  -> 201 { "payment_id": "pay_123", "status": "AUTHORIZED", "amount_capturable": 1840 }
  -> 202 { "payment_id": "pay_123", "status": "PROCESSING" }      # outcome not yet
known
  -> 402 { "payment_id": "pay_123", "status": "DECLINED", "decline_code":
"insufficient_funds" }

POST /v1/payments/{id}/capture          Idempotency-Key: ...   { "amount": 1840 }
POST /v1/payments/{id}/void             Idempotency-Key: ...
POST /v1/refunds                        Idempotency-Key: ...   { "payment_id":
"pay_123", "amount": 500 }
GET  /v1/payments/{id}                  -> 200 { status, amounts, attempts: [...],
ledger_txn_ids: [...] }
GET  /v1/accounts/{account}/balance?currency=USD   -> 200 { "available": ..., "pending":
..., "as_of_seq": ... }
POST /v1/payouts                        Idempotency-Key: ...   { "account":
"seller:s42", "currency": "USD" }

# Inbound from PSPs
POST /webhooks/psp/{provider}           (signature header, raw body)  -> 200 quickly,
process asynchronously
```

What to notice: the idempotency key is **required** on every mutating call, and the response for a repeated key is the stored original response (§22.15.3). The API can return `PROCESSING` honestly when the PSP outcome is unknown, rather than guessing. Amounts are integers in the currency's **minor unit**.

55.9.6 Data model and database schema

A relational database with serializable or carefully designed conditional updates (§11.13) is the natural home: payments need transactions, constraints and auditability far more than they need horizontal write scale at a few thousand per second. Partition by merchant or account when one cluster is not enough (§14.7).

```
        CREATE TABLE payments (
          payment_id     VARCHAR(32)  PRIMARY KEY,
          customer_id    VARCHAR(32)  NOT NULL,
          amount         BIGINT       NOT NULL CHECK (amount > 0),     -- minor units
          currency       CHAR(3)      NOT NULL,                        -- ISO 4217
          status         VARCHAR(16)  NOT NULL,                        -- see Figure
55.22
          captured       BIGINT       NOT NULL DEFAULT 0,
          refunded       BIGINT       NOT NULL DEFAULT 0,
          psp            VARCHAR(16),
          version        INT          NOT NULL DEFAULT 0,
          created_at     TIMESTAMPTZ  NOT NULL,
          CHECK (captured <= amount AND refunded <= captured)
        );

        -- One row per call to a PSP; the PSP idempotency key is derived and stored be-
fore the call.
        CREATE TABLE payment_attempts (
          attempt_id     VARCHAR(32)  PRIMARY KEY,
          payment_id     VARCHAR(32)  NOT NULL REFERENCES payments,
          operation      VARCHAR(12)  NOT NULL,                        -- AUTHORIZE |
CAPTURE | VOID | REFUND
          psp_idem_key   VARCHAR(64)  NOT NULL UNIQUE,
          psp_reference  VARCHAR(64),
          outcome        VARCHAR(12)  NOT NULL,                        -- PENDING |
SUCCEEDED | FAILED | UNKNOWN
          created_at     TIMESTAMPTZ  NOT NULL
        );

        CREATE TABLE idempotency_keys (                                -- §22.15.3
          account_id     VARCHAR(32)  NOT NULL,
          idem_key       VARCHAR(255) NOT NULL,
          request_hash   CHAR(64)     NOT NULL,
          state          VARCHAR(12)  NOT NULL,                        -- IN_PROGRESS |
COMPLETED
          response_code  INT,
          response_body  JSONB,
          locked_until   TIMESTAMPTZ,
          PRIMARY KEY (account_id, idem_key)
        );

        -- The ledger: append-only. No UPDATE or DELETE is ever granted on these tables.
        CREATE TABLE ledger_transactions (
          txn_id         BIGINT       PRIMARY KEY,                     -- monotonically
increasing sequence
          source_type    VARCHAR(16)  NOT NULL,                        --
PAYMENT_CAPTURE, REFUND, PAYOUT, FX, ...
          source_id      VARCHAR(64)  NOT NULL,
          posting_key    VARCHAR(96)  NOT NULL UNIQUE,                 -- idempotent
posting
          effective_at   TIMESTAMPTZ  NOT NULL,
          created_at     TIMESTAMPTZ  NOT NULL
        );
        CREATE TABLE ledger_lines (
          txn_id         BIGINT       NOT NULL REFERENCES ledger_transactions,
          line_no        SMALLINT     NOT NULL,
```

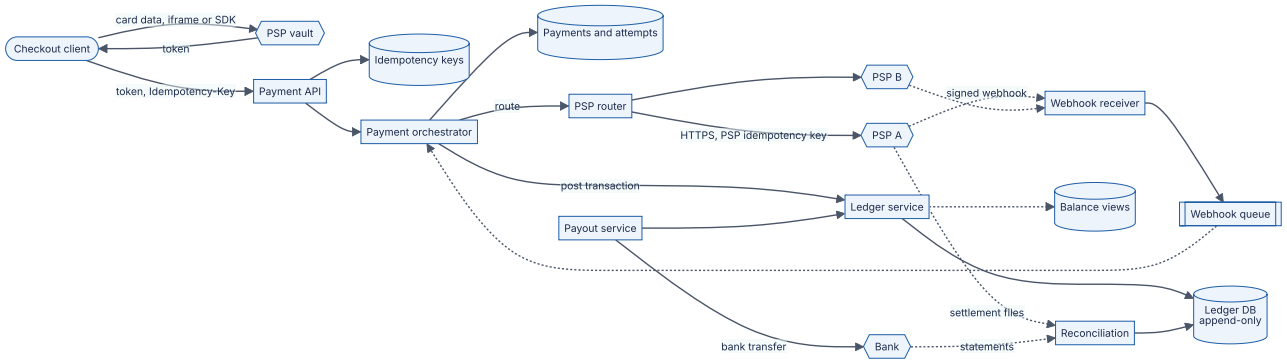
```
  account        VARCHAR(64)  NOT NULL,                    -- e.g.
seller_payable:s42
  currency       CHAR(3)      NOT NULL,
  amount         BIGINT       NOT NULL,                    -- + debit, -
credit, minor units
  PRIMARY KEY (txn_id, line_no)
);

CREATE TABLE webhook_events (
  provider       VARCHAR(16)  NOT NULL,
  event_id       VARCHAR(64)  NOT NULL,
  received_at    TIMESTAMPTZ  NOT NULL,
  raw_body       BYTEA        NOT NULL,
  processed_at   TIMESTAMPTZ,
  PRIMARY KEY (provider, event_id)                          -- duplicate de-
liveries collapse here
);
```

The balance invariant — every ledger transaction sums to zero per currency — cannot be expressed as a single-row `CHECK`; it is enforced by the posting code inside the inserting transaction (below), verified by a deferred check, and re-verified continuously by an independent auditor job.

55.9.7 High-level architecture

Figure 55.21 — Payment system architecture.



Reading the diagram. Card details go straight from the client to the PSP's vault through a hosted field or SDK and come back as a token, so our servers never see a card number. The payment API checks the idempotency store, then hands the request to the orchestrator, which records the payment and each attempt before calling a PSP through the router (which picks a provider by cost, method, region and health). PSP responses come back synchronously; later state changes (captures settling, disputes, refunds completing) arrive as signed webhooks, which the receiver stores and queues for asynchronous processing. Every money movement is posted to the ledger service as a balanced transaction; balances are derived views. The payout service moves seller balances to banks, again through the ledger. Reconciliation compares the ledger with PSP settlement files and bank statements daily. Storage boundaries: idempotency store, payments data-

base, append-only ledger, derived balances. Failure points: PSP timeouts (unknown outcome), webhook storms or gaps, and ledger posting failures; each is handled in §55.9.8. Scaling: the ledger partitions by account and time; PSP calls scale with router capacity and provider limits.

55.9.8 Detailed component design

Component 1: the double-entry ledger

FORMULA

Double-entry balance invariant

$$\sum_{\ell \in t,\ \mathrm{cur}(\ell)=c} a_\ell = 0 \quad \text{for every transaction } t \text{ and currency } c, \qquad B(x,c) = \sum_{\ell:\ \mathrm{acct}(\ell)=x,\ \mathrm{cur}(\ell)=c} a_\ell$$

Symbol	Meaning	Units
t	A ledger transaction (a set of lines posted atomically)	—
ℓ	A ledger line	—
a_ℓ	Signed amount of line ℓ : positive debit, negative credit	minor units
c	Currency (ISO 4217 code)	—
$B(x,c)$	Balance of account x in currency c , derived from all its lines	minor units

WORKED EXAMPLE

Worked example — one marketplace payment. A buyer pays $100.00 (10,000 cents). The PSP keeps $3.20; the platform's commission is 15%; the seller is owed the rest.

1. **Commission.** $0.15 \times 10,000 = 1,500$. **Seller share.** $10,000 - 1,500 = 8,500$. **PSP will settle.** $10,000 - 320 = 9,680$.
2. **Lines.** Debit `psp_receivable` +9,680; debit `psp_fees` +320; credit `seller_payable:s42` −8,500; credit `commission_revenue` −1,500.
3. **Check.** $9,680 + 320 - 8,500 - 1,500 = 0$. Balanced.
4. **Partial refund of $25.00**, shared proportionally: seller gives back $0.85 \times 2,500 = 2,125$, platform $0.15 \times 2,500 = 375$. Lines: debit `seller_payable:s42` +2,125; debit `commission_revenue` +375; credit `psp_receivable` −2,500. Sum: $2,125 + 375 - 2,500 = 0$.
5. **Seller balance.** $B = -8,500 + 2,125 = -6,375$, a credit balance: the platform owes the seller $63.75.

Interpretation. Money never appears or disappears; it moves between accounts, and every account's balance is the sum of its lines. *Engineering implication.* An unbalanced transaction is a bug caught at write time; a balance that disagrees with the sum of its lines is corruption caught by the auditor; a difference between `psp_receivable` and what the PSP actually paid is caught by reconciliation.

Design rules:

1. **Immutable lines.** Never update or delete. A mistake is fixed by a **reversal** transaction (the exact negation) plus a correct new one, so the history shows what was believed and when.
2. **Balanced at write.** The posting function rejects any transaction whose lines do not sum to zero per currency, inside the same database transaction that inserts them.
3. **Idempotent posting.** Each transaction has a `posting_key` derived from its business cause (`capture:pay_123`, `refund:re_9`); the unique constraint turns a re-delivered event into a no-op.
4. **Balances are derived.** Materialized balance views are updated in the same transaction (or by a consumer of the ledger stream) and stamped with the last `txn_id` included, so readers know how fresh a balance is; the auditor recomputes them from lines.
5. **Accounts model obligations, not just cash.** `psp_receivable` (money a PSP owes us), `seller_payable` (money we owe a seller), `psp_fees`, `commission_revenue`, `fx_clearing:EUR`. A balance on `psp_receivable` that does not drain after settlement is a reconciliation break.

```
        from collections import defaultdict
        from dataclasses import dataclass

        @dataclass(frozen=True)
        class Entry:
            account: str
            amount: int          # minor units; + debit, - credit
            currency: str

        class Ledger:
            """Append-only double-entry ledger with idempotent posting."""
            def __init__(self):
                self.journal = []                       # immutable list of (txn_id, en-
tries)
                self.seen = {}                          # idempotency key -> txn_id
                self.balances = defaultdict(int)        # (account, currency) -> balance

            def post(self, idem_key, entries):
                if idem_key in self.seen:               # a retry: return the original
result
                    return self.seen[idem_key]
                per_ccy = defaultdict(int)
                for e in entries:
                    per_ccy[e.currency] += e.amount
                if any(per_ccy.values()):
                    raise ValueError(f"unbalanced transaction: {dict(per_ccy)}")
                txn_id = f"txn_{len(self.journal) + 1}"
                self.journal.append((txn_id, tuple(entries)))
                for e in entries:
                    self.balances[(e.account, e.currency)] += e.amount
                self.seen[idem_key] = txn_id
                return txn_id

            def trial_balance(self):
                totals = defaultdict(int)
                for (_, ccy), bal in self.balances.items():
                    totals[ccy] += bal
                return dict(totals)

        L = Ledger()
        # Marketplace books: a buyer pays $100.00; the provider keeps $3.20;
        # the platform keeps a 15% commission; the seller is owed $85.00.
        capture = [Entry("psp_receivable", 9680, "USD"),
                   Entry("psp_fees", 320, "USD"),
                   Entry("seller_payable:s42", -8500, "USD"),
                   Entry("commission_revenue", -1500, "USD")]
        print(L.post("pay_123:capture", capture))
        print(L.post("pay_123:capture", capture))         # retry: same txn, no second
posting
        # Partial refund of $25.00: seller and platform give back their shares;
        # the provider keeps its fee in this example.
        print(L.post("pay_123:refund_1", [Entry("seller_payable:s42", 2125, "USD"),
                                          Entry("commission_revenue", 375, "USD"),
                                          Entry("psp_receivable", -2500, "USD")]))
        try:
            L.post("bad", [Entry("psp_receivable", 100, "USD"),
```

```
Entry("seller_payable:s42", -99, "USD")])
        except ValueError as e:
            print("rejected:", e)
        print("owed to seller s42:", -L.balances[("seller_payable:s42", "USD")])
        print("trial balance:", L.trial_balance(), "| journal rows:", len(L.journal))
```

Output:

```
txn_1
txn_1
txn_2
rejected: unbalanced transaction: {'USD': 1}
owed to seller s42: 6375
trial balance: {'USD': 0} | journal rows: 2
```

What to notice: the retried capture returns `txn_1` again and adds no row; the unbalanced posting is rejected before anything is written; and the trial balance — the sum of all balances per currency — is zero, which is the property the auditor job checks continuously over the real ledger.

> INDUSTRY EXAMPLE
>
> **Ledgers at Stripe.** Stripe has described Ledger, an internal system that records its financial data as an immutable, auditable log using double-entry bookkeeping, so that money movements can be checked to balance and unexplained movements detected; it reports that Ledger underpins a data-quality platform that explains the vast majority of its money movement automatically [Stripe 2024]. *Evidence: Primary* — [Stripe 2024]

Component 2: idempotency from the button to the bank

Exactly-once money movement is built from at-least-once delivery plus idempotence at every hop. Follow one key through the system.

1. **Client.** The checkout page generates an idempotency key when the customer reviews the order and stores it with the cart; every retry of “Pay” reuses it (§22.15.1).
2. **Payment API.** Inserts `(account_id, idem_key)` as `IN_PROGRESS` with a request fingerprint; a concurrent duplicate gets 409; a completed duplicate gets the stored response (§22.15.3).
3. **Payment attempt.** Before calling a PSP, the orchestrator **persists** an attempt row with a deterministic PSP idempotency key (`pay_123:auth:1`). Only then does it call the PSP with that key. If the process crashes after the call, the restarted orchestrator finds the attempt row and retries with the *same* key, so the PSP deduplicates.
4. **Unknown outcomes.** A PSP timeout leaves the attempt `UNKNOWN` . Never retry it with a new key and never assume failure. Instead: retry with the same key (safe), or

query the PSP for the attempt's status, or wait for the webhook; until resolved, the payment is `PROCESSING` and the customer is told so.

5. **Webhooks.** Each PSP event has a unique ID; the receiver inserts it into `webhook_events` with `(provider, event_id)` as the primary key, so a re-delivered event is stored once and processed once.
6. **Ledger posting.** Each business event posts with a deterministic `posting_key`; re-processing the same event cannot post twice.
7. **Payouts.** A payout is created with an idempotency key per seller and period, and the bank transfer reference is derived from it, so a retried payout job does not pay twice.

INDUSTRY EXAMPLE

Idempotency in practice. Stripe's API accepts an `Idempotency-Key` header on mutating requests and returns the stored result of the first request for retries with the same key; Stripe's engineering blog explains that clients must be able to retry safely because networks fail ambiguously [Leach 2017; Stripe Docs: idempotent requests]. Airbnb described building a shared idempotency library, Orpheus, for its payments services, so that each request's effects are recorded under an idempotency key and retries of failed or ambiguous requests cannot cause double payments [Chew 2019]. *Evidence: Primary* — [Leach 2017; Stripe Docs: idempotent requests; Chew 2019]

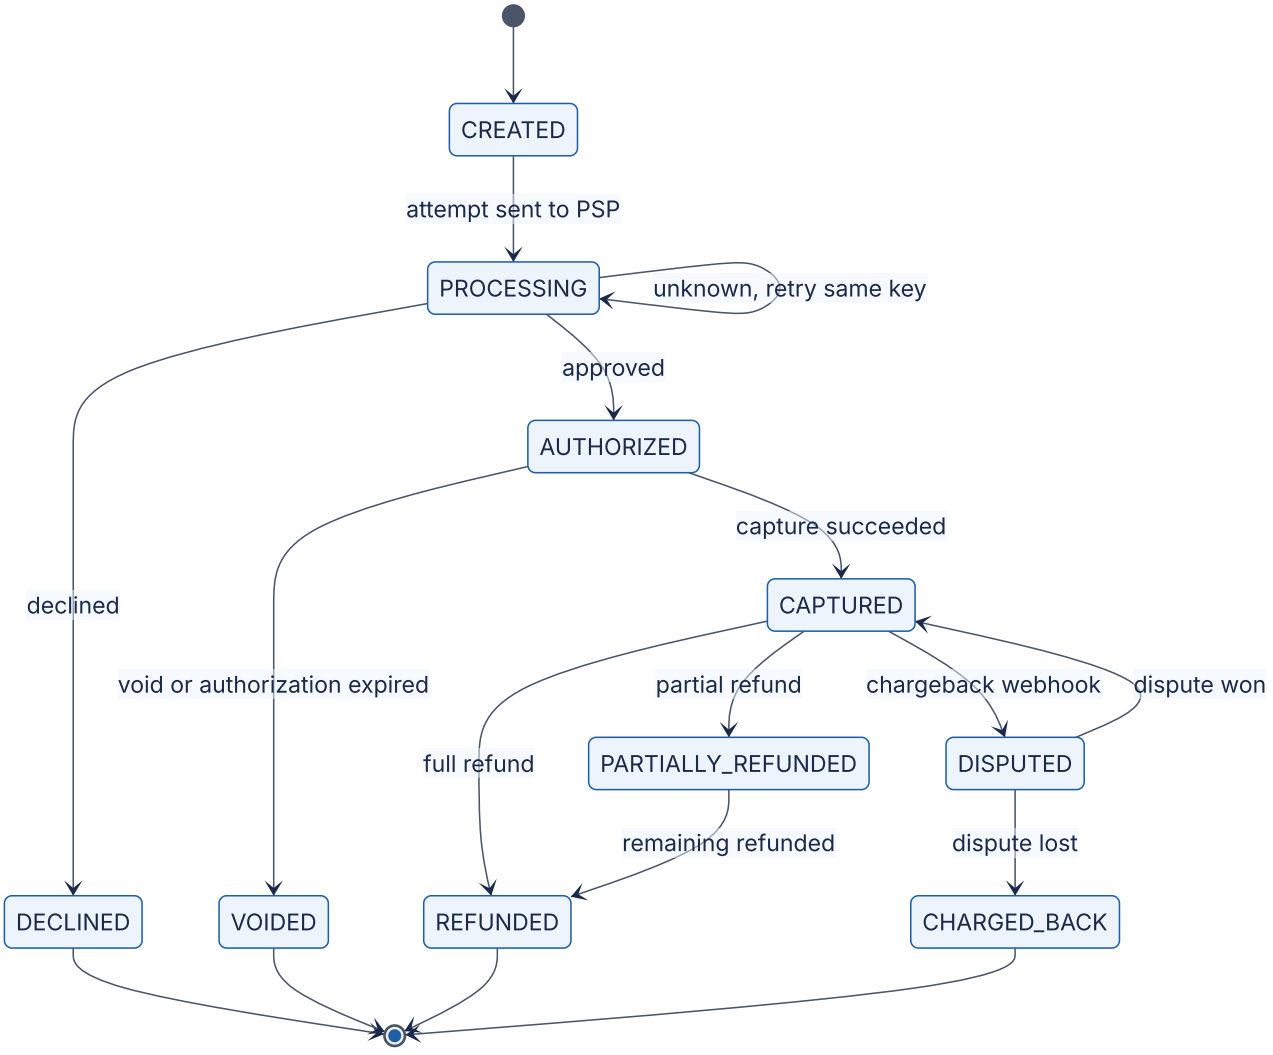
COMMON MISTAKE

"We use Kafka exactly-once, so payments are exactly once." Broker-level exactly-once (§31.11) covers reads and writes *within* the broker's transactions. A call to a PSP or a bank is an external side effect that no broker transaction can roll back. Exactly-once money movement needs idempotency keys honored by the external party and reconciliation for the cases where even that fails.

Component 3: PSP integration and webhooks

A card payment has a synchronous part and an asynchronous part. Authorization returns synchronously (approved or declined in a second or two). Capture is acknowledged quickly, but funds **settle** days later, and some events — disputes, refunds that fail, asynchronous payment methods such as bank debits — arrive only by webhook.

Figure 55.22 — Payment state machine.



Reading the diagram. Transitions come from synchronous PSP responses (authorization, capture) or from webhooks (disputes, settlement). `PROCESSING` loops while the outcome is unknown; it is never resolved by guessing. Each transition that moves money posts a ledger transaction with a deterministic posting key. Because webhooks can arrive late or out of order, a transition is applied only if it is valid from the current state; an older event (for example “authorized” arriving after “captured”) is recorded and ignored.

Webhook handling rules:

1. **Verify** the signature over the raw body with the provider’s secret, and reject events whose signed timestamp is too old (replay protection). Stripe, for example, signs webhook payloads with HMAC-SHA256 and includes a timestamp in the signature header [Stripe Docs: webhooks].
2. **Store, acknowledge, then process.** Insert into `webhook_events` and return 200 within a few hundred milliseconds; process from a queue. Slow processing must not cause the provider to retry and amplify load.
3. **Deduplicate** by `(provider, event_id)`; **order-tolerate** by applying only valid forward transitions; when in doubt, fetch the current object from the PSP’s API and act

on that, not on the event's snapshot.
4. **Detect gaps.** A payment stuck in `PROCESSING` for longer than a threshold triggers an active status query; webhooks are a notification, not the only source of truth.

Multiple PSPs add resilience and cost leverage: the router chooses by payment method, issuing country, fees, recent authorization rates and health. Failover between PSPs must never retry the *same* attempt at a different PSP while the first outcome is unknown, or the customer may be charged by both; resolve the first attempt (void or confirm failure) before routing elsewhere.

Component 4: reconciliation

Reconciliation is the safety net under every other mechanism. Each day:

1. **Ingest** PSP settlement reports (every transaction, fee and payout the PSP made) and bank statements (every deposit and withdrawal).
2. **Match** three ways: internal ledger lines ↔ PSP report lines (by PSP reference and amount) ↔ bank deposits (PSP payout batches by amount and date).
3. **Classify** differences: *timing* (captured today, settles tomorrow: expected, auto-resolved later), *missing internally* (PSP charged but we have no record — the dangerous case, often an unresolved `UNKNOWN`), *missing externally* (we recorded a capture the PSP did not perform), *amount mismatches* (fees, FX, partial captures).
4. **Resolve**: auto-fix known patterns by posting correcting ledger transactions with references to the break; route the rest to a finance operations queue with an aging SLA.
5. **Report**: unexplained balance on `psp_receivable` per PSP and currency, break counts and age; these are top-level health metrics of the payment system.

Component 5: PCI scope minimization and multi-currency

PCI scope. Any system that stores, processes or transmits cardholder data, or can affect its security, is in scope of the PCI Data Security Standard (version 4.0 published in 2022; version 4.0.1, a limited revision, in 2024) [PCI SSC 2024]. Shrink the scope by never touching card numbers: the browser or app sends them directly to the PSP's hosted fields or SDK, which returns a token (tokenization, §50.10). Our systems store the token, brand, last four digits and expiry only. Merchants whose payment pages are fully outsourced this way can typically validate with the shortest self-assessment questionnaire rather than a full assessment. The remaining in-scope surface — the page that embeds the hosted fields — still needs integrity controls against script injection.

Multi-currency. Store amounts as integers in minor units with an ISO 4217 code; the number of minor units differs by currency (0 for JPY, 2 for USD and EUR, 3 for KWD), so formatting and rounding must use the currency's exponent, never a hard-coded 100.

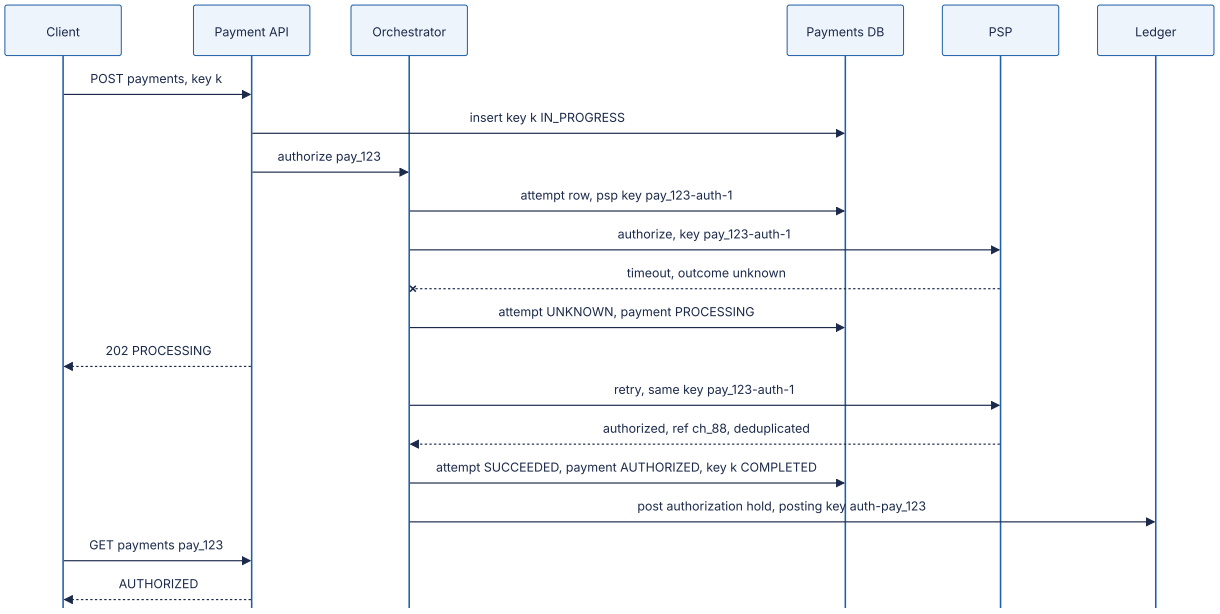
Never add amounts in different currencies. A conversion is an explicit ledger transaction through per-currency FX clearing accounts at a locked rate:

```
txn fx:pay_77  (buyer pays 50.00 EUR; seller is paid in USD at a locked rate of 1.0800)
  debit   psp_receivable       +5000 EUR
  credit  fx_clearing:EUR      -5000 EUR
  debit   fx_clearing:USD      +5400 USD
  credit  seller_payable:s9    -5400 USD
```

Each currency's lines sum to zero on their own. The FX clearing accounts accumulate the platform's currency position, which treasury hedges or settles, and any difference between the locked rate and the rate actually obtained is posted as FX gain or loss.

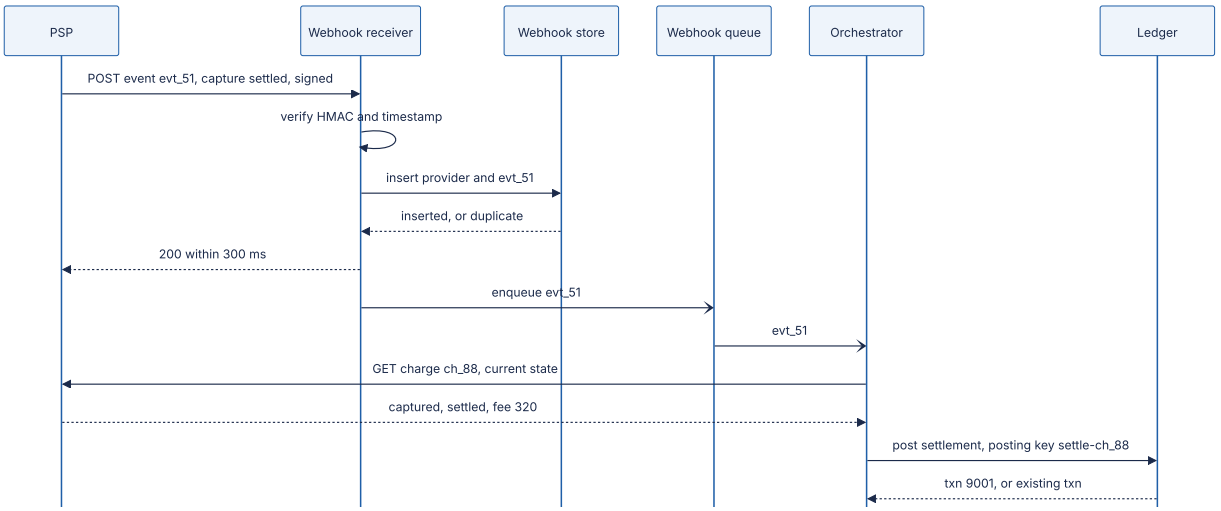
55.9.9 Data flow

Figure 55.23 — Write path: an authorization whose response is lost.



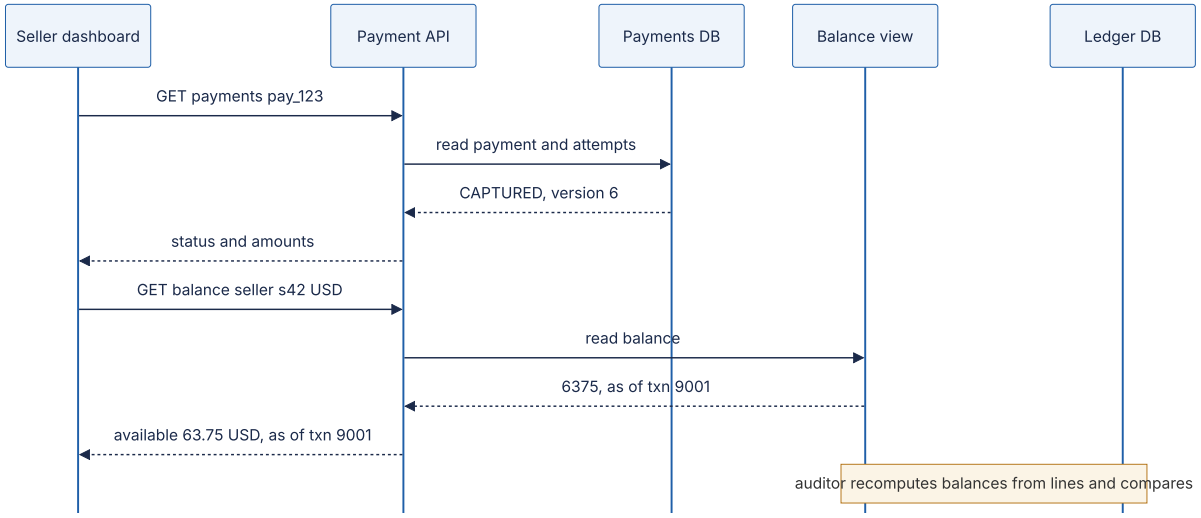
Reading the diagram. The API claims the client's key before any work, and the orchestrator persists the attempt and its PSP key before calling the PSP: these two writes are what make every later retry safe. The PSP call times out; the orchestrator records the outcome as unknown and the client is told `PROCESSING` rather than an error. The retry uses the same PSP key, so the PSP returns the original authorization instead of creating a second one. Only then is the state advanced and a ledger transaction posted with a deterministic key. Synchronous: client to API, orchestrator to PSP; the client learns the final state by polling or push. Failure points: a crash between steps (resume from the attempt row), a PSP that does not honor idempotency keys (query by attempt reference before retrying, and rely on reconciliation).

Figure 55.24 — Asynchronous write path: webhook to ledger.



Reading the diagram. The receiver does three things synchronously — verify, store, acknowledge — and nothing else, so the PSP sees fast 200s and does not retry. A duplicate delivery hits the primary key and is acknowledged without being enqueued again. Processing is asynchronous from a queue: the orchestrator fetches the current object from the PSP (so out-of-order or stale events cannot regress state) and posts a ledger transaction whose posting key makes a second processing a no-op. Failure points: an invalid signature (reject and alert: misconfiguration or attack), a processing backlog (the queue absorbs it; age-of-oldest alerts), a missing webhook (the stuck-state detector queries the PSP).

Figure 55.25 — Read path: payment status and seller balance.



Reading the diagram. Status reads come from the payments database, which holds the current state machine position; balance reads come from a materialized view stamped with the last ledger transaction it includes, so the dashboard can show “as of” and a payout can require a view at least as fresh as a given transaction. Reads never sum millions of ledger lines on the request path. An independent auditor recomputes balances from

ledger lines offline and alerts on any difference. All calls are synchronous; the view is updated asynchronously from the ledger or in the posting transaction.

55.9.10 Bottlenecks

1. **Hot accounts.** Every payment credits `commission_revenue` and debits `psp_receivable`; updating one balance row per payment serializes all postings. Derive these balances asynchronously, or split them into sub-accounts per partition and sum on read.
2. **PSP rate limits and latency** bound throughput at peaks; smooth with queues for non-interactive operations (captures, refunds) and spread across providers.
3. **Ledger growth.** Partition ledger lines by time; keep recent partitions hot and older ones in cheaper storage, still queryable for audits.
4. **Reconciliation batch windows** for large volumes: incremental matching through the day rather than one nightly job.

55.9.11 Failure scenarios

Table 55.20 — Failure scenarios for the payment system.

What fails	Impact	Detection	Recovery	Prevention
PSP timeout	Unknown authorization	Attempt in `UNKNOWN`	Retry with same key; query status; webhook	Persisted attempts; PSP idempotency
Crash after PSP success, before DB update	PSP charged; our record says pending	Stuck `PROCESSING` detector	Resume from attempt row, query PSP, post ledger	Attempt row written before the call
Webhook delivered twice or out of order	Double processing or state regression	Duplicate-key hits; invalid transitions	Dedupe table; forward-only transitions	Fetch current object before acting
Webhooks stop arriving	States not advancing	Age of last webhook per PSP	Poll PSP APIs	Gap detection; reconciliation
Unbalanced posting attempted	Would corrupt books	Posting function rejects	Fix the producer; nothing written	Balance check inside the transaction
Ledger and PSP disagree	Money unaccounted for	Reconciliation break	Correcting entries; finance investigation	Daily three-way reconciliation
Failover to a second PSP mid-attempt	Customer charged twice	Two successful attempts for one payment	Refund one automatically	Never re-route while first outcome unknown
Payout job retried	Seller paid twice	Duplicate bank references	Recall transfer; recover	Idempotent payout keys

55.9.12 Scaling strategy

At 10× (29,000 payments per second at peak), the payments database partitions by merchant or customer, the ledger by account with time partitions, and hot platform accounts become partitioned sub-accounts. Idempotency storage moves to the same partition as the payment, so the key check and the payment write share one local transaction. **At 100×**, go regional: payments, ledgers and PSP connections per region (data residency often requires it anyway, §44.9), with cross-region money movement modeled as explicit ledger transactions between regional clearing accounts, reconciled like any external counterparty.

55.9.13 Trade-offs

- **Synchronous certainty versus honest uncertainty:** returning `PROCESSING` complicates clients but is the only truthful answer after a timeout.
- **Authorize-then-capture versus immediate capture:** cheap cancellations versus authorization expiry and two calls per payment.
- **Real-time balances versus derived balances:** real-time balance rows create hot spots; derived views are slightly stale but scale.
- **One PSP versus several:** simpler integration and reconciliation versus resilience, better approval rates and price leverage.
- **Relational ledger versus specialized ledger databases:** relational gives constraints and familiarity; purpose-built ledger stores give append-only guarantees and throughput at very large scale.

55.9.14 Alternative designs

Table 55.21 — Recording money: approaches compared.

Approach	How it works	Advantages	Disadvantages	Choose when
Mutable balance column	`UPDATE accounts SET balance = balance - x`	Simple	No history; errors invisible; hot rows	Never for real money
Single-entry transaction log	One row per payment	Easy reporting	Cannot prove money is conserved	Simple stores relying on the PSP's books
Double-entry ledger, relational (this design)	Balanced, immutable lines	Invariants, audit, reconciliation	More rows; discipline needed	Platforms holding or splitting funds
Event-sourced payments plus ledger projection	Payment events as the source; ledger derived (§32.3)	Full replay	Projection bugs must be rebuildable	Teams already event-sourced
Purpose-built ledger database	Specialized store enforcing double entry	Throughput, built-in invariants	New technology; integration	Very high posting rates

55.9.15 Interview discussion

Pacing (45 minutes). Requirements (5 min: authorize, capture, refund, payouts, reconciliation; zero double charges); estimates (5 min: modest throughput, large ledger, the duplicate-charge arithmetic); architecture (10 min: Figure 55.21); deep dives (20 min: idempotency at every hop with the timeout scenario of Figure 55.23, the double-entry ledger with a worked transaction, webhooks and reconciliation); PCI and multi-currency (5 min).

Likely follow-ups. *How do you guarantee exactly once?* You do not, per hop; you make every hop idempotent and retry. *What if the PSP does not support idempotency keys?* Record the attempt reference, query before retrying, and rely on reconciliation. *Why not floats for money?* Binary floating point cannot represent 0.10 exactly; use integer minor units. *How do you correct a wrong ledger entry?* Post a reversal and a correct entry; never edit. *What is in PCI scope?* Only what touches card data; tokenize so that is almost nothing.

What distinguishes senior and staff answers. A senior candidate uses idempotency keys, a state machine and a ledger. A staff candidate traces the key through every hop including PSP and payouts, handles the unknown outcome explicitly, refuses to fail over between PSPs while an outcome is unknown, designs reconciliation as a first-class system, removes hot-account contention, and treats PCI scope as an architectural decision rather than a compliance afterthought.

55.9.16 Production considerations

- **Observability.** Authorization rate per PSP, card brand and country; latency; count and age of `UNKNOWN` attempts; webhook lag per PSP; ledger posting failures; reconciliation breaks by category and age; trial-balance check result (must always be zero).
- **Security.** Least-privilege access to payment data; no `UPDATE` or `DELETE` grants on ledger tables; tamper-evident audit logs (§10.12); secrets for PSP and webhook signing in a secrets manager (§10.8); four-eyes approval for manual ledger corrections and payouts.
- **Cost.** PSP fees dominate; routing by cost and approval rate is worth more than any infrastructure saving. Ledger storage grows linearly; tier old partitions.
- **Operations.** Finance operations is a user of this system: break queues, correction tooling with approvals, and clear runbooks for PSP outages (“pause captures, keep authorizing on the secondary PSP”). Rehearse PSP failover and webhook outages as game days.

55.10 Summary and revision notes

SUMMARY

- **Find the small strongly consistent core inside the large eventually consistent system.** Trip state, driver claims, inventory reservations, seat holds and ledger postings need conditional writes or transactions; positions, availability displays, tiles and traffic only need freshness.
- **Uber (§55.4).** About 1,000 trip requests/s against 500,000 location updates/s ($U = N_{\text{online}}/\Delta t$): a telemetry system with a transactional core. Location goes to an in-memory H3 cell index and a log, never to the trip database. Trips are persisted state machines with compare-and-set on a version and a transactional outbox. Prices are fixed in signed quotes; cities are isolation boundaries.
- **Ride matching (§55.5).** Expand hexagon rings until enough candidates are found, plus one safety ring ($C(k) = \rho(1 + 3k(k+1))A_{\text{cell}}$). Score a shortlist by road ETA, not distance. Batched assignment beats greedy (7.5 vs 3.5 min in the two-rider trap; 14% lower in the random test) at the cost of up to one window of latency. One driver, one ride: a lease-based claim returns a fencing token, and the accept commits trip and driver rows in one local transaction guarded by version and token.
- **Google Maps (§55.6).** The tile pyramid grows as 4^z; vector tiles to about zoom 14 with client overzoom replace hundreds of terabytes of raster per style. Versioned, immutable tile URLs make CDN caching trivial. Dijkstra is A* with $h = 0$; an admissible but weak bound saved only 27% in the grid test; contraction hierarchies trade preprocessing for queries that settle hundreds of nodes, and need re-customization (CRP) or re-scoring for live traffic.
- **Amazon (§55.7).** Product pages are a caching and fan-out problem; checkout is a saga (create order, reserve with TTL, authorize as pivot, confirm, capture at shipment). Reserve at order time, not at add-to-cart. A single inventory row serializes at about $1/t_h$; size sub-counters with $N \geq \lceil \lambda_w t_h / u \rceil$ and gate flash-sale demand.
- **Ticket booking (§55.8).** Seats are unique rows; holds are leases. Row locks, optimistic conditional updates and Redis holds all work with different contention and failure behavior; keep a database unique constraint on tickets as the final guard. Waiting rooms admit at a rate bounded by both backend capacity and unheld inventory; $q^* = S/(bc)$ tells you who will get tickets.
- **Payments (§55.9).** Exactly-once money movement is at-least-once plus idempotence at every hop: client key, API key store, persisted PSP attempt with a deterministic key, webhook deduplication, posting keys, payout keys. Treat a timeout as unknown, never as failure. The double-entry ledger is immutable and balanced per currency; balances are derived; reconciliation against PSP

> and bank is a first-class system. Tokenize to keep card data, and PCI scope, out of your systems; store money as integer minor units with ISO 4217 codes.

55.11 Knowledge checkpoint

1. Why should driver location updates never be written to the trip database?
2. What does compare-and-set on a trip's `version` prevent, and what does the loser of the race do?
3. With 1.5 million drivers online reporting every 3 s at 150 bytes, what are the update rate and ingress bandwidth?
4. Why does ring expansion stop one ring *after* the target candidate count is reached?
5. How many hexagons are in a 3-ring, and how many idle drivers do you expect at resolution 9 with a density of 4 drivers/km²?
6. Give a two-rider, two-driver example where greedy matching is worse than batched matching.
7. Why is a TTL lock on a driver not sufficient on its own to prevent double dispatch?
8. How many tiles are there at zoom 12, and in all levels from 0 to 12?
9. Why does A* remain exact only when the heuristic is admissible?
10. Why do contraction hierarchies struggle with live traffic, and name one remedy.
11. Why reserve inventory at order placement rather than at add-to-cart?
12. A hot item's row lock is held 4 ms per reservation and 3,000 attempts/s reach the store; how many sub-counters at 70% utilization?
13. What race does `SELECT ... FOR UPDATE ... ORDER BY seat_id` avoid, and what does `SKIP LOCKED` add?
14. In a waiting room with 30,000 seats, 2 tickets per order and 75% conversion, at which position does the event sell out?
15. Why must a payment orchestrator persist the PSP attempt row *before* calling the PSP?
16. Why should a webhook receiver acknowledge before processing, and how does it avoid double processing?
17. Show that the capture transaction in §55.9.8 balances, and explain how a wrong ledger entry is corrected.
18. How do you represent ¥1,500 and $15.00 in the ledger, and why not floats?

Answers

1. They arrive 500,000 times per second and are obsolete in seconds; the trip database would be sized for telemetry. They belong in an in-memory index plus an append-only log.
2. Two actors applying conflicting transitions (cancel versus accept) based on the same old state. The loser's update changes zero rows; it reloads the trip and acts on

the true state.

3. $1.5 \times 10^6 / 3 = 500,000$ updates/s; $500,000 \times 150 = 75$ MB/s $= 0.6$ Gb/s.
4. Reaching the count bounds how many candidates you have, not how close they are: a k-ring is jagged, so a nearer driver may sit in the next ring. The haversine sort trims the excess.
5. $1 + 3 \times 3 \times 4 = 37$ hexagons; $37 \times 0.105 = 3.885$ km^2 $\times 4 = 15.5$ drivers.
6. Riders at 1.0 and 2.2 km, drivers at 1.8 and 0.0 km on a line: greedy gives rider 1 the driver at 1.8 (0.8 km) and rider 2 the driver at 0 (2.2 km), 3.0 km total; batched gives 1.0 + 0.4 = 1.4 km.
7. A paused or partitioned holder can act after its lock expired, and an asynchronously replicated lock store can lose a lock on failover. The commit must check a fencing token in the database that stores the assignment.
8. $4^{12} = 16,777,216$; $(4^{13} - 1)/3 = 22,369,621$.
9. A* stops when the destination is popped; if h overestimates somewhere, a node on the true shortest path may be ranked behind the destination, so a worse path is returned.
10. Shortcut weights bake in travel times at preprocessing; changed weights invalidate them. Remedies: customizable route planning (fast re-customization), or CH on typical weights followed by re-scoring candidate routes with live speeds.
11. Carts are often abandoned; stock locked in carts for days would cause undersell. Reserving at order placement with a short TTL holds stock only while a purchase is actually in progress.
12. $\lceil 3,000 \times 0.004 / 0.7 \rceil = \lceil 17.1 \rceil = 18$.
13. Ordering avoids deadlocks between transactions locking overlapping seat sets in different orders; `SKIP LOCKED` lets best-available buyers take different free seats instead of waiting on the same locked rows.
14. $q^* = 30,000/(2 \times 0.75) = 20,000$.
15. If the process crashes after the PSP call, the restarted orchestrator must retry with the same PSP idempotency key; a key that existed only in memory would be lost, and a new key could charge twice.
16. Slow processing would make the provider time out and redeliver, amplifying load. A primary key on `(provider, event_id)` collapses duplicates; deterministic posting keys make re-processing a no-op.
17. $9,680 + 320 - 8,500 - 1,500 = 0$. Corrections post a reversal (exact negation) and a new correct transaction; lines are never edited.
18. `(1500, "JPY")` (exponent 0) and `(1500, "USD")` (exponent 2): same integer, different meaning, so the currency code is always stored. Binary floats cannot represent most decimal fractions exactly and accumulate rounding errors.

55.12 Interview questions

Basic

Q1. How would you show nearby cars to millions of riders without a million queries per second against the index? Answer. Compute one snapshot per occupied hexagon per second (cars within its k-ring) and send the same snapshot to every rider in that hexagon over their stream or from a cache. Cost scales with occupied hexagons, not riders; one second of staleness is invisible on a map.

Q2. What is a vector tile and why is it preferred over raster tiles? Answer. A tile containing geometry and attributes (as protocol buffers with integer tile-local coordinates) rendered by the client. One pyramid serves all styles, languages and pixel densities, supports overzoom so the pyramid can stop around zoom 14, and is smaller; the cost is client rendering work and a more complex build.

Q3. Why does a payment API require an idempotency key? Answer. A client that times out cannot know whether the charge happened; it must retry. With a key chosen before the first attempt, the server recognizes the retry and returns the original result instead of charging again (§22.15).

Intermediate

Q4. Design dispatch so that a driver is never assigned two rides. Answer. Claim the driver with a conditional update (`IDLE` to `OFFERED`) that increments a fencing token and sets a lease longer than the offer deadline. The accept commits, in one local transaction on the city shard, the trip's `MATCHING` to `DRIVER_ASSIGNED` (guarded by trip version) and the driver's `OFFERED` to `ASSIGNED` (guarded by the token). A late accept carries an old token and fails; a crashed matcher's lease expires.

Q5. How do you sell 5,000 units of a deal to 1 million interested customers without melting the inventory database? Answer. Static deal page from the CDN; an in-memory token gate admitting roughly as many buyers as units (with a small overbooking margin); sub-counters sized by $N \geq \lceil \lambda_w t_h / u \rceil$; per-account limits and bot defenses; short reservation TTLs; the database's conditional update remains the authority, so the approximate gate can only over-admit attempts, never oversell.

Q6. Compare row locks, optimistic updates and Redis holds for seat booking. Answer. Row locks queue waiters and need ordered locking; good for low contention and `SKIP LOCKED` best-available. Optimistic conditional updates fail fast and are the best default. Redis holds give the highest throughput but can be lost on failover, so keep a unique constraint on tickets as the final guard and void the losing payment.

Advanced

Q7. A PSP call times out and the user taps "Pay" again. Walk through what happens end to end. Answer. The client resends with the same idempotency key; the API finds the key `IN_PROGRESS` (409, retry later) or `COMPLETED` (stored response). The orchestrator's attempt row is `UNKNOWN`; it retries the PSP with the same PSP key, queries status, or awaits the webhook. It never retries with a new key or fails over to another PSP until the outcome is resolved. When resolved, state advances and the ledger posts with a deterministic posting key. Reconciliation catches any case where the PSP charged without our record.

Q8. Your routing service uses contraction hierarchies. Product wants routes that reflect accidents within two minutes. What do you change? Answer. Keep CH (or CRP) for candidate generation; apply closures as live weight overrides; re-score the top candidate routes with live segment speeds and the ETA model; or move to customizable route planning, whose customization step can rerun every minute or two. Version graph artifacts with the map so tiles and routes agree, and fall back to historical profiles when traffic is stale.

Q9. How would you make a stadium on-sale fair and survivable? Answer. Pre-registration with identity verification; a pre-queue randomized at the start time, then first in, first out; signed, identity-bound queue tokens served at the edge; admission rate bounded by purchase-flow capacity (Little's Law) *and* unheld inventory; atomic multi-seat holds with TTL and a payment-pending extension; a unique constraint on tickets; honest messaging for positions beyond q^*; and a rehearsed war-room plan.

55.13 Practical exercises

1. **Ring expansion.** Install the `h3` Python package and replace the square cells in the §55.5.8 program with H3 resolution-9 cells and `grid_disk`. For densities 0.3, 2 and 8 drivers/km², record the ring radius reached and compare with $C(k)$.
2. **Batch window experiment.** Extend the matching simulation with arrivals over time (Poisson, 30 requests/s) and drivers becoming free after trips. Plot mean pickup ETA plus mean waiting-for-batch time for windows of 0, 1, 2 and 4 s.
3. **Better heuristics.** Add landmark (ALT) lower bounds to the routing program: precompute Dijkstra distances from 4 corner landmarks and use $\max_L |d(L,t) - d(L,v)|$. Report nodes settled versus the top-speed heuristic.
4. **Seat-hold race.** In PostgreSQL, create the `seats` table, then run 50 concurrent clients trying to hold the same two seats with (a) check-then-update without a condition, (b) the conditional update, (c) `FOR UPDATE`. Count double holds and throughput.

5. **Ledger auditor.** Extend the §55.9.8 ledger with multi-currency FX transactions and write an auditor that recomputes balances from the journal, checks per-currency trial balances and reports any account whose stored balance differs.
6. **Idempotent webhook receiver.** Write a small HTTP endpoint that verifies an HMAC-SHA256 signature with a timestamp tolerance, stores events by `(provider, event_id)`, returns 200 immediately and processes asynchronously; test it with duplicated and reordered deliveries.

55.14 Design challenges

1. **Food delivery dispatch.** Extend §55.5 to couriers who carry two orders at once from different restaurants. Define the assignment problem (now a vehicle-routing problem with time windows), choose a batching strategy, and keep the one-courier-per-order invariant with fencing tokens.
2. **Offline maps.** Design downloadable offline regions for Google Maps: package size per region from the tile formula, an on-device routing graph, incremental updates when the map version changes, and how online traffic is merged when connectivity returns.
3. **Global flash sale.** A product launch sells 200,000 units worldwide in one minute from regional fulfillment networks. Design per-region inventory allocation, a global waiting room, rebalancing of unsold regional stock, and the payment authorization surge with two PSPs.
4. **Marketplace payouts.** Design weekly payouts to 5 million sellers in 40 currencies: ledger accounts, FX conversion, batching to banks, idempotent payout keys, handling returned transfers, and reconciliation of bank statements. Estimate ledger lines and storage per year.

55.16 Open verification items

- Ranney 2015 (QCon London) and Hoff 2015: confirm DISCO, S2 sharding, Ringpop and “driver phones as backup storage” against the talk video or slides; the callout relies on secondary summaries.
- Geisberger et al. 2008: confirm the reported sub-millisecond query times and pre-processing duration on the European road network before quoting numbers.
- Xu et al. 2018 (DiDi, KDD): confirm the full author list and the description of windowed bipartite matching with learned values.
- Chew 2019: confirm that the Airbnb post names the idempotency library “Orpheus”.
- Stripe 2024 Ledger post: confirm the publication date (about February 2024) and author attribution.
- Ticketmaster 2022: the statement (3.5 billion system requests, four times previous peak; over 2 million tickets sold) was reportedly removed from Ticketmaster’s site; confirm via an archived copy.
- Gray 2006: confirm the “more than 100 services per page” wording in the Vogels interview.
- Ringpop-node repository URL and description.

Chapter 56 — Case Studies V: Data Platforms

> **Level:** 3–4 · **Track:** A (Traditional) · **Estimated reading time:** 4 h

The four systems in this chapter have something in common that sets them apart from the services of Chapters 52–55: their main product is not a record that a user created, but **derived data** computed from enormous streams of other data. A search engine turns the web into an index; a recommender turns behavior logs into ranked lists; a monitoring platform turns telemetry into dashboards and pages; an analytics platform turns events into aggregates. In each, the request path is only the visible tip. Below it sits a pipeline that ingests, transforms, stores and refreshes data continuously, and the design is judged as much by how fresh, complete and cheap that derived data is as by how fast a single request returns.

Each case emphasizes a different hard problem, summarized in Table 56.1.

Table 56.1 — The four cases and their distinctive hard problems.

Case	Distinctive hard problem
§56.4 Search engine	Serving one query from an index spread over hundreds of machines, within a tail-latency budget, while the index is rebuilt and refreshed underneath it
§56.5 Recommendation system	Fitting a multi-stage funnel (retrieve, filter, rank, re-rank) and its feature fetches into about 200 ms, and logging exactly what was served so the models can learn
§56.6 Logging and monitoring platform	Ingesting bursty, multi-tenant telemetry cheaply, choosing what to index, and keeping alerting reliable when everything else is on fire
§56.7 Real-time analytics platform	Producing correct aggregates over out-of-order events, exactly once, and serving them in under a second

56.1 Learning objectives

After this chapter you should be able to:

- Design a web-scale search engine end to end: crawl, document-partitioned index build, a scatter–gather serving tree, staged ranking and freshness tiers, and size its serving fleet from query rate and corpus size.
- Design the serving architecture of a multi-stage recommender, allocate a latency budget across candidate generation, filtering, feature fetch, ranking and re-ranking,

and decide what to precompute and what to compute online.
- Design the logging pipeline that turns served recommendations into training data without training–serving skew.
- Design a multi-tenant logging and monitoring platform: agents, Kafka buffering, index-versus-columnar log storage, a metrics time-series store, retention tiers, and an alerting path that survives the failures it reports.
- Control observability cost with ingestion quotas, cardinality limits and sampling, and estimate storage per retention tier.
- Design a real-time analytics platform using event-time windows, watermarks and exactly-once aggregation, choose between stream pre-aggregation and an OLAP store, and justify a Lambda or Kappa architecture.
- Run each of these designs as a 45-minute interview, including the follow-up questions that separate senior from staff answers.

56.2 Prerequisites

Table 56.2 — Concept chapters each case applies.

Case	Concept chapters it leans on
All	Capacity estimation and percentiles — §2.11, §4.8; caching — Chapter 20; Kafka — Chapter 31; multi-tenancy — Chapter 47; cost — Chapter 51
§56.4 Search engine	Inverted indexes, BM25, distributed search and autocomplete — §16.3–§16.9; tail latency and hedged requests — §23.6–§23.7; batch processing — §29.4; web crawler case — §52.10
§56.5 Recommendation system	Caching patterns — §20.7; feature stores and training–serving skew — Chapter 62; recommendation modeling — Chapter 68; ANN search — Chapter 74; event-driven pipelines — §32.6
§56.6 Logging and monitoring	Observability, cardinality and alerting — Chapter 40; time-series databases — §12.8; columnar storage — §13.13; rate limiting — §22.3–§22.8; object storage tiers — §15.9
§56.7 Real-time analytics	Stream processing, windows, watermarks, Flink — §29.8–§29.9; Lambda and Kappa — §29.10; Kafka transactions — §31.11; exactly-once limits — §32.9; columnar storage — §13.13

56.3 How to use these case studies

Work through these cases with the method set out in §52.3: read the problem statement, then close the book and produce your own requirements, estimates and architecture before comparing; treat every number as an assumption to be challenged rather than a fact

about any company; follow the cross-references whenever a mechanism is summarized in a sentence instead of re-taught; and rehearse the interview pacing plan in each case's §N.15 out loud against a clock. Because the systems here are pipelines, add one habit specific to this chapter: for every design, trace one piece of data from its source to the moment a user sees its effect, and write down the delay contributed by each hop. That **freshness trace** is where most of the interesting trade-offs in data platforms hide.

56.4 Search Engine (web-scale)

56.4.1 Problem statement

Design a general-purpose web search engine. A user types a few words; within a few hundred milliseconds the engine returns ten links with titles and snippets, ordered so that the most useful page is first. Behind that page sit tens of billions of documents that the engine discovered by crawling the web, parsed, deduplicated, scored for quality and inverted into an index that no single machine can hold or search in time.

The system is three pipelines joined by storage: a **crawler** that fetches pages (designed in §52.10), an **indexer** that turns fetched pages into searchable index shards, and a **serving system** that answers queries against those shards. The distinctive hard problem is the serving system: every query must consult every part of an index partitioned across hundreds of machines, so the response time is set by the slowest of hundreds of parallel calls (§4.8.4), at more than 100,000 queries per second, while the index underneath is continuously replaced with fresher versions.

The inverted index itself, BM25, segment merging and Elasticsearch internals are taught in Chapter 16; this case applies them at a scale where the engineering choices change.

56.4.2 Functional requirements

1. **Search.** Given a query string, a locale and optional filters (language, safe search, time range), return a page of ten ranked results, each with URL, title and a query-dependent snippet, plus an estimated result count and pagination.
2. **Autocomplete.** As the user types, return up to ten query suggestions for the current prefix.
3. **Freshness.** Breaking news and fast-changing pages become searchable within minutes; popular pages reflect changes within a day; the long tail within weeks.
4. **Removals.** Legally required removals and pages that now return 404 disappear from results within hours, regardless of when the next index build happens.
5. **Spell correction and query understanding.** Correct obvious misspellings and expand synonyms (consumed as a service; not designed here).

Out of scope: ads, image and video verticals, knowledge panels, personalization and the ranking models themselves. The search-ranking models are the subject of §81.7 (Search Ranking case study); this case stops at the hand-off.

56.4.3 Non-functional requirements

Table 56.3 — Search engine non-functional requirements.

Property	Target	Why
Availability (query serving)	99.99% of queries answered; partial answers count as degraded, not failed	Search is the front door; users retry elsewhere within seconds
Server-side latency	p50 ≤ 100 ms, p99 ≤ 300 ms	Leaves room for network and rendering under a ~1 s perceived budget
Autocomplete latency	p99 ≤ 30 ms server-side	Suggestions must keep up with typing (§16.9.1)
Freshness	News tier ≤ 5 min; daily tier ≤ 24 h; base tier ≤ 30 days	Different content changes at different rates
Removal propagation	≤ 1 h for legal removals; ≤ 24 h for dead pages	Legal obligation and result quality
Consistency	Eventual; replicas may differ by one index version for minutes	A user cannot detect that two replicas differ slightly
Durability	Crawl repository and URL state: no loss of more than one day; index: derived, rebuildable	Re-crawling 30 billion pages takes weeks

Notice what is *not* demanded: strong consistency. The index is derived data, and two users seeing slightly different results for the same query is acceptable. That freedom is what makes aggressive replication, caching and partial answers possible.

56.4.4 Capacity estimation

All figures use decimal units (1 TB = 10^{12} bytes) and illustrative assumptions; they describe a teaching design, not any company's fleet.

WORKED EXAMPLE

Worked example — Query traffic. Assumptions: 5 billion queries per day; peak-to-average ratio 2 (traffic is global, so the diurnal swing is smaller than for a single-country service); each query produces on average 3 autocomplete requests while it is typed; a results cache answers 30% of queries.

1. Average query rate: $5 \times 10^9 / 86,400 = 57,870$ queries/s.
2. Peak query rate: $57,870 \times 2 = 115,741$ queries/s.
3. Autocomplete: $3 \times 5 \times 10^9 = 1.5 \times 10^{10}$ requests/day → 173,611/s average, **347,222/s at peak**.
4. Queries reaching the index after the cache: $115,741 \times (1 - 0.30) = 81,019$ queries/s at peak.
5. Result-page egress at 60 KB per page: $115,741 \times 60,000 \times 8 = 55.6$ Gbit/s at peak.

Interpretation. Autocomplete is three times the query rate but each request is tiny and cacheable; the index serving system sees about 81,000 expensive queries per second. **Engineering implication.** Size the index fleet for the post-cache rate, but plan for the cache to fail: a cold cache raises index load by $1/(1 - 0.3) = 1.43\times$ (§20.13).

WORKED EXAMPLE

Worked example — Index size and shard count. Assumptions: $N = 3 \times 10^{10}$ documents in the base tier; 400 distinct terms per document after analysis; 3 bytes per posting including compressed term frequency and positions (§16.3.4–§16.3.5); 1 KB per document of per-document ranking signals (the **forward index**); 4 KB per document of compressed text for snippets (the **document store**).

1. Inverted index: $3 \times 10^{10} \times 400 \times 3 = 3.6 \times 10^{13}$ B **= 36 TB**.
2. Forward index: $3 \times 10^{10} \times 1,000 = 30$ TB.
3. Document store: $3 \times 10^{10} \times 4,000 = 120$ TB.
4. Choose shards of 10^8 documents: $S = 3 \times 10^{10} / 10^8 = 300$ shards. Each holds 36 TB/300 = 120 GB of postings and 100 GB of forward index, which fit a 256 GB leaf server's memory and local flash respectively; the 400 GB per shard of document store lives on separate document servers.

Interpretation. The postings that every query touches total only 36 TB; the bulk of the bytes is text needed only for the ten winning results. **Engineering implication.** Split the index servers (all postings, touched by every query) from the document servers (text, touched for ten documents per query), as Google's published architecture did [Barroso et al. 2003].

The serving fleet is sized by CPU, because every query does work on every shard.

FORMULA

Index serving fleet

$$\text{Cores} = \frac{\lambda_{\text{peak}}\,(1-h)\,S\,c}{U} \qquad R = \lceil \frac{\text{Cores}}{S\,k} \rceil$$

Symbol	Meaning	Units
λ_{peak}	Peak query rate arriving at the search front end	queries/s
h	Results-cache hit ratio	dimensionless
S	Number of document-partitioned shards each query visits	count
c	CPU time one shard spends on one query	core-seconds
U	Target CPU utilization of leaf servers	dimensionless
k	Cores per leaf server (one shard per leaf)	cores
R	Number of complete replicas of the index needed	count

WORKED EXAMPLE

Worked example — How many leaf servers? Use $\lambda_{\text{peak}} = 115,741$, $h = 0.3$, $S = 300$, $c = 4$ ms (per-shard retrieval with WAND-style skipping, §16.5.6), $U = 0.5$, $k = 64$.

1. CPU per query across all shards: $300 \times 0.004 = 1.2$ core-seconds.
2. Cores: $81,019 \times 1.2/0.5 = 194,444$ cores.
3. Leaf servers: $194,444/64 = 3,038$; replicas $R = \lceil 3,038/300 \rceil = \lceil 10.13 \rceil = 11$.
4. One replica of 300 leaves serves $300 \times 64 \times 0.5/1.2 = 8,000$ queries/s.
5. Spread over three regions so that losing one region leaves at least 11: put 6 replicas in each region, 18 in total, or **5,400 leaf servers**.

Interpretation. Because $S \times c$ is the CPU to search the whole corpus once, the fleet grows with *query rate × corpus size*: doubling either doubles the cost, regardless of how you shard. Sharding decides latency; replication decides throughput.
Engineering implication. The levers that cut cost are those that reduce work per query: caching (h), early termination, and tiering so that most queries search only the best part of the corpus (§56.4.12).

WORKED EXAMPLE

Worked example — Crawl bandwidth, repository and index distribution. Assumptions: 4 billion fetches per day (an average revisit interval of $3 \times 10^{10} / 4 \times 10^{9} = 7.5$ days, weighted toward popular pages in practice); 50 KB of HTML per page; 4:1 compression in the repository; base index rebuilt weekly.

1. Fetch rate: $4 \times 10^{9} / 86,400 = 46,296$ pages/s.
2. Inbound bandwidth: $46,296 \times 50,000 \times 8 = 18.5$ Gbit/s.
3. Repository writes: $4 \times 10^{9} \times 12,500 = 50$ TB/day; latest copy of every page: $3 \times 10^{10} \times 12,500 = 375$ TB, or 562.5 TB with 1.5× erasure-coding overhead (§15.6).
4. Distributing a new base index: 36 TB × 18 replicas = 648 TB per weekly build, a sustained $648 \times 10^{12} / (7 \times 86,400) = 1.07$ GB/s.

Interpretation. Pushing the index to the fleet moves more bytes per week than the crawler fetches in a day. The fetch rate is also about 23 times the 2,000 pages/s of the §52.10 design, so that crawler's host-partitioned fleet must scale out by the same factor. **Engineering implication.** Distribute shards peer to peer or by tree fan-out rather than from one source, ship deltas where possible, and stagger the swap so that capacity never drops below $R = 11$.

The results cache is small by comparison: 200 million cached result pages at 5 KB each (ten document IDs, snippets and metadata) is 1 TB, spread across a cache tier (Chapter 20).

56.4.5 API design

The external API is deliberately thin; the interesting interfaces are the internal RPCs of the serving tree.

```
GET /search?q=noise+canceling+headphones&hl=en-US&start=0&num=10&safe=moderate
200 OK
{ "query_id": "q-7f3a…", "corrected_query": null, "estimated_total": 48200000,
  "results": [ { "url": "https://…", "title": "…", "snippet": "…<b>noise</b>…",
                 "index_tier": "base", "crawl_time": "2026-10-30T08:12:00Z" } ],
  "next_start": 10, "partial": false }

GET /complete?q=noise+can&hl=en-US
200 OK
{ "suggestions": ["noise canceling headphones", "noise canceling earbuds", …] }
```

```
        // Internal RPCs (illustrative)
        service Leaf {
          // Search one shard; return top-k candidates with cheap features for later
ranking stages.
          rpc Search(LeafRequest) returns (LeafResponse);
        }
        message LeafRequest {
          QueryPlan plan = 1;            // analyzed terms, operators, filters, per-term
weights
          uint32 k = 2;                  // candidates to return, e.g. 50
          uint64 index_version = 3;      // pin all shards of one request to one index
version where possible
          uint32 deadline_ms = 4;        // remaining budget; leaf returns best-so-far
when it expires
        }
        message LeafResponse {
          repeated Candidate candidates = 1;   // doc_id, score, small feature vector
          bool truncated = 2;                  // early-terminated by deadline
        }
        service DocServer {
          rpc Snippets(SnippetRequest) returns (SnippetResponse);  // doc_ids + query
terms -> title, URL, snippet
        }
```

`partial: true` tells the client (and the logs) that one or more shards did not answer in time; the page is still shown. `index_version` lets a request avoid mixing two versions of a shard set during a rollout. `deadline_ms` propagates the remaining budget downward (§22.11) so a leaf never works on an answer nobody is waiting for.

56.4.6 Data model and database schema

The engine has four kinds of storage, each with a different access pattern.

Table 56.4 — Search engine data stores.

Data	Key design	Store and justification
URL state (crawl schedule, last fetch, content hash, canonical URL, quality signals)	Row key = reversed host + path (`com.example.www/a/b`), so a site's URLs are contiguous	Wide-column store (§12.6): billions of rows, random updates from the crawler, scans by site for politeness and deduplication
Repository (fetched pages)	Content hash → compressed HTML, plus URL → latest hash	Distributed file system or object store (§15.4–§15.5): large immutable blobs, written once, read in bulk by index builds
Index shards (postings, lexicon, forward index)	Shard ID + index version → immutable files	Built offline, copied to leaf servers' memory and flash; never updated in place (§16.6.1)
Document store	Doc ID → compressed text and metadata	Separate shard set, read for ten documents per query

A URL-state row looks like this (column families in a Bigtable-style store):

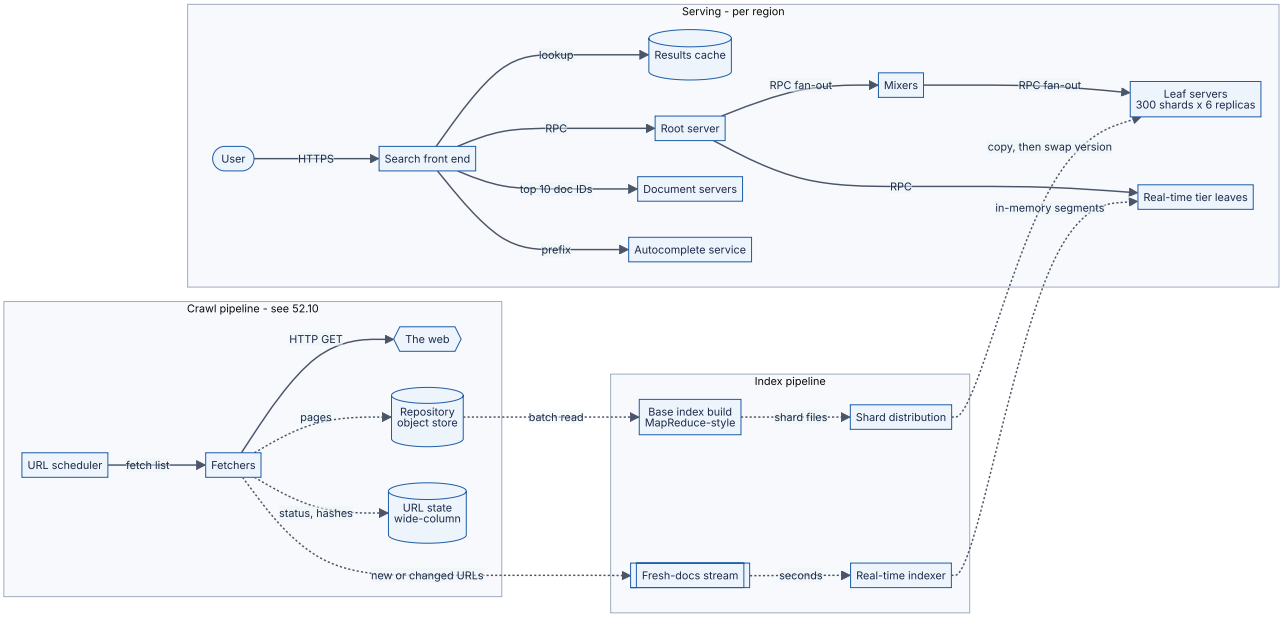
```
row key:  com.example.www/products/headphones
  crawl:   last_fetch=2026-10-30T08:12Z  next_fetch=2026-11-06T00:00Z  http_status=200
etag="…"
  content: sha256=9c1e…  simhash=0x8f3a…  length=48211  lang=en
  links:   inlinks_count=1832  canonical=com.example.www/products/headphones
  signals: static_quality=0.82  spam_score=0.03  doc_id=000001842377
```

Two decisions in this model matter more than the store choice:

1. **Document IDs are assigned in static-quality order within each shard.** A page's query-independent quality (link-based authority such as PageRank [Brin and Page 1998], spam score, freshness) is known before any query arrives. Numbering documents so that better pages get smaller IDs means postings lists are walked best-first, and a leaf can stop early once it has found enough good candidates.
2. **Shards are assigned by document, not by term.** Each shard is a complete small index over its 10^8 documents (§16.7.1). Documents are assigned by a hash of the canonical URL, which spreads every site and every topic evenly, so no shard is hot for any particular query.

56.4.7 High-level architecture

Figure 56.1 — Web search engine: crawl, index and serve.



Reading the diagram. Three subgraphs are three independently scaled systems joined only through storage and streams. In the **crawl pipeline** the scheduler hands fetch lists to fetchers, which make HTTP requests to the web, write compressed pages asynchronously (dotted arrows) to the repository, and update the URL-state table; §52.10 de-

signs this part. In the **index pipeline** a periodic batch job reads the whole repository and builds the base-tier shards, while a stream of new or changed URLs feeds a real-time indexer whose small in-memory segments become searchable in seconds. Shard distribution copies finished shards to leaf servers asynchronously and swaps versions only when a complete replica is ready. In the **serving** subgraph all arrows are synchronous RPCs within a request: the front end checks the results cache, then asks the root, which fans out to mixers and they to the 300 base-tier leaves of one replica, while the root also queries the real-time tier; the front end then fetches snippets for the winning ten documents from document servers. Storage boundaries are the repository, URL state, the leaf servers' local index copies and the document store. Failure points: a slow leaf (tail latency), a bad index version (rolled back by version pin), cache loss (load spike), and the fresh-docs stream lagging (stale news). Scaling: replicas for query rate, shards for corpus size, more mixer levels for fan-out.

56.4.8 Detailed component design

Index construction and sharding by document

The base index is a batch job over the repository, a textbook MapReduce (§29.4):

1. **Parse and deduplicate.** For each fetched page, extract text, links, title and anchors; compute a content fingerprint (for example SimHash) and drop near-duplicates, keeping the canonical URL. On the web a large fraction of pages are duplicates or near-duplicates, and every duplicate kept costs index space and fills result pages with redundant links.
2. **Assign to shard and number.** Shard $= \text{hash(canonical URL)} \mod S$. Within each shard, sort documents by static quality and assign doc IDs in that order.
3. **Map:** emit (shard, term, doc ID, positions) for every term occurrence, plus anchor text attributed to the *target* page, which is often a better description of a page than the page itself, an observation already central to the original Google prototype [Brin and Page 1998].
4. **Shuffle** by (shard, term); **reduce** writes each shard's postings in doc-ID order, compressed (§16.3.4), together with the shard's lexicon and forward index.
5. **Validate.** Before release, run a fixed set of golden queries against the new shard set and compare result overlap and quality metrics with the serving version; refuse to ship a build whose metrics regress beyond a threshold. Index builds fail silently far more often than they fail loudly: a parser bug that drops every title produces a perfectly valid, perfectly useless index.

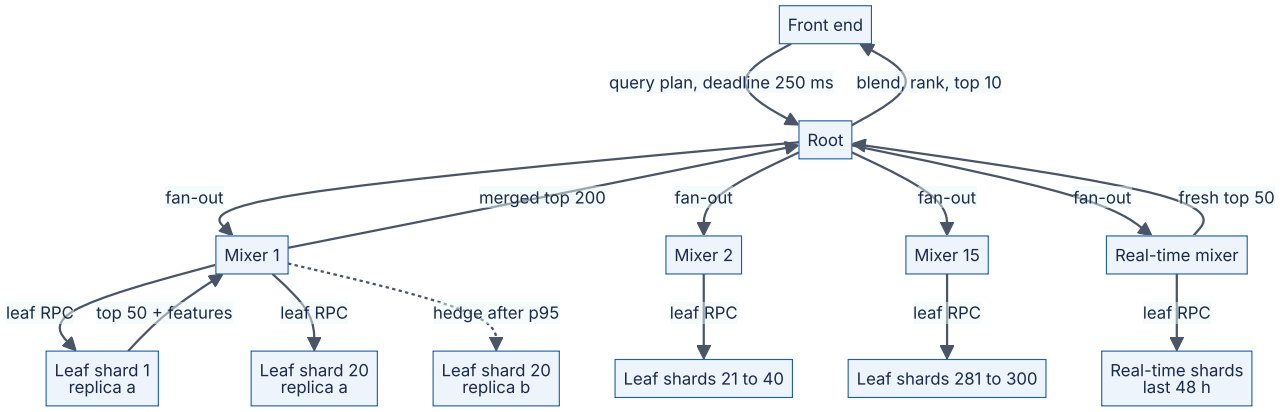
Why not term partitioning, which would let a two-word query visit only two shards? Because at this scale postings for common terms are gigabytes long, every multi-term query would ship them across the network, and popular terms would make their shards permanently hot (§16.7.1). Document partitioning trades a fan-out to every shard for

small, balanced, independent shards, and the fan-out is then a tail-latency problem we know how to manage.

The serving tree and tail latency

A root server cannot hold 300 open RPCs per query and merge 300 lists while staying responsive, so the fan-out is organized as a tree, as Google described in its early cluster architecture and later in Dean's retrospectives [Barroso et al. 2003; Dean 2009]. With 15 mixers each covering 20 leaves, the root merges 15 lists and each mixer merges 20.

Figure 56.2 — Two-level serving tree with a real-time tier.



Reading the diagram. The front end sends a parsed query plan and a deadline to the root. The root fans out synchronously to 15 base-tier mixers and one real-time mixer; each mixer fans out to its 20 leaves (only a few are drawn). Each leaf searches its shard, keeps its best 50 candidates by a cheap score and returns them with a small feature vector; mixers merge to their best 200, and the root blends base and fresh candidates, applies the expensive ranking stages and returns ten document IDs. The dotted edge is a **hedged request**: if leaf 20's replica a has not answered by the mixer's observed p95 for that leaf, the mixer sends the same request to replica b and uses whichever answers first (§23.7). Every leaf is a storage boundary holding one shard in memory. Failure points are any leaf (handled by hedging and partial results), any mixer (its 20 shards vanish unless the root retries another mixer replica), and the root itself (replicated behind the front end's load balancer). Scaling: more leaves per mixer or an extra mixer level as S grows.

Fan-out amplification (§4.8.4, §16.7.3) dictates the leaf latency target. If each leaf's p99 is 40 ms and the 300 leaves were independent, only $0.99^{300} = 4.9\%$ of queries would see every leaf under 40 ms. Four techniques from the tail-latency literature [Dean and Barroso 2013] make the design work:

1. **Hedged requests** to a second replica after the per-leaf p95, costing a few percent extra load (§23.7).
2. **Good-enough partial results.** When the deadline expires, a mixer returns what it has and marks the response partial. Losing one shard of 300 removes 0.33% of the

corpus; for most queries the top ten is unchanged, because the best documents are spread across shards and each shard contributes only its own best.

3. **Canary requests.** A query that crashes a leaf (a "query of death" triggered by a pathological term or a parser bug) would crash all 300 at once. Sending a new query pattern first to one or two leaves, and fanning out only after they answer, bounds the damage to a handful of processes.
4. **Deadline-aware leaves.** A leaf walks postings in static-quality order and checks the propagated deadline; when it expires it returns its best-so-far marked `truncated`. Because good documents come first, truncation costs little relevance.

Ranking stages

Ranking is a funnel in which each stage scores fewer documents with more expensive features. The systems shape is what this case owns; what the models learn is Chapter 81's job.

Table 56.5 — Ranking stages and where they run.

Stage	Runs on	Documents scored per query	Features	Cost per document
Retrieval (L0)	Leaf	Millions of postings walked; ~10^4 matching docs per shard	BM25 per field (§16.5.3), static quality, term proximity	Sub-microsecond
First-pass ranking (L1)	Leaf	~10^4 per shard → keep 50	Small model on cheap features from the forward index	~1 µs
Second-pass ranking (L2)	Root	3,000 merged → keep 100	Learned model with richer query–document features (Chapter 81)	Tens of µs
Final re-ranking	Root / front end	100 → 10	Diversity (no five links from one site), freshness boosts, policy filters, removals	Small

Two systems consequences follow. First, every feature used at L2 must have been either shipped up from the leaf in the candidate's feature vector or be fetchable for 3,000 documents within a few milliseconds; feature placement is a capacity decision. Second, the leaf's choice of 50 candidates bounds recall: a document the leaf discarded can never be rescued by a better model at the root. Raising per-leaf k from 50 to 100 doubles fan-in bytes and L2 work, which is exactly the kind of quality-versus-cost knob that ranking engineers and infrastructure engineers negotiate.

Freshness tiers

A weekly batch rebuild cannot satisfy a five-minute news requirement, and rebuilding 36 TB every five minutes is impossible. The answer is to split the corpus by **rate of change** into tiers that are indexed differently and merged at query time.

Table 56.6 — Index freshness tiers.

Tier	Contents	Size	Index method	Staleness
Real-time	Pages first seen or changed in the last 48 h from news, social and frequently changing sites	~3.5×10^8 docs	Streaming: in-memory segments, refreshed every few seconds (§16.10)	Seconds to minutes
Daily	Popular pages recrawled daily	~2×10^9 docs	Incremental build per shard, swapped daily	≤ 24 h
Base	Everything else	3×10^{10} docs	Full batch rebuild, swapped weekly, shard by shard	Days to weeks
Removal overlay	URLs to suppress (legal removals, 404s, spam)	Millions of entries	Replicated set pushed to every root within minutes	Minutes

A document can exist in several tiers at once (an old version in base, a new version in real-time). The root deduplicates by canonical URL and keeps the newest version; the **removal overlay** is applied last, which is how a legally required removal takes effect in minutes even though the base tier still contains the page until next week.

The real-time tier is sized by its ingest rate: at 2,000 new or changed documents per second over 48 hours it holds $2,000 \times 172,800 = 3.46 \times 10^8$ documents, about 1% of the base tier, which fits comfortably in memory across a few dozen leaves. Published systems follow this split. Twitter's Earlybird served tweets within seconds from in-memory indexes separate from its archive [Busch et al. 2012], and Google's Percolator replaced batch MapReduce rebuilds with incremental, transaction-based processing for its web index, reporting that the average age of documents in search results fell by 50% [Peng and Dabek 2010].

INDUSTRY EXAMPLE

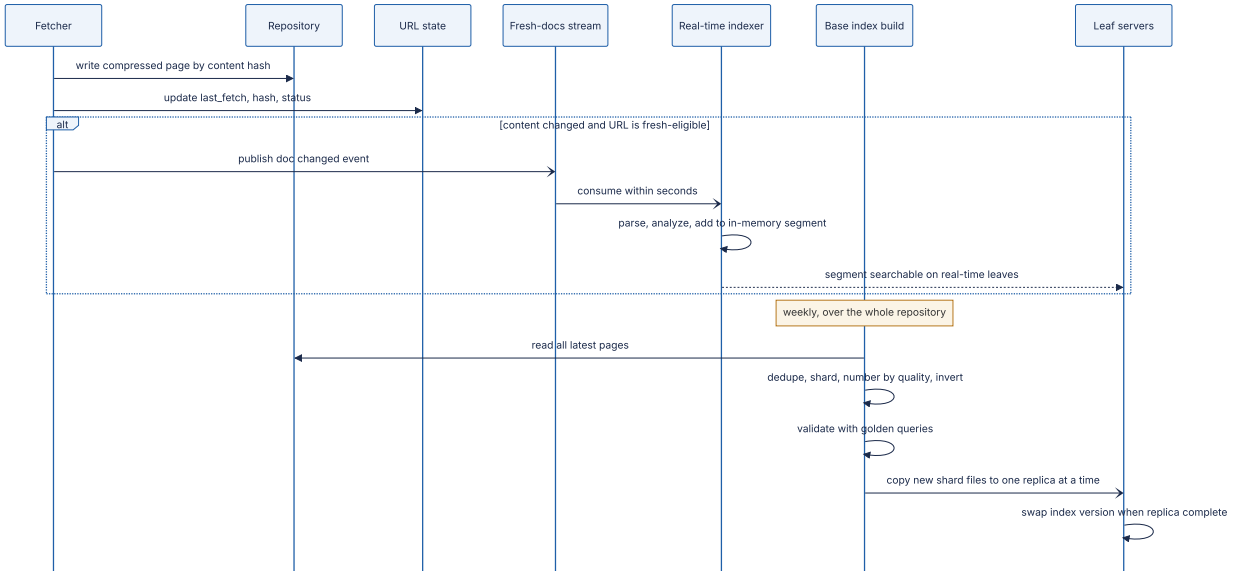
Google: from batch rebuilds to incremental indexing. Google's Percolator paper describes the move of the web indexing system from a chain of MapReduce passes over the whole repository to incremental processing driven by observers and cross-row transactions on Bigtable. The trade-off it reports is explicit: incremental processing reduced document age in results by about half but used substantially more resources per document than the batch pipeline, which remained the better tool when the whole corpus had to be reprocessed. *Evidence: Primary* — [Peng and Dabek 2010]

Autocomplete

Autocomplete is a separate service: precomputed top-k suggestions per prefix in an in-memory trie or finite-state transducer (§16.9.2–§16.9.3), rebuilt from the query log with time decay, plus a small trending layer. At 347,222 requests/s it is the highest-rate service, but each request is a sub-millisecond memory lookup, and short prefixes are cached at the edge. Suggestions must pass the same policy and removal filters as results, and the build must drop queries issued by too few distinct users so that private queries never surface.

56.4.9 Data flow

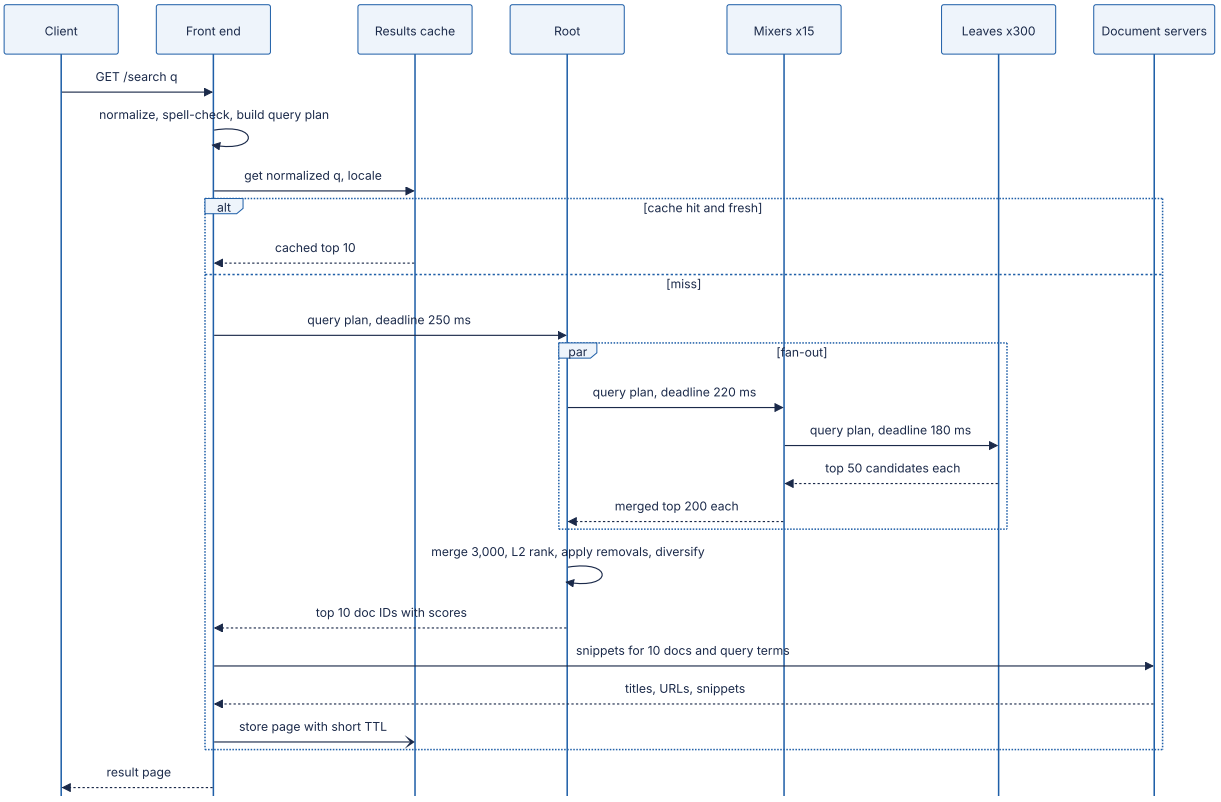
Figure 56.3 — Write path: from a changed page to searchable in two tiers.



Reading the diagram. The fetcher's two writes are synchronous and durable: the page to the repository (keyed by content hash, so an unchanged page costs no new storage) and the URL-state row. If the content changed and the URL belongs to a fresh-eligible site, the fetcher publishes an asynchronous event (half arrow) that the real-time indexer

consumes, analyzes and adds to an in-memory segment searchable within seconds. Separately and on its own schedule, the base build reads the entire repository, runs the batch pipeline of §56.4.8, validates the result and copies shards asynchronously to leaf servers one replica at a time; each replica swaps to the new version only when all its shards have arrived, so a query never mixes old and new shards. Failure points: the stream lagging (fresh content late but not lost, since the base build will include it), a bad build (caught by validation, or rolled back by pinning the old version), and copy bandwidth (§56.4.4). Scaling: the real-time path scales with change rate, the batch path with corpus size.

Figure 56.4 — Read path: one query.



Reading the diagram. All calls are synchronous RPCs except the asynchronous cache fill. The front end normalizes the query so that “Noise Canceling” and “noise canceling” share a cache entry, then checks the cache; news-sensitive queries get short TTLs (minutes) so a cached page does not hide breaking results. On a miss, the deadline shrinks at each level (250 → 220 → 180 ms) so that every level has time to merge whatever arrived. Leaves return candidates, not documents; only the final ten are sent to document servers, which build query-dependent snippets from stored text. The root applies the removal overlay after ranking so that no cached or stale shard can resurrect a removed URL. Failure points: a slow leaf (hedge or partial result), document server miss (show URL and title from the forward index instead of a snippet), cache stampede for a sudden hot query (single-flight per key, §20.11). Scaling: add replicas behind each tree level.

56.4.10 Bottlenecks

1. **Leaf CPU walking postings.** Work grows with postings walked; common terms have corpus-length postings. Mitigate with quality-ordered postings and early termination, WAND and block-max skipping (§16.5.6), and cached intersections for frequent term pairs.
2. **Fan-out tail latency.** The slowest of 300 leaves sets latency. Mitigate with hedging, partial results, isolating background work from serving cores, and latency-induced probation [Dean and Barroso 2013].
3. **Index distribution.** 648 TB per weekly build competes with serving; use peer-to-peer copying, throttling and per-replica copy windows.
4. **Breaking-news bursts.** Identical queries hit a cold cache; coalesce requests per normalized query.
5. **Document servers.** 810,000 random document reads per second at peak; keep the hot fraction in memory.

56.4.11 Failure scenarios

Table 56.7 — Search engine failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
One leaf slow (GC, noisy neighbor, failing disk)	p99 rises for every query on that replica	Per-leaf latency percentiles; hedge rate per leaf	Hedging; probation removes the leaf from rotation	Resource isolation; health-based routing
One shard unavailable in all replicas of a region	0.33% of corpus missing; mostly invisible	`partial=true` rate	Route that shard's RPCs cross-region	Spread a shard's replicas across failure domains
Bad index build (parser bug drops titles)	Relevance collapses on rollout	Golden-query metrics; click-through drop on canary replica	Pin previous index version; roll back	Build validation gate; canary one replica first
Query of death	Crash of every leaf the query reaches	Correlated crash loops; crash-triggering query in logs	Block the query pattern at the front end	Canary requests; fuzzing the query parser
Results cache lost	Index load rises 1.43×	Cache hit-ratio alert	Shed low-priority traffic; warm cache from logs	Capacity headroom for $h = 0$; replicated cache
Fresh-docs stream lag	News results stale	Consumer lag and "age of newest doc" metric	Scale indexers; skip backlog older than base tier	Lag alert well below freshness SLO
Spam or SEO attack floods index	Low-quality results	Quality metrics on sampled queries; spam classifier scores	Demote via removal overlay and signals	Spam scoring in the build; link-graph signals
Region loss	One third of capacity gone	Global load balancer health checks	Shift traffic to two remaining regions	Six replicas per region so two regions carry peak

56.4.12 Scaling strategy

At 10× query rate (1.16 million queries/s): replicas scale linearly, from 18 to about 180 by the formula of §56.4.4, which is expensive. Before buying, reduce work per query. **Quality tiering** splits the base index into a small tier of the best documents (say 5 billion) and the full tier; most queries are satisfied by the small tier, and only those that find too few good matches cascade to the full one. If 80% of queries stop at a tier one-sixth the size, the expected CPU per query falls from 1.2 to $1.2 \times \frac{1}{6} + 0.2 \times 1.2 = 0.44$ core-seconds, a 63% reduction. Larger results caches, cached postings intersections and more aggressive early termination follow.

At 10× corpus (3×10^{11} documents): shards grow to 3,000, so fan-out grows tenfold. Add a third tree level (root → 15 → 15 → 14) so that no node merges more than about 20 inputs, increase per-shard size where memory allows to limit S, and lean harder on tiering, because CPU per query scales with corpus size.

At 100× both: exhaustive lexical retrieval becomes the dominant cost, so retrieval moves to much smaller candidate sets (per-term top lists, learned sparse or dense retrieval,

Chapters 74–75) with the long tail searched only when the head fails, and index builds become continuous and incremental per shard.

56.4.13 Trade-offs

Table 56.8 — Search engine design trade-offs.

Decision	Option chosen	Alternative	Why
Partitioning	By document	By term	Balanced shards, small fan-in, independent failures; fan-out is managed by tail-tolerance techniques
Shard size	10^8 docs, 120 GB in memory	Smaller shards	Fewer shards mean lower fan-out tail; memory per leaf caps size
Completeness	Partial results allowed	Wait for all shards	A missing 0.33% rarely changes the top 10; waiting multiplies tail latency
Freshness	Tiered (real-time, daily, base)	Single incrementally updated index	Each tier uses the cheapest method that meets its staleness target
Removals	Overlay applied at serve time	Wait for rebuild	Legal deadlines are shorter than build cycles
Ranking placement	Cheap L1 on leaves, heavy L2 at root	Heavy model everywhere	Heavy model on 3×10^6 docs per query is unaffordable
Caching	Results cache with short TTL for fresh queries	No cache, or long TTL	30% fewer index queries vs. staleness for news

56.4.14 Alternative designs

- **Elasticsearch or OpenSearch.** For site, enterprise or vertical search up to a few billion documents, a managed Lucene cluster (§16.8) provides sharding, replicas, query-then-fetch and near-real-time refresh. It stops fitting when per-shard overhead, cross-region index distribution and custom multi-stage ranking inside leaves dominate.
- **Incremental-only indexing** [Peng and Dabek 2010] removes the weekly rebuild and its distribution burst, at higher cost per document; full rebuilds remain necessary when analysis code changes.
- **Semantic and hybrid retrieval.** Dense retrieval with ANN indexes (Chapter 74) runs alongside lexical retrieval and the candidate lists are fused (§16.11); the serving tree is unchanged.
- **Term partitioning** fails on long postings and hot terms at web scale (§16.7.1).

56.4.15 Interview discussion

Table 56.9 — 45-minute pacing plan for the search engine.

Minutes	Focus	What to produce
0–5	Scope	Web search, ten blue links, freshness tiers, autocomplete; ranking models out of scope
5–10	Estimates	Corpus 30B docs → 36 TB postings; 116k queries/s peak; serving cores ∝ rate × corpus
10–20	Architecture	Three pipelines; Figure 56.1; document partitioning and serving tree
20–32	Deep dive: serving	Scatter–gather, 0.99^{300}, hedging, partial results, deadlines, ranking funnel
32–40	Deep dive: freshness	Tiers, real-time indexer, removal overlay, index distribution and version pinning
40–45	Wrap-up	Failures (query of death, bad build), 10× scaling via tiering, open questions

Likely follow-ups.

- *"Why not shard by term so a query hits only a few machines?"* Postings of common terms are gigabytes; multi-term queries would ship them over the network and popular terms would create hot shards. Document partitioning keeps network fan-in at kilobytes per leaf.
- *"How do you keep p99 under 300 ms with 300 shards?"* Hedged requests after the per-leaf p95, deadlines propagated down the tree, partial results, and quality-ordered postings so a truncated leaf still returns good documents.
- *"How does a takedown work if the index rebuilds weekly?"* A removal overlay replicated to every root, applied after ranking, plus suppression in caches and autocomplete.
- *"How do you know a new index is good?"* Golden-query comparison in the build, then a canary replica with live traffic and click metrics before the rest of the fleet swaps.
- *"Where does PageRank fit?"* It is a static, query-independent quality signal computed offline over the link graph and stored per document; it orders doc IDs and feeds the L0 and L1 scores.

What distinguishes senior and staff answers. A senior answer gets document partitioning, the serving tree and caching right and quantifies fan-out. A staff answer also shows that serving cost scales with query rate times corpus size and goes after work per

query (tiering, early termination) rather than only adding replicas; treats the index build as a release with validation, canarying and rollback; separates freshness requirements into tiers with different machinery; and names operational hazards such as the query of death and index-distribution bandwidth before the interviewer does.

56.4.16 Production considerations

- **Observability.** Per-leaf latency histograms and hedge rates; `partial` and `truncated` rates; newest-document age per tier; index version per replica; golden-query metrics per build; cache hit ratio. Sample traces of the serving tree (§40.6).
- **Security and abuse.** Spam and SEO manipulation make spam scoring part of the build. Query logs are highly sensitive: restrict access, apply minimum-user thresholds to anything derived from them, and limit retention (§50.8). Rate-limit scrapers (§22.3).
- **Cost.** Leaf servers dominate, and cost per thousand queries tracks corpus searched per query, so tiering, caching and early termination are the levers.
- **Operations.** Index rollout is the riskiest routine change: one replica, canary, then region by region with a pinned fallback. Keep the crawler polite (§52.10); blocked sites become stale results.

56.5 Recommendation System (systems view)

56.5.1 Problem statement

Design the serving system behind a personalized home feed: a user opens the app and, within a fraction of a second, sees twenty items (videos, products or posts) chosen for them from a catalog of 50 million. Every scroll asks for the next page; every impression, click, like and watch is recorded and becomes training data for tomorrow’s models.

This case is the **systems view**. What the models are (two-tower retrieval, deep ranking networks, embedding tables, exploration policies) belongs to Chapter 68, and complete product case studies such as YouTube or Instagram recommendations are in Chapter 81. Here the models are black boxes with known costs, and the design questions are those of a data platform: how candidates flow through a multi-stage funnel, how about 200 milliseconds is divided among the stages, where features live so that hundreds of candidates can be scored without hundreds of network calls, what is precomputed and what is computed online, what can be cached, and how the system records what it served so the models can learn from it without **training–serving skew** (Chapter 62).

56.5.2 Functional requirements

1. **Get feed.** For a user, surface (home, related items) and pagination cursor, return a ranked page of 20 items with a recommendation token.
2. **Eligibility filtering.** Never return items the user has already seen recently, items from blocked creators, items unavailable in the user's region, or items removed by policy.
3. **In-session responsiveness.** Actions taken in this session (a skip, a long watch) influence the next page within seconds.
4. **New users and new items.** A user with no history receives a reasonable feed; a newly published item is eligible for recommendation within 15 minutes.
5. **Event logging.** Record every impression with the context and features used to rank it, and every engagement event, joinable by request.
6. **Experimentation.** Route a configurable fraction of users to alternative candidate sources, rankers or re-ranking policies, and attribute outcomes to the variant served.

Out of scope: model training algorithms, the feature-engineering logic itself, and content moderation (consumed as a policy signal).

56.5.3 Non-functional requirements

Table 56.10 — Recommendation system non-functional requirements.

Property	Target	Why
Availability	99.95% for personalized results; 99.99% for *some* results (fallback)	An empty feed is far worse than a less personal one
Server-side latency	p50 ≤ 80 ms, p99 ≤ 200 ms for a page of 20	The feed renders on app open; each 100 ms of delay costs engagement
Freshness: user actions	Reflected in the next request (≤ 5 s)	In-session adaptation is a major quality lever
Freshness: new items	Eligible within 15 min	Creators expect new uploads to be distributed
Logging completeness	≥ 99.9% of impressions logged and joined to outcomes	Missing or biased logs corrupt training
Consistency	Eventual; seen-filter best effort within a session	Showing an item twice is a minor defect, not a correctness failure
Model rollout	New ranker live within 1 h of approval, reversible in minutes	Models are retrained daily or more often

56.5.4 Capacity estimation

WORKED EXAMPLE

Worked example — Request rate and funnel volume. Assumptions: 200 million daily active users; 15 feed requests per user per day (5 sessions × 3 pages); peak-to-average ratio 3 (one country dominates, evening peak); funnel shape: 2,000 candidates retrieved → 1,500 after filtering → light ranker keeps 400 → heavy ranker scores 400 → re-ranker returns 20 (plus 5 held in reserve for the next page).

1. Requests per day: $2 \times 10^8 \times 15 = 3 \times 10^9$.
2. Average rate: $3 \times 10^9 / 86,400 = 34,722$ requests/s; peak $\times 3 = 104,167$ requests/s.
3. Light-ranker scorings at peak: $104,167 \times 1,500 = 1.56 \times 10^8$ per second.
4. Heavy-ranker scorings at peak: $104,167 \times 400 = 4.17 \times 10^7$ per second.
5. Heavy-ranker compute at 0.1 ms of CPU per candidate (batched inference) and 50% target utilization: $4.17 \times 10^7 \times 10^{-4} / 0.5 = 8,333$ cores, about 131 servers of 64 cores. The light ranker at 5 µs per candidate needs $1.56 \times 10^8 \times 5 \times 10^{-6} / 0.5 = 1,563$ cores.

Interpretation. The user sees 20 items, but the system scores 1,900 per request. **Engineering implication.** Every stage exists to make the next, more expensive stage affordable; changing the heavy ranker's input from 400 to 800 candidates doubles its fleet.

WORKED EXAMPLE

Worked example — Feature fetch. Assumptions: 50 million items with 1 KB of item features each; user features 5 KB per user; the top 5 million items account for 95% of candidates.

1. Item-feature lookups if fetched remotely per candidate: $104,167 \times 1,500 = 1.56 \times 10^8$ lookups/s at peak, an impossible load for a remote key-value store at this latency budget, even batched.
2. Full item-feature table: $5 \times 10^7 \times 1,000 = 50$ GB; the hot 5 million items: 5 GB.
3. User-feature reads: one per request, $104,167 \times 5,000 = 521$ MB/s at peak from the online feature store.

Interpretation. Item features are shared by all users and change slowly; user features are private and change fast. **Engineering implication.** Replicate the hot item features into every ranking server's memory (5 GB is cheap), refreshed by a stream, and fall back to a remote batched read for the 5% tail; fetch user features once per request.

WORKED EXAMPLE

Worked example — Precomputation and logging volume. Assumptions: 400 million monthly active users; a nightly job stores 300 candidates per user at 12 bytes each (8-byte item ID, 4-byte score); each served item's impression log carries 1 KB of logged features; each request logs 5 KB of request context; 10 billion engagement events per day at 200 bytes.

1. Precomputed candidates: $4 \times 10^8 \times 300 \times 12 = 1.44$ TB, replicated in a key-value store.
2. Impressions: $3 \times 10^9 \times 25 = 7.5 \times 10^{10}$ per day (868,000/s average), counting the 5 reserve items as logged-but-not-shown.
3. Impression feature logs: $7.5 \times 10^{10} \times 1,000 = 75$ TB/day; request context: $3 \times 10^9 \times 5,000 = 15$ TB/day; engagements: $10^{10} \times 200 = 2$ TB/day.

Interpretation. The training-data stream (about 92 TB/day) is larger than any serving store in the system. **Engineering implication.** Treat logging as a first-class pipeline with its own capacity plan, compression and retention (for example 30 days of full logs, then sampled), not as a side effect of serving.

The latency budget is the design's central constraint, and it composes differently for sequential and parallel stages.

FORMULA

Latency budget of a staged pipeline

$$T_{\text{request}} = \sum_{j \in \text{sequential}} t_j + \max_{i \in \text{parallel sources}} t_i + t_{\text{slack}}$$

Symbol	Meaning	Units
T_{request}	Server-side latency target for one request (here the p99 goal)	ms
t_j	Time allotted to sequential stage j (filter, feature fetch, rank, re-rank)	ms
t_i	Time allotted to parallel candidate source i; the stage waits for the slowest it does not cut off	ms
t_{slack}	Reserve for queueing, retries and garbage-collection pauses	ms

WORKED EXAMPLE

Worked example — Dividing 200 ms. Allocate: request context and user features 10 ms; candidate generation 40 ms (four sources in parallel, each with a 35 ms deadline); filtering 10 ms; item and real-time feature assembly 25 ms; light ranker 10 ms; heavy ranker 50 ms; re-ranking 10 ms; response and asynchronous log enqueue 5 ms.

1. Sum of allocations: $10 + 40 + 10 + 25 + 10 + 50 + 10 + 5 = 160$ ms.
2. Slack: $200 - 160 = 40$ ms, 20% of the budget.
3. Because percentiles do not add (§4.8), using per-stage p99s as allocations is conservative: all stages rarely hit their p99 on the same request. The danger runs the other way for parallel sources: with four sources each meeting 35 ms at p99, the chance that all four meet it is $0.99^4 = 96\%$ (§4.8.4), so the stage must cut off late sources rather than wait.

Interpretation. The heavy ranker and candidate generation take 45% of the budget; everything else must be cheap. **Engineering implication.** Give each stage a hard deadline derived from this table and propagate the remaining budget (§22.11); a stage that misses its deadline degrades (fewer candidates, a cached score) rather than delaying the response.

56.5.5 API design

```
GET /v1/feed?surface=home&cursor=eyJwIjoyfQ&count=20
Authorization: Bearer …
200 OK
{ "request_id": "r-91c2…",          // joins impressions and engagements to this re-
sponse
  "items": [ { "item_id": "v-88412", "position": 0, "rec_token": "r-91c2…:0" }, … ],
  "next_cursor": "eyJwIjozfQ",
  "degraded": false }                // true when a fallback path served this page

POST /v1/events
{ "events": [ { "type": "impression", "rec_token": "r-91c2…:0", "ts": "2026-11-
05T19:02:11.204Z" },
              { "type": "watch", "rec_token": "r-91c2…:0", "watch_ms": 41200, "ts": "…"
} ] }
202 Accepted
```

```
        // Internal RPCs (illustrative)
        service CandidateSource { rpc Retrieve(RetrieveRequest) returns (CandidateList);
}  // user context, n, deadline
        service FeatureService  { rpc BatchGet(FeatureRequest) returns
(FeatureResponse); } // entity keys, feature set version
        service Ranker          { rpc Score(ScoreRequest) returns (ScoreResponse); }
// candidates + features -> scores
        message ScoreRequest {
          string model_version = 1;          // pinned per experiment arm
          bytes  user_features = 2;
          repeated Candidate candidates = 3; // item ID + assembled feature vector
          uint32 deadline_ms = 4;
        }
```

The `request_id` and per-item `rec_token` are the most important fields in the API: they are the join keys that turn an engagement event into a labeled training example. Events are accepted asynchronously (`202`) and batched by the client.

56.5.6 Data model and database schema

Table 56.11 — Recommendation system data stores.

Data	Key	Store and justification
User features (long-term profile, embeddings)	`user_id`	Online feature store on a low-latency key-value database (Chapter 62; §12.4); one read per request
Real-time user features (last 50 actions, session counters)	`user_id`	In-memory store with TTL (Redis-style, §20.6), updated by a stream job within seconds
Item features	`item_id`	Bulk-loaded into ranker memory, refreshed by stream; backing copy in the feature store
Candidate indexes	Embedding → item IDs; `item_id` → co-visited items	ANN index in memory (Chapter 74); co-visitation table in a key-value store
Precomputed candidates	`user_id`	Key-value store, overwritten nightly (1.44 TB)
Seen filter	`user_id`	Per-user Bloom filter or capped set of recent item IDs (§17.4)
Impression and event logs	Partitioned by date and hour	Kafka (§31) → data lake tables in a columnar format

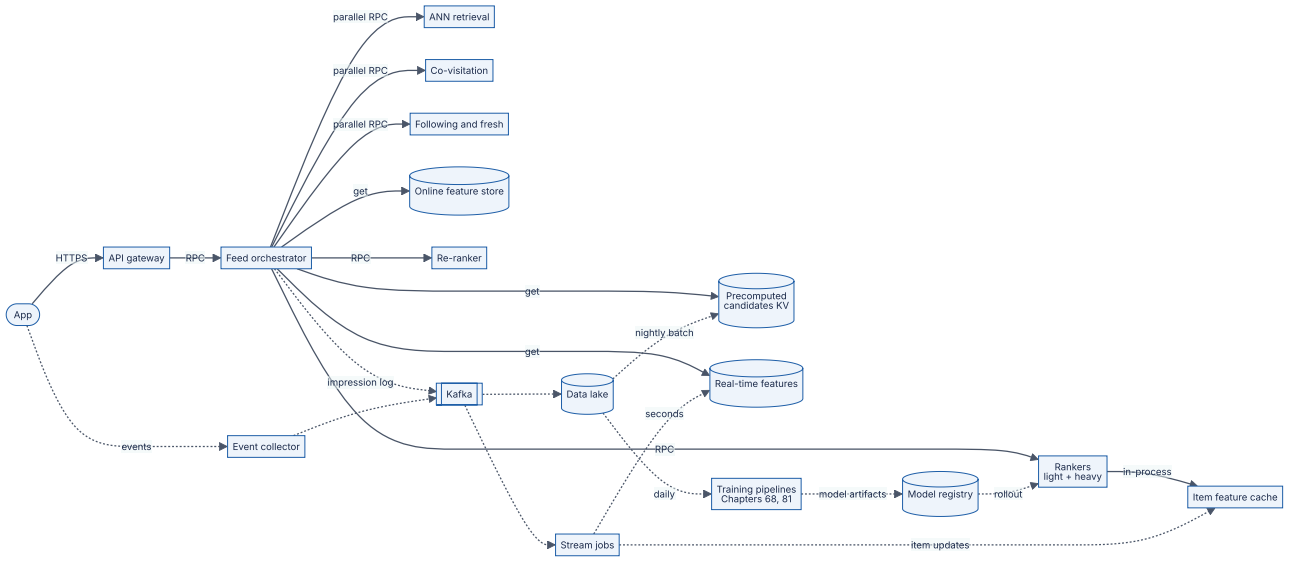
The impression log is the contract between serving and training, so its schema is designed as carefully as any database table:

```
        -- Data-lake table, written from the serving log stream (illustrative)
        CREATE TABLE impressions (
          request_id        STRING    NOT NULL,   -- join key with engagement events
          position          INT       NOT NULL,   -- slot shown, for position-bias cor-
rection
          user_id_hash      STRING    NOT NULL,   -- keyed hash, not the raw ID (Chapter
50)
          item_id           STRING    NOT NULL,
          served_at         TIMESTAMP NOT NULL,
          surface           STRING    NOT NULL,
          experiment_arms   ARRAY<STRING>,        -- which variants produced this result
          candidate_source  STRING,               -- provenance: which retriever pro-
posed it
          model_version     STRING    NOT NULL,
          heavy_score       DOUBLE,
          features          BINARY,               -- exact feature vector used at serv-
ing time
          feature_set_ver   STRING    NOT NULL,
          shown             BOOLEAN   NOT NULL    -- false for reserve items never ren-
dered
        )
        PARTITIONED BY (dt DATE, hr INT);
```

Logging the exact `features` the ranker saw, rather than recomputing them later from tables, is what prevents training–serving skew: the training example contains precisely the inputs the model received in production, including any staleness or default values (Chapter 62 treats the alternatives).

56.5.7 High-level architecture

Figure 56.5 — Recommendation serving and logging architecture.



Reading the diagram. Solid arrows are the synchronous request path; dotted arrows are asynchronous data flows. The app calls the gateway, which calls the **feed orchestra-**

tor, the only component that knows the funnel. The orchestrator fetches user and real-time features and precomputed candidates, calls several candidate sources in parallel, filters, sends candidates with assembled features to the rankers (whose item features are an in-process cache), calls the re-ranker, and returns. On the asynchronous side, the orchestrator logs every impression to Kafka and the app sends engagement events through a collector to the same Kafka cluster. Stream jobs update real-time user features within seconds and push item-feature changes to rankers; the data lake accumulates logs for daily training, whose models flow through a registry to the rankers, and for the nightly precomputation job. Storage boundaries: feature stores, precomputed candidates, ANN index memory, Kafka and the lake. Failure points: any candidate source (cut off by deadline), the feature store (default features), rankers (fall back to light ranker or precomputed order), and the logging path (must never block serving). Scaling: each service scales horizontally and independently; rankers dominate.

56.5.8 Detailed component design

Candidate generation: many sources, one deadline

No single retrieval method finds everything a user might want, so the orchestrator queries several **candidate sources** in parallel and merges them, the two-stage shape (candidate generation narrowing millions to hundreds, then ranking) that YouTube's published deep-learning recommender made widely known [Covington et al. 2016].

Table 56.12 — Candidate sources and their systems profile.

Source	What it finds	Data structure	Freshness	Typical latency
Two-tower ANN retrieval	Items whose embedding is near the user's	In-memory ANN index over item embeddings (Chapter 74)	Index rebuilt hourly; new items inserted incrementally	5–15 ms
Co-visitation / item-to-item	Items engaged with after the user's recent items	Key-value table item → top-N related items	Updated by streaming counts	2–10 ms
Social / following	New items from followed creators	Per-user inbox (fan-out-on-write, compare Chapter 53)	Seconds	2–5 ms
Trending and fresh	Popular or new items in the user's region	Small in-memory lists per region	Minutes	< 2 ms
Precomputed	Expensive batch candidates (graph walks, heavy models)	Key-value by user	Nightly	2–5 ms

The merge cannot sort by score, because scores from different sources are not comparable (an ANN cosine similarity of 0.8 and a co-visitation count of 1,200 have no common scale). Instead the orchestrator takes up to a quota from each source and interleaves by rank, deduplicating as it goes; the rankers then put everything on one scale.

```
        """Merge candidate lists from several retrieval sources under per-source quotas.
        Scores from different sources are not comparable, so we interleave by rank, not
by score."""

        def merge_candidates(results, quotas, total, excluded):
            """results: source -> ranked list of item IDs, or None if the source missed
its deadline.
            quotas: source -> max items taken from that source. excluded: items to fil-
ter out."""
            queues = {s: [i for i in (lst or []) if i not in excluded][:quotas[s]]
                      for s, lst in results.items()}
            merged, seen, origin = [], set(), {}
            while len(merged) < total and any(queues.values()):
                for source in sorted(queues):              # one pass = one item from
each source
                    q = queues[source]
                    while q:
                        item = q.pop(0)
                        if item not in seen:               # dedupe across sources
                            seen.add(item)
                            merged.append(item)
                            origin[item] = source          # keep provenance for logging
and debugging
                            break
                    if len(merged) == total:
                        break
            return merged, origin

        if __name__ == "__main__":
            results = {
                "ann_two_tower": ["v1", "v2", "v3", "v4", "v5"],
                "co_visitation": ["v2", "v6", "v7"],
                "following":     ["v8", "v1", "v9"],
                "trending":      None,                     # timed out: the request pro-
ceeds without it
            }
            quotas = {"ann_two_tower": 4, "co_visitation": 3, "following": 3, "trend-
ing": 2}
            merged, origin = merge_candidates(results, quotas, total=8, excluded={"v3"})
            print(merged)
            print({s: sum(1 for v in origin.values() if v == s) for s in quotas})
```

Output:

```
['v1', 'v2', 'v8', 'v4', 'v6', 'v9', 'v5', 'v7']
{'ann_two_tower': 3, 'co_visitation': 3, 'following': 2, 'trending': 0}
```

What to notice:

- A source that missed its deadline (`None`) simply contributes nothing; the request is not delayed. Monitoring must count these, or a silently dead source looks like a quality regression.
- Excluded items (here `v3`, already seen) are removed *before* the quota is applied, so filtering does not waste a source's quota.
- `v2` and `v1` were proposed by two sources but appear once; `origin` records which source got credit, which is logged as `candidate_source` so that each source's contribution to engagement can be measured.
- Sources are visited in a fixed order (alphabetical here, by priority in practice), which makes results deterministic and debuggable.

Feature assembly and ranking

Ranking 1,500 candidates requires a feature vector for each. Features come from three places with different costs:

1. **User features** (one row per request): fetched once from the online feature store, plus the real-time store for the last few minutes of activity.
2. **Item features** (one row per candidate): served from the ranker's in-process cache of hot items (the 5 GB computed above), refreshed by a change stream; misses go to the feature store in one batched call with a short deadline, and on timeout the ranker uses default values and records that it did so.
3. **User–item cross features** (for example, how often this user engaged with this creator): the most predictive and the most expensive, because they are keyed by pairs. Keep them small and keyed by user (a per-user map of creator → counts fetched once), never as one remote lookup per candidate.

Rankers run the light model on all candidates and the heavy model on the top 400, in batches, so that the per-candidate cost is amortized; batching on accelerators is the natural evolution when the heavy model grows (Chapters 64 and 66). Two design rules keep the stage stable. Rankers are **stateless replicas** pinned to one model version per experiment arm, so a rollout is a routing change. And the orchestrator routes a user's requests consistently to the same ranker pool during a model transition, so one user never sees pages ranked by two different models alternating.

Re-ranking, precomputation and caching

Re-ranking applies list-level logic that a per-item score cannot express: no more than two consecutive items from one creator, a mix of content types, exploration slots for new items (Chapter 68 covers why), and business or policy rules. It operates on 400 items with cheap logic, so it is fast, but it has outsized influence on what users see and must be versioned and experimented on like a model.

Precomputed versus online is not a binary choice; it is decided per stage.

Table 56.13 — Precomputed versus online recommendation.

	Fully precomputed	Hybrid (chosen)	Fully online
What it is	Nightly job writes each user's final list	Some candidate sources precomputed; filtering and ranking online	Every stage at request time
Latency	One key-value read (< 5 ms)	~80–200 ms	~80–200 ms or more
Freshness	Up to a day stale; ignores this session	Reacts to the current session	Fully fresh
Cost	Computes lists for users who never come back	Pays online only for active users	Highest online compute
Failure behavior	Very robust	Falls back to precomputed list	Needs separate fallback
Choose when	Email digests, low-traffic surfaces, fallback	Main feeds	Highly contextual surfaces (search-like, related items)

Caching in a personalized system is narrower than in a content site, because most responses are unique to one user and one moment. What *is* cacheable: item features (in-process), candidate lists for related-item surfaces keyed by item (shared by all users who view that item), trending lists, and the user's **own next page**. The re-ranker keeps five reserve items and the orchestrator caches the ranked remainder for the session with a TTL of a few minutes, so a scroll often needs only filtering and a light refresh rather than the full funnel; an engagement event that should change the feed invalidates that entry.

Logging for training

The logging path has three jobs: record what was served (impressions with features), record what happened (engagements), and join them into labeled examples.

1. **Impressions** are logged by the orchestrator at serving time, asynchronously to Kafka, with the features the ranker actually used. Logging must never block or fail the request; if the log producer's buffer is full, the system drops logs and counts the drops rather than slowing users down.
2. **Engagements** arrive later, from the client, keyed by `rec_token`. Labels are delayed: a "watched to completion" label might arrive minutes later, a purchase days later.
3. **The join** is a streaming job (§29.8) keyed by `request_id`, with a window as long as the slowest label that matters (for example 30 minutes for watch labels), emitting an example when the window closes. Impressions with no engagement become negative examples only after the window closes, never before, otherwise slow positives are recorded as negatives.

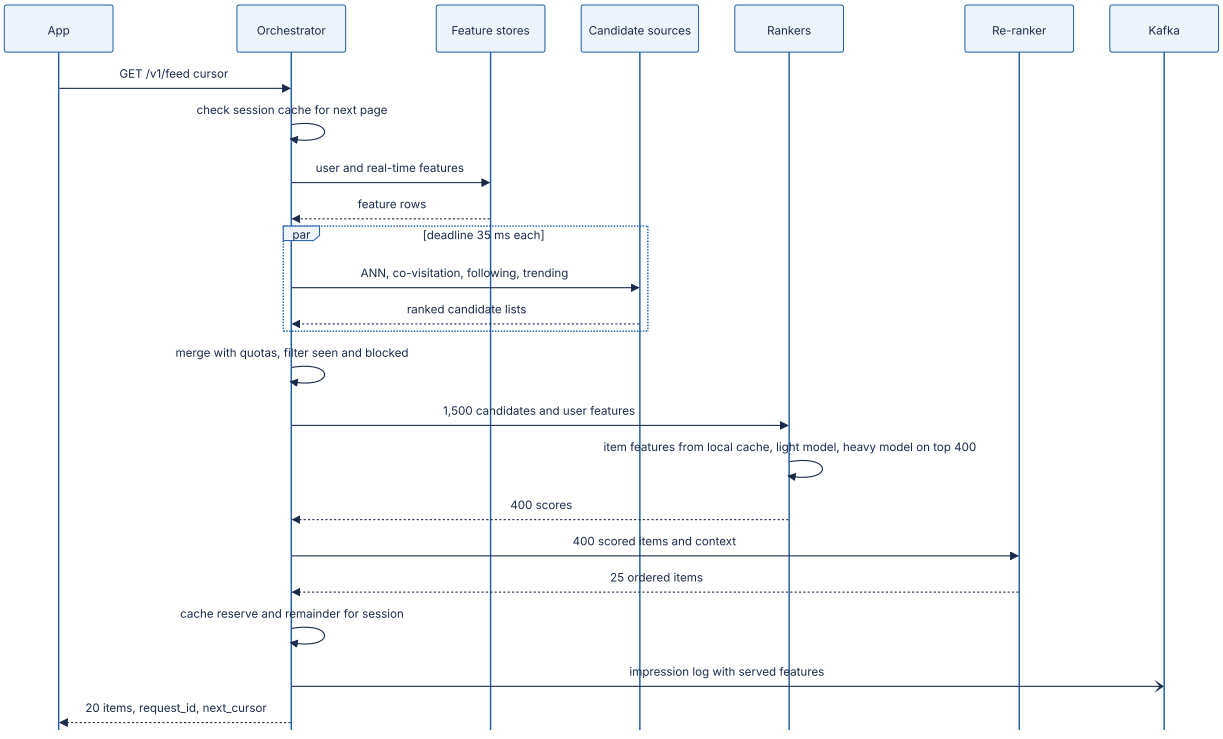
Two traps are common enough to design against: logging only the 20 items shown (so the model never learns about candidates it scored low, a feedback-loop problem examined in Chapter 68), and logging features recomputed at join time rather than as served (skew). The design logs the 5 reserve items with `shown = false` and, for a small random sample of requests, the full 400 heavy-ranked candidates with their scores.

INDUSTRY EXAMPLE

Pinterest Pixie: precomputation by graph walk, served from memory. Pinterest described Pixie, a recommendation service that keeps a pruned graph of pins and boards in the memory of each serving machine and generates candidates in real time by running many short, biased random walks from the user's recent pins, instead of precomputing per-user lists. The systems lesson is that a candidate source can trade memory (the whole graph replicated on every server) for freshness and simplicity (no per-user precomputation, no cross-machine calls during a walk). *Evidence: Primary* — [Eksombatchai et al. 2018]

56.5.9 Data flow

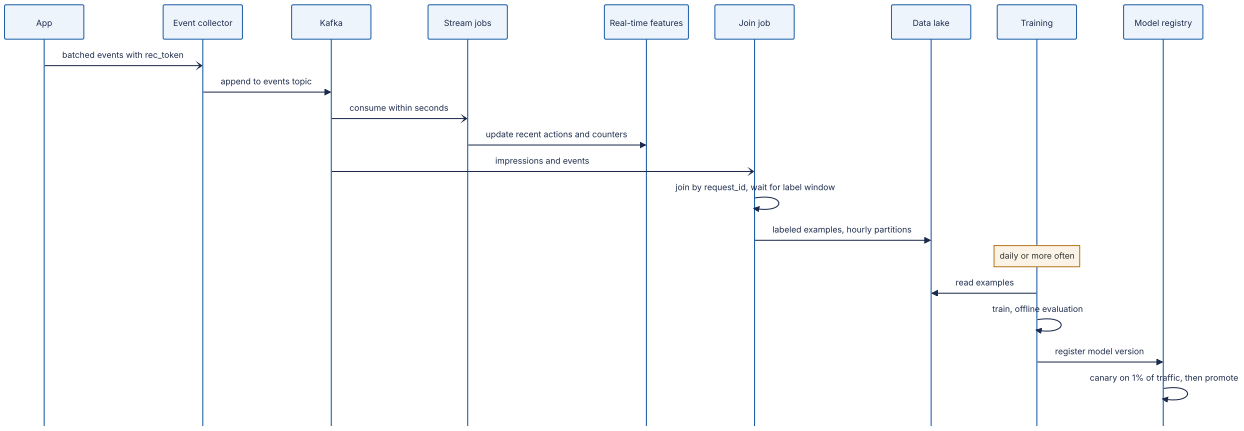
Figure 56.6 — Read path: serving one feed page.



Reading the diagram. The orchestrator first checks whether this is a continuation it has already ranked; if so, it returns from the session cache after re-filtering. Otherwise it fetches user features, calls all candidate sources in parallel with a 35 ms deadline each, merges and filters, and sends candidates to the rankers, which assemble item features lo-

cally and run both models. The re-ranker produces the final order. Only the impression log is asynchronous (half arrow), and it is sent after the response is ready so that a slow Kafka producer cannot delay users. Failure points and fallbacks: a candidate source misses its deadline (merge without it); the feature store times out (use defaults and flag them in the log); rankers fail (use light-ranker scores or the precomputed list, setting `degraded`). Scaling: rankers and candidate sources scale independently behind the orchestrator, which is stateless apart from the session cache.

Figure 56.7 — Write path: from engagement to features, examples and models.



Reading the diagram. Engagement events flow asynchronously from the app to the collector, which appends them durably to Kafka; that append is the commit point. Two consumers read the same topic for different purposes: stream jobs update real-time features within seconds (this is what makes the next page respond to a skip), and the join job matches impressions with engagements by `request_id`, waits for the label window and writes labeled examples to the lake. Training reads the lake on its own schedule, and new model versions go through the registry, canary and promotion (Chapters 66 and 69 own model serving and rollout). Failure points: Kafka unavailable (collectors buffer and retry with idempotent producers, §31.6.3); the join job late (training delayed, serving unaffected); a bad model (caught at canary). Scaling: partition topics by user so per-user ordering holds and consumers scale with partitions.

56.5.10 Bottlenecks

1. **Heavy-ranker compute.** It dominates the fleet; candidates per request multiply it directly. Levers: tighter light-ranker cut-off, batching, accelerators, model distillation (Chapter 67).
2. **Feature fetch fan-out.** Any design that issues one remote call per candidate fails at 1.56×10^8 lookups/s. Keep item features local and cross features keyed by user.
3. **ANN index memory and rebuilds.** The retrieval index must hold 50 million embeddings in memory on every replica and absorb new items within 15 minutes; incremental insertion plus periodic full rebuild (Chapter 74).

4. **Hot users and hot items.** A celebrity's new post enters millions of following-inboxes (the fan-out problem of Chapter 53); a viral item's feature row is read by every ranker, which the in-process cache absorbs.
5. **Logging throughput.** 92 TB/day of logs is a Kafka and lake capacity problem; compress, sample the full-candidate logs, and partition by hour.

56.5.11 Failure scenarios

Table 56.14 — Recommendation system failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
One candidate source down or slow	Less diverse feeds; slight engagement drop	Per-source timeout rate; share of served items by source	Merge proceeds without it; page on-call if sustained	Deadlines; quotas so no source is a single point
Online feature store slow	Rankers use defaults; ranking quality drops	Default-feature rate in logs; store p99	Serve with defaults; shed experimental traffic	Replicas; local caches of user features for active sessions
Ranker fleet overloaded	Latency SLO missed	Ranker queue length, p99	Reduce heavy-ranker input from 400 to 200; fall back to light ranker	Autoscaling on queue length; load shedding by priority
Bad model version	Engagement drops sharply	Canary metrics versus control; online prediction-distribution drift	Route traffic back to previous version	Canary at 1%; automatic rollback on guardrail metrics
Logging pipeline drops impressions	Biased training data; silent quality decay	Ratio of logged impressions to served requests	Backfill impossible; quarantine affected partitions	Monitor completeness; durable local buffer in orchestrator
Training–serving skew (feature computed differently)	Model performs worse online than offline	Compare logged serving features with training features	Retrain on logged features	Log features as served (§56.5.6)
Whole personalization stack down	No personalized feed	Error rate on `/feed`	Serve precomputed list, then regional trending list	Layered fallbacks tested by chaos experiments (§39.11)

56.5.12 Scaling strategy

At 10× traffic (1 million requests/s at peak): heavy-ranker cores grow to about 83,000, so this is the point to move ranking to accelerators with large batches and to cut candidates per request; candidate sources replicate horizontally; the in-process item cache is unchanged, since it does not grow with traffic. Kafka and the lake grow tenfold, so full-candidate logging becomes sampled at a lower rate.

At 10× catalog (500 million items): the ANN index no longer fits on one machine and becomes sharded by item with scatter–gather (the same tail-latency mathematics as §56.4.8), or tiered (a hot index of recent and popular items plus a cold sharded index). The item-feature cache keeps covering the hot head, but the miss path grows and needs its own capacity.

At 100×: the architecture splits into **regional cells** (§44.10), each with its own replicas of candidate indexes and rankers and a regional feature store, with global training. Precomputation is restricted to inactive users and fallback, because nightly computation for billions of users that mostly do not return is wasted.

56.5.13 Trade-offs

Table 56.15 — Recommendation system trade-offs.

Decision	Chosen	Alternative	Why
Funnel depth	Retrieve → filter → light rank → heavy rank → re-rank	Single model over all candidates	Makes the heavy model affordable on 400 rather than 2,000 items
Candidate merge	Quotas and interleave by rank	Merge by score	Scores across sources are not comparable
Item features	Replicated in ranker memory	Remote lookup per candidate	156 million lookups/s is infeasible remotely
Precomputation	Hybrid, with precomputed fallback	Fully online or fully precomputed	Freshness for active users, robustness for failures
Missing data	Default features and degraded flag	Fail the request	An imperfect feed beats an error
Logging	Features as served, plus reserve and sampled full candidates	Recompute features at training time	Prevents skew; enables learning about unshown items
Model rollout	Versioned rankers, canary, consistent routing per user	Swap all at once	Reversible in minutes, no mixed rankings per user

56.5.14 Alternative designs

- **Precompute everything.** A nightly batch writes each user’s feed to a key-value store: cheap and robust, the norm for email digests, but blind to the current session and wasteful for users who do not return.
- **Single-stage retrieval.** For catalogs of a few hundred thousand items, one model can score everything; the funnel is overhead when the catalog is small.
- **Graph-walk retrieval from memory.** Pixie-style walks replace several candidate sources with one, trading memory for freshness [Eksombatchai et al. 2018].

- **Managed recommender services** suit teams without ML infrastructure, at the cost of control over the funnel, features and logging.

56.5.15 Interview discussion

Table 56.16 — 45-minute pacing plan for the recommendation system.

Minutes	Focus	What to produce
0–5	Scope	Systems view of a home feed; models as black boxes with cost; logging in scope
5–10	Estimates	104k requests/s; 1,500 → 400 → 20 funnel; 42 million heavy scorings/s; feature lookups
10–20	Architecture	Figure 56.5; orchestrator, sources, feature stores, rankers, logging
20–30	Deep dive: latency budget	200 ms table, deadlines, parallel sources, degraded modes
30–38	Deep dive: features and logging	Local item features, served-feature logging, delayed-label join
38–45	Wrap-up	Failures and fallbacks, 10× scaling, experimentation

Likely follow-ups.

- *"Why not one big model?"* Because scoring 50 million items, or even 2,000 with the heavy model, does not fit the latency or cost budget; each stage makes the next affordable.
- *"How does the feed react to what I just did?"* Events go through Kafka to a stream job that updates the real-time feature store within seconds; the next request reads it, and the session cache is invalidated by significant actions.
- *"What if the feature store is down?"* Rankers use defaults, record that they did, and set `degraded`; if the rankers are down, serve precomputed lists, then trending.
- *"How do you avoid training–serving skew?"* Log the features exactly as served, keyed by request, and train on those logs.
- *"How would you A/B test a new ranker?"* Hash users into arms, pin the ranker version per arm, log the arm with every impression, and compare engagement and guardrail metrics (Chapter 57 owns the statistics).

What distinguishes senior and staff answers. A senior answer draws the funnel, sizes the ranker fleet and puts deadlines on stages. A staff answer derives the feature-placement decision from the lookup rate, treats logging as a product with completeness SLOs and a delayed-label join, designs degraded modes explicitly, and recognizes that the serv-

ing system shapes the training data and therefore the future model, so changes to filtering, re-ranking or logging are experiments, not refactors.

56.5.16 Production considerations

- **Observability.** Per-stage latency and deadline-miss rates; share of served items by candidate source; default-feature rate; ranker score distributions per model version (a shifted distribution is the earliest sign of a broken feature); logging completeness ratio; engagement per experiment arm.
- **Security and privacy.** Behavioral logs are personal data: hash identifiers (§50.10), enforce retention and deletion in the lake and derived features, and restrict raw-impression access. Apply minimum-count thresholds to item-to-item sources so outputs cannot expose small groups.
- **Cost.** Heavy ranking and logging dominate. The cheapest improvements are usually a smaller heavy-ranker input, sampled full-candidate logging, and not precomputing for inactive users.
- **Operations.** Models change daily, so automate rollout, canaries and one-click rollback, and drill fallbacks: disable rankers in one cell and verify that the precomputed feed is served within the SLO.

56.6 Logging and Monitoring Platform

56.6.1 Problem statement

Design the internal observability platform for a company running 100,000 containers across 2,000 services owned by 300 teams. Every container emits logs and exposes metrics; engineers search logs while debugging, watch dashboards, and are paged by alerts when service-level objectives are threatened. The platform is shared, so each team is a **tenant** (Chapter 47) with its own quotas, retention and bill.

Chapter 40 teaches the signals themselves: structured logs, metric types, cardinality, tracing, Prometheus and alerting rules. This case designs the platform that carries them. Its distinctive hard problems are three: ingesting bursty telemetry (an incident multiplies log volume exactly when the platform is most needed) without loss and without unbounded cost; choosing **what to index**, because indexing everything is the single largest cost driver; and keeping the **alerting path** working when the rest of the platform, or the infrastructure beneath it, is failing.

56.6.2 Functional requirements

1. **Ingest logs** (structured JSON lines from standard output) and **metrics** (Prometheus scrape or OTLP push) from every node, tagged with tenant, service,

environment and host.
2. **Search logs** by tenant, service and time range, filter by fields and free text, and **live-tail** a service.
3. **Query metrics** with a PromQL-compatible language for dashboards and ad hoc analysis.
4. **Alert** on metric rules and on metrics derived from logs (for example, error lines per minute), with grouping, deduplication, silencing and routing to paging, chat and ticketing.
5. **Tenant controls**: per-tenant ingestion quotas, active-series limits, retention policies and a monthly usage report.
6. **Access control and redaction**: tenants see only their data unless granted; personal data is masked in the pipeline (§40.4.5).

Distributed traces travel through the same collectors and Kafka cluster but are stored and sampled as Chapter 40 describes (§40.6.3–§40.6.4); this case does not repeat that design.

56.6.3 Non-functional requirements

Table 56.17 — Logging and monitoring non-functional requirements.

Property	Target	Why
Ingestion availability	99.9%; no loss of accepted data except by explicit, counted sampling or quota drops	Logs are evidence during incidents and audits
Log freshness	p99 ≤ 30 s from emission to searchable	Engineers debug live incidents
Metric freshness	≤ 30 s from scrape to queryable	Alerts depend on it
Alerting availability	99.99%; evaluation delay ≤ 1 min	The platform’s most critical function
Log query latency	1 h of one service: p95 ≤ 2 s; 7 days with filters: p95 ≤ 30 s	Interactive debugging
Dashboard latency	p95 ≤ 1 s for 24-hour panels	Many panels per dashboard
Retention	Logs: 7 days hot, 30 days warm, 1 year archive for audit streams; metrics: 15 days raw, 13 months downsampled	Debugging versus trend analysis versus compliance
Isolation	One tenant’s burst cannot raise another tenant’s ingestion latency beyond SLO	Shared platform (§47.7)

56.6.4 Capacity estimation

WORKED EXAMPLE

Worked example — Log volume. Assumptions: 100,000 containers; 20 lines/s per container on average; 400 bytes per line; incident peak 3× average.

1. Lines per second: $10^5 \times 20 = 2 \times 10^6$; bytes: $2 \times 10^6 \times 400 = 800$ MB/s.
2. Per day: $800 \times 10^6 \times 86,400 = 6.91 \times 10^{13}$ B **= 69.12 TB/day** raw.
3. Peak: 6×10^6 lines/s, 2.4 GB/s.

Interpretation. This is the same volume formula as §40.4.4, applied to a whole company: volume follows lines per container, not the number of services. **Engineering implication.** Size the ingestion path (agents, Kafka, ingesters) for 2.4 GB/s, but size storage for the average, since Kafka absorbs peaks.

WORKED EXAMPLE

Worked example — Storage per retention tier. Assumptions: 10:1 compression for logs in columnar or chunked storage; hot tier 7 days on local SSD with 2 replicas; warm tier days 8–30 in object storage (durability provided by the object store); 10% of volume (audit and security streams) archived for the rest of the year; alternative: a full-text inverted index whose index plus stored source occupies 0.5× raw, with 1 replica (2 copies).

1. Compressed per day: $69.12/10 = 6.91$ TB.
2. Hot: $6.91 \times 7 \times 2 = 96.8$ TB of SSD.
3. Warm: $6.91 \times 23 = 159$ TB of object storage.
4. Archive: $6.91 \times 0.1 \times 335 = 232$ TB of object storage (cold class).
5. Full-text indexing of everything, hot tier only: $69.12 \times 0.5 \times 2 \times 7 = 484$ TB of SSD, five times the columnar hot tier, plus the CPU to build the inverted index at 800 MB/s.

Interpretation. The ratios are illustrative and vary with data, but the shape is robust: indexing every token multiplies hot storage and ingest CPU. **Engineering implication.** Default to cheap storage with indexes on a few fields (§56.6.8) and offer full-text indexing only to tenants whose queries need it, billed accordingly.

WORKED EXAMPLE

Worked example — Metrics. Assumptions: 50 million active series; 15 s scrape interval; 1.37 bytes per sample after Gorilla-style compression [Pelkonen et al. 2015; §12.8.2]; about 4 KB of ingester memory per active series for its in-memory chunk and index entries (illustrative); replication factor 3 in ingesters.

1. Samples per second: $5 \times 10^7 / 15 = 3.33 \times 10^6$.
2. Storage per day: $3.33 \times 10^6 \times 86,400 \times 1.37 = 395$ GB; 15 days raw: 5.9 TB.
3. Downsampled to 5-minute resolution for 13 months (395 days): $5 \times 10^7 \times 288 \times 395 \times 1.37 = 7.8$ TB.
4. Ingester memory: $5 \times 10^7 \times 4,000 \times 3 = 600$ GB across the ingester fleet.

Interpretation. Metrics need about 17 times less disk per day than compressed logs (395 GB versus 6.91 TB), but their cost lives in memory and scales with the number of *series*, not samples. **Engineering implication.** The metrics platform's capacity limit is cardinality (§40.5.3); enforce it per tenant at ingestion.

Kafka sits between agents and storage as a shock absorber, and its size follows from the outage it must ride out.

FORMULA

Buffer size and drain time

$$B = \frac{r}{\rho} T_{\text{ret}} f \qquad T_{\text{drain}} = \frac{T_{\text{out}} r}{c - r}$$

Symbol	Meaning	Units
B	Disk needed across the Kafka cluster	bytes
r	Average raw ingest rate	bytes/s
ρ	Producer compression ratio	dimensionless
T_{ret}	Retention, at least the longest downstream outage to survive	s
f	Replication factor	count
T_{out}	Duration of a downstream (storage) outage	s
c	Maximum consumption rate of the downstream ingesters	bytes/s
T_{drain}	Time to consume the backlog after recovery while new data keeps arriving	s

WORKED EXAMPLE

Worked example — Riding out a six-hour storage outage. Use $r = 800$ MB/s, $\rho = 4$, $T_{\text{ret}} = 24$ h, $f = 3$, $T_{\text{out}} = 6$ h.

1. Buffer: $800/4 \times 86,400 \times 3 = 5.18 \times 10^{13}$ B **= 51.8 TB** of broker disk.
2. With ingesters provisioned at $c = 2r$: $T_{\text{drain}} = 6 \times r/(2r - r) = 6$ h.
3. With $c = 1.25r$: $T_{\text{drain}} = 6/0.25 = 24$ h. No data is lost (the backlog never exceeds 6 hours of age, well inside 24 hours of retention), but logs are hours stale for a full day.

Interpretation. Retention protects against loss; consumer headroom determines how long the platform stays stale afterwards. **Engineering implication.** Provision ingesters at about 2× average rate and allow them to scale out during catch-up; prioritize draining the newest data for live debugging while the backlog drains in parallel.

56.6.5 API design

```
# Ingestion (tenant identified by an authenticated token, never trusted from a header
alone)
POST /v1/logs                         OTLP/HTTP log records, gzip; 200 or 429 with
Retry-After

GET  /api/tenants/{tenant}/usage?month=2026-10
```

A `429` from ingestion is a designed signal, not an error: agents back off and buffer locally (§22.3.4). Query endpoints enforce limits on time range, bytes scanned and result size per tenant, because a single careless query (“all logs, last 30 days, containing ‘error’”) can consume the cluster.

56.6.6 Data model and database schema

Logs are stored as a wide, append-only table sorted by tenant, service and time, so that the dominant query ("this service, this time range") reads a contiguous range. In a ClickHouse-style columnar store [ClickHouse Docs]:

```
-- Illustrative ClickHouse DDL; check syntax against your server version
CREATE TABLE logs
(
    tenant    LowCardinality(String),
    service   LowCardinality(String),
    ts        DateTime64(3),
    level     LowCardinality(String),
    host      LowCardinality(String),
    trace_id  String,
    body      String,
    attrs     Map(LowCardinality(String), String),
    INDEX idx_trace trace_id TYPE bloom_filter(0.01) GRANULARITY 4,
    INDEX idx_body  body     TYPE tokenbf_v1(32768, 3, 0) GRANULARITY 4
)
ENGINE = MergeTree
PARTITION BY toDate(ts)
ORDER BY (tenant, service, ts)
TTL toDateTime(ts) + INTERVAL 7 DAY TO VOLUME 'warm',
    toDateTime(ts) + INTERVAL 30 DAY DELETE
SETTINGS storage_policy = 'hot_warm';
```

What to notice:

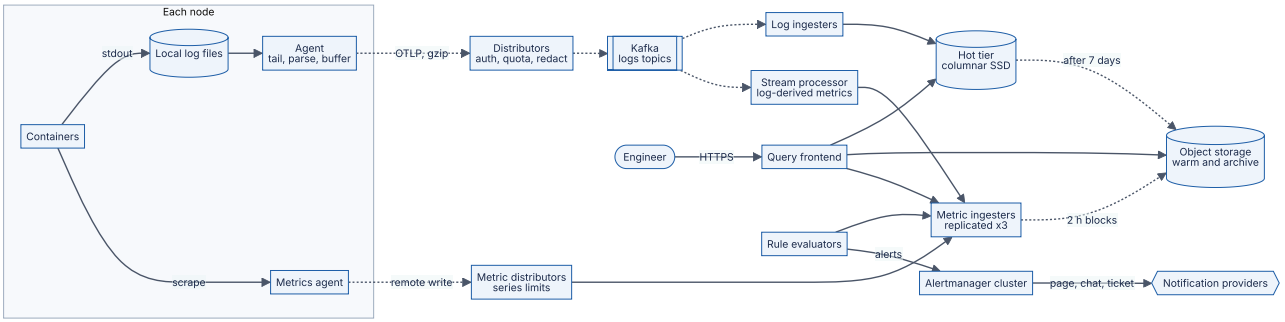
- `ORDER BY (tenant, service, ts)` defines the sparse primary index, one entry per granule of rows (8,192 by default), so a service-and-time query skips almost every granule [ClickHouse Docs].
- `LowCardinality` dictionary-encodes repetitive strings; together with per-column compression this is where the 10:1 ratio comes from.
- The two **data-skipping indexes** are small per-granule Bloom filters (§17.4): they let a trace-ID lookup or a token search skip granules that cannot match, without a full inverted index.
- `TTL … TO VOLUME 'warm'` moves parts to object-storage-backed disks after 7 days; `DELETE` enforces retention by dropping whole parts, which is cheap because partitions are by day.

Metrics use the time-series model of §12.8: a series is identified by its metric name and sorted label set, hashed to a series ID; an inverted index maps each label pair to the series that carry it; samples live in compressed chunks per series, grouped into 2-hour blocks that are uploaded to object storage and compacted (§40.8.4).

Tenant configuration (limits, retention, routing, ownership) is small, strongly consistent data in a relational database, cached by every distributor.

56.6.7 High-level architecture

Figure 56.8 — Multi-tenant logging and monitoring platform.



Reading the diagram. On each node, containers write to local files (the first durable buffer) and an agent tails, parses and batches them; a metrics agent scrapes local endpoints. Both ship asynchronously to stateless **distributors**, which authenticate the tenant, enforce ingestion quotas and series limits, redact, and either append logs to Kafka or forward metric samples to replicated metric ingesters. Kafka is the second durable buffer: log ingesters consume it to build columnar parts on the hot SSD tier, which age into object storage, while a stream processor derives metrics from logs (error counts per service) and writes them to the metrics path. Metric ingesters hold recent samples in memory and upload 2-hour blocks to object storage. Synchronous paths are the engineer's queries through the query frontend (to hot storage, object storage and ingesters) and the rule evaluators' queries; alerts flow to the Alertmanager cluster and on to external notification providers. Failure points: distributors (stateless, replaceable), Kafka (replicated), ingesters (replicated; replay from Kafka), object storage (provider durability), and the rule-to-notification path, which §56.6.8 isolates. Scaling: add distributors and ingesters horizontally, partition Kafka by tenant and service, and shard metric series by hash.

56.6.8 Detailed component design

Collection and buffering

Agents (Fluent Bit, Vector or the OpenTelemetry Collector) tail container log files rather than receiving logs over the network from applications, so that an agent restart or a platform outage never blocks an application's writes. Each agent keeps a bounded **disk buffer** (for example 1 GB or one hour, whichever is smaller) and sends compressed batches every second or 1 MB. When distributors return `429` or are unreachable, the agent backs off with jitter (§22.12) and keeps buffering; when the buffer is full it drops the oldest DEBUG and INFO lines first and counts every drop in a metric.

Distributors are stateless and do the per-tenant work before anything is stored: authenticate, apply the tenant's token-bucket ingestion quota (§22.4), apply sampling rules, redact, and append to Kafka. Kafka topics are partitioned by hash of (tenant, service), so

a service's lines stay ordered and one consumer handles them; the largest tenants ("whales", §47.6.2) get dedicated topics so that their bursts queue separately. Kafka's role is the one formalized in §56.6.4: absorb the 3× incident peak and any downstream outage up to 24 hours, so that storage is sized for the average.

Log storage: what to index

The central design decision is how much indexing to do at write time to make reads fast. Chapter 40 compares the three families (Table 40.3); applied to this platform's 69 TB/day the comparison becomes quantitative.

Table 56.18 — Log storage options at 69 TB/day.

	Full-text inverted index (Elasticsearch/OpenSearch)	Label index + compressed chunks (Loki-style)	Columnar with skip indexes (ClickHouse-style)
What is indexed	Every token of every field	Only stream labels (tenant, service, level)	Sort key (tenant, service, time) plus optional Bloom-filter skip indexes
Hot storage (7 days, 2 copies)	~484 TB SSD (§56.6.4)	Chunks in object storage; small index	~97 TB SSD
Ingest CPU	Highest: tokenization and index merges	Lowest: compress and upload	Low to medium: sort and compress parts
"1 h of one service, grep 'timeout'"	Milliseconds	~0.3 s brute-force scan (below)	Sub-second; token skip index helps
"Trace ID across all services, 7 days"	Milliseconds	Scans everything: hours	Seconds with a Bloom skip index on `trace_id`
Aggregations ("errors per endpoint per minute")	Moderate	Slow	Fastest
Choose when	Security investigations, free-text across everything	Most queries start from service and time	Wide structured events, heavy aggregation

The brute-force numbers follow from scan rates. A service producing 1% of the volume writes 8 MB/s raw, 28.8 GB per hour. If decompress-and-filter runs at about 1 GB/s per core (an illustrative figure; measure your own), one hour scans in $28.8/100 = 0.29$ s on 100 query cores and 7 days in 48 s. But a query with no label selectivity across all services for 7 days scans 484 TB raw: $484,000/100 = 4,838$ s, or 1.3 hours. Label-only indexing is excellent for the common case and unusable for the needle-in-a-haystack case, which is why the design adds a Bloom-filter skip index on `trace_id` and on tokens: a few bytes per granule turn most needle queries back into seconds.

INDUSTRY EXAMPLE

Grafana Loki: index the labels, not the text. Loki's documentation describes a log store that indexes only a small set of labels per stream and stores log content as compressed chunks in object storage, then filters content at query time in parallel. The documented consequence is guidance to keep label cardinality low (labels like service and environment, not user or request IDs), because each unique label combination is a separate stream with its own index entry and chunks; high-cardinality values belong in the log line or in structured metadata. *Evidence: Primary* — [Grafana Loki Docs]

The platform's choice is the columnar store as the default for all tenants, a full-text index tier only for the security team's audit streams (about 2% of volume), and object storage for warm and archive data with on-demand **rehydration** into a temporary hot cluster for investigations of old incidents.

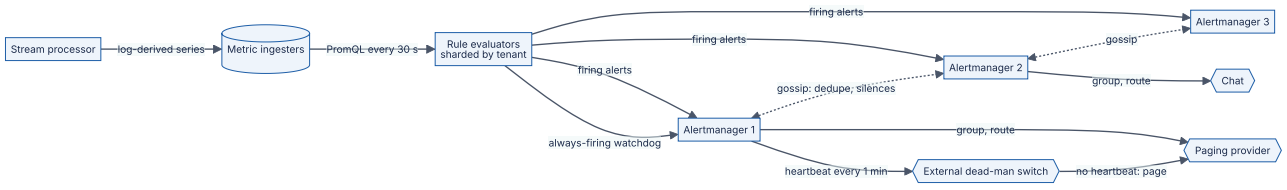
Metrics time-series store

Metrics follow the scalable-Prometheus pattern of §40.8.4. Each node's agent scrapes locally (keeping the pull model's health signal, §40.5.4) and remote-writes to **metric distributors**, which check the tenant's series limit, then hash each series to three **ingesters** (consistent hashing, §14.8). Ingesters keep the last two hours in memory, write a write-ahead log for crash recovery, and upload immutable blocks to object storage; **compactors** merge blocks and produce 5-minute downsampled blocks for long ranges; **store gateways** serve old blocks. Queries fan out to ingesters for recent data and to store gateways for older data, and a query frontend splits long ranges by day and caches results for completed days.

Alerting pipeline

Figure 56.9 shows the alerting path separately because its reliability requirements are stricter than the rest of the platform's.

Figure 56.9 — The alerting pipeline and its independent watchdog.



Reading the diagram. Rule evaluators, sharded by tenant and rule group, query the metric ingesters every 30 seconds. Log-based alerts do not query the log store: the stream processor turns log patterns into metric series as logs flow past, so alerting depends only on the metrics path. Firing alerts go to *every* Alertmanager replica; the repli-

cas gossip asynchronously (dotted) to share silences and notification state, so each alert is sent once even though three replicas received it (§40.10.3). Alertmanager groups related alerts, applies inhibition, and routes them to external providers. The bottom path is the **watchdog**: an alert that always fires, whose notifications act as a heartbeat to an external dead-man's-switch service in a different failure domain; if heartbeats stop, because evaluators, Alertmanager or the network have failed, the external service pages on-call directly. Storage boundary: only the ingesters (the evaluators and Alertmanagers keep small local state). Failure points: an evaluator shard falling behind (missed evaluations are counted and alerted on), metric ingestion delay (rules see stale data, so rules should check data freshness), and loss of the whole platform (caught by the watchdog). Scaling: shard evaluators by tenant; Alertmanager load is small.

Three design rules make alerting trustworthy. First, **separate failure domains**: the alerting path does not depend on the log store, the query frontend, or the dashboards, and its components run on dedicated capacity with higher priority than ad hoc queries. Second, **monitor the monitor** externally, because a monitoring system cannot report its own total failure. Third, **alert on the platform's own SLOs** (ingestion lag, rule evaluation delay, dropped samples) with burn-rate rules (§39.7.3, §40.10.2), routed to the platform team.

Multi-tenant cost control

Without controls, observability cost grows faster than the business, because every new feature adds lines, labels and dashboards. The platform enforces four controls at ingestion, where they are cheapest:

1. **Ingestion quotas.** A token bucket per tenant in MB/s with a burst allowance (§22.4); over-quota data is rejected with `429`, which the agent buffers and then drops lowest-severity first.
2. **Cardinality limits.** A maximum number of active series per tenant and per metric. When a deploy adds a `user_id` label, a counter with 50 endpoints × 10 statuses × 100 pods (50,000 series) becomes $5 \times 10^4 \times 10^6 = 5 \times 10^{10}$ series (§40.5.3); the limit rejects *new* series while existing series keep flowing, so dashboards stay correct and the owning team gets an alert.
3. **Sampling and dropping rules.** Per-tenant rules drop DEBUG in production, sample successful-request INFO lines by request (§40.4.4), and never sample errors.
4. **Showback.** Monthly usage per tenant (GB ingested, GB-days stored, active series, bytes scanned by queries), priced and published (§51.5.2), so teams see the cost of what they emit.

```
        """Per-tenant active-series limiter, as a metrics distributor might apply it.
        Samples for known series are always accepted; a NEW series is rejected once the
tenant is at its limit."""
        from collections import defaultdict

        class SeriesLimiter:
            def __init__(self, limits, default_limit):
                self.limits, self.default = limits, default_limit
                self.active = defaultdict(set)          # tenant -> set of series keys
(reset as series go stale)
                self.rejected = defaultdict(int)        # exported as a per-tenant met-
ric

            @staticmethod
            def series_key(metric, labels):
                return metric + "{" + ",".join(f"{k}={labels[k]}" for k in sorted(la-
bels)) + "}"

            def admit(self, tenant, metric, labels):
                key = self.series_key(metric, labels)
                series = self.active[tenant]
                if key in series:
                    return True
                if len(series) >= self.limits.get(tenant, self.default):
                    self.rejected[tenant] += 1
                    return False
                series.add(key)
                return True

        if __name__ == "__main__":
            lim = SeriesLimiter(limits={"payments": 1000}, default_limit=500)
            ok = 0
            for user in range(2000):                    # a bad deploy adds a user_id
label
                ok += lim.admit("search", "http_requests_total",
                                {"endpoint": "/q", "status": "200", "user_id":
str(user)})
            ok += lim.admit("search", "http_requests_total", {"endpoint": "/q", "sta-
tus": "200", "user_id": "7"})
            print("accepted:", ok, "active:", len(lim.active["search"]), "rejected:",
lim.rejected["search"])
            print("other tenant unaffected:", lim.admit("payments", "up", {"pod": "p-
1"}))
```

Output:

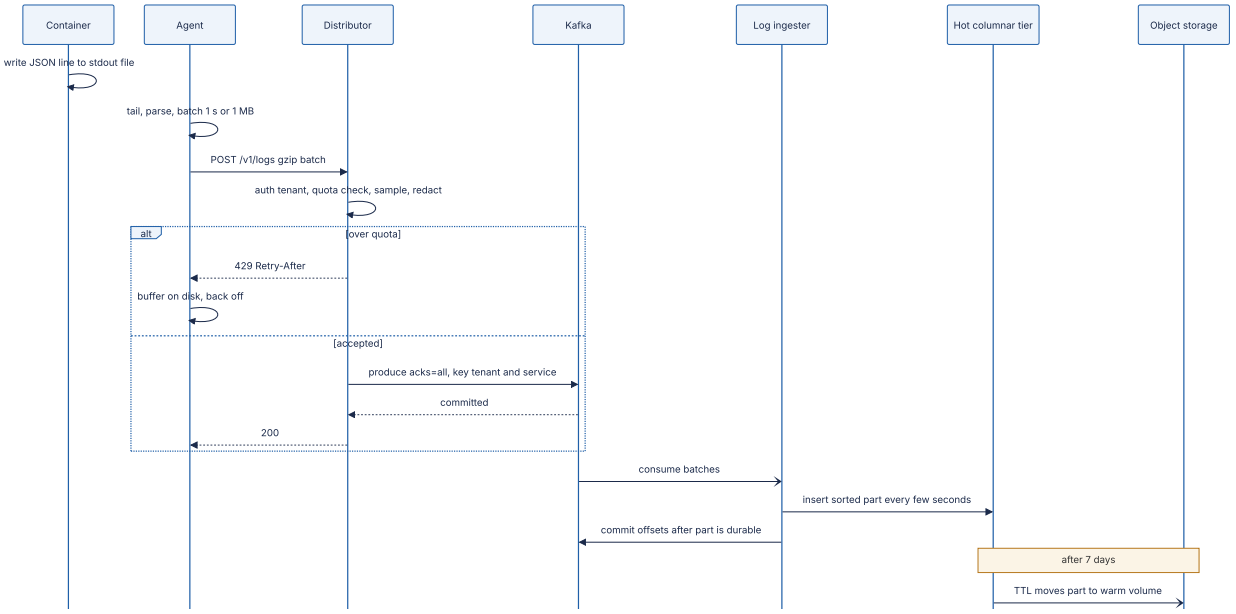
```
accepted: 501 active: 500 rejected: 1500
other tenant unaffected: True
```

What to notice: the series key sorts labels, so `{a=1,b=2}` and `{b=2,a=1}` are the same series; an existing series (`user_id=7`) is still accepted after the limit is hit; the rejection counter is per tenant, so the alert goes to the team that caused it; and one tenant's explo-

sion does not consume another tenant's allowance. A production limiter runs per distributor with limits divided by the number of distributors (or coordinated through the ingesters) and expires series that have not been written for the staleness period.

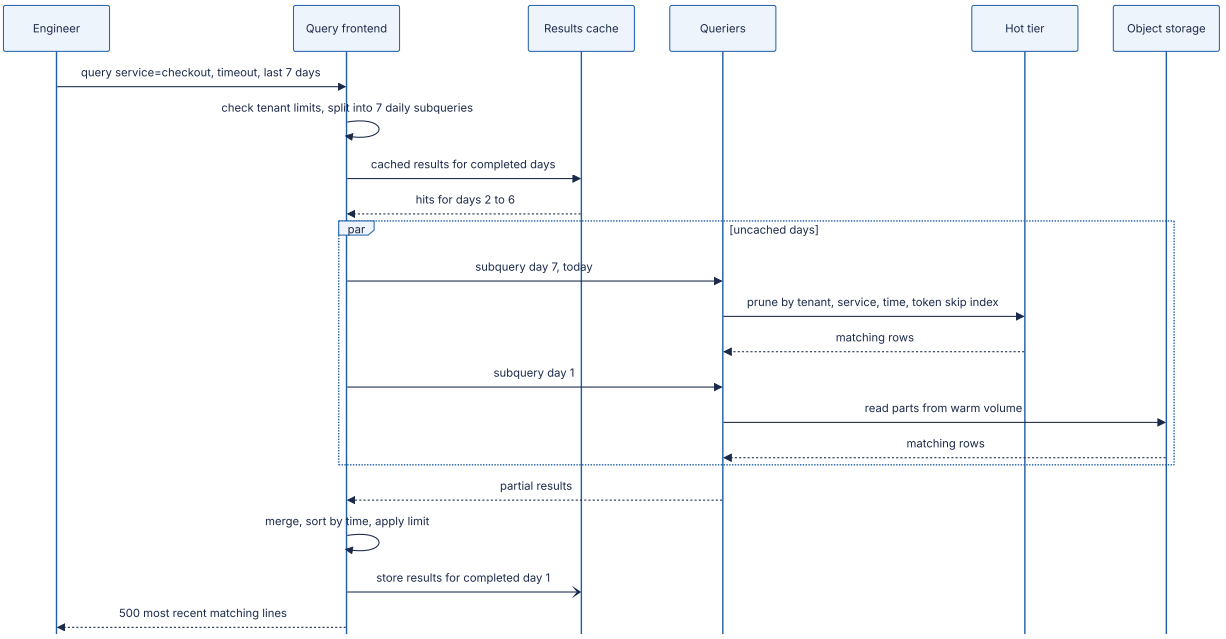
56.6.9 Data flow

Figure 56.10 — Write path: a log line from container to searchable.



Reading the diagram. The application's only synchronous action is writing to a local file, so the platform can never block it. The agent ships batches synchronously to a distributor, which either rejects with `429` (the agent buffers and retries later) or appends to Kafka with `acks=all` (§31.6.2) and acknowledges only after the append is replicated, making Kafka the commit point. Ingesters consume asynchronously, write sorted columnar parts, and commit Kafka offsets only after the part is durable, so a crashed ingester rereads and re-inserts; duplicate inserts are avoided by inserting each batch with a deterministic deduplication token derived from topic, partition and offset range. Seven days later the storage TTL moves the part to object storage asynchronously. Failure points: agent disk full (counted drops), distributor overload (`429`), Kafka unavailable (agents buffer), ingester crash (replay). Freshness is batch interval + Kafka + part insertion, typically 5–15 seconds.

Figure 56.11 — Read path: a log query over seven days.



Reading the diagram. The query frontend is the control point: it enforces per-tenant limits on time range and bytes scanned, splits the query by day so that subqueries run in parallel and results for completed days can be cached (a completed day's logs never change), and merges results. Queriers prune by the sort key and skip indexes, so they read only the checkout service's granules that might contain "timeout". Today's data comes from the hot tier and day 1 from object storage, which is slower, so the slowest subquery sets the latency. Failure points: an expensive query (rejected or queued fairly per tenant, §47.8.2), object storage throttling (retries with backoff), a querier crash (subquery retried). Scaling: queriers are stateless and autoscale on queue depth.

56.6.10 Bottlenecks

1. **Incident amplification.** Error storms multiply log volume exactly when engineers query most. Kafka absorbs the write burst; query fairness per tenant and separate query capacity for the alerting path protect reads.
2. **Cardinality in metric ingesters.** Memory scales with active series; one bad label can exhaust an ingester. Series limits at distributors are the defense.
3. **Unselective log queries.** A query without service selectivity over long ranges scans hundreds of terabytes; bytes-scanned limits, skip indexes and asynchronous "search jobs" that write results to a file are the defenses.
4. **Small parts and merges.** Inserting many tiny batches creates many small columnar parts and merge pressure; ingesters batch for a few seconds per partition.
5. **Object-storage request rates.** Many small objects mean many GET requests; compaction into larger parts and blocks keeps request counts and costs down.

56.6.11 Failure scenarios

Table 56.19 — Logging and monitoring failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Hot-tier cluster outage	Logs not searchable; ingestion continues into Kafka	Ingester errors, consumer lag	Restore; ingesters drain backlog	24 h Kafka retention; 2× ingester headroom
Kafka cluster degraded	Distributors return errors; agents buffer	Produce error rate, under-replicated partitions	Agents retry; scale or repair brokers	Replication 3, `min.insync.replicas=2`, rack awareness
Cardinality explosion in one tenant	Ingester memory pressure for everyone	Active series per tenant; ingester memory	Series limit rejects new series; alert owner	Per-tenant and per-metric limits; label linting in CI
Log storm from one service	Quota exhaustion; other tenants' latency	Ingest rate per tenant	Token bucket throttles that tenant only	Per-tenant quotas; dedicated topics for whales
Rule evaluators fall behind	Alerts late or missing	Evaluation duration and missed-iteration metrics	Scale evaluators; shed recording rules first	Shard by tenant; dedicated capacity
Whole platform down	No alerts at all	External dead-man's switch stops receiving heartbeats	Page platform on-call directly	Watchdog alert to an external service
Personal data leaked into logs	Compliance incident	Pattern scanners on samples; reports	Delete affected partitions; rotate secrets	Redaction in distributors; source allowlists

56.6.12 Scaling strategy

At 10× volume (690 TB/day of logs, 500 million series): components scale horizontally but cost scales with them, so change what is kept: make sampling the default, shorten hot retention, and convert repetitive logs into metrics in the stream processor. Split the platform into **cells** (§44.10) of tenants, each with its own Kafka, ingesters and storage, bounding cluster size and blast radius.

At 100×: data stays in the region that produced it (7 PB/day cannot cross regions) and queries federate across cells; tenants are billed at true cost, and long-term retention moves to open columnar files in object storage queried on demand.

56.6.13 Trade-offs

Table 56.20 — Logging and monitoring trade-offs.

Decision	Chosen	Alternative	Why
Default log store	Columnar with skip indexes	Full-text inverted index	~5× less hot storage and lower ingest CPU; full text kept for audit tenant
Buffering	Agent disk + Kafka	Direct agent → storage	Absorbs incident peaks and storage outages; de-couples ingestion from indexing
Over-quota behavior	Reject with `429`, agent buffers then drops low severity	Accept everything	Protects other tenants and the bill; drops are counted and visible
Log-based alerts	Metrics derived in the stream	Periodic log queries	Alerting independent of the log store; cheaper and faster
Metrics cardinality	Hard per-tenant series limits	Unlimited	Memory is the binding constraint; protect the shared fleet
Alerting reliability	Separate path plus external watchdog	Same cluster as dashboards	The monitor must survive what it monitors

56.6.14 Alternative designs

- **Hosted observability vendor.** Cheaper in engineering time below this scale; per-GB pricing grows with volume and data leaves your network. Hybrids (vendor for metrics and traces, self-hosted object storage for bulk logs) are common.
- **Wide structured events** (§40.3.3) in a columnar store unify logs and metrics at the cost of larger events and new instrumentation discipline.
- **Elasticsearch for everything.** Simplest when volume is modest and free text dominates; the most expensive option at 69 TB/day.
- **Push-only metrics** (OTLP) simplify crossing network boundaries but lose the scrape's implicit "target is up" signal.

56.6.15 Interview discussion

Table 56.21 — 45-minute pacing plan for the logging and monitoring platform.

Minutes	Focus	What to produce
0–5	Scope	Logs and metrics, multi-tenant, alerting critical; traces referenced
5–12	Estimates	800 MB/s logs, 69 TB/day, tiers; 50M series, 3.3M samples/s; Kafka buffer
12–20	Architecture	Figure 56.8: agents, distributors, Kafka, ingesters, storage, query, alerting
20–30	Deep dive: log storage	Index versus columnar versus label-only; skip indexes; scan arithmetic
30–38	Deep dive: alerting and tenancy	Separate alert path, watchdog, quotas, cardinality limits, showback
38–45	Wrap-up	Failures, 10× via sampling and cells, cost

Likely follow-ups.

- *"Why Kafka in the middle?"* To absorb incident bursts and storage outages without dropping data or blocking agents, and to let several consumers (storage, stream-derived metrics, security) read the same data.
- *"How do you stop one team from taking down the platform?"* Per-tenant token-bucket quotas, active-series limits, query limits on bytes scanned, fair queuing of queries, and dedicated topics or cells for whales.
- *"How do you know alerting works?"* Separate failure domain, always-firing watchdog to an external dead-man's switch, and SLO alerts on evaluation delay and ingestion lag.
- *"Why not index everything?"* At 69 TB/day the inverted index roughly quintuples hot storage and dominates ingest CPU, and most queries start from service and time anyway.

What distinguishes senior and staff answers. A senior answer draws a sound pipeline with buffering, chooses a storage engine with reasons and mentions cardinality. A staff answer quantifies the index-versus-scan trade-off and designs for the needle query with skip indexes, sizes Kafka from an outage duration and consumer headroom, isolates and externally monitors the alerting path, and treats cost as a product feature with quotas, limits and showback, because the platform's main long-term risk is not failure but unbounded growth.

56.6.16 Production considerations

- **Observability of the platform itself.** Ingestion lag (emission to searchable), per-tenant accepted, throttled and dropped bytes, Kafka consumer lag, ingester memory

and series counts, rule-evaluation delay, query queue time and bytes scanned. These are the platform's SLIs (§39.6).

- **Security.** Logs contain secrets and personal data despite best efforts: authenticate agents with per-node credentials, enforce tenant isolation at query time from the authenticated identity (never from a client-supplied label, §47.12.2), redact in distributors, encrypt at rest, and audit who searched what.
- **Cost.** Hot storage and ingest CPU dominate; object storage is cheap but request-priced. Publish cost per tenant monthly and make the cheapest path (structured, sampled, metric-ified) the default in the logging libraries.
- **Operations.** Upgrade ingesters and Kafka with rolling restarts that respect replication; rehearse a full hot-tier loss by replaying from Kafka; and review retention against legal requirements, since keeping logs longer than necessary is both a cost and a liability.

56.7 Real-time Analytics Platform

56.7.1 Problem statement

Design the analytics platform behind an advertising network's reporting. Advertisers open a dashboard and see impressions, clicks, conversions and spend for their campaigns, sliced by ad, country, device and time, with the current minute's numbers updating every few seconds. The same numbers feed budget pacing (stop serving a campaign that has spent its daily budget) and, after the day closes, invoicing.

Three properties make this hard and distinguish it from the logging platform of §56.6. First, events arrive **out of order**: a phone that was offline uploads yesterday's impressions this morning, so "clicks between 10:00 and 10:01" depends on *when the click happened* (event time), not when it arrived (processing time) (§29.8.1). Second, the numbers are **money**: a click counted twice is an overcharge, a click lost is lost revenue, so aggregation must be effectively exactly once (§31.11, §32.9). Third, queries come from tens of thousands of external users who expect **sub-second** answers over months of data. The design must choose between aggregating in the stream and aggregating in an OLAP store at query time, and between Lambda and Kappa architectures (§29.10).

56.7.2 Functional requirements

1. **Ingest events** (impression, click, conversion) from ad servers and client SDKs, each with a globally unique event ID, event time, advertiser, campaign, ad, country, device and cost.
2. **Live dashboards**: per-advertiser metrics at 1-minute granularity for the last 48 hours, refreshing every few seconds.

3. **Historical reports**: any date range over 13 months at hour or day granularity, grouped and filtered by any dimension.
4. **Budget pacing feed**: per-campaign spend so far today, available to ad servers within seconds.
5. **Billing-grade daily close**: final, deduplicated per-campaign totals for the previous day, reproducible on demand.
6. **Corrections**: invalid-traffic (fraud) filtering may retract clicks hours later; reports must reflect retractions.

56.7.3 Non-functional requirements

Table 56.22 — Real-time analytics non-functional requirements.

Property	Target	Why
Freshness, live metrics	p95 ≤ 10 s from event to query result	Advertisers watch launches live; pacing needs it
Freshness, final minute value	≤ 2 min after the minute ends	Late events must be waited for before a minute is “final”
Correctness	No duplicates or loss in billing totals; live numbers within 0.5% of final	Invoices must match; dashboards may lag corrections briefly
Query latency	p50 ≤ 100 ms, p99 ≤ 500 ms	Interactive dashboards with many panels
Query availability	99.95%	Customer-facing
Ingestion durability	No accepted event lost (99.999% of events)	Each event is revenue
Retention	Minute grain 48 h; hour grain 13 months; raw events 2 years in the lake	Detail where it is used, cost elsewhere
Isolation	An advertiser sees only its own data	Multi-tenant, external users

56.7.4 Capacity estimation

WORKED EXAMPLE

Worked example — Ingestion. Assumptions: 2 million events/s average, 5 million/s at peak; 500 bytes per event as received; producer compression 4:1; Kafka retention 7 days with replication 3 (long enough to replay a week through a fixed job, §56.7.8).

1. Raw bandwidth: $2 \times 10^6 \times 500 = 1$ GB/s average, 2.5 GB/s at peak.
2. Per day: $10^9 \times 86,400 = 86.4$ TB raw.
3. Kafka disk: $86.4/4 \times 7 \times 3 = 453.6$ TB.

Interpretation. Retaining a week in Kafka is what makes “fix the job and replay” a routine operation instead of a crisis. **Engineering implication.** Size Kafka for replay, not only for buffering, and set the raw-event lake copy as the source for anything older.

WORKED EXAMPLE

Worked example — Rollup ratio and storage. Assumptions: in a typical minute, the 120 million events (2 million/s × 60) fall into 4 million distinct combinations of (advertiser, campaign, ad, country, device, event type); a rolled-up row stores the dimensions plus counts and spend in about 60 bytes compressed in a columnar store; raw events compress 8:1 in columnar form.

1. Rollup ratio: $1.2 \times 10^8 / 4 \times 10^6 = 30$ events per row.
2. Minute rows per day: $4 \times 10^6 \times 1,440 = 5.76 \times 10^9$; storage $5.76 \times 10^9 \times 60 = 345.6$ GB/day.
3. If minute grain were kept 13 months (395 days) with 2 replicas: $345.6 \times 395 \times 2 = 273$ TB. Keeping minute grain only 48 hours and hour grain for 13 months cuts this by an order of magnitude.
4. Raw events in columnar form: $86.4/8 = 10.8$ TB/day; 7 days × 2 replicas = 151 TB.

Interpretation. Rollup by 30× is what makes 13 months of interactive history affordable; keeping raw events queryable for more than a few days would dominate cost. **Engineering implication.** Store several granularities (raw for days, minute for 48 h, hour for 13 months) and let the query layer pick the coarsest one that answers each query.

WORKED EXAMPLE

Worked example — Query load and work per query. Assumptions: 20,000 dashboards open at peak; 10 panels each, refreshing every 30 s; 1,000 additional API queries/s; a large advertiser has 2,000 distinct dimension combinations per minute and 3,000 per hour.

1. Dashboard queries: $20,000 \times 10/30 = 6,667$/s; total about 7,667 queries/s.
2. A 7-day panel at minute grain scans $2,000 \times 1,440 \times 7 = 2.02 \times 10^7$ rows; at hour grain $3,000 \times 24 \times 7 = 5.04 \times 10^5$ rows, 40× fewer.

Interpretation. At 7,667 queries/s the cluster can afford hundreds of thousands of rows per query, not tens of millions. **Engineering implication.** Route each query to the coarsest rollup that answers it, and partition by advertiser so that a query touches one advertiser's data on a few servers.

The freshness requirement is a budget that every hop draws on, and exactly-once processing draws the largest share.

FORMULA

Freshness budget of a windowed streaming aggregate

$$F_{\text{live}} = t_{\text{collect}} + t_{\text{broker}} + t_{\text{commit}} + t_{\text{ingest}} \qquad F_{\text{final}} = W + \delta + t_{\text{commit}} + t_{\text{ingest}} + t_{\text{collect}} + t_{\text{broker}}$$

Symbol	Meaning	Units
F_{live}	Worst-case delay before an event is visible in live (non-final) results	s
F_{final}	Worst-case delay, from the start of a window, until its final value is visible	s
t_{collect}	Client or collector batching interval	s
t_{broker}	Broker append and replication	s
t_{commit}	Wait for the exactly-once commit, at most the checkpoint interval (§29.9.2)	s
t_{ingest}	OLAP consume, index and make queryable	s
W	Window length	s
δ	Watermark's out-of-orderness bound	s

WORKED EXAMPLE

Worked example — Can we meet 10 seconds? Use $t_{\text{collect}} = 0.5$ s, $t_{\text{broker}} = 0.1$ s, checkpoint interval 5 s, $t_{\text{ingest}} = 2$ s, $W = 60$ s, $\delta = 10$ s.

1. $F_{\text{live}} = 0.5 + 0.1 + 5 + 2 = 7.6$ s, inside the 10 s target.
2. With a 30 s checkpoint interval instead, $F_{\text{live}} = 32.6$ s: the exactly-once commit alone breaks the target.
3. $F_{\text{final}} = 60 + 10 + 5 + 2 + 0.5 + 0.1 = 77.6$ s, inside the 2-minute target.

Interpretation. The transactional commit that provides exactly-once output also delays its visibility by up to one checkpoint interval, because read-committed consumers see nothing until the transaction commits. **Engineering implication.** Choose the checkpoint interval from the freshness budget (here 5 s), and check that checkpoints of the job's state complete comfortably within it; if they cannot, serve live numbers from a path that does not wait for the commit (§56.7.8).

56.7.5 API design

External users do not get raw SQL: a structured query API lets the platform enforce tenant isolation, choose rollups and bound cost.

```
POST /v1/events                       (ad servers and SDKs; batched; idempotent by
event_id)
{ "events": [ { "event_id": "01JC…", "type": "click", "event_time": "2026-11-
05T10:00:41.120Z",
                "advertiser_id": 4411, "campaign_id": 98, "ad_id": 1203, "country":
"DE",
                "device": "mobile", "cost_micros": 420000 } ] }
202 Accepted

POST /v1/reports/query                (advertiser token; advertiser_id taken from the
token)
{ "metrics": ["impressions", "clicks", "spend"], "dimensions": ["campaign_id", "coun-
try"],
  "filters": { "device": ["mobile"] }, "granularity": "minute",
  "interval": "2026-11-05T09:00Z/2026-11-05T10:00Z" }
200 OK
{ "rows": [ { "ts": "2026-11-05T09:00Z", "campaign_id": 98, "country": "DE",
              "impressions": 18342, "clicks": 211, "spend": 88.62 }, … ],
  "final_until": "2026-11-05T09:58Z",      // windows before this are final; later ones
may change
  "granularity_used": "minute" }

GET /v1/pacing/campaigns/{campaign_id}/spend_today    (internal, for ad servers)
```

`final_until` is the API's honest statement about event time: it exposes the watermark, so a dashboard can draw the last two minutes as provisional rather than presenting incom-

plete numbers as fact.

56.7.6 Data model and database schema

The event schema is registered in a schema registry (§32.6.3) and evolves compatibly. The OLAP store holds three tables with the same dimensions at different grains: raw events (7 days), minute rollup (48 hours) and hour rollup (13 months), each partitioned by time and by hash of `advertiser_id` and sorted by advertiser first, so one advertiser's rows are contiguous.

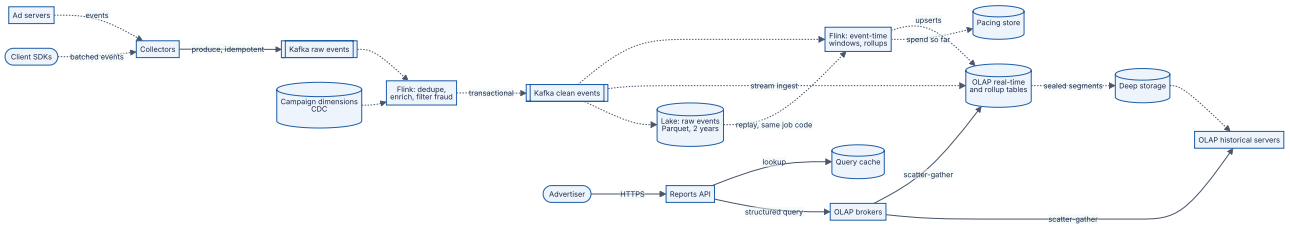
The rollup written by the streaming job is designed for **idempotent upserts**: each row carries the *full* value of a window, not an increment, plus a version, so writing the same row twice, or a corrected row later, converges to the right answer. In ClickHouse terms [ClickHouse Docs]:

```
        -- Illustrative; check syntax against your server version
        CREATE TABLE agg_minute
        (
            advertiser_id  UInt64,
            campaign_id    UInt64,
            ad_id          UInt64,
            country        LowCardinality(String),
            device         LowCardinality(String),
            minute         DateTime,
            impressions    UInt64,
            clicks         UInt64,
            spend_micros   UInt64,
            version        UInt64          -- e.g. watermark or emit time of the produc-
ing job
        )
        ENGINE = ReplacingMergeTree(version)
        PARTITION BY toDate(minute)
        ORDER BY (advertiser_id, campaign_id, minute, ad_id, country, device)
        TTL minute + INTERVAL 2 DAY DELETE;
```

What to notice: `ReplacingMergeTree(version)` keeps, for each sorting key, the row with the highest version, but only when background merges run, so queries that must be exact read with `FINAL` (or aggregate with `argMax(clicks, version)`) to collapse versions not yet merged; the sort key starts with `advertiser_id`, which is also the tenant filter on every query; the TTL implements the 48-hour retention of this grain.

56.7.7 High-level architecture

Figure 56.12 — Real-time analytics platform (Kappa architecture with a lake for history).



Reading the diagram. Dotted arrows are asynchronous data flow; solid arrows are synchronous requests. Collectors accept events and append them to the raw Kafka topic with idempotent producers. A first Flink job deduplicates by event ID, enriches events with campaign dimensions arriving by change data capture, applies fraud filters, and writes clean events transactionally. A second job computes event-time windowed rollups and writes idempotent upserts to the OLAP store and campaign spend to the pacing store; the OLAP store also ingests clean events directly, so recent raw events are queryable within seconds. Sealed segments move to deep storage (object storage) and are served by historical servers. The advertiser's query passes through the reports API, which checks a query cache and sends a structured query to OLAP brokers, which scatter it to real-time and historical servers and merge results. The lake keeps two years of raw events and can be replayed through the same aggregation code. Storage boundaries: both Kafka topics, the OLAP servers, deep storage, the pacing store and the lake. Failure points: Flink job failure (restart from checkpoint), OLAP real-time server loss (re-consume from Kafka offsets), broker overload (cache, limits). Scaling: Kafka partitions and Flink parallelism for ingestion; OLAP servers by advertiser hash and time for queries.

56.7.8 Detailed component design

Event time, watermarks and late data

The aggregation job assigns each event to a one-minute **tumbling window** by its event time (§29.8.2). A **watermark** (§29.8.3) declares "no events older than T are still expected"; here it trails the largest event time seen by $\delta = 10$ s. When the watermark passes a window's end, the window fires its first result. Events that arrive later but within an **allowed lateness** of 120 s update the window and re-emit its full value; events later than that go to a **side output** of corrections that the daily close applies. This is the Dataflow model's separation of *what* is computed, *where* in event time, *when* in processing time results are emitted, and *how* refinements relate [Akidau et al. 2015].

```
        """Event-time tumbling windows with a watermark, allowed lateness and deduplica-
tion.
        Emits idempotent UPSERTs of the full window value, so replaying output is harm-
less."""
        from collections import defaultdict

        WINDOW, OUT_OF_ORDER, LATENESS = 60, 10, 120          # seconds

        class WindowedCounter:
            def __init__(self):
                self.max_ts = float("-inf")
                self.state = defaultdict(lambda: [0, 0.0])     # (window_start, cam-
paign) -> [clicks, spend]
                self.fired, self.seen_ids = set(), set()
                self.out, self.too_late = [], []

            def watermark(self):
                return self.max_ts - OUT_OF_ORDER               # "no event older than
this is still expected"

            def on_event(self, event_id, ts, campaign, spend):
                if event_id in self.seen_ids:                   # producer retry or re-
play: drop the duplicate
                    return
                start = ts - ts % WINDOW
                if start + WINDOW + LATENESS <= self.watermark():
                    self.too_late.append(event_id)              # beyond allowed late-
ness: route to batch correction
                    return
                self.seen_ids.add(event_id)
                key = (start, campaign)
                self.state[key][0] += 1
                self.state[key][1] += spend
                if key in self.fired:                           # late but allowed: re-
emit the corrected full value
                    self.out.append(("UPSERT", key, tuple(self.state[key]), "late-up-
date"))
                self.max_ts = max(self.max_ts, ts)
                self._fire()

            def _fire(self):
                for key in sorted(self.state):
                    if key not in self.fired and key[0] + WINDOW <= self.watermark():
                        self.fired.add(key)                     # watermark passed win-
dow end: emit first result
                        self.out.append(("UPSERT", key, tuple(self.state[key]), "on-
time"))

        if __name__ == "__main__":
            w = WindowedCounter()
            events = [("e1", 5, "c1", 0.5), ("e2", 50, "c1", 0.5), ("e3", 61, "c1",
0.5),
                      ("e2", 50, "c1", 0.5),                    # duplicate delivery
                      ("e4", 75, "c1", 0.5),                    # watermark 65 -> window
[0,60) fires
                      ("e5", 58, "c1", 0.5),                    # late but within late-
```

```
ness: correction
                    ("e6", 200, "c1", 0.5),                 # watermark 190 -> window
[60,120) fires
                    ("e7", 30, "c1", 0.5)]                  # 30 falls in [0,60);
0+60+120 <= 190 -> too late
            for e in events:
                w.on_event(*e)
            for row in w.out:
                print(row)
            print("too late:", w.too_late)
```

Output:

```
('UPSERT', (0, 'c1'), (2, 1.0), 'on-time')
('UPSERT', (0, 'c1'), (3, 1.5), 'late-update')
('UPSERT', (60, 'c1'), (2, 1.0), 'on-time')
too late: ['e7']
```

What to notice:

- The duplicate `e2` is dropped by event ID, so a producer retry cannot double-charge. In production the seen-ID set is keyed state with a TTL a little longer than window plus lateness, held in the stream processor's state backend and included in its checkpoints.
- Window [0, 60) fires when `e4` moves the watermark to 65, then is *corrected* when late `e5` arrives; because each output is the full value, the sink overwrites rather than adds, and a replay of the output converges to the same table.
- `e7` arrives after the watermark has passed the window end plus lateness, so it is not silently dropped but routed to corrections.
- A real job also purges state for windows past their lateness and emits early, speculative results for open windows if live panels need them.

Choosing δ and the lateness is a measured decision: plot the distribution of (arrival time − event time) per source. Server-side events are late by seconds; mobile SDK events can be late by hours. Mixing them in one watermark would make the server events wait for the phones, so the job keeps separate watermarks per source class, or treats mobile backfill as corrections.

Exactly-once aggregation

"Exactly once" here means the *effect* on the aggregates is as if each event were counted once, despite retries, crashes and replays (§32.9). The design composes three mechanisms, each covering a different hop:

1. **Producer to Kafka**: idempotent producers (§31.6.3) prevent duplicates from broker-level retries; client-level retries (an SDK resending a batch after a timeout) produce genuine duplicates with the same event ID, which only step 2 can remove.

2. **Inside the stream processor**: deduplication by event ID in keyed state, and Flink's checkpointing with asynchronous barrier snapshots (§29.9.2) makes state and input offsets consistent, so after a crash the job rewinds to the last checkpoint and reprocesses without double counting in its state.
3. **To the outside world**: output must not be duplicated on replay. Two options exist. **Transactional sinks** write to Kafka in transactions committed on checkpoint completion (two-phase commit, §31.11.2), with the freshness cost computed in §56.7.4. **Idempotent sinks** write full window values keyed by (window, dimensions) as upserts, so any number of replays converges; this is the design used for the OLAP rollup table, and it needs no transaction coordination with the OLAP store.

The OLAP store's own Kafka ingestion must also neither skip nor duplicate: Druid and Pinot both record, with each segment they publish, the Kafka offsets it covers, so a restarted ingestion task resumes exactly where the last published segment ended [Apache Druid Docs; Im et al. 2018].

Pre-aggregation versus an OLAP store

Table 56.23 — Where to aggregate.

	Stream pre-aggregation into a key-value store	OLAP store over raw events	Hybrid (chosen)
What it is	Stream job computes fixed rollups; serve by key	Ingest events; aggregate at query time with columnar scans	Stream rollups for known grains, OLAP for raw and ad hoc
Query flexibility	Only the precomputed group-bys	Any filter and group-by	Precomputed fast path; flexible slow path
Query latency	~1 ms lookups	10–500 ms, depending on rows scanned	Mostly tens of ms
Storage	Smallest	Largest (raw)	Raw only for 7 days
Freshness	Window plus commit	Seconds (real-time ingestion)	Seconds for raw, ~1 min final rollups
Corrections	Recompute affected keys	Replace segments for the interval	Upserts plus segment replacement
Choose when	Fixed counters (pacing)	Exploration and drill-down	Customer reporting at scale

The OLAP stores in this space (Druid, Pinot, ClickHouse) share a design shaped by this workload: immutable, time-partitioned **columnar segments**; dictionary encoding and bitmap or inverted indexes on dimensions so filters are cheap; optional **ingestion-time rollup**; and a split between real-time servers that index recent events in memory and historical servers that load sealed segments from deep storage [Yang et al. 2014; Im et al. 2018; ClickHouse Docs].

INDUSTRY EXAMPLE

Druid: real-time and historical nodes over immutable segments. The Druid paper describes an analytical store built for interactive queries on event streams: real-time nodes ingest from a message broker and make events queryable immediately, periodically hand off immutable columnar segments to deep storage, historical nodes load and serve those segments, broker nodes route queries and merge partial results, and coordinator nodes manage segment placement. The segment is the unit of distribution, replication and replacement, which is what makes batch corrections a matter of swapping segments for a time interval. *Evidence: Primary* — [Yang et al. 2014]

INDUSTRY EXAMPLE

Pinot at LinkedIn: user-facing analytics. The Pinot paper describes LinkedIn's real-time OLAP system serving analytics features to members (not only internal analysts), with a hybrid of real-time segments consumed from Kafka and offline segments built from batch data, and a pre-aggregation index (the star-tree) that trades storage for bounded query cost on group-by queries. *Evidence: Primary* — [Im et al. 2018]

Serving sub-second queries

Query latency is controlled by the number of rows each query touches and the number of servers it waits for:

1. **Rollup selection.** The reports API picks the coarsest table that answers the query: hour grain for a 30-day chart, minute grain for the last 6 hours, raw only for drill-down into the last few days (40× fewer rows, §56.7.4).
2. **Partition-aware routing.** Segments are partitioned by hash of `advertiser_id`, and every query filters on it, so the broker sends the query only to the servers holding that advertiser's partition instead of scattering to all of them, which shrinks fan-out and its tail (§16.7.3).
3. **Segment pruning and indexes.** Time ranges prune segments; sorted advertiser columns and bitmap indexes turn filters into range reads and bitmap intersections.
4. **Caching.** Results for intervals that are final (before `final_until`) never change and can be cached for hours; only the live edge is recomputed, so a dashboard refreshing every 30 seconds mostly hits the cache.
5. **Isolation.** Per-advertiser query rate limits and a cap on rows scanned protect the cluster from one expensive customer (§47.8).

Lambda or Kappa

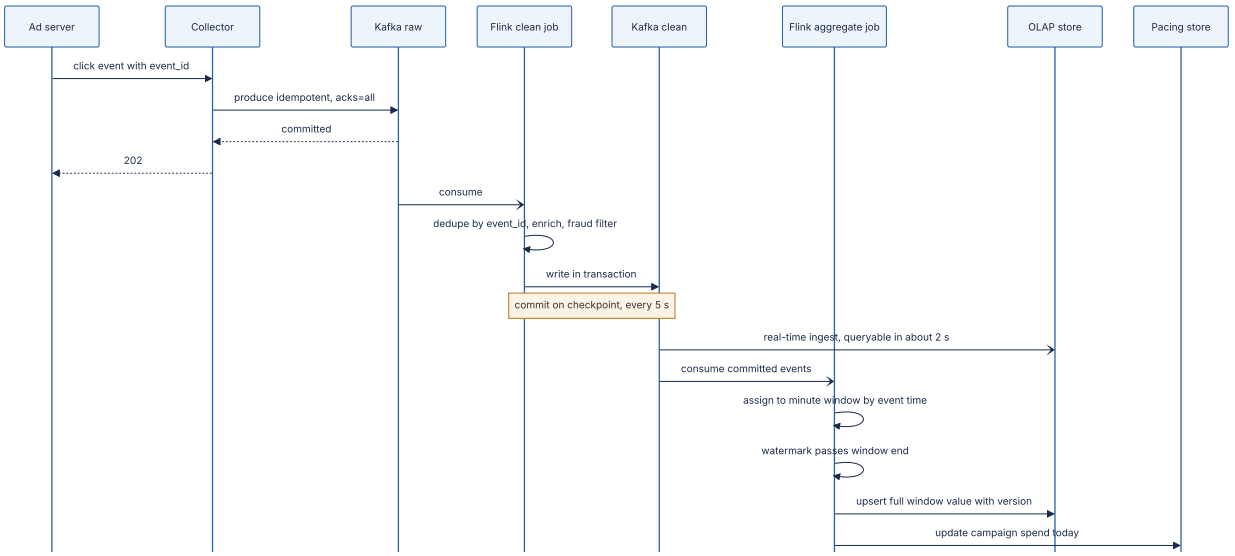
Figure 56.13 — Lambda versus Kappa for this platform.

Reading the diagram. In the **Lambda** subgraph two different jobs compute the same metrics: a streaming speed layer for recent data and a batch layer that periodically recomputes from the lake; queries merge both views [Marz and Warren 2015]. Its cost is two implementations of the same logic that must agree. In the **Kappa** subgraph there is one job; to change logic or fix a bug, a second version replays history from Kafka (or from the lake as a bounded source through the same code) into a new table, and the serving alias is swapped when it catches up [Kreps 2014]. All arrows except the query merge and alias swap are asynchronous. Storage boundaries: Kafka, the lake and the output tables. Failure points: in Lambda, divergence between the two code paths; in Kappa, replay throughput and the retention window. Scaling: replay parallelism equals Kafka partitions or lake files.

The platform uses Kappa, because one code path is easier to keep correct for billing, Flink runs the same program over bounded and unbounded inputs, and seven days of Kafka retention plus the lake cover replays. The daily billing close is not a second implementation: it is the same aggregation run as a bounded job over the closed day, with the corrections side output applied, writing replacement segments for that day.

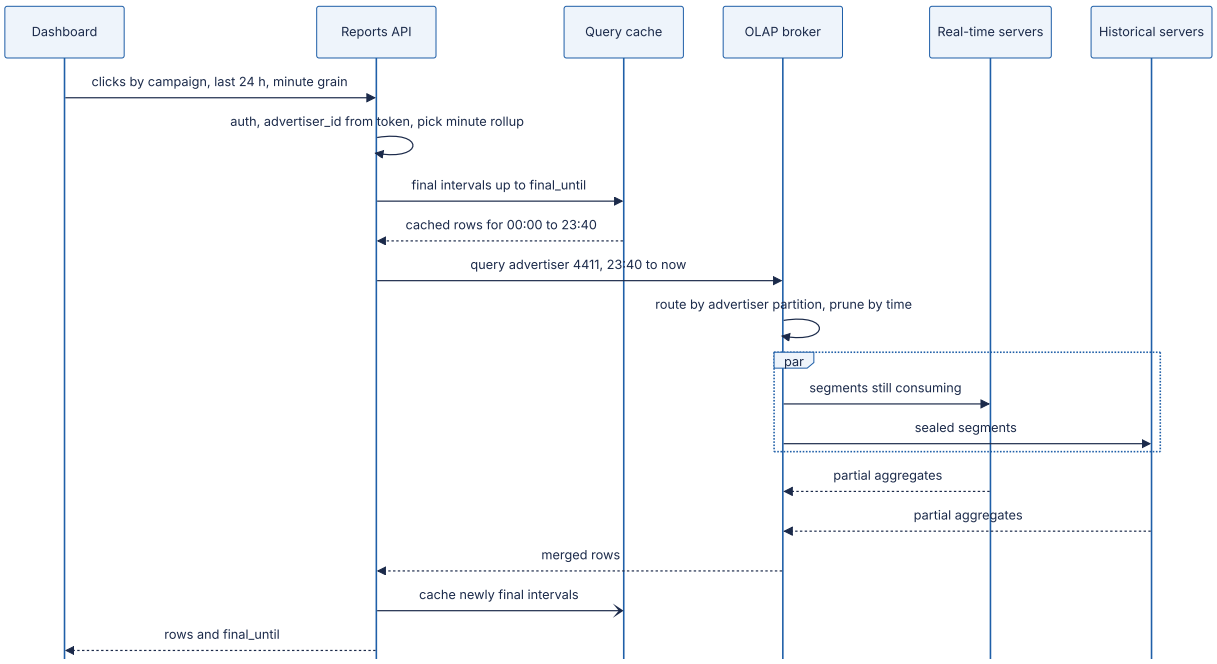
56.7.9 Data flow

Figure 56.14 — Write path: a click from event to rollup.



Reading the diagram. The collector acknowledges only after Kafka has durably replicated the event, the point at which the event cannot be lost. The clean job consumes asynchronously, deduplicates and enriches, and writes to the clean topic inside a transaction that commits with each checkpoint; downstream consumers read only committed data. Two consumers then act in parallel: the OLAP store ingests clean events for live raw queries, and the aggregation job windows them by event time, emitting full-value upserts when the watermark passes each window’s end (and re-emitting for allowed late events), plus spend updates to the pacing store. Failure points: collector crash before acknowledgment (client retries; duplicate removed by event ID), clean-job crash (restart from checkpoint; uncommitted transaction aborted), OLAP ingestion restart (resumes from offsets stored with its last segment). Scaling: partitions of both topics bound the parallelism of both jobs.

Figure 56.15 — Read path: a dashboard panel.



Reading the diagram. All calls are synchronous except the cache fill. The API derives the tenant from the token (never from the request body), chooses the rollup table, and splits the interval at `final_until`: final intervals come from the cache, and only the live edge goes to the broker. The broker routes by advertiser partition so only a few servers are involved, prunes segments by time, and merges partial aggregates from real-time and historical servers. Failure points: a slow server (replica selection, timeouts), cache miss storms after a deploy (warm the cache, coalesce identical queries), and a real-time server restart (its replica answers while it re-consumes). Scaling: add replicas of hot advertiser partitions and historical servers for longer retention.

56.7.10 Bottlenecks

1. **Hot keys in aggregation.** A single huge advertiser or a viral campaign concentrates events on one key; pre-aggregate locally before the keyed shuffle (two-phase aggregation) or salt the key (§29.6.3).
2. **State size and checkpoint duration.** Deduplication state for 2 million events/s over a few minutes of lateness is large; incremental checkpoints and a RocksDB-style state backend keep checkpoint time well inside the 5 s interval (§29.9.1).
3. **Real-time segment memory.** Consuming segments are held in memory until sealed; seal by size or time to bound memory.
4. **Late mobile backfill.** Hours-late events cannot all be held open in the stream; they flow to corrections and the daily close.
5. **Dashboard refresh storms.** Thousands of panels refreshing in sync; jitter refresh timers and cache final intervals.

56.7.11 Failure scenarios

Table 56.24 — Real-time analytics failure scenarios.

What fails	Impact	Detection	Recovery	Prevention
Flink job crash	Live numbers pause	Checkpoint age; consumer lag	Restart from last checkpoint; replay since then	Regular savepoints; resource headroom
Watermark stalls (one idle or stuck partition)	No windows fire; dashboards freeze	`final_until` stops advancing	Mark idle sources; restart stuck consumer	Idle-source detection; per-partition lag alerts
Bug in aggregation logic	Wrong numbers in reports	Reconciliation against independent daily counts	Fix, replay into new table, swap alias (Kappa)	Shadow runs of new job versions; reconciliation checks
Duplicate events from SDK retries	Overcount and overbilling	Duplicate-ID rate metric	Dedupe in clean job; recompute affected day	Event IDs generated at source; idempotent ingestion
OLAP real-time server lost	Recent data missing on that replica	Server health; segment availability	Replica serves; replacement re-consumes from offsets	Two replicas of consuming segments
Clock skew on devices	Events land in wrong windows	Event-time minus arrival-time distribution	Clamp implausible timestamps; correct at close	Server-side receive time recorded alongside client time
Expensive customer query	Latency for others	Per-tenant query time and rows scanned	Throttle tenant	Rows-scanned caps, rate limits, rollup routing

56.7.12 Scaling strategy

At 10× events (20 million/s): Kafka partitions, Flink parallelism and OLAP real-time servers scale out; the deduplication state grows tenfold, which favors deduplicating closer to the source (collectors keyed by event ID) and shorter lateness for server-side sources. Rollup storage grows with distinct dimension combinations rather than events, so it grows less than 10× if the advertiser base is stable.

At 10× queries: more replicas of hot partitions, a larger cache of final intervals, and materialized per-dashboard rollups for the most common panels.

At 100×: split into regional pipelines that aggregate locally and ship rollups (not raw events) to a global store for cross-region reports, so that cross-region bandwidth scales with the rollup rate instead of the event rate; move long-range history to open columnar tables in the lake queried by a separate engine, keeping the OLAP store for the last months.

56.7.13 Trade-offs

Table 56.25 — Real-time analytics trade-offs.

Decision	Chosen	Alternative	Why
Time semantics	Event time with watermarks	Processing time	Reports must reflect when things happened; replays must give the same answer
Lateness	10 s watermark, 120 s lateness, corrections after	Wait longer before firing	Freshness for 99% of events; correctness preserved by the close
Exactly-once output	Idempotent full-value upserts to OLAP; transactions inside Kafka	Transactions everywhere	Avoids coordinating transactions with the OLAP store
Aggregation location	Hybrid: stream rollups and OLAP raw	Only one	Fast common queries and flexible drill-down
Architecture	Kappa with lake replay	Lambda	One code path for billing logic
Checkpoint interval	5 s	30–60 s	Fits freshness budget; costs more checkpoint I/O

56.7.14 Alternative designs

- **Lambda with a batch system of record.** Sound when trusted batch logic already exists; the cost is two implementations and periodic disagreements to explain.
- **Pure OLAP.** Ingest deduplicated events with ingestion-time rollup and aggregate only at query time: simpler, adequate at modest query load, costlier at thousands of queries per second over months.
- **Warehouse micro-batches.** Minutes of freshness and seconds of query latency with very little to operate; fine for internal analytics, not live customer dashboards.
- **Approximate distinct counts.** HyperLogLog sketches in rollups (§17.5) make unique-user counts mergeable across minutes and dimensions at about 1–2% error.

56.7.15 Interview discussion

Table 56.26 — 45-minute pacing plan for the real-time analytics platform.

Minutes	Focus	What to produce
0–5	Scope	Advertiser dashboards, pacing, billing close; freshness and correctness targets
5–10	Estimates	2M events/s, 86 TB/day, rollup ratio 30, 7.7k queries/s
10–18	Architecture	Figure 56.12: Kafka, clean job, aggregate job, OLAP, lake
18–30	Deep dive: correctness	Event time, watermarks, lateness, dedupe, exactly-once per hop
30–38	Deep dive: serving	Rollup selection, partition routing, caching final intervals
38–45	Wrap-up	Lambda versus Kappa, failures, 10× scaling

Likely follow-ups.

- *"What if an event arrives an hour late?"* It is beyond allowed lateness, goes to the corrections side output, and is applied by the daily close; the API's `final_until` tells users which numbers are final.
- *"How do you guarantee a click is billed once?"* Event IDs at the source, deduplication in keyed state, checkpointed state and offsets, and idempotent full-value upserts; reconciliation at close.
- *"Why not just put everything in Druid or ClickHouse?"* You can at modest scale; stream rollups cut query cost and give exactly-once billing logic in one place.
- *"Lambda or Kappa?"* Kappa, because one code path for money is easier to keep correct; replay from Kafka or the lake covers fixes.

What distinguishes senior and staff answers. A senior answer uses event time, watermarks and an OLAP store correctly. A staff answer derives the checkpoint interval from the freshness budget, decomposes exactly-once into per-hop mechanisms and chooses idempotent sinks where transactions would couple systems, separates provisional from final numbers in the API, and plans replay and reconciliation as everyday operations rather than emergencies.

56.7.16 Production considerations

- **Observability.** Event-time lag (now minus watermark) per job and per source; checkpoint duration and age; duplicate and late-event rates; corrections volume; OLAP ingestion lag; query latency per tenant; daily reconciliation differences between independent counts.
- **Security.** Tenant isolation from the authenticated token in the API and enforced again as a mandatory filter in the query layer; no raw SQL for external users; audit

logs of report access; personal data minimized in events (no raw user identifiers in the analytics store, §50.10).

- **Cost.** Kafka retention for replay, raw-event OLAP storage and query fan-out dominate; keep raw events queryable only for days, route queries to coarse rollups, and cache final intervals.
- **Operations.** Treat job upgrades as data migrations: run the new version in shadow, compare outputs, then swap. Rehearse a full replay of a day from the lake. Keep the billing close reproducible: same code, same inputs, same output.

56.8 Summary and revision notes

SUMMARY

- **Data platforms serve derived data.** Judge them by freshness, completeness and cost of the derived data as much as by request latency; trace each datum from source to user and budget every hop.
- **Search engine:** three pipelines (crawl, index, serve). Shard by document; serving cores $\approx \lambda(1-h)Sc/U$, so cost scales with query rate × corpus size. A root–mixer–leaf tree with deadlines, hedged requests, partial results and canary requests tames the 0.99^S fan-out tail. Rank in stages (BM25 and static quality on leaves, learned ranking at the root, Chapter 81). Freshness comes from tiers (real-time, daily, base) plus a removal overlay; quality tiering cuts work per query.
- **Recommendation system:** a funnel (2,000 → 1,500 → 400 → 20) inside a 200 ms budget; parallel candidate sources with deadlines, merged by quota because scores are incomparable; item features replicated in ranker memory because per-candidate remote lookups are infeasible; hybrid precomputation with fallbacks; impressions logged with features as served and joined to delayed labels.
- **Logging and monitoring:** agents with disk buffers, distributors enforcing tenant quotas, Kafka sized by $B = (r/\rho)T_{\text{ret}}\,f$ with drain time $T_{\text{out}}\,r/(c-r)$. Default to columnar or label-indexed storage with skip indexes; full-text indexing costs about 5× the hot storage. Metrics cost is cardinality; enforce series limits. Alerting runs on a separate path with an external dead-man's switch.
- **Real-time analytics:** event-time windows, watermarks and allowed lateness with corrections; exactly-once decomposed per hop (idempotent producers, checkpointed dedupe state, idempotent full-value upserts); checkpoint interval chosen from the freshness budget; multiple rollup grains, partition-aware routing and caching of final intervals for sub-second queries; Kappa with replay from Kafka or the lake.

56.9 Knowledge checkpoint

1. Why does the search serving fleet's size grow with query rate times corpus size, regardless of the shard count?
2. With 300 independent shards each meeting 40 ms at p99, what fraction of queries see all shards under 40 ms?
3. What problem does a removal overlay solve that a faster index build does not?
4. Why are doc IDs assigned in static-quality order within a shard?
5. Why can a recommendation orchestrator not merge candidate lists by score?
6. Why are item features cached in ranker memory but user features fetched remotely?
7. What is logged with each impression to prevent training–serving skew?
8. Why must an impression become a negative example only after the label window closes?
9. Kafka retains 24 h; ingesters run at 1.25× the average rate. How long are logs stale after a 6-hour storage outage?
10. Why are log-based alerts computed in the stream rather than by querying the log store?
11. What does a cardinality limit reject, and what does it keep accepting?
12. Why does a 30 s checkpoint interval break a 10 s freshness target for transactional output?
13. Why does the analytics job emit full window values rather than increments?
14. What does `final_until` tell a dashboard?
15. What is the main operational argument for Kappa over Lambda for billing data?

Answers

1. $S \times c$ is the CPU to search the whole corpus once; more shards make each shard's work smaller but not the total. Sharding sets latency; replicas set throughput.
2. $0.99^{300} = 4.9\%$.
3. Legal removals must take effect within an hour; the overlay is applied at serve time to every tier and cache, independent of build schedules.
4. Postings are walked best-first, so leaves can terminate early or on deadline and still return good candidates.
5. Scores from different sources have different scales and meanings; take quotas per source and let the ranker put candidates on one scale.
6. Item features are shared, change slowly and are needed for ~1,500 candidates per request (1.56×10^8 lookups/s if remote); user features are one row per request.
7. The exact feature vector, model version, experiment arms, position, candidate source and request ID.
8. Positive labels can arrive late; labeling early records slow positives as negatives.
9. $6/(1.25 - 1) = 24$ hours of catch-up; no loss, because backlog age stays under 24 h.

10. To keep alerting independent of the log store’s availability and query latency, and to make it cheap and continuous.
11. It rejects new series beyond the tenant’s limit; samples for existing series continue, so dashboards stay correct.
12. Read-committed consumers see output only after the transaction commits at the checkpoint, adding up to 30 s.
13. Full values make sinks idempotent: replays and late corrections overwrite and converge instead of double-counting.
14. Windows before it are final; later ones may still change as late events arrive.
15. One implementation of the money logic; fixes are replays of the same code, not reconciling two code paths.

56.10 Interview questions

Basic

Q1. In a web search engine, why are index servers separated from document servers?

Answer. Every query touches postings on every index shard, but needs text only for the ten winning documents. Separating them lets the index (36 TB in §56.4.4) stay in memory on many replicated leaves while the much larger document store (120 TB) is read for ten documents per query on a smaller fleet. It also lets the two scale independently.

Q2. What is the purpose of Kafka in a logging pipeline?

Answer. It is a durable buffer between producers and storage: it absorbs incident bursts and storage outages without blocking applications or losing data, and lets several consumers (storage, stream-derived metrics, security) read the same data. Its retention must exceed the longest outage you want to survive, and ingesters need headroom to drain the backlog.

Intermediate

Q3. Allocate a 200 ms latency budget for a recommender and explain what happens when a stage misses its deadline.

Answer. For example: context and user features 10 ms, candidate sources 40 ms in parallel, filtering 10, feature assembly 25, light ranker 10, heavy ranker 50, re-ranking 10, response 5, slack 40. Each stage gets a deadline from the remaining budget. A late candidate source is dropped from the merge; a feature-store timeout yields default features flagged in the log; an overloaded heavy ranker scores fewer candidates or the light

ranker's order is used; total failure serves a precomputed list. The response sets `degraded`, and each fallback is counted.

Q4. Compare an inverted-index log store with a label-indexed chunk store for a 70 TB/day platform.

Answer. The inverted index makes any field or token search fast but roughly quintuples hot storage and dominates ingest CPU. The label store ingests cheaply into object storage and answers "this service, this time, grep" in about a second, but needle queries without label selectivity scan hundreds of terabytes. A columnar store with Bloom-filter skip indexes sits between them and is best for aggregations. A good design defaults to the cheap store, adds skip indexes for trace IDs and tokens, and offers full-text indexing only to tenants who need it.

Advanced

Q5. Design exactly-once campaign spend aggregation from mobile and server events.

Answer. Generate event IDs at the source. Use idempotent producers to Kafka. In Flink, deduplicate by event ID in keyed state with a TTL longer than window plus lateness; assign events to event-time windows with a watermark per source class; checkpoint state and offsets together. Write rollups as full-value upserts keyed by window and dimensions (idempotent), and write cross-job topics transactionally with a checkpoint interval chosen from the freshness budget. Route events later than allowed lateness to a corrections output applied by a bounded daily close using the same code. Reconcile daily totals against an independent count before invoicing.

Q6. Your search engine must handle 10× query volume next year. What do you change first?

Answer. Reduce work per query before adding replicas: quality tiering (most queries search a small top tier, about a 63% CPU reduction at an 80% stop rate), larger results caches, cached postings intersections, and more aggressive early termination. Then add replicas per region with N+1 regional headroom, revisit index distribution bandwidth (more replicas means more copies per build), and add a tree level if the root's fan-in grows. Measure relevance with each change, since tiering and early termination trade recall for cost.

56.11 Practical exercises

1. **Fleet calculator.** Write a Python function that, given corpus size, postings per document, shard memory, per-shard CPU per query, query rate, cache hit ratio and re-

gion count, returns shard count, replicas per region and leaf servers. Reproduce §56.4.4, then compute the effect of quality tiering.
2. **Funnel simulator.** Simulate a recommendation request with four candidate sources whose latencies are log-normal, a 35 ms deadline, and the merge function of §56.5.8. Report the distribution of candidates per request and the fraction of requests missing each source.
3. **Cardinality audit.** Take a Prometheus `/metrics` page from any service you run, count series per metric, and compute how the total would change if a label with 10,000 values were added to the largest metric.
4. **Watermark tuning.** Extend the window code of §56.7.8 with per-source watermarks. Generate server events delayed by 0–2 s and mobile events delayed by a long-tailed distribution, and plot freshness against the fraction of events routed to corrections for several δ values.

56.12 Design challenges

1. **Code search.** Adapt §56.4 to searching 100 million source repositories with regular-expression queries. What replaces the word-level inverted index, how does freshness work on every push, and how does the serving tree change?
2. **Notifications as recommendations.** Redesign §56.5 for push notifications: one decision per user per hour, strict frequency caps, and no request from the user. Which stages become batch, and how is logging joined to delayed opens?
3. **Security analytics.** Combine §56.6 and §56.7 into a platform that detects suspicious login patterns within 30 seconds across 1 PB of logs per day, while keeping a year of searchable history for investigations. Which data is indexed, which is aggregated, and where do the detection rules run?

56.14 Open verification items

- Percolator: confirm the "about 50%" reduction in document age and the paper's wording on resource cost relative to the MapReduce pipeline.
- Druid and Pinot: confirm current documentation on offsets recorded with segment metadata (exactly-once Kafka ingestion); confirm star-tree and member-facing use cases as described in Im et al. 2018.
- Pixie: confirm that the paper describes the full pruned graph held in memory on each serving machine.
- ClickHouse DDL (tokenbf_v1 parameters, `TTL … TO VOLUME` with a `DateTime64` column via `toDateTime`, `Map(LowCardinality(String), String)`, default granule 8,192 rows): test on a current release.
- Illustrative ratios to replace with measurements: 3 bytes per posting, 4 KB of ingester memory per series, 1 GB/s per core scan rate, full-text index at 0.5× raw,

10:1 log compression.

Appendix E — Learning Roadmap and Proficiency Levels

> **Deliverable 3.** This appendix turns the 93 chapters into a schedule. It defines five proficiency levels, what you must know and be able to do at each, and week-by-week milestones for three tracks: the full 12-month program, a 16-week interview track, and a 24-week ML/AI infrastructure track for working engineers.

E.1 How to use this roadmap

1. Find your starting level with the self-assessment in §E.3. Do not skip a level because a topic "sounds familiar" — the readiness criteria test whether you can *explain and apply* a concept, not whether you recognize its name.
2. Pick a track (§E.4–E.6). Each week lists chapters, a hands-on task and a checkpoint. Budget the stated hours; if a week overruns, extend it rather than skipping the exercise — implementation is where understanding consolidates (Ch 3, §3.7).
3. At the end of every month, run the month's **milestone review**: answer the knowledge checkpoints of each chapter from memory, redraw the month's key architecture diagrams without notes, and solve one design challenge aloud in 45 minutes.
4. Record progress in a design journal (template in Ch 3, §3.10).

E.2 The five proficiency levels

Figure E.1 — Proficiency ladder.

WARNING / TRADE-OFF

Diagram failed to render. Source:

```
flowchart LR
  L1["Level 1<br/>Absolute beginner"] --> L2["Level 2<br/>Intermediate engineer"]
  L2 --> L3["Level 3<br/>Advanced engineer"]
  L3 --> L4["Level 4<br/>Senior / Staff"]
  L4 --> L5["Level 5<br/>Expert / Principal"]
```

Reading the diagram. The levels are cumulative: each assumes every competency of the previous one. The arrows are not time-boxed — a strong backend engineer may al-

ready sit at Level 3 for traditional systems but at Level 1 for ML infrastructure. Assess each track (A: traditional, B: ML/AI) separately.

Level 1 — Absolute beginner

Dimension	Definition
Required knowledge	Ch 1–8, 11, 35. What a client, server, API, database, process, thread, IP address, DNS lookup and HTTP request are; functional vs non-functional requirements; powers of ten and basic percentiles.
Expected competencies	Trace one HTTP request from browser to database and back, naming every hop. Write a CRUD REST API with a relational database. Model a simple domain in tables with primary/foreign keys. Do a back-of-the-envelope estimate of requests per second from daily active users.
Practical projects	P-01 REST API service; P-02 URL shortener (single node).
Architecture exercises	Draw a single-server web app; then add a load balancer and a second app server and explain what breaks (sessions).
Interview readiness	Not yet ready for system design rounds. Can answer “what happens when you type a URL?” thoroughly.
Explain independently	TCP vs UDP; what an index is and why it speeds reads but slows writes; what latency vs throughput mean; why HTTPS needs certificates.

Level 2 — Intermediate engineer

Dimension	Definition
Required knowledge	Ch 9–10, 12, 14, 17–22, 24, 30, 33, 36–37, 57. Replication, sharding, consistent hashing, caching patterns, CDNs, load-balancing algorithms, rate limiting, queues and pub/sub, monolith vs microservices, ML basics.
Expected competencies	Turn a vague prompt into numbered FRs/NFRs with targets. Estimate storage, bandwidth and RPS with peak factors. Choose SQL vs NoSQL with justification. Add a cache and explain invalidation and stampede protection. Design a rate limiter and pick an algorithm.
Practical projects	P-03 Redis cache; P-04 rate limiter; P-05 load-balancer simulation; P-06 message queue.
Architecture exercises	URL shortener, Pastebin, rate limiter and notification system (Ch 52) at 10^7 DAU.
Interview readiness	Can complete an entry-level (new-grad / mid-level) system design round: correct high-level architecture, reasonable estimates, identifies the main bottleneck.
Explain independently	Cache-aside vs write-through; why sharding needs a good key; at-least-once delivery and why consumers must be idempotent; Little’s Law applied to a thread pool.

Level 3 — Advanced engineer

Dimension	Definition
Required knowledge	Ch 13, 15–16, 23, 25–27, 29, 31–32, 34, 38–43, 58–62, 66. Storage engines, consistency models, Raft, quorums, Kafka internals, outbox/saga/CQRS, observability, Kubernetes, CI/CD, ML lifecycle, feature stores, model serving.
Expected competencies	Design a complete distributed application with explicit consistency choices, failure handling and observability. Explain a database's write path down to WAL and fsync. Design an ML system from problem formulation to online serving with a feature store.
Practical projects	P-07 distributed KV store; P-08 replicated DB simulation; P-09 notification service; P-10 real-time chat; P-11 distributed job scheduler.
Architecture exercises	All of Ch 52–53; ML case studies 81.5 (product recommendation) and 82.3 (spam detection).
Interview readiness	Passes a senior-level (L5/E5 equivalent) traditional round and a mid-level ML system design round: deep-dives on request, quantifies trade-offs, discusses failure modes unprompted.
Explain independently	Raft leader election and log matching; why `R + W > N` gives read-your-writes only under certain conditions; Kafka ISR and `acks=all`; point-in-time feature joins and training–serving skew.

Level 4 — Senior / Staff engineer

Dimension	Definition
Required knowledge	Ch 28, 44, 46–48, 50–51, 63–65, 67–80. Distributed transactions, multi-region design, cluster scheduling, multi-tenancy, security architecture, cost; GPU performance, distributed training, model optimization, recommendation architecture, MLOps, LLM inference, RAG, agents, AI platforms.
Expected competencies	Make and defend architecture decisions spanning teams: multi-region active–active, tenant isolation, SLOs and error budgets, cost models. Size a GPU fleet for training and for LLM serving from first principles. Design a RAG or agent platform with evaluation, guardrails and observability.
Practical projects	P-12 event-driven microservices; P-13 real-time analytics pipeline; P-14 recommendation engine; P-15 distributed ML inference; P-18 production RAG; P-19 scalable LLM inference.
Architecture exercises	All of Ch 54–56 and 81–86. Write a design document with ADRs for one case study and have it reviewed.
Interview readiness	Passes staff-level rounds: drives the conversation, scopes ambiguity, prioritizes the hardest sub-problem, connects technical choices to business, cost and organizational constraints.
Explain independently	Spanner commit-wait; why cells limit blast radius; ZeRO stage 3 memory math; continuous batching and PagedAttention; when RAG beats fine-tuning; how to evaluate an agent.

Level 5 — Expert / Principal architect

Dimension	Definition
Required knowledge	Ch 45, 49, 80 plus the primary papers cited across Parts V, IX, XIII and XVI. Theory (FLP, CAP proofs, BFT bounds, consistency hierarchies, scaling laws) and practice at 10^4–10^5 machine scale.
Expected competencies	Set multi-year technical direction; evaluate novel systems from papers; reason about organization-wide failure domains, reliability economics and sustainability; design platforms other teams build on.
Practical projects	P-16 distributed training platform; P-17 multi-tenant feature store; P-20 multi-agent orchestration platform.
Architecture exercises	Critique a published architecture (e.g., a Dynamo, Spanner or PagedAttention paper) and propose a design for a changed constraint. Lead a postmortem-driven redesign.
Interview readiness	Principal-level: articulates long-term trade-offs, migration strategy, organizational design (Conway's law), and the economics of the platform.
Explain independently	Why consensus is impossible in a fully asynchronous system with one crash failure and how real systems sidestep it; goodput at 16k-GPU scale; the cost/latency frontier of an LLM product.

E.3 Self-assessment

Score yourself 0–2 on each statement (0 = cannot, 1 = with notes, 2 = from memory, aloud, in under five minutes). Start at the first level where your total is below 14 of 20.

Table E.1 — Placement self-assessment.

Level	Ten statements to score
1	Explain DNS resolution · TCP handshake · HTTP request/response · process vs thread · what an index is · primary/foreign keys · REST verbs and status codes · latency vs throughput · p99 · RPS from DAU
2	Cache-aside and invalidation · consistent hashing · token bucket · L4 vs L7 load balancing · replication lag · sharding keys · at-least-once delivery · CDN pull vs push · SQL vs NoSQL choice · precision vs recall
3	Raft election · quorum math · Kafka partitions/ISR · outbox pattern · LSM vs B-tree · Kubernetes control plane · SLO/error budget · feature store PIT join · dynamic batching · canary analysis
4	2PC failure modes · multi-region active–active · tenant isolation options · cost model of a service · data/tensor/pipeline parallelism · KV-cache memory · RAG evaluation · agent guardrails · model routing · DRF scheduling
5	FLP intuition · linearizability vs serializability · PBFT bound · TrueTime · ZeRO-3 communication · MFU at scale · scaling laws · disaggregated serving · failure rates at 10k GPUs · multi-year platform migration

E.4 Track 1 — Full 12-month program (beginner to Level 4)

Budget: 10–12 hours per week · 52 weeks · Levels 1 → 4. Each week: read (≈ 60%), implement or exercise (≈ 30%), recall and explain (≈ 10%).

Figure E.2 — Twelve-month program at a glance.

WARNING / TRADE-OFF

Diagram failed to render. Source:

```
gantt
  title Twelve-month program
  dateFormat  YYYY-MM-DD
  axisFormat  M%m
  section Level 1
  Thinking, maths, CS foundations      :a1, 2027-01-04, 8w
  Web, data basics, OOD                :a2, after a1, 5w
  section Level 2
  Data systems, scale, caching         :b1, after a2, 7w
  Distributed basics, messaging        :b2, after b1, 5w
  section Level 3
  Distributed depth, Kafka, EDA        :c1, after b2, 5w
  Production infra, case studies I-II  :c2, after c1, 6w
  section Level 3-4 ML
  ML foundations, data, GPUs, serving  :d1, after c2, 8w
  section Level 4
  LLMs, RAG, agents, AI infra          :e1, after d1, 5w
  Expert topics, case studies, interviews :e2, after e1, 3w
```

Reading the diagram. Bars are sequential phases; the dates are an example start (any Monday works). Levels overlap at the boundaries because review weeks consolidate the previous level while starting the next. The ML phase begins only after production infrastructure because serving, MLOps and AI-infrastructure chapters assume Kubernetes, observability and deployment knowledge.

Table E.2 — Weekly milestones, 12-month program.

Wk	Chapters	Hands-on task	Checkpoint
1	1, 3	Set up design journal and flashcard deck	Explain FR vs NFR with three examples each
2	2	Write requirements + context diagram for a food-ordering app	Present it in 10 minutes
3	4 (§4.3–4.9)	Estimation drills: 20 powers-of-ten problems	Score ≥ 18/20
4	4 (§4.10–4.18)	Simulate an M/M/1 queue in Python; compare with formula	Explain why latency explodes near 100% utilization
5	5	Cache-stride benchmark	Draw the memory hierarchy with latencies from memory
6	6	Race condition + mutex fix; event-loop echo server	Explain epoll vs thread-per-connection
7	7	`dig`, `curl -w`, Wireshark on a TLS handshake	Narrate “type a URL” end to end
8	Review	Redo checkpoints Ch 1–7	**Month 2 milestone review**
9	8	P-01 REST API with pagination and JWT	Defend cursor vs offset pagination
10	11	Schema design + `EXPLAIN` on indexed vs unindexed queries	Explain B+ tree lookups in I/Os
11	35, 36	Refactor a small codebase with SOLID	Class diagram from memory
12	9, 10	SSE + WebSocket demo; password hashing	Choose a real-time technique for 3 scenarios
13	Review	P-02 URL shortener (single node)	**Level 1 exit**: self-assessment ≥ 14
14	12	Model one domain in a document DB and a wide-column DB	SQL vs NoSQL decision for 5 prompts
15	13	Toy LSM tree (memtable + SSTables + compaction)	Draw write path with WAL
16	14	Consistent-hashing ring with virtual nodes	Keys moved when adding a node
17	15, 16	Inverted index + BM25 in Python	Explain erasure coding overhead
18	17	Bloom filter, HyperLogLog, Snowflake IDs	False-positive-rate calculation

Wk	Chapters	Hands-on task	Checkpoint
19	18, 19	P-05 load-balancer simulation	Power-of-two-choices intuition
20	20, 21	P-03 Redis cache-aside with stampede protection	Five caching patterns from memory
21	22	P-04 distributed rate limiter	Token bucket parameters for a given SLA
22	23	Load test with `wrk` / `k6`; find the bottleneck	Explain coordinated omission
23	24	Lamport and vector clocks implementation	Two partial-failure stories
24	30	P-06 message queue with acks and DLQ	Delivery semantics table from memory
25	33, 37	Implement 6 design patterns	Monolith vs microservices debate
26	Review	Ch 52.1–52.4 case studies	**Level 2 exit** + **Month 6 milestone**
27	25	Jepsen-style anomaly hunt on a toy store	Consistency hierarchy diagram
28	26	Raft (election + log replication) — MIT 6.5840 style	Explain fencing tokens
29	27, 28	P-07 distributed KV store with quorums	2PC failure walkthrough
30	29, 31	Kafka locally: partitions, consumer groups, lag	Partition count sizing
31	32, 34	Outbox + saga demo	Choreography vs orchestration
32	38	Four LLD problems (parking lot, elevator, LRU, vending)	45-min LLD mock
33	39, 40	SLOs, burn-rate alerts, OpenTelemetry tracing	Error-budget policy
34	41, 42	Deploy P-01 to Kubernetes with HPA	Kubernetes control-plane walk-through
35	43	CI/CD with canary; Terraform a VPC	Rollback plan
36	52, 53	P-09 notification service; P-10 chat	Two 45-min mocks
37	54, 55	YouTube, Uber, payment system cases	Two 45-min mocks
38	Review	56 + P-11 job scheduler	**Level 3 exit (Track A)**

Wk	Chapters	Hands-on task	Checkpoint
39	57	Train/evaluate a classifier; compute all metrics	Precision/recall trade-off for fraud
40	58, 59	Small MLP in PyTorch; memory math	ML lifecycle diagram
41	60, 61	Batch + streaming feature pipeline	Lambda vs Kappa
42	62, 63	Feast feature store with PIT join	Training–serving skew causes
43	64	Roofline analysis of a matmul	Compute- vs memory-bound
44	65	DDP on 2 GPUs (or simulated); FLOPs estimate	6ND estimate for a model
45	66, 67	Serve a model with dynamic batching; quantize it	Batch size vs latency curve
46	68–71	P-14 two-tower recommender; drift monitor	Multi-stage funnel sizing
47	72	Implement attention + KV cache in NumPy	KV-cache size for a 70B model
48	73	Run vLLM; measure TTFT/TPOT vs concurrency	Continuous batching explanation
49	74, 75	P-18 production RAG with hybrid search + reranking	Retrieval metrics
50	76–78	Agent with tool calling, guardrails and eval set	Prompt-injection defenses
51	79, 80, 81–86 (2 cases)	Model gateway with token-based rate limits	Two ML/AI mocks
52	87–92	Full mock loop: 2 traditional + 2 ML/AI	**Level 4 readiness review**

Level 5 content (Ch 45, 49, 80 deep dives, primary-paper reading) is a continuing program after week 52: one paper and one design critique per week.

E.5 Track 2 — 16-week interview track (Level 2–3 engineer → senior interviews)

Budget: 12–15 hours/week. Assumes Level 2 fundamentals.

Table E.3 — Interview track.

Wk	Focus	Chapters	Practice
1	Framework and estimation	2, 4, 87, 88, 89	30 estimation drills
2	Data systems refresh	11, 12, 14	Q-T-01 … Q-T-04
3	Caching, CDN, LB	19, 20, 21	Q-T-05 … Q-T-08
4	Traffic management	22, 17	Rate limiter + URL shortener mocks
5	Distributed core	24, 25, 26	KV-store mock
6	Replication and transactions	27, 28	Payment-system mock
7	Messaging	30, 31, 32	Notification-system mock
8	Microservices and reliability	34, 39, 40	Mid-point mock with a peer
9	Social systems	53	News feed, chat, Twitter mocks
10	Media and files	54	YouTube, Dropbox mocks
11	Location and commerce	55	Uber, ticketing mocks
12	Data platforms	56, 16	Search, logging mocks
13	Senior depth	44, 47	Multi-region mock
14	Company preparation	90	Company-specific mocks
15	Practice library sweep	91	10 timed questions
16	Final review	Summaries of all above	3 full mocks; rubric self-score ≥ “Hire”

E.6 Track 3 — 24-week ML/AI infrastructure track (software engineer → ML/AI systems)

Budget: 10–12 hours/week. Assumes Level 3 on Track A.

Table E.4 — ML/AI track.

Wk	Chapters	Deliverable
1–2	4.9, 57	Metrics notebook; A/B test sample-size calculator
3	58	PyTorch MLP; parameter/activation memory worksheet
4	59, 60	Architecture diagram of an end-to-end ML system
5–6	61, 29	Lakehouse table + streaming feature job
7	62, 63	Feature store with PIT-correct training set
8–9	64	GPU profiling exercise; roofline worksheet
10–11	65	Multi-GPU training run; parallelism plan for a 70B model
12	66	Model server with dynamic batching and autoscaling
13	67	Quantization + ONNX/TensorRT comparison
14	68	Two-tower retrieval + ranker
15	69, 70	CI/CD/CT pipeline with drift-triggered retraining
16	71	Fairness audit and model card
17	72	Transformer from scratch (small)
18–19	73	LLM serving benchmark; capacity plan
20	74, 75	Production RAG with evaluation harness
21	76, 77	LoRA fine-tune; tool-using agent
22	78, 79	Eval pipeline; model gateway with routing and fallback
23	80, 81–85	Two case studies written as design docs
24	86, 92	Four ML/AI mock interviews

E.7 Monthly milestone review template

1. **Recall:** answer every knowledge-checkpoint question for the month's chapters without notes; mark misses for spaced repetition.

2. **Redraw:** reproduce the month’s three most important architecture diagrams from memory; compare with the book.
3. **Quantify:** solve three estimation problems from Ch 89 in under five minutes each.
4. **Design:** solve one design challenge aloud in 45 minutes; self-score with the Ch 88 rubric.
5. **Build:** demo the month’s project to someone else, including one injected failure.
6. **Reflect:** write half a page in the design journal — what is still unclear, which open question to research next.

Appendix A — Glossary

> Generated by `build/build.py` from the definition callouts in every chapter; the first (defining) occurrence of each term is used. Canonical usage rules are in `docs/project/terminology.md`.

A

Abstract factory — An interface for creating a *family* of related objects (for example a blob store and a work queue) without naming their concrete classes, so that a client receives products that are guaranteed to belong together [Gamma et al. 1994]. *(§37.4)*

Abstraction — Representing something by the operations that matter to its users while leaving out the details of how they are carried out. In code, an **abstract class** is a class that cannot be instantiated and may contain both implemented methods and **abstract methods** (declared, with no body) that subclasses must implement. An **interface** declares a set of methods a type promises to provide; in Java it has no instance state, and since Java 8 it may include `default` method bodies built only on its other methods. *(§35.7.1)*

Access-control model — A rule system that answers "may subject S perform action A on resource R (in context C)?" The three models in common use differ in what the rules are written in terms of: **roles** (RBAC), **attributes** (ABAC) or **relationships** (ReBAC). *(§8.12.1)*

ACID — The four guarantees of a database transaction, named by Härder and Reuter [Härder and Reuter 1983]: **Atomicity** — all of a transaction's writes take effect, or none do. **Consistency** — a transaction takes the database from one state satisfying all declared invariants (constraints) to another. **Isolation** — concurrently executing transactions do not see each other's partial effects; at the strongest level, the outcome equals some serial execution. **Durability** — once a commit is acknowledged, its effects survive crashes. *(§11.12)*

Active–passive and active–active — In an **active–passive** pair, one balancer carries all traffic while a standby monitors it and takes over the VIP on failure. In **active–active**, all balancers carry traffic at once (spread by DNS, ECMP or anycast), and survivors absorb a failed member's share. *(§19.7)*

Active–passive (warm or hot standby) — One **active** region serves all traffic and owns all writes; one or more **passive** regions receive replicated data and take over only on

failover. In **warm standby** the passive region runs a scaled-down application tier that must scale up during failover; in **hot standby** it runs at full capacity, ready to take all traffic at once (§39.8). *(§44.6.1)*

Active recall — Deliberately retrieving information from memory without looking at the source, for example by answering a question, drawing a diagram or explaining aloud. Its measured benefit for later retention is called the **testing effect**. *(§3.4.2)*

Activity diagram — A behavior diagram that models a workflow as **actions** connected by **control flows**, with **decision** and **merge** nodes for branching, **fork** and **join** bars for concurrency, and **activity partitions** (swimlanes) that assign actions to the participant responsible for them. Its semantics are based on tokens flowing through the graph, similar to a Petri net [OMG 2017]. *(§38.7.1)*

Adapter — A wrapper that converts the interface of an existing class into the interface its clients expect, so that classes with incompatible interfaces can work together [Gamma et al. 1994]. *(§37.9)*

Address space — The range of memory addresses a process can use. On Linux x86-64 with 4-level page tables, user space spans 2^{47} bytes = 128 TiB of *virtual* addresses; the kernel occupies the upper half and is not accessible from user mode. *(§6.3.2)*

Aggregate — A cluster of entities and value objects treated as one unit for data changes, with one **root** entity. Outside objects reference only the root, every change goes through it, and it enforces the aggregate's **invariants**. One transaction modifies one aggregate [Evans 2003; Vernon 2013]. *(§34.4.3)*

Allocation versus usage — **Allocated (reserved) utilization** is the fraction of capacity claimed by requests or reservations; **used utilization** is the fraction actually consumed. The difference, **slack**, is capacity that is paid for, promised to someone, and idle. *(§46.3.2)*

Analysis — The process that converts raw text into the terms stored in (or looked up from) an inverted index. An **analyzer** is a pipeline of zero or more **character filters** (rewrite the raw character stream), exactly one **tokenizer** (split the stream into tokens with positions and offsets) and zero or more **token filters** (modify, remove or add tokens). *(§16.4.1)*

Anticorruption layer (ACL) — A layer owned by a downstream context that translates between an upstream model and its own, so the upstream's concepts, codes and quirks never appear in the downstream model [Evans 2003]. *(§34.5.3)*

Anycast — An addressing scheme in which the same IP prefix is announced via BGP from many locations at once. Each client's packets are routed to whichever announcing location is "closest" according to BGP path selection. *(§7.5.3)*

Apache Flink — An open-source distributed engine that executes dataflow programs as a graph of long-running, pipelined operators, treating batch as a bounded special case of streaming. It provides event-time processing with watermarks, large keyed state, and exactly-once state consistency through asynchronous distributed snapshots [Carbone et al. 2015a]. *(§29.9.1)*

API gateway — A reverse proxy (§7.12) that is the single entry point for external clients into a set of services. It routes requests and applies **edge concerns** once: TLS termination, authentication, rate limiting, request validation, caching, protocol translation and sometimes aggregation [Richardson 2018]. *(§34.6.1)*

Architectural decision — A design choice that addresses an architecturally significant requirement — one that affects structure, quality attributes, interfaces or technology in a way that is costly to change later. Examples: choosing a relational database over a key-value store; storing files in object storage; making photo processing asynchronous. *(§1.8.1)*

Architecture Decision Record (ADR) — A short document that captures one architectural decision: its context, the decision itself, its status, and its consequences. ADRs are numbered, kept in sequence (often in the code repository), and never edited to reverse a decision — a new ADR *supersedes* the old one [Nygard 2011]. *(§1.8.1)*

Architecture documentation — The written and diagrammed record of a system's structure and of the decisions that shaped it. It is written so that people who were not in the room (new team members, reviewers, your future self) can understand *what* the system is and *why* it is that way. *(§2.12.1)*

Association, aggregation, composition — An **association** is a structural relationship in which instances of one class hold links to instances of another. **Aggregation** (UML "shared aggregation") is an association marked as whole–part, in which a part may be shared by several wholes and exists independently of them. **Composition** (UML "composite aggregation") is a whole–part association in which each part belongs to at most one whole at a time, and the whole is responsible for the part's existence: if the composite is deleted, its parts are deleted with it [OMG 2017]. *(§38.8.1)*

Assume breach — A design stance that treats the compromise of any single component, credential or person as a given and asks how far the attacker gets next. **Blast radius** is the set of assets an attacker can reach from one compromised principal; architecture reduces it by limiting what each principal may do and where it may connect. *(§50.3.3)*

Asymmetric (public-key) cryptography — Cryptography using a mathematically linked **key pair**: a **public key** that can be shared with anyone and a **private key** kept secret by its owner. What one key does, only the other can undo or verify. Security rests on problems believed hard to invert: factoring large integers (RSA) or computing discrete logarithms on elliptic curves (ECC). *(§10.4.3)*

Asynchronous (message-based) communication — An interaction in which the sender hands a **message** to an intermediary — a **message broker** — and continues without waiting for the receiver to process it. The broker stores the message until a receiver takes it, so sender and receiver need not be available at the same time. *(§30.3.1)*

Atomic commitment — A protocol by which a set of **participants** (nodes that each executed part of a transaction) reach a single outcome, commit or abort, such that: (1) all participants that decide reach the same decision; (2) a participant cannot reverse a decision once made; (3) commit is decided only if every participant voted yes; (4) if there are no failures and every participant voted yes, the decision is commit; and (5) once failures are repaired and no new ones occur for long enough, every participant eventually decides [Bernstein et al. 1987]. *(§28.3.1)*

Audit log — An append-only record of security-relevant events — who (actor), did what (action), to which resource, when, from where, and with what result — retained so that actions can be investigated and attributed. A log is **tamper-evident** if any modification, deletion or reordering of past entries can be detected. *(§10.12)*

Authenticated encryption with associated data (AEAD) — A symmetric scheme that provides confidentiality for the plaintext *and* integrity for both the ciphertext and optional unencrypted **associated data** (AAD), producing an authentication **tag** that decryption checks before releasing any plaintext. AES-GCM and ChaCha20-Poly1305 are AEAD schemes. *(§10.4.2)*

Authentication (AuthN) — Verifying *who* a client is. **Authorization (AuthZ)** is deciding *what* that verified identity may do (§8.12). AuthN failures return `401`; AuthZ failures return `403`. *(§8.11)*

Autocomplete (typeahead) — A service that, given the prefix a user has typed so far, returns a short ranked list (typically 5–10) of likely completions, usually popular past queries or entity names, on every keystroke or after a short pause. *(§16.9.1)*

Autoscaling — Automatically changing the number of instances of a service in response to a measured or forecast signal, within configured minimum and maximum bounds. **Reactive** autoscaling responds to current metrics; **scheduled** autoscaling follows a calendar; **predictive** autoscaling acts on a forecast. *(§18.8.2)*

Availability — The fraction of time (or of requests) for which a system serves correctly: A = uptime/(uptime + downtime), or, request-based, A = successful requests/valid requests. It is commonly quoted in “nines”: 99.9% is “three nines”. *(§4.14.1)*

Availability classes (Bailis et al.) — A guarantee is **totally available** if every non-failing replica can commit every transaction without contacting any other replica, even when the network is arbitrarily partitioned. It is **sticky available** if this holds whenever each client keeps talking to replicas that have seen all of that client’s previous operations. It is

unavailable if some partition forces some transaction to block or abort [Bailis et al. 2014a]. *(§45.3.2)*

Availability, reliability, durability, resilience — **Availability** is the fraction of time, or of valid requests, for which a system serves correctly (§4.14). **Reliability** is the probability that the system performs its required function correctly over a stated period, $R(t)$ (§4.15); in SRE usage the word is also used broadly for "the system does what users need", of which availability is the most-measured part [Beyer et al. 2016]. **Durability** is the probability that acknowledged data is not lost (§4.16). **Resilience** is the ability to absorb a fault, keep delivering an acceptable (possibly degraded) service, and recover to full service. *(§39.3.1)*

B

Backend for frontend (BFF) — A server-side component dedicated to one kind of user interface (iOS, web, partner API), owned by or aligned with that interface's team, which aggregates and reshapes downstream calls into exactly the API that interface needs [Newman 2015]. *(§34.6.2)*

Back-of-the-envelope estimation — A quick calculation, done with round numbers and stated assumptions, that gives the order of magnitude of a system's load and resource needs (requests per second, storage, bandwidth, memory, number of nodes). The aim is to be within a factor of about 2–3 of the truth with a few minutes of arithmetic. This section introduces the method. Chapter 89 is the full handbook. *(§2.11.1)*

Backpressure — A flow-control mechanism in which a slower downstream component signals upstream components to reduce their sending rate, by blocking, by advertising available capacity, or by rejecting, so that work in progress stays bounded instead of piling up in unbounded buffers. *(§22.10)*

Backup types — A **full backup** copies the entire data set. An **incremental backup** copies what changed since the *previous backup of any type*. A **differential backup** copies what changed since the *last full backup*. A **snapshot** is a point-in-time image, usually copy-on-write, taken by the storage layer. *(§39.9.1)*

Backward and forward compatibility — **Backward compatibility**: newer code can read data written by older code. **Forward compatibility**: older code can read data written by newer code [Kleppmann 2017, ch. 4]. *(§8.9.3)*

Batch processing — Running a computation over a **bounded** dataset (one whose size is known when the job starts, such as "yesterday's logs") that reads immutable input files, writes new output files, and is judged mainly by **throughput** (bytes or records processed per second) and total completion time rather than by the latency of individual records. *(§29.3.1)*

BGP — A **path-vector** routing protocol in which neighboring routers (peers) exchange, over a TCP session on port 179, announcements of the form “prefix P is reachable via AS path [X, Y, Z]”. Each AS chooses among the paths it hears according to its own **policy**, then re-announces its chosen path (with its own ASN prepended) to the peers its policy allows. *(§7.5.2)*

Bisection bandwidth — The minimum total link capacity, in one direction, crossing any cut that divides the network’s endpoints into two equal halves. **Full bisection bandwidth** means every endpoint in one half can send to the other half at full injection rate simultaneously. *(§49.10.4)*

Bit and byte — A **bit** (symbol b) is a single binary digit, 0 or 1. A **byte** (symbol B) is 8 bits. Storage and memory are conventionally measured in bytes; network link speeds are conventionally measured in bits per second (bps). *(§4.5.1)*

Block, file and object storage — **Block storage** exposes a numbered array of fixed-size blocks (typically 512 B or 4 KiB) that a client reads and writes by offset; the client’s own file system or database gives the blocks meaning. **File storage** exposes a hierarchical namespace of directories and byte-addressable files with POSIX-like operations (open, read at offset, write at offset, rename, lock), shared by many clients over a protocol such as NFS or SMB. **Object storage** exposes a flat namespace of immutable **objects**, each a byte string plus metadata addressed by a key within a **bucket**, accessed over HTTP with whole-object PUT, GET (optionally a byte range), DELETE and LIST. *(§15.3.1)*

Bloom filter — A probabilistic data structure for set membership, introduced by Burton Bloom in 1970, that stores a set of n items in an array of m bits using k hash functions [Bloom 1970]. A query answers either “definitely not in the set” or “probably in the set”. It never gives a **false negative** (saying “no” for an item that was added), and gives a **false positive** (saying “yes” for an item that was not added) with a probability p that depends on m, n and k. *(§17.4.1)*

Blue–green deployment — A deployment that runs two complete production environments, one live (say blue) and one idle (green). The new version is deployed to and tested on the idle environment, and then all traffic is switched to it at once at the routing layer; the old environment is kept, unchanged, for instant rollback [Fowler 2010]. *(§43.5.1)*

Borg vocabulary — A **cell** is the set of machines managed as one unit, typically inside one datacenter building; the median cell had about 10,000 machines. A **job** is a named group of identical **tasks** (processes in containers) with a priority and resource requirements. An **alloc** is a reserved set of resources on one machine into which one or more tasks can be placed; an **alloc set** is a job-like group of allocs across machines. *(§46.5.1)*

Bottleneck — The resource whose capacity limits the throughput of the whole system for a given workload. Throughput cannot rise above the bottleneck’s capacity no matter how

much the other resources are improved. Formally, it is the resource with the highest **service demand** per request (defined below). *(§2.6.1)*

Bounded context — An explicit boundary (in code, data and team ownership) within which one domain model and its ubiquitous language apply consistently. The same word may mean different things in different contexts [Evans 2003]. *(§34.5.1)*

Branch prediction — Hardware that guesses the outcome of a conditional jump (a **branch**, e.g. an `if` or a loop condition) before it is computed, so that the pipeline can keep fetching instructions. A wrong guess is a **misprediction** and forces a pipeline flush. *(§5.3.4)*

Broker and controller — A **broker** is a Kafka server process that stores partition replicas and serves produce and fetch requests. The **controller** is the component that owns cluster **metadata** (which brokers are alive, which topics and partitions exist, which replica leads each partition, and the in-sync replica sets) and makes decisions such as leader election when a broker fails. *(§31.4.1)*

B-tree and B+ tree — A **B-tree** is a balanced search tree whose nodes are disk pages holding many sorted keys; every leaf is at the same depth, and nodes split and merge to stay between half-full and full [Bayer and McCreight 1972]. A **B+ tree** is the variant used by almost every relational database: internal nodes hold only separator keys and child pointers, all keys and values (or row pointers) live in the leaves, and leaves are linked to their siblings so range scans can walk sideways [Comer 1979; Petrov 2019]. *(§11.8.1)*

B-tree storage engine — A storage engine that keeps each table or index as a B+ tree of fixed-size pages and **updates pages in place**: a change to a key rewrites the page that holds it. Internal pages hold separator keys and child page numbers; leaf pages hold the keys with either the rows themselves (a clustered index) or pointers to them. *(§13.6.1)*

Bucket, key, object and flat namespace — A **bucket** is a named container with its own access policy, region and configuration. An **object** is an immutable byte string (from zero bytes to tens of terabytes) plus system metadata (size, content type, checksum, version ID) and user metadata. A **key** is the object's full name within the bucket, for example `photos/2026/10/u42/abc.jpg`. The namespace is **flat**: the slashes are ordinary characters, and "folders" are an illusion produced by listing keys that share a **prefix** and grouping them at a **delimiter** (usually `/`). *(§15.4.1)*

Buffer pool — A region of memory, managed by the database itself, divided into page-sized **frames** that cache disk pages. A **page table** maps page IDs to frames; each frame carries a **pin count** (how many threads are using it right now), a **dirty flag** (whether it differs from the disk copy) and bookkeeping for the **replacement policy** that chooses which page to evict. *(§13.4.1)*

Builder — A separate object that assembles a complex product step by step, validates the combination of choices, and returns a finished (ideally immutable) product from a final `build()` call [Gamma et al. 1994; Bloch 2018]. *(§37.5)*

Bulkhead — Partitioning a service's limited resources (threads, connections, memory, instances) into isolated pools, one per dependency, tenant or workload class, so that exhaustion of one pool cannot starve the others. *(§22.14)*

Byzantine fault — A fault in which a node deviates arbitrarily from its protocol: it may send wrong values, send *different* values to different peers (**equivocation**), replay or delay messages, or collude with other faulty nodes. The name comes from Lamport, Shostak and Pease's allegory of generals, some of them traitors, who must agree on a battle plan by messenger [Lamport et al. 1982]. *(§45.7.1)*

C

Cache — A store that holds copies of data whose authoritative version lives elsewhere (the **backing store** or **source of truth**), placed so that reading the copy is faster or cheaper than reading the original. A lookup that finds the data is a **hit**; one that does not is a **miss**. The **cache hit ratio** h is hits divided by lookups; the **miss ratio** is $1 - h$. *(§20.3.1)*

Cache-aside — The application reads the cache first; on a miss it reads the database and populates the cache itself. On a write it updates the database and then **deletes** (invalidates) the cache entry. The cache never talks to the database. Also called **look-aside** or **demand-filled** caching. *(§20.7.1)*

Cache avalanche — A large fraction of cache entries becomes unavailable at once, because many keys expire together or because cache nodes fail or restart, so the database suddenly receives the full read load. *(§20.13)*

Cache coherence — The guarantee that all cores observe a single, consistent sequence of values for each memory location, even though each core keeps private copies in its own caches. *(§5.4.6)*

Cache key — The value a cache uses to decide whether two requests may receive the same stored response. By default it is the method plus the full URL (scheme, host, path and query string), extended by any request headers listed in the response's `Vary` header. *(§21.6.2)*

Cache line — The fixed-size unit in which data moves between memory and caches. On x86-64 and most ARM server cores a line is 64 bytes; some designs (for example Apple's M-series cores) use 128 bytes (as of 2024). A load of a single byte brings its whole line into the cache. *(§5.4.3)*

Cache penetration — Requests for keys that do not exist in the database. Because there is nothing to cache, every such request misses and reaches the database. A bug or an attacker iterating random IDs can push the database's full read load through the cache. *(§20.12)*

Cache stampede (thundering herd, dog-piling) — When a popular entry expires or is evicted, many concurrent requests miss at once and all recompute or reload it, multiplying load on the backend exactly when it is busiest. *(§20.11)*

Cache tiers — The **edge** tier is the set of PoPs that accept user connections. A **mid-tier** (also *parent*, *regional* or *upper-tier* cache) is a smaller set of larger caches that edges consult on a miss. An **origin shield** is a mid-tier designated as the single path to a given origin. The **origin** is the customer's own infrastructure that holds the authoritative content. *(§21.4.1)*

CALM theorem — *Consistency As Logical Monotonicity*: a problem has a consistent, coordination-free distributed implementation if and only if it is **monotonic**, meaning that adding inputs can only add outputs, never retract one [Hellerstein & Alvaro 2020; Ameloot et al. 2013]. *(§45.6.6)*

Canary release — A deployment that sends a small, controlled fraction of production traffic to the new version, compares its behavior with the current version, and increases the fraction in steps only while the comparison stays healthy; otherwise traffic is returned to the old version [Sato 2014a]. *(§43.6.1)*

Capacity planning — The recurring process of forecasting demand, translating it into the resources needed to serve it within the service-level objective with stated headroom and redundancy, and acquiring those resources before they are needed, allowing for the lead time to obtain them. *(§18.11.1)*

CAP theorem (Gilbert and Lynch) — In an asynchronous network model, where messages may be delayed arbitrarily and there are no clocks, it is impossible to implement a read/write data object that guarantees both of the following in all fair executions, including those in which messages are lost: **Consistency (C):** the object is **atomic**, that is, linearizable (§25.3). **Availability (A):** every request received by a non-failing node must eventually result in a response. **Partition tolerance (P)** is not a property the system chooses; it is the assumption that the network may lose arbitrarily many messages between nodes. *(§25.8.1)*

Cardinality and dimensionality — The **cardinality** of a field is the number of distinct values it takes: `http.method` has about 5, `user_id` may have millions. **Dimensionality** is the number of fields attached to each event. A **wide event** (also called a canonical log line) is one structured record per unit of work, typically per request per service, carrying dozens to hundreds of fields. *(§40.3.3)*

Causal consistency — Writes that are **causally related** must be seen by every client in their causal order; writes that are **concurrent** (neither happens before the other) may be seen in different orders by different clients. Formally, each client's view must be a legal sequential history that respects the causal order induced by program order and reads-from [Ahamad et al. 1995]. *(§25.5.1)*

Cell-based architecture — A style in which a workload is deployed as multiple independent, complete copies called **cells**, each with its own compute and data and each serving a fixed subset of customers (or other partition key), placed behind a thin **cell router** that sends each request to its customer's cell. Cells share nothing at run time, so a failure, bad deployment or poison request affects only one cell. The fraction of customers affected by a failure is its **blast radius** [AWS 2023]. *(§33.12.1)*

Central processing unit (CPU) — The hardware that executes a program's **instructions**: simple operations such as "add these two numbers", "load a value from memory address X", or "if this value is zero, jump to instruction Y". A modern CPU package contains several independent **cores**, each of which can execute its own stream of instructions. *(§5.3.1)*

Certificate Transparency (CT) — A system of public, append-only, Merkle-tree-based logs into which CAs record every certificate they issue, so that mis-issued certificates become publicly detectable [RFC 6962]. *(§10.5)*

Chain of Responsibility — A request is passed along a chain of handler objects; each handler either handles it, or does some work and passes it to the next, so the sender does not know which handler will act [Gamma et al. 1994]. *(§37.15.3)*

Chain replication — Replicas are arranged in a linear **chain**. Every update enters at the **head** and is forwarded node by node to the **tail**; the tail replies to the client. Every query is answered by the tail. A separate, fault-tolerant **master** service detects failures and reconfigures the chain [van Renesse and Schneider 2004]. *(§27.5.1)*

Change data capture (CDC) — Extracting every committed insert, update and delete from a database, in commit order, as a stream of change events that other systems consume. **Log-based CDC** reads the database's replication log (PostgreSQL's write-ahead log via logical decoding, MySQL's binary log) rather than querying tables. *(§32.6.1)*

Chaos engineering — "The discipline of experimenting on a system in order to build confidence in the system's capability to withstand turbulent conditions in production" [Principles of Chaos Engineering]. *(§39.11)*

Choreography and orchestration — In **choreography**, each service reacts to other services' events and publishes its own; the saga's control flow is distributed across the participants and exists nowhere as one piece of code. In **orchestration**, a dedicated **or-**

chestrator sends commands to participants, receives their replies and decides the next step; the control flow lives in one place [Richardson 2018]. *(§32.8)*

Chubby — Google's lock service, providing coarse-grained advisory locks and small files in a file-system-like namespace, replicated across a five-node **cell** with Paxos, and used chiefly for leader election, naming and storing small amounts of configuration [Burrows 2006]. *(§26.14.1)*

CIDR block — An address range written as `address/prefix-length`, for example `192.168.10.64/26`. The prefix length n says that the first n bits identify the network; the remaining $32 - n$ bits (IPv4) or $128 - n$ bits (IPv6) identify hosts. The **subnet mask** is the same information as a dotted number with n one-bits followed by zeros (`/26` = `255.255.255.192`). *(§7.4.2)*

Circuit breaker — A client-side proxy for calls to a dependency that tracks recent failures and, when they cross a threshold, **opens**: it fails calls immediately without contacting the dependency for a cool-down period, then lets a few trial calls through (**half-open**) and **closes** again only if they succeed. *(§22.13)*

Class — A template that describes the attributes and methods every object of a kind will have. Creating an object from a class is called **instantiation**; the object is an **instance** of the class. *(§35.3.1)*

Class diagram — A structure diagram showing classifiers (classes, interfaces, enumerations), their **attributes** and **operations**, and the **relationships** among them. A class is drawn as a box with up to three compartments: name, attributes, operations. *(§38.3.2)*

Class invariant — A condition on an object's state that is true whenever no method of the object is running: after the constructor finishes and after every public method returns. *(§35.4.1)*

Clean architecture — Robert C. Martin's synthesis of hexagonal, onion and similar architectures, drawn as concentric circles: **entities** (enterprise business rules) at the center, then **use cases** (application business rules), then **interface adapters** (controllers, presenters, gateways), then **frameworks and drivers** (web, database, devices) at the edge, governed by one **dependency rule**: source-code dependencies point only inward [Martin 2017]. *(§33.11.1)*

Client–server architecture — A way of dividing a system into two roles: a **client**, which initiates requests on behalf of a user or another program, and a **server**, which waits for requests, performs work on shared resources (data, computation) and returns responses. The two communicate over a network using an agreed **protocol**. *(§8.3.1)*

Client-side load balancing — The calling process obtains the list of backend endpoints from service discovery (§34.7) and chooses a backend for each request itself, with no

proxy in the path. A **lookaside** balancer is an external service that tells clients *which* backends to use (and with what weights) while the traffic still flows directly from client to backend. *(§19.10)*

Clock rate — The frequency at which a core's internal circuitry steps from one state to the next, measured in hertz (cycles per second). A 4 GHz core has a **cycle time** of 1 / (4×10^9) s = 0.25 ns. *(§5.3.2)*

Cloud computing — "A model for enabling ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction" [Mell and Grance 2011]. NIST lists five **essential characteristics**: on-demand self-service, broad network access, resource pooling, rapid elasticity and measured service; three **service models** (SaaS, PaaS, IaaS); and four **deployment models** (private, community, public, hybrid). *(§41.3.1)*

Clustered and secondary index — In a **clustered index** (an index-organized table), the leaf level of the index *is* the table: rows are stored in key order inside the index's leaf pages. A table can have at most one. A **secondary index** stores, for each key, a pointer to the row; the table can have many. *(§11.7.2)*

Cluster scheduler — The component that assigns units of work (**tasks**, pods, containers) to machines in a cluster, decides which work waits when capacity is short, and reclaims capacity from lower-priority work. A **cluster manager** wraps the scheduler with admission, quota, health monitoring, restarts and an API. *(§46.3.1)*

Cohesion and coupling — **Cohesion** is how strongly the elements inside one module (here, one class) belong together: whether they serve a single purpose. **Coupling** is how strongly one module depends on others: how much it must know about them, and how likely a change in one is to force a change in the other. Good designs have **high cohesion and low coupling**. Both terms come from structured design [Stevens, Myers & Constantine 1974]. *(§35.10.1)*

Cohesion and coupling (service level) — **Cohesion** is the degree to which code inside one service changes together for the same reasons. **Coupling** is the degree to which a change in one service forces a change, redeploy or coordinated release in another. Newman's shorthand: "the code that changes together, stays together" [Newman 2021]. *(§34.3.2)*

Cold start — The extra latency an invocation pays when no initialized execution environment is available and the platform must create one: placement, sandbox creation, code loading, runtime start-up and the function's own initialization, all before the handler runs. An invocation served by an existing environment is a **warm start**. *(§48.5.1)*

Columnar storage (column store) — A layout that stores each column of a table contiguously — all values of `price`, then all values of `country` — instead of storing each row's fields together. Column stores are optimized for analytical queries that read a few columns of many rows [Abadi et al. 2013]. *(§13.13.1)*

Command — An object that encapsulates a request (the operation and its arguments) so that it can be stored, passed around, queued, logged, replayed and undone [Gamma et al. 1994]. In this book's terminology a command is a request to do something, as opposed to an event, a fact that has happened. *(§37.12)*

Command Query Responsibility Segregation (CQRS) — An architecture that uses one model to process commands (writes that enforce invariants) and one or more separate models to answer queries, each read model shaped for the queries it serves and typically updated asynchronously from the write side's events [Young 2010; Fowler 2011b]. *(§32.4.1)*

Commitment portfolio, coverage and utilization — A **commitment portfolio** is the mix of purchase options that serves a workload: commitments (reserved instances, savings plans, committed-use discounts) for the steady base, on-demand for the variable middle, and spot for interruptible work. **Coverage** is the share of eligible usage billed at committed rates. **Commitment utilization** is the share of purchased commitment actually consumed. The **effective savings rate** is the total discount achieved against what the same usage would have cost on demand. *(§51.6.1)*

Compaction — The background merge of sorted runs in an LSM tree that removes overwritten values and tombstones and bounds the number of runs a read must consult. A **compaction strategy** decides which runs to merge and when; it sets the engine's read, write and space amplification. *(§13.9.1)*

Compare-and-swap (CAS) — An atomic CPU instruction that, in one indivisible step, compares a memory location with an expected value and, only if they are equal, replaces it with a new value, reporting whether it succeeded. On x86-64 it is `LOCK CMPXCHG`; ARMv8.1 and later provide `CAS`, and earlier ARM uses load-linked/store-conditional pairs. *(§6.10.4)*

Competing consumers — A pattern in which several consumer processes read from the same queue concurrently, each message going to whichever consumer takes it first, so that adding consumers raises throughput [Hohpe and Woolf 2003]. *(§30.4.1)*

Component — A unit of a system with a clear responsibility and an interface — for example a web service, a database, a cache, a message queue, a load balancer or a third-party payment provider. *(§1.3.1)*

Component diagram — A structure diagram that shows **components** (modular, replaceable units that encapsulate their contents) and the **interfaces** they *provide* (offer to oth-

ers, drawn as a “lollipop” circle) and *require* (need from others, drawn as a “socket” half-circle), connected by **assembly connectors** that wire a required interface to a matching provided one [OMG 2017]. *(§38.5.1)*

Components of network delay — **Propagation delay**: time for a signal to travel the physical distance. **Transmission (serialization) delay**: time to push all of a packet’s bits onto the link. **Queuing delay**: time spent waiting in buffers behind other packets. **Processing delay**: time for a device to examine headers, look up routes and copy the packet. *(§7.15.1)*

Composition and delegation — **Composition** builds an object out of other objects that it holds in its fields (a **has-a** relationship). **Delegation** is the object forwarding part of its work to one of those parts by calling the part’s methods. “Favor object composition over class inheritance” is the second principle stated in the GoF introduction [Gamma et al. 1994, ch. 1]. *(§35.8.1)*

Concept-mastery loop — A fixed sequence of ten learning activities applied to one system-design concept. Each activity produces a concrete artifact (a definition, a diagram, a program, a design). The concept counts as mastered only when you can rebuild every artifact without notes. *(§3.3.1)*

Concurrency and parallelism — **Concurrency** is the *structuring* of a program as multiple tasks whose lifetimes overlap, so that progress on one does not wait for the others to finish. **Parallelism** is the *simultaneous execution* of multiple computations on multiple hardware units (cores, CPUs, GPUs). *(§6.8)*

Concurrency (FaaS) — The number of execution environments serving invocations at the same instant. On platforms with one request per environment it equals in-flight requests. Providers limit concurrency, not request rate, because concurrency is what consumes memory on workers. *(§48.6.1)*

Condition variable — A queue of threads waiting for some condition on shared state to become true, always used together with a mutex. `wait` atomically releases the mutex and sleeps; `notify` (`signal`) wakes one waiter and `notify_all` (`broadcast`) wakes all. *(§6.10.3)*

Conflict-free replicated data type (CRDT) — A data type whose replicas can be updated independently and concurrently without coordination and are guaranteed to converge to the same state once they have received the same updates, a property called **strong eventual consistency** [Shapiro et al. 2011a]. *(§27.14.3)*

Confused deputy — A program (the deputy) that holds authority from several sources and is tricked into using one principal’s authority on behalf of another. Hardy named it after a compiler that, given an output file name by a user, overwrote a billing file the compiler itself had permission to write [Hardy 1988]. *(§47.12.2)*

Congestion window (cwnd) — A sender-side limit, in bytes or segments, on unacknowledged data in flight, based on the sender's estimate of what the network path can absorb. The sender may have at most $\min(\text{cwnd}, \text{rwnd})$ bytes outstanding. *(§7.7.7)*

Connection gateway — A dedicated, thin service tier whose only job is to terminate long-lived client connections (WebSocket, SSE, long polling), authenticate them, track which user and topics each connection belongs to, and move messages between those connections and back-end services through a messaging layer. It contains no business logic. *(§9.9.1)*

Connection pooler — A component that keeps a few open database connections and lends them to many clients per session, transaction or statement, either inside the application or as a shared proxy. *(§14.13.1)*

Consensus — A set of processes, each of which may **propose** a value, must **decide** on a single value such that: **agreement** — no two correct processes decide differently; **validity** (integrity) — the decided value was proposed by some process; **termination** — every correct process eventually decides. Once decided, a value never changes. *(§26.3.1)*

Consistency hierarchy — The partial order on guarantees in which model A is **stronger** than model B when every history A allows is also allowed by B. It joins two families: **transactional isolation levels**, which constrain how groups of operations on many objects interleave, and **non-transactional consistency models**, which constrain which values single operations on single objects may return. *(§45.3.1)*

Consistent hashing — A way of assigning keys to nodes so that, when a node is added or removed, only about K/N of the K keys change owner, where N is the number of nodes. Both keys and nodes are hashed onto the same circular number space (the **ring**). Each key belongs to the first node found by moving clockwise from the key's position [Karger et al. 1997]. *(§3.3.2)*

Consistent hashing with bounded loads — A variant of consistent hashing in which every backend has a **capacity** of $\lceil (1+\varepsilon)\, m/n \rceil$ for m current items (requests, sessions) and n backends. An item goes to the first backend clockwise from its hash that is below capacity, so overflow from a full backend walks on to the next [Mirrokni, Thorup & Zadimoghaddam 2018]. *(§19.4.7)*

Consumer-driven contract (CDC) — A specification, generated by the consumer's tests, of the requests a consumer sends to a provider and the parts of the responses it relies on. The provider verifies every consumer's contract against its real implementation in its own build, so a breaking change fails before deployment [Robinson 2006; Pact Docs]. *(§34.8.5)*

Consumer group — A set of consumer instances sharing a `group.id` that divide a topic's partitions among themselves so that **each partition is consumed by exactly one mem-**

ber at a time. Different groups consume the same topic independently, each with its own offsets. *(§31.7.2)*

Consumer lag — For one partition, lag = **log end offset** (or high watermark) minus the group's **committed offset**: the number of records written but not yet processed by the group. Group lag is the sum over partitions. *(§31.7.3)*

Container — A process (or group of processes) that the Linux kernel runs with a restricted *view* of the system, provided by **namespaces**, and a restricted *share* of its resources, enforced by **control groups (cgroups)**, starting from a root file system unpacked from an **image**. A container shares the host's kernel; it is not a virtual machine. *(§42.3.1)*

Container image — An immutable, content-addressed package containing a root file system, stored as an ordered list of **layers** (each a compressed tar archive of file-system changes), plus a **configuration** (entry point, environment, user, working directory) and a **manifest** that lists them by cryptographic digest. The **OCI Image Specification** standardizes the format [OCI Image Spec]. *(§42.4.1)*

Container registry — A content-addressed store for images and related artifacts, organized into repositories, that serves manifests by **tag** or **digest** and layers (blobs) by digest over the HTTP API standardized by the **OCI Distribution Specification** [OCI Distribution Spec]. *(§42.5.1)*

Content-defined chunking (CDC) — Splitting a byte stream into variable-size chunks whose boundaries are chosen by the content itself: a rolling hash is computed over a small sliding window, and a boundary is declared wherever the hash matches a pattern (for example, its low 13 bits equal a fixed value). Each chunk is then identified by a cryptographic hash of its bytes, so identical chunks are stored once (**deduplication**). *(§15.8.3)*

Content delivery network (CDN) — A distributed system of caching reverse proxies (§7.12) deployed in many network locations, which serves content on behalf of an **origin** (the authoritative server for the content) from the location nearest each user, fetching from the origin only on a cache miss. *(§21.3.1)*

Context diagram — A diagram that shows the whole system as a single box, surrounded by the people (actors) and external systems that interact with it, with each interaction labeled. Context diagrams come from structured analysis [DeMarco 1979] and are Level 1 of the C4 model [Brown C4]. *(§2.4.1)*

Context switch — The kernel operation that stops one thread running on a CPU core, saves its CPU state into its PCB, and loads the saved state of another thread so that it resumes where it left off. *(§6.4)*

Continuous integration (CI) — The practice of merging every developer's work into a shared mainline at least daily, with each merge verified by an automated build and test run. **Definition — Continuous delivery (CD).** The practice of keeping the mainline always releasable, so that any commit that passes the automated pipeline *could* be deployed to production by pushing a button [Humble and Farley 2010]. **Definition — Continuous deployment.** Continuous delivery with the button removed: every commit that passes the pipeline is deployed to production automatically. *(§43.3.1)*

Control group (cgroup) — A kernel mechanism that groups processes into a hierarchy and applies resource accounting and limits to each group through **controllers** (cpu, memory, io, pids). **cgroup v2** is the unified hierarchy, stable since Linux 4.5 (2016), in which every controller uses one tree and one set of interface files [Linux Docs: cgroup v2]. *(§42.3.2)*

Control plane and data plane — The **control plane** is the set of services that make decisions (who may watch, which file, from which server); the **data plane** is the set of components that move the bulk bytes once decided. They are scaled, deployed and failed independently: the data plane is sized for bandwidth, the control plane for request rate and availability. *(§54.5.1)*

Control plane and data plane (multi-tenant) — The **data plane** serves tenants' requests: routers, services, caches and databases. The **control plane** manages tenants: onboarding and offboarding, provisioning and placement, configuration, tiers and limits, identities, and metering for billing. It serves operators and tenant administrators, not end-user traffic [AWS SaaS Fundamentals 2022]. *(§47.10.1)*

Coordinated omission — A measurement error in which the load generator, by waiting for slow responses before sending more requests, fails to send (and therefore fails to measure) the requests that would have experienced the slowness. The tester and the system "coordinate" to omit the worst samples. The term and diagnosis are due to Gil Tene [Tene, How NOT to Measure Latency]. *(§23.5.3)*

Correlation ID — An identifier generated at the edge of the system for each incoming request (or taken from the client) and attached to every log line, span and downstream call made on that request's behalf, so that all records of one request can be retrieved together. When distributed tracing is in place, the **trace ID** serves as the correlation ID. *(§40.4.2)*

Cost as a non-functional requirement — A **cost requirement** is a measurable bound on what a system may spend to deliver its function, stated per unit of business value (for example, "infrastructure cost at most $0.01 per order at 15 million orders a month") rather than as a total. Like a latency or availability objective, it is set during requirements, checked in design review and monitored in production. *(§51.3.1)*

Cost-based optimizer — The component that enumerates equivalent physical plans for a query (access paths, join orders, join algorithms), estimates each plan's cost from **statistics** about the data using a **cost model**, and returns the plan with the lowest estimated cost. *(§11.10.1)*

Count-Min sketch — A $d \times w$ array of counters with one hash function per row that estimates the frequency of any item in a stream. Each update increments one counter per row; each query returns the minimum of the item's d counters. The estimate never underestimates and, with probability at least $1 - \delta$, overestimates by at most εN, where N is the total of all updates [Cormode & Muthukrishnan 2005]. *(§17.6.1)*

CPU-bound and I/O-bound — A workload is **CPU-bound** when its speed is limited by how fast the processor can execute instructions; giving it a faster CPU or more cores speeds it up. It is **I/O-bound** when it spends most of its time waiting for storage or the network; a faster CPU barely helps, but more concurrency or faster devices do. A related category, **memory-bound**, is limited by memory latency or bandwidth (§5.9) — the CPU looks "busy" but is mostly stalled. *(§5.8)*

CPU cache — A small, fast memory built from SRAM (static RAM) on the processor chip that holds copies of recently used main-memory data, so that most loads and stores do not have to wait for DRAM. *(§5.4.1)*

CPU scheduler — The part of the kernel that decides which ready thread runs next on each core and for how long. The rule it follows is the **scheduling policy**; the mechanism that performs the switch is the dispatcher (§6.4). *(§6.5)*

Critical section — A region of code that accesses shared state and must not be executed by more than one thread at a time. Guaranteeing this is **mutual exclusion**. *(§6.9)*

Cross-region write conflict — Two writes to the same record, accepted in different regions, neither of which had seen the other when it was accepted. Such writes are **concurrent** in the happens-before sense (§24.10); a system must either prevent them (ownership, consensus) or resolve them after the fact. *(§44.8.1)*

Cryptographic hash function — A deterministic function H that maps an input of any length to a fixed-length output (the **digest**), such that it is computationally infeasible to (1) find an input that hashes to a given digest (**preimage resistance**), (2) given one input, find a different input with the same digest (**second-preimage resistance**), and (3) find any two distinct inputs with the same digest (**collision resistance**). *(§10.4.1)*

Cuckoo filter — A hash table of b-slot buckets that stores a short **fingerprint** of each item (an f-bit hash) in one of two candidate buckets. Membership checks two buckets for a matching fingerprint; deletion removes one copy of the fingerprint. *(§17.4.7)*

D

Database-per-service — Each service's persistent data is private to that service and reachable by others only through its API or published events. The service may use its own database server, its own schema on a shared server, or private tables, provided no other service reads or writes them [Richardson 2018]. *(§34.11.1)*

Database-per-tenant, schema-per-tenant and shared tables — In **database-per-tenant**, each tenant's data lives in its own database or cluster, and the connection selects the tenant. In **schema-per-tenant**, tenants share a server but each has its own schema, selected by the search path or qualified names. In **shared tables**, all tenants' rows share tables and are distinguished by a `tenant_id` column that every query must filter on, ideally enforced by the database with **row-level security (RLS)**. *(§47.5.1)*

DataFrame, Dataset and Catalyst — A **DataFrame** is a distributed table with a known schema (named, typed columns), manipulated with relational operators or SQL. A **Dataset** (Scala and Java) adds compile-time types to the same abstraction; in Python and R, every DataFrame is untyped at compile time. **Catalyst** is Spark SQL's extensible query optimizer, which turns DataFrame or SQL queries into an optimized physical plan using rule-based and cost-based transformations of trees [Armbrust et al. 2015]. *(§29.5.4)*

Data locality — Scheduling a task on or near the node that stores its input, so that the input is read from local disk or memory instead of over the network. Schedulers rank placements as **process-local** (data cached in the same executor), **node-local**, **rack-local** and **off-rack** (any). *(§29.7)*

Data platform — The shared infrastructure that collects an organization's data, stores it durably in open or managed formats, makes it queryable by several compute engines, and serves results to analysts, applications and machine-learning pipelines, with a catalog and access control across all of it. *(§49.5.1)*

Data residency, localization, sovereignty — **Data residency** is a requirement, from law, contract or customer policy, about the geographic location where data is stored and processed. **Data localization** is the stricter form: data (or a copy) must remain inside a country. **Data sovereignty** is the broader principle that data is subject to the laws of the place where it is collected or stored, which raises the question of which governments can compel access to it. *(§44.9.1)*

Dead-letter queue (DLQ) — A separate queue or topic to which a broker or consumer moves messages that cannot be processed (delivery limit exceeded, rejected as invalid, expired), preserving them for inspection and later reprocessing instead of losing or endlessly retrying them [Hohpe and Woolf 2003, "Dead Letter Channel"]. *(§30.11.1)*

Deadline — An absolute point in time by which a client needs an RPC to complete. gRPC transmits it as a remaining timeout; when it passes, the client stops waiting with `DEADLINE_EXCEEDED` and the server can see that the call was canceled [gRPC Docs: Deadlines]. *(§8.8.4)*

Deadlock — A state in which each thread in a set is waiting for a resource held by another thread in the same set, so none can ever proceed. *(§6.11.1)*

Decomposition — Dividing a system into smaller parts (**components**) so that each part has one clear responsibility, a well-defined interface, and as few dependencies on other parts as possible. Each part can then be understood, built, scaled and changed mostly on its own. *(§2.3.2)*

Decorator (GoF) — An object that implements the same interface as the object it wraps, forwards calls to it, and adds behavior before or after them, so responsibilities can be added at run time and stacked in any order without subclassing [Gamma et al. 1994]. *(§37.10)*

Defense in depth — An architecture in which an asset is protected by several layers of controls, each of which can stop or reveal an attack on its own, chosen so that the layers fail for *different* reasons. An attacker must defeat every layer on the path to the asset; a defender needs only one layer to hold or to raise an alarm. *(§50.3.1)*

Deliberate practice — Effortful practice designed to improve performance. It targets specific weaknesses, has clear goals, gives immediate feedback and is usually guided by a teacher or coach [Ericsson et al. 1993]. *(§3.4.6)*

Delivery guarantees — **At-most-once**: each message is processed zero or one times; failures lose messages but never duplicate them. **At-least-once**: each message is processed one or more times; failures cause duplicates but never loss. **Exactly-once** (more precisely **effectively-once**): the *observable effect* of processing is as if each message were processed exactly once, even though delivery may happen more than once. *(§30.8)*

Denormalization — Deliberately storing a fact more than once, or storing a derived value, to make important reads cheaper, while accepting the cost of keeping the copies consistent. *(§11.5.5)*

Dependency injection (DI) — A technique in which an object receives the objects it depends on (its dependencies) from outside, typically through its constructor, instead of creating or looking them up itself. The code that creates and connects all objects is the **composition root** [Fowler 2004]. *(§37.14)*

Dependency Inversion Principle (DIP) — (a) High-level modules should not depend on low-level modules; both should depend on abstractions. (b) Abstractions should not depend on details; details should depend on abstractions [Martin 2002]. **High-level** mod-

ules hold policy: the business rules that justify the system (checkout, invoicing). **Low-level** modules hold detail: mechanisms that could be swapped without changing the business (a payment vendor's SDK, SMTP, SQL). *(§36.7.1)*

Design assumption — A belief about the workload, the environment or the business that the design depends on but that has not yet been verified, for example "80% of requests are reads" or "the payment provider responds within 1 s at p99". An assumption is **stated** when it is written down with its value, its source, your confidence in it and how it will be checked. *(§2.7.1)*

Design by contract — A method of specifying software in which each routine states a **precondition** (what must be true when it is called: the caller's obligation), a **postcondition** (what it guarantees when it returns: the supplier's obligation), and each class states an **invariant** (what is true of every instance between calls). The approach, and the term, come from Bertrand Meyer and the Eiffel language [Meyer 1997]. *(§35.9.1)*

Design document (design doc) — A written proposal, produced before significant implementation, that states a problem, its goals and non-goals, a proposed design, the alternatives considered, and cross-cutting concerns (security, privacy, operations, cost), so that others can review it while changes are still cheap. *(§1.10.1)*

Designing for failure — Treating component failure as a *normal, expected event* rather than an exception. For every component and dependency, the design states what happens when it is slow, returns errors or disappears, and makes sure the **blast radius** (the set of users and features affected) is as small as possible. *(§2.9.1)*

Design pattern — A named description of a recurring design problem, the core of a solution (a set of collaborating classes or functions and their responsibilities), and the trade-offs of applying it. A pattern is a template you adapt, not a library you import [Gamma et al. 1994]. *(§37)*

Deterministic database — A database in which replicas and partitions first agree on a global order of transaction *inputs*, then execute transactions so that the outcome depends only on that order and the initial state. Every node that executes the same log reaches the same state, so no node needs to ask another whether to commit [Thomson et al. 2012]. *(§28.9.1)*

Digital rights management (DRM) license — A small, encrypted message issued by a license server that contains the content key (or keys) needed to decrypt an encrypted video, bound to a specific device and session and carrying usage rules (expiry, maximum resolution, offline permission). The video segments themselves are encrypted once and can be cached anywhere; only the license is personal. *(§54.5.1)*

Digital signature — A scheme with three algorithms: key generation, **sign** (using the private key, produces a signature over a message) and **verify** (using the public key,

checks a signature against a message). A valid signature shows that the message was approved by the holder of the private key and has not changed since. Because verification needs only the public key, *anyone* can verify, which provides non-repudiation. *(§10.4.5)*

Direct memory access (DMA) — A mechanism that lets a device controller read from or write to main memory directly, without the CPU copying each word; the CPU only sets up the transfer and is told when it finishes. *(§5.7.3)*

Direct serialization graph (DSG) — For a history of committed transactions with a known **version order** for each object (the order in which versions of x were installed), the DSG has a node per committed transaction and an edge $T_i \rightarrow T_j$ whenever T_j directly conflicts with T_i in one of three ways [Adya 1999]: - **Write dependency** ($T_i \overset{ww}{\rightarrow} T_j$): T_i installs a version of x and T_j installs the *next* version of x. - **Read dependency** ($T_i \overset{wr}{\rightarrow} T_j$): T_i installs a version of x and T_j reads that version. (A predicate read that observes T_i's change to the set of matching rows also counts.) - **Anti-dependency** ($T_i \overset{rw}{\rightarrow} T_j$): T_i reads a version of x and T_j installs the next version, so T_i did not see T_j's write. Predicate anti-dependencies arise when T_j changes the set of rows matching a predicate T_i read. *(§45.4.1)*

Direct server return (DSR) — A forwarding mode in which the balancer delivers request packets to the backend but the backend sends responses **directly to the client**, using the VIP as its source address, bypassing the balancer on the return path. *(§19.3.1)*

Disaster recovery, RTO, RPO — **Disaster recovery (DR)** is the set of plans and mechanisms for restoring service and data after an event that redundancy within the normal deployment cannot absorb: loss of a region, mass data corruption, ransomware, a destructive operator error. The **recovery time objective (RTO)** is the maximum acceptable time from disruption to restored service. The **recovery point objective (RPO)** is the maximum acceptable amount of data loss, measured as time before the disruption whose writes may be lost [AWS 2021]. *(§39.8.1)*

Distributed denial of service (DDoS) — An attack that makes a service unavailable by overwhelming some finite resource — network bandwidth, packet-processing capacity, connection-state tables, or application CPU, memory and database capacity — with traffic from many sources at once, typically a **botnet** of compromised devices or abused open servers. *(§10.11)*

Distributed file system — A file system whose namespace and data are spread across many machines, so that files can be larger than any one disk and throughput can grow with the number of machines, while clients still use file-like operations (create, open, read, write or append, delete). *(§15.5.1)*

Distributed monolith — A system deployed as multiple services that cannot be changed, deployed or operated independently: services share databases, must be released together, or call each other synchronously so tightly that one failure stops all of

them. It has the costs of distribution and the coupling of a monolith [Newman 2021]. *(§34.14.1)*

Distributed system — A set of independent computers (**nodes**) that have no shared memory and no shared clock, communicate only by exchanging messages over a network, and cooperate to provide a service. Van Steen and Tanenbaum describe it from the user's side as "a collection of autonomous computing elements that appears to its users as a single coherent system" [van Steen and Tanenbaum 2017]. *(§24.3.1)*

DNS time to live (TTL) — A per-record value, in seconds, that tells any cache how long it may reuse the record before asking again. **Negative caching** stores "this name does not exist" (NXDOMAIN) answers for a duration derived from the zone's SOA record [RFC 2308]. *(§7.6.4)*

Document database — A database that stores self-describing, hierarchical records — **documents**, usually JSON or a binary encoding of it such as BSON — grouped into **collections**, and that can index and query fields inside the documents, including nested fields and array elements. *(§12.5.1)*

Domain-driven design (DDD) — An approach that places a model of the business domain, built jointly by developers and domain experts, at the center of the design, expresses it directly in code, and divides large domains into explicitly bounded models [Evans 2003; Vernon 2013]. *(§34.4)*

Domain event — An immutable record of something domain experts care about that happened, named in the past tense (`OrderPlaced`, `CourierAssigned`), carrying the identifiers and facts its consumers need [Evans 2003; Vernon 2013]. *(§34.4.4)*

Domain Name System (DNS) — A hierarchical, distributed database that maps human-readable **domain names** (such as `www.example.com`) to data, most often IP addresses, and the protocol used to query it [RFC 1034; RFC 1035]. *(§7.6.1)*

Double-checked locking — A lazy-initialization idiom that checks whether an object exists without a lock (fast path), and only if it does not, takes a lock, checks again, and creates it. It avoids locking on every access but is only correct if the language's memory model guarantees that a thread seeing the reference also sees the fully constructed object. *(§37.16.5)*

DRAM (dynamic random-access memory) — The technology used for main memory. Each bit is stored as charge in a tiny capacitor that leaks and must be **refreshed** every few tens of milliseconds. DRAM is **volatile**: its contents are lost when power is removed. *(§5.5.1)*

Dremel — Google's interactive query engine for read-only nested data, published in 2010, which combines a columnar encoding of nested records with a multi-level **serving**

tree that executes aggregation queries over trillions of rows in seconds; it is the engine behind Google BigQuery [Melnik et al. 2010; Melnik et al. 2020]. *(§49.6.1)*

Duck typing — A style of polymorphism in which an object is acceptable wherever it supports the operations actually used, regardless of its declared class ("if it walks like a duck and quacks like a duck"). Checking happens when the method is called. **Structural typing** is the static version: a type checker accepts an object if its shape matches a declared protocol. *(§35.6.2)*

Durability — The probability that data, once acknowledged as written, is not lost over a given period (usually a year). It is quoted in nines like availability: "eleven nines of durability" means an annual loss probability of 10^{-11} per object. *(§4.16.1)*

Durable execution — A programming model in which a function's progress is persisted by an engine as it runs, so that the function survives process crashes, deploys and arbitrarily long waits and continues exactly where it left off, as if the process had never died [Temporal Docs]. *(§32.11.1)*

Durable subscription — A subscription whose messages the broker retains while the subscriber is disconnected, so the subscriber receives everything published since it subscribed, within the retention period. An **ephemeral** (non-durable) subscription exists only while the subscriber is connected; messages published while it is away are never delivered to it. *(§30.5.2)*

Dynamic site acceleration (DSA) — Routing uncacheable requests through the CDN anyway, so that TCP and TLS terminate near the user and the edge forwards each request to the origin over pre-established, tuned, long-lived connections, sometimes along an overlay path chosen from measurements. *(§21.7.2)*

E

Elasticsearch cluster — A set of nodes that share one cluster state (index definitions, mappings and the location of every shard copy). An **index** is a logical collection of documents divided into **primary shards**; each primary has zero or more **replica shards**; every shard is one Lucene index. *(§16.8.1)*

Encapsulation — The process by which each layer of the stack prepends its own header (and sometimes appends a trailer) to the data unit handed down by the layer above, treating that data unit as an opaque payload. **Decapsulation** is the reverse at the receiver. *(§7.3.1)*

End-to-end encryption (E2EE) — Encryption in which the keys needed to decrypt a message exist only on the communicating endpoints, so intermediaries that store or for-

ward the message, including the service operator, cannot read it. Transport encryption (TLS) protects each hop; E2EE protects the content from every hop. *(§53.5.8)*

Entity and value object — An **entity** has a continuous identity that persists as its attributes change: two orders for the same pizza are two orders. A **value object** is defined entirely by its attributes, has no identity and is usually immutable: `Money(24.50, "USD")`, `Address` [Evans 2003]. *(§34.4.2)*

Envelope encryption — Encrypting data with a **data-encryption key (DEK)** generated for that data, then encrypting ("wrapping") the DEK with a KEK held in a KMS, and storing the wrapped DEK alongside the ciphertext [AWS Docs: KMS concepts]. *(§10.9.2)*

Erasure code and RS(k, m) — An **erasure code** transforms k data fragments into $k + m$ fragments such that the original data can be rebuilt from some subset of them after the others are lost ("erased"). A **Reed–Solomon** code RS(k, m) is a **maximum distance separable (MDS)** code: *any* k of the $k + m$ fragments suffice, so it tolerates the loss of any m fragments. A code is **systematic** when the first k fragments are the unmodified data, so healthy reads need no decoding. *(§15.6.1)*

Error budget — The amount of unreliability an SLO permits over its window: $1 - \text{SLO}$, expressed as a number of bad requests or bad minutes. While budget remains, the team may spend it on risk (releases, experiments, migrations); when it is exhausted, reliability work takes priority [Beyer et al. 2016]. *(§39.7.1)*

Event-driven architecture (EDA) — A style in which components communicate mainly by producing and consuming **events**, immutable records of facts that happened ("OrderPlaced"), through a broker or log, so that producers do not know which consumers exist or when they will run. *(§33.8)*

Event loop — A single thread that repeatedly waits for events (ready sockets, expired timers, completed tasks) using an I/O multiplexing call, and dispatches each event to a short, non-blocking handler. *(§6.13.4)*

Event sourcing — A persistence pattern in which the system of record for an entity is the append-only, ordered sequence of **domain events** that changed it (`AccountOpened`, `MoneyDeposited`, …). Current state is not stored as truth; it is derived by replaying the events, a **left fold** of a pure function `apply(state, event)` over the sequence [Fowler 2005]. *(§32.3.1)*

Event storming — A collaborative workshop technique created by Alberto Brandolini in which domain experts and developers place domain events (past tense, on sticky notes) along a timeline, then add commands, actors, policies ("whenever X, then Y"), external systems and hotspots (open questions), and group the result into aggregates and candidate bounded contexts [Brandolini: Introducing EventStorming]. *(§34.5.4)*

Eventual consistency — If no new updates are made to an object, eventually all reads return the last updated value [Vogels 2009]. Equivalently, replicas that have received the same set of updates **converge** to the same state. **Strong eventual consistency** strengthens this: replicas that have received the same updates are in the same state immediately, with no further coordination, which is what conflict-free replicated data types (CRDTs) guarantee (§27.14). *(§25.7.1)*

Exabyte scale — A storage system whose capacity is measured in exabytes (1 EB = 10^{18} bytes = 1,000 PB = 1 million TB), typically spread over thousands of servers and tens to hundreds of thousands of drives in one or a few datacenters, and serving many tenants at once. *(§49.3.1)*

Execution environment, slot and worker — An **execution environment** is an isolated sandbox containing one function version's runtime and initialized code. The Firecracker paper calls a ready environment on a host a **slot**: it serves one function, one invocation at a time, but many invocations in sequence. A **worker** is a bare-metal host that runs hundreds or thousands of slots, each in its own microVM [Agache et al. 2020]. *(§48.4.1)*

Exemplar — A reference from an aggregated metric sample to an individual event that contributed to it, typically a trace ID attached to one histogram bucket observation, with its value and timestamp [OpenMetrics; Prometheus Docs: Exemplars]. *(§40.11.2)*

Expand–contract (parallel change) — A pattern for making a backward-incompatible change as a sequence of compatible steps: **expand** the schema or interface to support both old and new forms, **migrate** readers, writers and existing data to the new form, then **contract** by removing the old form once nothing uses it [Sato 2014b]. *(§43.13.2)*

Expected value — The probability-weighted average outcome of a random quantity X: $E[X] = \sum_i x_i \, P(X = x_i)$. It is the long-run average over many repetitions. *(§4.6.3)*

Exponent — In b^n, the **base** b is multiplied by itself n times; n is the **exponent** (or power). By convention $b^0 = 1$ and $b^{-n} = 1/b^n$. *(§4.3.1)*

External consistency — If transaction T_1 commits before T_2 starts, in absolute (wall-clock) time, then T_1's commit timestamp is smaller than T_2's. Combined with serializability, this is **strict serializability**: the serial order respects real-time order, as linearizability does for single objects (§25.3). *(§28.8.3)*

F

Factory method — A method declared in a base class that returns a product through an interface, which subclasses override to decide which concrete product to create. The base class's other methods use the product without knowing its class [Gamma et al. 1994]. *(§37.3.2)*

Failover — The sequence that replaces a failed node in a role: **detection**, **election** of a replacement, **reconfiguration** (making the replacement consistent and fencing the old node) and **client redirection**. *(§27.11.1)*

Failure detector — A component that outputs, for each monitored process, whether it currently **suspects** that process has crashed. It is **complete** if every crashed process is eventually suspected and **accurate** if live processes are not suspected. In an asynchronous network no detector can be both perfectly complete and perfectly accurate, because a slow process is indistinguishable from a dead one [Chandra and Toueg 1996]. *(§27.10.1)*

Fair queuing and weighted fair queuing — **Fair queuing** keeps a queue per flow (here, per tenant) and serves them so that each backlogged flow gets an equal share of capacity, however much any one flow sends [Demers et al. 1989]. **Weighted fair queuing (WFQ)** gives flow i a share proportional to weight w_i. The allocation is **max–min fair**: no tenant can get more without taking from one that has less. *(§47.8.2)*

False sharing — A performance problem in which threads on different cores write to *different* variables that happen to sit in the *same* cache line, so the coherence protocol bounces the line between cores as if they were sharing data. *(§5.4.7)*

Fault tolerance, redundancy and failure domain — **Fault tolerance** is the ability to keep providing correct service despite faults in some components. **Redundancy** is extra capacity or extra copies that make this possible. A **failure domain** is a set of components that can fail together because they share something: a power feed, a rack switch, a zone, a region, a software version, a configuration system or an operator. *(§39.4.1)*

Feature flag (feature toggle) — A runtime switch in the code that selects between code paths without a new deployment; its value is read from configuration or a flag service and can depend on the request context (user, tenant, region) [Hodgson 2017]. **Definition — Deploy versus release.** To **deploy** is to install a version of the code in production. To **release** is to let users experience a change. Feature flags make them separate events. *(§43.7.1)*

Fencing token — A number, increasing with every grant of a lock or lease, that the holder attaches to every request to the protected resource. The resource remembers the highest token it has accepted and rejects any request carrying a lower one. *(§26.13)*

FinOps — **FinOps** (cloud financial operations) is an operational practice in which engineering, finance, product and leadership collaborate to make data-driven spending decisions on variable, usage-based technology costs, so that the organization gets the most business value per unit spent. The FinOps Foundation organizes the practice into a repeating lifecycle of three phases (**inform**, **optimize** and **operate**), a set of personas, and capabilities grouped into domains [FinOps Foundation: Framework; Storment and Fuller 2023]. *(§51.5.1)*

Firewall — A device or software function that permits or denies traffic according to rules. A **stateless** (packet-filter) firewall evaluates each packet independently against rules on addresses, ports and protocol. A **stateful** firewall tracks connections, so a reply to an allowed outbound connection is automatically permitted. **Application-layer firewalls**, including web application firewalls (WAFs), parse protocols such as HTTP to block malicious requests. *(§7.14)*

Fixed window counter — A limiter that divides time into aligned windows of length W (for example each clock minute), keeps one counter per key per window, and admits a request if the current window's counter is below the limit L. The counter resets at each window boundary. *(§22.6.1)*

FLP impossibility — In a fully asynchronous message-passing system with reliable links, no *deterministic* protocol can solve **consensus** (all correct processes decide the same value, the value was proposed by some process, and every correct process eventually decides) if even one process may crash-stop [Fischer et al. 1985]. *(§24.13.1)*

Forward secrecy — A property of a key-exchange protocol whereby compromise of a party's long-term private key does not reveal session keys from past sessions. It is achieved by using fresh **ephemeral** key pairs for every session (the "E" in ECDHE) and deleting them afterward. *(§10.4.4)*

Four golden signals — Google's site reliability engineering guidance says that if you can measure only four metrics of a user-facing system, measure **latency** (time to serve a request, tracking successful and failed requests separately), **traffic** (demand, such as requests per second), **errors** (rate of failed requests, explicit or implicit) and **saturation** (how "full" the service is, emphasizing its most constrained resource) [Beyer et al. 2016, ch. 6]. *(§23.3.3)*

Fragile base class problem — A change to a base class that is correct on its own breaks subclasses, because the subclasses depend on implementation details of the base (which methods call which) that were never part of its documented interface. *(§35.5.2)*

Fragmentation (stranded capacity) — Free capacity that cannot be used by the tasks that need it, either because no single node has enough of it (**external fragmentation**), or because another resource on the same node is exhausted (**stranding**, in Borg's term). *(§46.7.2)*

Freshness and validation — A stored response is **fresh** while its age is below its **freshness lifetime** and may then be served without contacting the origin; once **stale**, it must normally be **revalidated**, by sending a conditional request (`If-None-Match` with the stored `ETag` , or `If-Modified-Since`), to which the origin answers `304 Not Modified` (keep using the copy) or `200 OK` with a new body [RFC 9111; RFC 9110]. *(§21.6.1)*

Functional dependency — In a relation R, the functional dependency $X \to Y$ holds if any two rows that agree on the columns X also agree on the columns Y. X is the **determinant**. Example: `product_id → product_name` because one product ID always has one name. *(§11.5.1)*

Functional requirement (FR) — A statement of a behavior the system must provide: an input, action or event, and the observable result. Functional requirements describe *what* the system does — for example, "a signed-in user can upload a JPEG or PNG photo up to 20 MB, and it appears in their followers' feeds". *(§1.6.1)*

Future and promise — A **future** is a read-only placeholder for a result that will be available later; a **promise** (Java's `CompletableFuture`, Python's `asyncio.Future`) is the writable side that the producer completes with a value or an error. Together they let a caller start work, continue, and later wait for or chain on the result. *(§37.16.3)*

G

Gang scheduling — Placing all tasks of a parallel job at the same time, or none of them. **Co-scheduling** is the weaker form: place a minimum number together and let the rest follow. *(§46.10.1)*

Garbage collection (GC) — Automatic reclamation of heap memory that the program can no longer reach. A **tracing** collector finds live objects by following references from **roots** (stacks, globals, registers) and reclaims everything else. A **stop-the-world (STW) pause** is an interval in which all application threads (the **mutator**) are halted so the collector can work on a consistent heap [Jones et al. 2023]. *(§23.9.1)*

Geohash — A string encoding of a latitude/longitude cell, published by Gustavo Niemeyer in 2008, formed by alternately bisecting the longitude and latitude ranges, interleaving the resulting bits (longitude first) and writing every 5 bits as one base-32 character [Niemeyer 2008]. Each additional character subdivides the cell into 32 smaller cells, so a geohash that is a prefix of another names a cell containing it. *(§17.9.2)*

Geo-replication; replication lag — **Geo-replication** copies data between regions. It is **synchronous** when a write is acknowledged only after a copy (or a quorum of copies) in another region has it, and **asynchronous** when the write is acknowledged locally and shipped afterward. **Replication lag** ℓ is the time between a write's local commit and its application in a given remote replica. *(§44.7.1)*

GitOps — An operating model in which the desired state of a system is declared in Git, and software agents running inside the target environment continuously pull that state and reconcile the live system to it. The OpenGitOps principles state that the desired state is **declarative**, **versioned and immutable**, **pulled automatically** and **continuously reconciled** [OpenGitOps 2021]. *(§43.10)*

Global traffic management — **Global traffic management (GTM)** is the set of mechanisms that choose, for each client or request, which region (or edge site) serves it, using proximity, measured latency, health, capacity and policy. It is global server load balancing (§19.9) extended with residency rules, home-region affinity and evacuation controls. *(§44.5.1)*

Gossip protocol — A protocol in which, every round, each node exchanges state with f randomly chosen peers (the **fanout**). In **push** gossip informed nodes send updates; in **pull** gossip nodes ask peers for news; **push–pull** does both. **Anti-entropy** gossip exchanges full state; **rumor mongering** spreads only recent updates and stops after a while [Demers et al. 1987]. *(§27.10.3)*

Graceful degradation — A design property in which, under failure or overload, a system keeps delivering its most important functions, possibly with reduced quality (staler data, fewer features, simpler results), instead of failing completely. *(§39.5.1)*

Graph database — A database whose data model is a graph of **vertices** (nodes) and **edges** (relationships), optimized for traversing edges. In the **property graph** model, nodes carry labels, edges carry a type and a direction, and both carry key-value properties. In the **RDF** model, all data is a set of subject–predicate–object **triples**. *(§12.7.1)*

GraphQL — A query language for APIs and a runtime for executing those queries against a strongly typed **schema**. The client sends a document describing exactly the fields it wants; the server returns JSON of the same shape [GraphQL Spec]. *(§8.7.1)*

Gray failure — A component failure that is *differentially observable*: some observers (often the system's own failure detector) consider the component healthy, while others (often the applications using it) experience it as failed or badly degraded. *(§24.8.2)*

Group of pictures (GOP) and closed GOP — Encoded video consists of **keyframes** (I-frames), which can be decoded alone, and predicted frames that reference other frames. A GOP is the run of frames from one keyframe to the next. A **closed GOP** references no frame outside itself, so a segment that starts at a closed-GOP keyframe can be encoded, stored and decoded independently of its neighbors. This independence is what makes parallel segment encoding and adaptive streaming possible. *(§54.4.1)*

gRPC — An open-source RPC framework, originally developed at Google and released in 2015, that uses Protocol Buffers as its interface definition language and message format and HTTP/2 as its transport [gRPC Docs]. *(§8.8.2)*

H

Happened-before (→) — The smallest relation on events such that: (1) if a and b occur in the same process and a comes first, $a \to b$; (2) if a is the sending of a message and b its re-

ceipt, $a \to b$; (3) if $a \to b$ and $b \to c$, then $a \to c$. Two distinct events are **concurrent** ($a \parallel b$) if neither $a \to b$ nor $b \to a$. *(§24.10.1)*

Hard disk drive (HDD) — A storage device that records data magnetically on spinning platters, read and written by heads mounted on a moving arm (the **actuator**). Data is organized in concentric **tracks** divided into **sectors** of 512 or 4096 bytes. *(§5.6.1)*

Hash function — A deterministic function h that maps an input of any length to a fixed-size integer (for example 32, 64 or 128 bits), called the **hash** or **digest**. A **non-cryptographic hash function** is designed for speed and statistical uniformity on ordinary inputs. A **cryptographic hash function** additionally resists an adversary who tries to find collisions or preimages (§10.4.1). *(§17.3.1)*

Hash slot (Redis Cluster) — One of 16,384 buckets into which Redis Cluster divides the keyspace: `slot = CRC16(key) mod 16384`. Each primary owns a set of slots. If a key contains `{...}`, only the substring inside the braces (a **hash tag**) is hashed, so related keys can be forced into one slot [Redis Docs: Cluster specification]. *(§20.6.4)*

Head and tail sampling — **Head sampling** decides at the root span, before the request runs, usually with a probability applied to the trace ID; the decision propagates in the sampled flag so that the whole trace is kept or dropped consistently. **Tail sampling** decides after the trace completes, when its duration, errors and attributes are known, by buffering all spans of each trace in a collector until a decision timer expires [OpenTelemetry Docs: Sampling]. *(§40.6.3)*

Health check — A mechanism by which a balancer decides whether a backend should receive traffic. An **active** check sends synthetic probes (a TCP connect, an HTTP `GET /healthz`, a gRPC health RPC) on a timer. A **passive** check, also called **outlier detection**, watches real traffic for errors, timeouts or latency and **ejects** misbehaving backends for a period. *(§19.5.1)*

Hedged request — A request sent to one replica and, if no response arrives within a **hedge delay** d, sent again to a second replica; the client uses whichever response arrives first and cancels or ignores the other [Dean and Barroso 2013]. *(§23.7.1)*

Hexagonal architecture (ports and adapters) — A style, described by Alistair Cockburn, in which the application's core logic interacts with the outside world only through **ports**, interfaces defined by and in the language of the core, and each external technology (web framework, database, message broker, test harness) connects through an **adapter** that implements or calls a port [Cockburn 2005]. **Driving (primary) ports** are how the outside asks the application to do something; **driven (secondary) ports** are how the application asks the outside for something. *(§33.10.1)*

High-level design (HLD) — A description of a system as a set of major components (services, data stores, queues, caches, external dependencies), their responsibilities, the in-

terfaces and protocols between them, data flows, and deployment topology — at a level of detail where each component is a box whose internals are not yet specified. *(§1.5.1)*

High-performance computing (HPC) — The use of many tightly interconnected processors working together on a single computational problem (simulating climate, fluid flow, molecules, nuclear physics, or training a large model) to solve it faster or at a larger size than any single machine could. A **supercomputer** is a system built for this, optimized for floating-point throughput and low-latency communication between nodes. *(§49.8.1)*

α–β (Hockney) model — Sending an n-byte message costs $\alpha + n\beta$, where α is a fixed per-message **latency** (software overhead plus network) and β the time per byte (inverse bandwidth). Reductions add $n\gamma$ for computation; γ is usually small and is ignored below [Thakur et al. 2005]. *(§49.9.2)*

Home region; geo-partitioning — **Geo-partitioning** splits data by a geographic key so that each record has exactly one **home region** that owns its writes. Requests for a record are served by, or forwarded to, its home region. **Follow-the-sun** placement moves ownership or leadership over time to where activity is (for example, moving a partition's leader to the region in daytime working hours), and is a variant of the same idea. *(§44.6.4)*

Horizontal scaling (scaling out) — Increasing capacity by adding more nodes that share the workload, for example by running 20 identical application servers behind a load balancer instead of one. Removing nodes when load falls is **scaling in**. *(§18.4.1)*

Hot key — A single key whose request rate exceeds what the node holding it can serve, so partitioning cannot help: all requests for one key go to one node. *(§20.15)*

Hot partition and hot key — A **hot partition** receives enough excess requests or data to saturate its node while peers idle. A **hot key** is a single key causing that excess. **Skew** is uneven distribution of data or load in general. *(§14.10.1)*

HTTP adaptive streaming — Video is encoded at several quality levels (a **bitrate ladder**), each cut into **segments** of a few seconds stored as ordinary files. A **manifest** lists the levels and segment URLs. The player downloads the manifest, then fetches segments one by one over HTTP, choosing a level for each segment. *(§21.8.1)*

HTTP cookie — A small name–value pair that a server asks the browser to store, via the `Set-Cookie` response header, and that the browser automatically returns in the `Cookie` request header on later requests to matching URLs [RFC 6265]. *(§8.10.1)*

Hybrid logical clock — A timestamp (l, c) where l is the largest physical clock value the node has seen (from its own clock or from any message) and c is a logical counter that orders events sharing the same l. Timestamps compare lexicographically: first by l, then by c. *(§24.12.1)*

HyperLogLog (HLL) — A probabilistic algorithm that estimates the number of distinct items (the **cardinality**) in a multiset using m small registers, with relative standard error about $1.04/\sqrt{m}$, independent of the cardinality itself [Flajolet et al. 2007]. *(§17.5.1)*

Hypervisor — Software (sometimes with hardware assistance) that runs multiple **guest** operating systems on one physical host, giving each the illusion of its own machine. A **type 1** hypervisor runs directly on hardware (Xen, KVM as part of Linux, Hyper-V); a **type 2** runs as an application on a host OS (VirtualBox). Modern CPUs provide hardware virtualization extensions (Intel VT-x, AMD-V, Arm virtualization extensions) so that guest instructions run natively and only privileged operations trap to the hypervisor. *(§41.8.2)*

I

IAM building blocks — A **principal** is an entity that makes requests: a human user, a workload, or a federated identity. A **policy** is a document of statements, each with an **Effect** (Allow or Deny), **Actions** (for example `s3:GetObject`), **Resources** (identified by ARN or resource path) and optional **Conditions** (source network, tags, MFA, time). **Identity-based policies** attach to principals; **resource-based policies** (bucket policies, key policies, queue policies) attach to resources and name which principals may use them. A **role** is an identity with permissions but no long-term credentials: trusted principals **assume** it and receive temporary credentials (on AWS, from the Security Token Service, typically valid for an hour). *(§41.12.1)*

Idempotence — An operation is **idempotent** if applying it once or many times leaves the system in the same state. **Drift** is any difference between the state the code declares and the state that actually exists. *(§43.8.1)*

Idempotency key — A unique value, generated by the client once per *logical* operation and sent with every attempt of that operation (for example in an `Idempotency-Key` header), that the server uses to recognize retries: the first attempt executes and its result is stored under the key; later attempts with the same key return the stored result instead of executing again. *(§22.15.1)*

Idempotent consumer — A message consumer whose effect on state is the same whether a given message is processed once or many times, achieved either because the operation is naturally idempotent or because the consumer detects and skips messages it has already processed. *(§32.10)*

Idempotent method — A method for which the intended effect on the server of sending the same request $N > 0$ times is the same as sending it once [RFC 9110 §9.2.2]. The *response* may differ (a second `DELETE` may return 404); the *state* does not. *(§8.6.3)*

Identity and equality — **Identity** asks “are these the same object in memory?” (Python `is`, Java `==` on references). **Equality** asks “do these objects represent the same value by

a rule the class defines?" (Python `==` via `__eq__`, Java `equals`). Unless a class overrides equality, both languages default to identity. *(§35.3.2)*

Incident — An unplanned event that degrades or threatens a service's SLOs, security or data and requires a coordinated response. **Incident management** is the process of detecting, coordinating, mitigating and learning from incidents. *(§39.12.1)*

Index — A secondary data structure, kept in sync with a table by the database, that maps values of one or more **key columns** to the locations of the rows holding them, so that rows can be found without scanning the whole table. Most relational indexes are B+ trees (§11.8); others include hash, GiST, GIN and BRIN indexes in PostgreSQL and full-text and spatial indexes in MySQL. *(§11.7.1)*

In-doubt (blocked) transaction — A transaction at a participant that has voted yes but has not learned the outcome. It must hold its locks and cannot decide until the coordinator, or another participant that knows the outcome, answers. *(§28.4.3)*

Infrastructure as code (IaC) — Managing infrastructure (networks, machines, load balancers, databases, DNS, permissions) through machine-readable definition files kept in version control and applied by tools, instead of through manual console clicks or ad hoc scripts [Morris 2020]. *(§43.8.1)*

Inheritance — A mechanism by which a class (the **subclass**, **child** or **derived class**) is defined as an extension of another (the **superclass**, **parent** or **base class**). The subclass automatically has the parent's attributes and methods, may add new ones, and may **override** inherited methods by providing its own version with the same name and parameters. *(§35.5.1)*

Instance type and family — An **instance type** is a fixed shape of virtual hardware: vCPUs, memory, network bandwidth, local storage and accelerators. Types are grouped into **families** optimized for a ratio of resources. In AWS naming, `m7g.xlarge` means family `m` (general purpose), generation `7`, attribute `g` (AWS Graviton Arm processor), size `xlarge` (4 vCPUs). A **vCPU** is one hardware thread on most x86 instances (two vCPUs per physical core with simultaneous multithreading) and one physical core on Graviton. *(§41.8.1)*

Instruction pipeline — A technique in which the core splits instruction execution into stages and works on different stages of several consecutive instructions at the same time, like an assembly line. *(§5.3.3)*

Interface Segregation Principle (ISP) — Clients should not be forced to depend on methods that they do not use [Martin 2002]. A **fat interface** serves many kinds of client; a **role interface** describes what one kind of client needs from its collaborator [Fowler 2006]. *(§36.6.1)*

Interleaving — Mixing different kinds of problems or concepts within one practice session (A B C A C B), instead of finishing all practice on one kind before moving to the next (AAA BBB CCC, called **blocking**). *(§3.4.5)*

Inverted index — A mapping from each distinct **term** (a normalized word or token) to a **postings list**: the sorted list of identifiers of the documents that contain the term, optionally with the term's frequency and positions in each document. The set of all terms is the **dictionary** (or **vocabulary**, or **lexicon**). *(§16.3.1)*

I/O (input/output) — Any transfer of data between the CPU/memory and a device outside it: storage, network cards, GPUs, keyboards. A **device controller** on each device does the physical work; the CPU communicates with it through **device registers** and shared memory. *(§5.7)*

IOPS — Input/output operations per second: the number of independent read or write requests a device completes per second, quoted for a stated request size (usually 4 KiB) and **queue depth** (number of requests outstanding at once). *(§5.6.5)*

IP address — A numeric identifier assigned to a network interface that the Internet Protocol uses to deliver packets. An **IPv4** address is 32 bits, written as four decimal octets (`203.0.113.25`) [RFC 791]. An **IPv6** address is 128 bits, written as eight groups of four hexadecimal digits separated by colons (`2001:db8:0:1::25`) [RFC 8200]. *(§7.4.1)*

Isolation anomalies — **Dirty write:** a transaction overwrites another's uncommitted write. **Dirty read:** a transaction reads another's uncommitted write (which may later roll back). **Non-repeatable (fuzzy) read:** a transaction reads a row twice and sees different committed values because another transaction updated it in between. **Phantom:** a transaction runs the same *predicate* query twice (`WHERE status = 'pending'`) and gets a different set of rows because another transaction inserted or deleted matching rows. **Lost update:** two transactions read the same value, both compute a new value from it and write; the second write silently overwrites the first. **Read skew:** a transaction sees part of another transaction's effects (reads account A before a transfer commits and account B after it). **Write skew:** two transactions read an overlapping set of rows, each checks an invariant, then each writes a *different* row; each write is valid alone but together they violate the invariant. *(§11.13.1)*

Isolation boundary and attack surface — An **isolation boundary** separates one tenant's running code from others': a process, container, user-space kernel, hypervisor or separate hardware. Its **shared attack surface** is the interface callable across it: for a container, the host kernel's several hundred system calls; for a VM, the far smaller virtual-hardware interface. *(§47.9.1)*

ISR, LEO and high watermark — Each partition has a **replication factor** (RF) of replicas on different brokers; one is the **leader**, which handles all writes, and the others are **followers**, which fetch from the leader. The **in-sync replica set (ISR)** is the leader plus

the followers that have fully caught up within `replica.lag.time.max.ms` (default 30 s). Each replica's **log end offset (LEO)** is the offset its next appended record will get. The **high watermark (HW)** is the offset below which every ISR member has the record; records below the HW are **committed** and are the only ones consumers can read. *(§31.9.1)*

J

Join-semilattice — A set S with a partial order $\leq$ in which every pair of elements x, y has a **least upper bound** (join) $x \sqcup y$: an element with $x \leq x \sqcup y$ and $y \leq x \sqcup y$, and $x \sqcup y \leq z$ for every other upper bound z. Any join is commutative, associative and idempotent (ACI). A function m on S is **inflationary** if $x \leq m(x)$ and **monotone** if $x \leq y$ implies $m(x) \leq m(y)$. *(§45.6.1)*

JSON Web Token (JWT) — A compact, URL-safe string representing a set of **claims** (statements about a subject) as a JSON object, digitally signed (JWS) or encrypted (JWE) so its integrity can be verified [RFC 7519]. This section covers the signed form, which is by far the most common. *(§8.13.1)*

K

Key management service (KMS) — A managed service, backed by hardware security modules (HSMs), that generates and stores **key-encryption keys (KEKs)** that never leave it in plaintext, performs cryptographic operations with them on request, enforces access policies on every use and logs every call. Examples: AWS KMS, Google Cloud KMS, Azure Key Vault, HashiCorp Vault's Transit engine. *(§10.9.2)*

Keys — A **superkey** is a set of columns whose values are unique across all rows. A **candidate key** is a minimal superkey: remove any column and it stops being unique. The **primary key** is the candidate key chosen as the row's main identifier; it must be unique and NOT NULL. Other candidate keys are enforced with `UNIQUE` constraints. A **foreign key** is a column (or set) in one table whose values must match a key of another table, a rule called **referential integrity**. *(§11.4.1)*

Key-value store — A database whose primary interface is `get(key)`, `put(key, value)` and `delete(key)`, where the value is opaque to the database or has a small set of built-in types. The key alone determines where the value lives. *(§12.4.1)*

Kubernetes — An open-source container orchestrator that runs workloads across a cluster of nodes from **declarative** specifications. Users write the *desired state* of API objects to a central API server; independent **controllers** continuously compare it with the *observed state* and act to close the gap [Kubernetes Docs: Components]. *(§42.6.1)*

L

Lambda and Kappa architectures — The **Lambda architecture** runs two parallel paths over the same immutable master dataset: a **batch layer** that periodically recomputes complete, accurate views from all history, and a **speed layer** that processes recent data incrementally with low latency; a **serving layer** merges the two at query time [Marz and Warren 2015]. The **Kappa architecture** uses a single stream-processing path over a replayable log; to change logic or fix a bug, it reprocesses history by replaying the log through a new version of the job [Kreps 2014]. *(§29.10)*

Lamport clock — Each process P_i keeps an integer counter C_i, initially 0. **Rule 1:** before each event (local, send or receive), $C_i \leftarrow C_i + 1$; a send attaches the new C_i to the message. **Rule 2:** on receiving a message with timestamp t_m, set $C_i \leftarrow \max(C_i, t_m)$, then apply rule 1. The event's timestamp is the resulting C_i. *(§24.10.2)*

Last-writer-wins (LWW) — Each write carries a timestamp, and when replicas hold different values for an item, the one with the greatest timestamp is kept and the others are discarded. *(§27.14.1)*

Latency and bandwidth (hardware) — **Latency** is the time from issuing one request to receiving its first byte (for example, ~100 ns for a DRAM load). **Bandwidth** is the maximum rate at which data can be moved once transfers are flowing (for example, ~38 GB/s for one DDR5-4800 channel). Achieved bandwidth is **throughput**. *(§5.9.1)*

Law of Demeter (object form) — A method `M` of an object `O` should call methods only on: `O` itself; `M`'s parameters; objects `M` creates; and `O`'s own fields (its direct parts) [Lieberherr & Holland 1989]. Informally: "talk only to your immediate friends", or "use only one dot" (excluding fluent builders and value-object chains). *(§35.10.2)*

Layer 4 (L4) and layer 7 (L7) load balancing — An **L4 load balancer** makes its decision from transport-layer information (IP addresses, ports, protocol) and balances **connections or flows**: every packet of one TCP connection goes to the same backend. An **L7 load balancer** terminates the client connection, parses the application protocol (usually HTTP), and balances **requests**: two requests on one connection may go to different backends. *(§19.3.1)*

Layered architecture — A style that organizes code into horizontal **layers**, each with one kind of responsibility (presentation, business logic, persistence), where each layer may depend only on layers below it. A **tier** is a *physical* deployment boundary (browser, application server, database server); an **n-tier architecture** maps layers onto separately deployed tiers. *(§33.3.1)*

Leader election — A protocol by which the nodes of a group choose one node, the **leader**, to coordinate some activity (ordering writes, running a scheduler, owning a parti-

tion), and choose a replacement when it fails. The goal is *at most one* leader at a time (safety) and *eventually some* leader (liveness). *(§26.5.1)*

Leaderless replication — Any replica of a key may accept reads and writes; the client, or a **coordinator** node acting for it, sends each request to several replicas in parallel and treats it as successful once enough of them respond. There is no failover because there is no leader [DeCandia et al. 2007]. *(§27.7.1)*

Leaf–spine (folded Clos) network — A two-tier topology in which every **leaf** (top-of-rack) switch connects to every **spine** switch, and servers attach only to leaves. Any two servers on different leaves are exactly two switch hops apart (leaf → spine → leaf), and traffic is spread across all spines with ECMP. It is a form of the multistage **Clos network**, first described by Charles Clos in 1953 for telephone switching. Larger fabrics add a third tier. *(§7.17.1)*

Leaky bucket — (a) **As a queue:** requests enter a FIFO buffer of capacity Q that is drained at a constant rate r; arrivals that find the buffer full are dropped. Output is perfectly smooth. (b) **As a meter:** a counter (the "water level") increases by one per admitted request and leaks at rate r; a request that would overflow capacity is rejected immediately. The meter form makes the same admit/reject decisions as a token bucket with the same rate and capacity. *(§22.5.1)*

Lease — A time-bounded grant of a right (to cache data, to act as leader, to hold a lock) from a grantor to a holder. Within the term the holder may act without consulting the grantor; after the term, the right lapses automatically, even if the holder has crashed or is unreachable [Gray and Cheriton 1989]. *(§26.11.1)*

Least connections — Send each new connection or request to the backend with the fewest **active** (in-flight) connections or requests, as counted by the balancer. *Weighted least connections* divides each count by the backend's weight. Envoy calls the request-counting variant **least request**; AWS ALB calls it **least outstanding requests**. *(§19.4.2)*

Least response time — Choose the backend with the lowest recent latency, usually an **exponentially weighted moving average (EWMA)** of observed response times, often multiplied by the in-flight count so that both queue length and speed count. *(§19.4.3)*

Linearizability — A history is **linearizable** if each operation can be assigned a single instant, its **linearization point**, somewhere between its invocation and its response, such that (1) the operations, ordered by these points, form a **legal sequential history** of the object (every read returns the value of the most recent preceding write), and (2) therefore whenever a precedes b in real time, a comes before b in that order. Pending operations may be either included (with a linearization point after their invocation) or dropped. An object is linearizable if all its histories are [Herlihy & Wing 1990]. *(§25.3.2)*

Liskov Substitution Principle (LSP) — Subtypes must be substitutable for their base types [Martin 2002]. More precisely, S is a **behavioral subtype** of T if every property you can prove about objects of type T, using T's specification, also holds for objects of type S [Liskov and Wing 1994]. *(§36.5.1)*

Little's Law — For any stable system observed over a long period, the average number of items in the system equals the average arrival rate multiplied by the average time each item spends in the system: $L = \lambda W$ [Little 1961]. *(§4.11.1)*

Load balancer — A component that receives traffic addressed to a single service endpoint, the **virtual IP address (VIP)** or service name, and distributes it across a **pool** of **backends** (also called *upstreams*, *targets* or *real servers*) according to a **balancing algorithm**, while excluding backends that are unhealthy. *(§19.3.1)*

Load shedding and throttling — **Load shedding** is a server rejecting some requests early and cheaply (usually with 503) because accepting them would push it past capacity, regardless of whether each client is within its quota. **Throttling** is slowing a client down, by delaying or rejecting its requests; rate limiting is the quota-based form. **Goodput** is the rate of requests completed *usefully*: correctly and before the client gave up. *(§22.9.1)*

Local and global secondary indexes — A **local** (document-partitioned) index lives in each partition and covers only its rows. A **global** (term-partitioned) index covers all rows and is partitioned by the *indexed value*, so all entries for one value live together [Kleppmann 2017]. *(§14.11.1)*

Log — An append-only, totally ordered sequence of records. Each record is assigned a monotonically increasing integer position called its **offset** when it is appended. Records are never modified in place; readers read sequentially from any offset they choose. *(§31.3.1)*

Log and structured log — A **log** is a time-ordered record of discrete events emitted by a program. A **structured log** encodes each event as a set of named fields (usually JSON, or key–value pairs), so that machines can filter and aggregate by field instead of parsing free text with regular expressions. *(§40.4.1)*

Logarithm — The logarithm base b of x, written $\log_b x$, is the exponent to which b must be raised to give x: if $b^y = x$ then $y = \log_b x$. *(§4.4.1)*

Log compaction — A retention policy (`cleanup.policy=compact`) that keeps **at least the latest record for each key** and discards older records with the same key, so the partition converges to a snapshot of the latest value per key while preserving the offsets and order of the records that remain. A record with a null value, a **tombstone**, marks a key as deleted and is itself removed after `delete.retention.ms` (default 24 hours). *(§31.10.2)*

Log matching property — If two logs contain an entry with the same index and term, then (1) the entries store the same command, and (2) the logs are identical in all preceding entries. *(§26.7.4)*

Log-structured merge tree (LSM tree) — A storage structure that buffers writes in a sorted in-memory table (the **memtable**), periodically writes it out as an immutable sorted file (a **sorted string table, SSTable**), and merges SSTables in the background (**compaction**) into progressively larger sorted runs organized in **levels**. Introduced by O'Neil, Cheng, Gawlick and O'Neil [O'Neil et al. 1996]; the memtable/SSTable design popularized by Google's Bigtable [Chang et al. 2006] and implemented in LevelDB, RocksDB, Cassandra, HBase, ScyllaDB and many others. *(§13.8.1)*

Log-structured storage — A storage design in which every write — insert, update or delete — is appended to the end of a file, and existing data is never modified in place. Old versions become garbage that a background **compaction** (or merge) process removes by copying live data into new files. *(§13.7.1)*

Long polling — A technique in which the client sends an HTTP request that the server deliberately does not answer until either new data is available or a server-side timeout T_{hold} expires; on receiving any response, the client immediately sends the next request. *(§9.4.1)*

Low-level design (LLD) — A description of the internals of one component: its modules, classes or functions, data structures, algorithms, database schemas, API request and response formats, error handling and state transitions — at a level of detail from which an engineer can write code. *(§1.5.1)*

Low-level design (LLD) interview — A 45–60-minute interview in which you design the classes, interfaces, relationships and key algorithms of a single component or small application (a parking lot, an LRU cache, a rate limiter), usually ending with working or near-working code for the core classes. It is also called an *object-oriented design* or *machine coding* interview. It contrasts with the high-level design interview (§1.5, Chapter 87), which designs a distributed system out of services and data stores. *(§38.9.1)*

M

Maglev hashing — A consistent-hashing scheme that builds a **lookup table** of prime size M in which every entry names a backend. Each backend has its own pseudo-random **preference permutation** of table positions; backends take turns claiming their next preferred empty position until the table is full. A packet's backend is `table[hash(5-tuple) mod M]` : one array read [Eisenbud et al. 2016]. *(§19.4.8)*

Managed database service — A database engine operated by the provider: provisioning, OS and engine patching, automated backups with point-in-time recovery, replication and failover across zones, monitoring and storage scaling are provider tasks exposed through an API. You keep schema design, queries, indexes, capacity choices, parameter tuning and access control. Examples: Amazon RDS and Aurora, Google Cloud SQL and AlloyDB, Azure SQL Database and Azure Database for PostgreSQL/MySQL. *(§41.11.1)*

MapReduce — A programming model and execution system in which the user writes two functions: **map**, which turns one input record into zero or more intermediate key–value pairs, and **reduce**, which receives one intermediate key with *all* values emitted for it and produces output. The system handles splitting, scheduling, regrouping by key, and failures [Dean and Ghemawat 2004]. *(§29.4.1)*

Matrix — A rectangular grid of numbers with m rows and n columns (an $m \times n$ matrix). A set of n embeddings of dimension d is naturally stored as an $n \times d$ matrix, one embedding per row. *(§4.9.3)*

Max-min fairness — An allocation is max-min fair if no user's share can be increased without decreasing the share of a user who has an equal or smaller share. With one resource, it is computed by **water filling**: raise every unsatisfied user's allocation equally until each is either satisfied or the resource is exhausted. **Weighted fair share** raises allocations in proportion to weights. *(§46.9.1)*

Mean and median — The **mean** (arithmetic average) of n values is their sum divided by n. The **median** is the middle value after sorting (the average of the two middle values when n is even); half of the values are at or below it. *(§4.7.1)*

Memory hierarchy — The layered arrangement of storage technologies in a computer, from small, fast and expensive per byte (registers, caches) to large, slow and cheap per byte (disks, tape), in which each level acts as a cache for the level below it. *(§5.5.2)*

Merkle tree (hash tree) — A tree in which every leaf holds the hash of a data block and every interior node holds the hash of its children's hashes. The **root hash** summarizes the entire data set: changing any block changes the root [Merkle 1987]. *(§17.8.1)*

Message authentication code (MAC) — A short tag computed from a message and a secret key, $t = \mathrm{MAC}_K(m)$, such that without K it is infeasible to produce a valid tag for any new message. **HMAC** is the standard construction from a hash function: $\mathrm{HMAC}_K(m) = H((K \oplus \text{opad}) \parallel H((K \oplus \text{ipad}) \parallel m))$ [Krawczyk et al. 1997]. *(§10.4.6)*

Message, command, event — A **message** is the transport unit a broker carries: headers plus a payload. A **command** is a message that asks one specific receiver to do something ("ResizePhoto"); it may be refused. An **event** is a message stating a fact that has already happened ("PhotoUploaded"); it cannot be refused, only reacted to, and its publisher does not know who reacts [Hohpe and Woolf 2003]. *(§30.6.1)*

Message ordering — **Global (total) ordering**: all consumers observe all messages in one sequence. **Per-key (partial) ordering**: messages that share a key — an account, an order, a device — are processed in send order, while messages with different keys may be processed in any relative order. *(§30.9)*

Message queue (point-to-point channel) — A broker-managed, durable buffer of messages in which each message is delivered to, and processed by, exactly one of the queue's consumers; once a consumer acknowledges a message, the broker removes it [Hohpe and Woolf 2003]. *(§30.4.1)*

Metadata service — The component that maps names to data: directory entries, file or object attributes (size, owner, permissions, version, checksum) and the locations of each chunk or fragment. It is on the path of every open, create, list and delete, while the data path bypasses it. *(§15.7.1)*

Metering, showback and chargeback — **Metering** records each tenant's consumption of billable or scarce resources as durable usage events. **Showback** reports the cost attributed to each tenant (or internal team) without billing it. **Chargeback** bills that cost to the tenant or team's budget. External SaaS turns metering into invoices; internal platforms use showback or chargeback to make teams see the cost of what they consume. *(§47.11.2)*

Metric — A numeric measurement aggregated over time and identified by a name plus a set of **labels** (key–value pairs). Each unique combination of name and label values is one **time series**, a sequence of `(timestamp, value)` samples. For example, `http_requests_total{service="checkout", method="POST", status="500"}` is one series. *(§40.5)*

Microservice — A service built around one business capability, owned by one team, deployable independently, and the sole owner of its data, which others reach only through its API or events. Lewis and Fowler describe the style as "an approach to developing a single application as a suite of small services, each running in its own process and communicating with lightweight mechanisms," built around business capabilities and independently deployable [Lewis and Fowler 2014]. *(§34.3.1)*

Microservices — An architectural style that builds one application as a suite of small services, each running in its own process, owning its own data, communicating over lightweight network mechanisms, built around a business capability, and **independently deployable** by the team that owns it [Lewis and Fowler 2014]. *(§33.7.1)*

Mobile push notification — A message sent by an application's server to a platform-operated push service — Apple Push Notification service (**APNs**) for Apple platforms, Firebase Cloud Messaging (**FCM**) for Android (and optionally iOS and web) — which delivers it, on a best-effort basis, over a single persistent connection that the operating system maintains to that service on behalf of all apps. *(§9.8.1)*

Modular monolith — A monolith whose code is divided into **modules** aligned with business domains, where each module exposes a small **public interface**, hides its internals and data, and may depend only on an explicitly declared, acyclic set of other modules. Boundaries are enforced by tooling, not just convention. *(§33.5.1)*

Monitoring — Collecting, aggregating and displaying predefined measurements of a system, and alerting when they cross thresholds, so that operators learn about *known* failure modes. The Google SRE book defines it as “collecting, processing, aggregating, and displaying real-time quantitative data about a system” [Beyer et al. 2016, ch. 6]. *(§40.3.1)*

Monolith — A system whose functionality is built, tested and deployed as **one deployable unit**, typically one process image running as identical replicas and backed by one shared database. “Monolith” describes the *deployment* unit; it says nothing about whether the code inside is well structured. *(§33.4.1)*

Monotonic reads — A client never sees data move backwards: after reading some version, its later reads return that version or newer. *(§14.4.3)*

MPI (Message Passing Interface) — A standardized library interface, maintained by the MPI Forum since 1994 (MPI-4.1 published in 2023), through which the processes of a parallel program exchange data by explicit messages. Each process is a **rank** (an integer from 0 to $p-1$) within a **communicator**, a group of processes with its own isolated message context; `MPI_COMM_WORLD` contains all of them [MPI Forum 2023]. *(§49.9.1)*

Multi-core processor — A single chip containing several complete cores, each with its own pipeline and private caches, sharing the last-level cache and memory. *(§5.3.6)*

Multipart upload — A protocol for uploading one large object as independently uploaded **parts**: the client *initiates* an upload and receives an upload ID, uploads numbered parts (in any order, in parallel, retrying any part), then *completes* the upload with the list of part numbers and their ETags, at which point the store assembles the object atomically. Until completion, or after an *abort*, the object is not visible. *(§15.8.1)*

Multi-primary replication — More than one node accepts writes for the same data and replicates to the others (also **multi-leader** or **active–active**). Concurrent uncoordinated changes to the same row create **write conflicts** that must be detected and resolved. *(§14.5.1)*

Multitenant file system — One storage cluster shared by several applications (**tenants**) with different workloads, in which each tenant can tune durability, layout and performance for its own data while sharing drives, servers and operations. *(§49.4.2)*

Multi-writer active–active — Every region accepts writes to any record locally and replicates them asynchronously to the other regions; concurrent writes to the same

record in different regions are **conflicts** that must be detected and resolved (§44.8). This is multi-leader replication (§27.6) at regional scale. *(§44.6.3)*

Mutex (mutual-exclusion lock) — An object with two operations, `lock` and `unlock`, guaranteeing that at most one thread holds it at a time. A thread that calls `lock` while another holds it waits. *(§6.10.1)*

MVCC — A concurrency-control technique in which a write creates a new **version** of a row instead of overwriting it in place, and each transaction reads the versions visible in its **snapshot**: the set of transactions that had committed when the snapshot was taken. Readers therefore never block writers and writers never block readers; only writers of the same row wait for each other. *(§11.14.1)*

N

Namespace and journal — A **namespace** is a unit of sharing and synchronization: a user's root folder or a shared folder, mounted into each member's tree. Each namespace has an append-only **journal** on the server: every committed change (add, modify, delete, move) gets the next journal ID. A device's sync position in a namespace is simply the last journal ID it has applied, its **cursor**. *(§54.8.1)*

Narrow and wide dependencies — A **narrow dependency** exists when each partition of the parent RDD is used by at most one partition of the child (`map`, `filter`, `union`, a join of co-partitioned inputs). A **wide (shuffle) dependency** exists when a child partition may depend on many or all parent partitions (`groupByKey`, `reduceByKey`, a join of unpartitioned inputs), which requires a shuffle. *(§29.5.2)*

Natural and surrogate keys — A **natural key** is a candidate key with business meaning (email address, ISBN, country code). A **surrogate key** is a meaningless value generated by the system (an auto-increment integer, a UUID) whose only job is identification. *(§11.4.2)*

Near-real-time (NRT) search — A search system in which newly written documents become searchable after a short, bounded delay (typically one second to a minute) rather than immediately, because making them visible requires creating a new segment and reopening the searcher. *(§16.10.1)*

Network Address Translation (NAT) — A function, usually in a router or gateway, that rewrites the source and/or destination IP addresses (and usually ports) of packets as they pass, keeping a **translation table** so that replies can be rewritten back. The most common form, **source NAT with port translation** (NAPT, often just "NAT"), lets many hosts with private addresses share one public address [RFC 3022]. *(§7.13)*

Network partition — A network fault after which some nodes that are running correctly cannot exchange messages with some other running nodes for a period of time. (This book reserves “partition” alone for a subset of data, §14.6; a network fault is always a **network partition**.) *(§24.7.1)*

NewSQL (distributed SQL) — Relational databases that keep SQL and ACID transactions with serializable or strong isolation while scaling horizontally across nodes and regions, by partitioning data into ranges replicated with a consensus protocol. The term was coined by analyst Matthew Aslett in 2011 [Pavlo & Aslett 2016]. *(§12.11)*

Noisy neighbor — A tenant whose consumption of a shared resource degrades other tenants’ performance. It need not exceed any limit; it only has to consume a resource that others also need and that is not partitioned. *(§47.7.1)*

Non-functional requirement (NFR) — A requirement on *how well* the system performs its functions, or on constraints under which it operates, expressed as a measurable target — for example “p99 feed latency ≤ 300 ms at 2,000 RPS” or “monthly availability ≥ 99.9%”. NFRs are also called **quality attributes** or, informally, the **“-ilities”** (scalability, availability, durability, …). *(§1.7.1)*

Normal forms (1NF to BCNF) — **1NF:** every column holds a single atomic value (no lists or repeating groups). **2NF:** 1NF, and no non-key column depends on only *part* of a composite candidate key. **3NF:** 2NF, and no non-key column depends on another non-key column (no transitive dependency); formally, for every non-trivial $X \to A$, either X is a superkey or A is part of some candidate key. **BCNF (Boyce–Codd normal form):** for every non-trivial $X \to A$, X is a superkey. BCNF removes 3NF’s exception for key columns. *(§11.5.2)*

NoSQL database — A database that does not use the relational table-and-join model as its primary data model and typically trades some combination of cross-record transactions, ad-hoc querying and fixed schemas for horizontal scale-out, flexible schemas or availability during failures. The name is usually read as “not only SQL”; it describes a movement, not a specification. *(§12.3.1)*

NUMA (non-uniform memory access) — A memory architecture in which each processor socket (or each chiplet group within a socket) has its own directly attached memory. A core can access all memory in the machine, but accessing its **local** memory is faster than accessing **remote** memory attached to another socket. *(§5.10)*

O

OAuth 2.0 — An authorization framework that lets a third-party application obtain *limited* access to an HTTP service on behalf of a resource owner, by obtaining an **access to-**

ken from an authorization server instead of using the owner's credentials [RFC 6749]. *(§8.14.1)*

Object — A value in a running program that bundles **state** (data, stored in **attributes** or **fields**) with **behavior** (functions that operate on that data, called **methods**). Each object has its own copy of the state. *(§35.3.1)*

Observability — A property of a system and its telemetry: how well you can understand *any* internal state the system gets into, including states never seen before, by asking new questions of the data it already emits, without shipping new code [Majors, Fong-Jones and Miranda 2022]. The term comes from control theory, where a system is observable if its internal state can be inferred from its outputs. *(§40.3.1)*

Observer — A one-to-many dependency in which a **subject** keeps a list of **observers** and notifies each of them when its state changes, so that the subject does not depend on what the observers do [Gamma et al. 1994]. *(§37.8)*

Offload ratio — The fraction of traffic a CDN serves without contacting the origin. **Request offload** counts requests; **byte offload** counts bytes. Both are a cache hit ratio (§20.3) measured at the boundary between the CDN and the origin. *(§21.5.1)*

OIDC workload identity federation — A mechanism in which the CI platform issues each job a short-lived, signed OpenID Connect (OIDC) token describing the job (repository, branch, environment), and the cloud provider exchanges that token for temporary credentials according to a trust policy, so that no long-lived cloud key is stored in the pipeline. *(§43.11.1)*

Open and closed workload models — In an **open** model, new requests arrive at a rate that is independent of how fast the system answers: users on the internet do not wait for each other. In a **closed** model, a fixed population of N users (or load-generator threads) each sends a request, waits for the response, optionally pauses for a **think time** Z, and only then sends the next. A **partly open** model has sessions that arrive openly but issue several requests each, closed-loop, within the session [Schroeder et al. 2006]. *(§23.5.2)*

OpenAPI Specification (OAS) — A vendor-neutral, machine-readable format (YAML or JSON) for describing HTTP APIs: paths, operations, parameters, request and response bodies (as JSON Schema), status codes and security schemes [OpenAPI Specification]. It grew out of Swagger and is maintained by the OpenAPI Initiative; version 3.1 aligned its schemas with JSON Schema, and version 3.2.0 was released in September 2025. *(§8.16)*

Open/Closed Principle (OCP) — Software entities (classes, modules, functions) should be **open for extension** but **closed for modification**: you should be able to add new behavior by adding new code, without editing code that already works and is already depended upon [Martin 2002]. The principle was first stated by Bertrand Meyer [Meyer 1988]. *(§36.4.1)*

OpenTelemetry (OTel) — A vendor-neutral, open-source framework of APIs, SDKs, a wire protocol (OTLP), semantic conventions and a Collector for generating, collecting and exporting traces, metrics, logs and (newer) profiles. It was formed in 2019 by merging the OpenTracing and OpenCensus projects and is hosted by the Cloud Native Computing Foundation [OpenTelemetry Docs]. *(§40.7)*

Operating system (OS) — The software layer that manages a computer's hardware (CPU, memory, storage, network) and provides running programs with safe, shared, abstract access to it. The privileged core of the OS that runs with full hardware access is the **kernel**. *(§6.3.1)*

Operational transformation (OT) — A technique for real-time collaborative editing in which each user applies their own edits immediately, and edits received from others are **transformed** (their positions adjusted) against concurrent edits already applied, so that all copies converge to the same document while each edit keeps its intended effect [Ellis and Gibbs 1989]. *(§54.7.1)*

Operation, history — An **operation** is one call by a client on a shared object, such as `write(x, 1)` or `read(x)`. It has an **invocation** event (the client sends the request, at real time t_{inv}) and, if the client hears back, a **response** event (at t_{resp}, carrying the return value). A **history** is the sequence of invocation and response events observed in one execution. An operation without a response is **pending**: it may or may not have taken effect. *(§25.3.1)*

Order of magnitude — A factor of ten. Two quantities differ by k orders of magnitude when their ratio is about 10^k. Reasoning in orders of magnitude means estimating only the *power of ten* of a quantity (is it 10, 1,000 or 1,000,000 requests per second?) because that, not the exact value, decides the architecture. *(§2.10.1)*

Origin shielding — Routing every cache miss for an origin through one designated cache tier (the **shield**), so that the origin sees at most one request per object per freshness period, regardless of how many edge PoPs missed. *(§21.5.3)*

Out-of-order (OoO) execution — A technique in which the core executes instructions as soon as their inputs are ready rather than strictly in program order, while still making the results *appear* in program order (it **retires** them in order). *(§5.3.5)*

OWASP Top 10 — A consensus ranking of the most critical web application security risk categories, published by the Open Worldwide Application Security Project from vulnerability data contributed by testing organizations plus a community survey. This section uses the **2021 edition** [OWASP 2021]. A 2025 edition has since been published; it keeps broken access control at #1, folds SSRF into it, and adds categories for software supply-chain failures and mishandling of exceptional conditions, so the architectural controls below remain applicable. *(§10.7)*

P

PACELC — If there is a **P**artition, how does the system trade off **A**vailability and **C**onsistency; **E**lse, when the system is running normally, how does it trade off **L**atency and **C**onsistency? A system is labeled by its two choices, for example PA/EL or PC/EC. *(§25.9.1)*

Page — The fixed-size unit (typically 4–16 KiB) in which a storage engine reads, writes, caches and logs data. A page on disk is sometimes called a **block**; the engine keeps a copy of a page in memory in a **frame** of its buffer pool. *(§13.3.1)*

Page cache — The kernel's in-RAM cache of file contents, organized in pages. Reads are served from it when possible; writes normally modify pages in it (marking them **dirty**) and return immediately, with the kernel writing them back to storage later. *(§6.6.6)*

Parallel file system — A POSIX file system whose files are striped across many storage servers so that thousands of clients can read and write one file or many files concurrently at aggregate bandwidths of terabytes per second; examples are Lustre and IBM Storage Scale (formerly Spectrum Scale and GPFS). *(§49.11)*

Partial failure — A state in which some components of a system have failed while others continue to work, so that an operation may be applied in some places and not others, and the working components cannot reliably tell which components failed. *(§24.8.1)*

Partition key, sort key and item collection — In DynamoDB every **item** (a record of up to 400 KB, as of 2026) has a primary key made of a **partition key** and, optionally, a **sort key**. DynamoDB hashes the partition key to choose the storage partition. All items sharing a partition key form an **item collection**, stored together and ordered by sort key, so a single **Query** can return a contiguous, sorted range of them. *(§12.4.3)*

Partition (shard) — A subset of a dataset's rows, stored and served together, such that every row belongs to exactly one partition. **Partitioning** spreads partitions over nodes; **sharding** is a synonym used mostly for separate database servers. This book uses *partition* and *shard* interchangeably and reserves **network partition** for network splits (§24.7). The columns that choose a row's partition form the **partition key** (or **shard key**). *(§14.6.1)*

Partition skew and salting — **Skew** is an uneven distribution of records across partitions, usually caused by a few very frequent keys (a celebrity user, a null or default value, a bot). **Salting** appends a random suffix from a small range to hot keys so their records spread over several partitions, then removes the suffix in a second, much smaller aggregation (or, for joins, replicates the matching rows of the other side once per salt value). *(§29.6.3)*

PE, PA, PDP and PEP — The **policy engine (PE)** makes the grant or deny decision using enterprise policy and external inputs. The **policy administrator (PA)** carries out that

decision by establishing or tearing down the session path (for example, issuing a session token or configuring a gateway). Together the PE and PA form the **policy decision point (PDP)**. The **policy enforcement point (PEP)** sits in the data path between subject and resource and enables, monitors and terminates connections on the PA's instructions [Rose et al. 2020]. *(§50.4.2)*

Percentile — The *q*-th percentile of a set of measurements is the value at or below which *q*% of the measurements fall. Latency percentiles are written **p50** (the median), **p95**, **p99** and **p99.9** (also written p999): the 50th, 95th, 99th and 99.9th percentiles. *(§4.8.1)*

Percentile latency (p50, p95, p99, p99.9) — The latency value below which the given percentage of requests fall. If p99 latency is 300 ms, 99% of requests completed in 300 ms or less and 1% took longer. p50 is the median. *(§1.7.1)*

Percolator transaction — A snapshot-isolated, multi-row, multi-table transaction built entirely by a client library on top of a store that offers only single-row atomic updates and multiple timestamped versions per cell. Ordering comes from a central **timestamp oracle**; atomicity comes from making one row's lock, the **primary lock**, the commit point for the whole transaction [Peng and Dabek 2010]. *(§28.7.1)*

Per-conversation sequence number — A strictly increasing integer assigned by the single owner of a conversation to each message at the moment it becomes durable. It defines the display order for every member and device, serves as the cursor for history paging and sync, and lets a client detect missing messages as gaps between consecutive numbers. *(§53.4.8)*

Performance engineering — The practice of measuring, explaining and improving the **latency**, **throughput** and **resource efficiency** of a system against explicit targets, using repeatable methods rather than intuition. Its outputs are diagnoses (why is it slow?), changes (make it faster or cheaper) and predictions (how much capacity will we need?). *(§23.3.1)*

Per-tenant keys, BYOK and crypto-shredding — With **per-tenant keys**, each tenant's data encryption keys (DEKs) are wrapped by a key-encryption key (KEK) unique to that tenant in a key management service (KMS), which is envelope encryption (§10.9.2). **Bring your own key (BYOK)** lets the tenant create or import the KEK in a KMS it controls, so it can audit and revoke every use; **hold your own key (HYOK)** keeps it outside the provider entirely. **Crypto-shredding** deletes data by destroying its key, making every copy, including backups, unreadable. *(§47.5.4)*

PKCE (Proof Key for Code Exchange, "pixy") — An extension in which the client creates a random secret, the **code verifier**, sends only its SHA-256 hash, the **code challenge**, with the authorization request, and must present the verifier when redeeming the authorization code. An attacker who intercepts the code cannot redeem it without the verifier [RFC 7636]. *(§8.14.3)*

Pod — The smallest deployable unit in Kubernetes: one or more containers that are always scheduled together on one node and share a network namespace (one IP address and port space), IPC namespace and volumes. Pods are disposable: a replaced pod is a new pod with a new name and IP. *(§42.7.1)*

Point of presence (PoP) — A CDN site in one metropolitan area or interconnection facility, containing load balancers, caching proxy servers with RAM and SSD storage, and connections to local networks. Large CDNs operate hundreds of PoPs; some also place servers inside Internet service provider (ISP) networks. *(§21.3.2)*

Poison message — A message that fails processing every time it is delivered — because it is malformed, refers to data that does not exist, or triggers a bug — and that, if redelivered indefinitely, wastes consumer capacity and (in ordered lanes) blocks every message behind it. *(§30.10)*

Polyglot persistence — Using several different data-storage technologies within one system, each chosen for the access pattern it serves best, rather than forcing all data into one database [Fowler 2011; Sadalage & Fowler 2012]. *(§12.13.1)*

Polymorphism — The ability of one piece of code to work with values of different types. **Subtype polymorphism** means code written against a type also works with any of its subtypes, and each object responds to a method call with its own implementation. **Dynamic dispatch** is the run-time mechanism that picks which implementation runs, based on the object's actual class rather than the declared type of the variable. *(§35.6.1)*

Power of two choices (P2C) — For each request, pick **two** backends uniformly at random and send the request to the less loaded of the two (by in-flight count, EWMA latency or another load signal). *(§19.4.4)*

Practical Byzantine Fault Tolerance (PBFT) — A state-machine replication protocol for $n = 3f + 1$ replicas that tolerates f Byzantine replicas and any number of faulty clients, is safe under asynchrony and live under partial synchrony, and orders requests with three phases (pre-prepare, prepare, commit) led by a **primary** that is replaced through a **view change** when it misbehaves [Castro & Liskov 1999; Castro & Liskov 2002]. *(§45.9.1)*

Preemption — Evicting running lower-priority work so that a pending higher-priority task can be placed. The evicted tasks are **victims**; the pending task is the **preemptor**. *(§46.8.1)*

Presumed abort (PA) — A 2PC variant in which a coordinator that has no information about a transaction answers inquiries with "abort". Aborts therefore need no forced coordinator record, no forced participant record and no acknowledgments. *(§28.4.5)*

Primary–backup replication — One replica, the **primary**, receives all requests, executes them and propagates the result to one or more **backups**. If the primary fails, a

backup is **promoted** to primary. It is also called **passive replication** [Alsberg and Day 1976; Budhiraja et al. 1993]. *(§27.4.1)*

Primary key in CQL — In Cassandra Query Language, `PRIMARY KEY ((a, b), c, d)` declares `(a, b)` as the **partition key** — hashed to choose the replicas and defining what is stored together — and `c, d` as **clustering columns**, which order rows *within* the partition on disk. *(§12.6.2)*

Priority inversion — A situation in which a high-priority thread is blocked waiting for a lock held by a low-priority thread, while a medium-priority thread, which needs no lock, preempts the low-priority one, so the high-priority thread effectively runs at the lowest priority. *(§6.11.5)*

Probability — A number between 0 and 1 that measures how likely an event is: 0 means impossible, 1 means certain. If an experiment is repeated many times, the probability of event A, written $P(A)$, is the long-run fraction of repetitions in which A happens. *(§4.6.1)*

Process — A running instance of a program: its code, its private **virtual address space**, one or more threads of execution, and the OS resources it holds (open files, sockets, signal handlers, credentials). *(§6.3.2)*

Process control block (PCB) — The kernel data structure that records everything needed to stop a process and later resume it exactly where it left off. In Linux it is `struct task_struct`. *(§6.3.3)*

Process state — The scheduling status of a process (or thread): whether it is running on a CPU, ready and waiting for a CPU, or blocked waiting for an event. *(§6.3.4)*

Producer–consumer — Producers put work items into a shared **bounded** buffer and consumers take them out, decoupling the rate at which work is created from the rate at which it is processed; when the buffer is full, producers block or are rejected, which is **backpressure** (§22.10). *(§37.16.1)*

Profiler — A tool that attributes a resource (CPU time, wall-clock time, allocated bytes, lock wait time) to the code locations that consumed it. A **sampling profiler** interrupts the program at a fixed frequency and records the current call stack; a function’s share of samples estimates its share of time. An **instrumenting** (deterministic, tracing) profiler inserts hooks at every function entry and exit and records exact call counts and durations. *(§23.4.1)*

Prometheus — An open-source monitoring system and time-series database, started at SoundCloud in 2012 and a graduated CNCF project since 2018, that scrapes metrics over HTTP, stores them locally, evaluates recording and alerting rules, and is queried with PromQL [Prometheus Docs: Overview]. *(§40.8)*

Protocol — A set of rules two parties agree on for exchanging messages: message formats, the meaning of each field, and the actions each side takes on sending, receiving or timing out. A **protocol stack** is a set of protocols layered so that each uses the service provided by the layer below and offers a service to the layer above. *(§7.3.1)*

Proxy — An intermediary that terminates a client's connection and opens its own connection onward, relaying requests and responses. A **forward proxy** acts on behalf of **clients** and is chosen by them (or their network administrator). A **reverse proxy** acts on behalf of **servers** and is chosen by the site operator; clients usually do not know it exists. *(§7.12)*

Pseudonymization and anonymization — **Pseudonymization** replaces direct identifiers with pseudonyms such that the data can no longer be attributed to a person *without additional information kept separately* (GDPR Article 4(5)); pseudonymized data is still personal data. **Anonymization** makes re-identification not reasonably likely by any means, taking into account the means reasonably likely to be used (GDPR Recital 26); truly anonymous data falls outside GDPR [EU 2016]. *(§50.10.1)*

Public key infrastructure (PKI) — The set of roles, policies and systems that bind public keys to identities. A **certificate** (X.509) is a document stating "this public key belongs to this name (for example `api.example.com`), valid from date A to date B", signed by a **certificate authority (CA)**. A client trusts a certificate if it can build a **chain** of valid signatures from it to a **root CA** certificate in its local **trust store**. *(§10.5)*

Publish/subscribe (pub/sub) — A messaging style in which a publisher sends a message to a named **topic** without knowing its receivers, and the broker delivers a copy to every **subscription** registered on that topic [Hohpe and Woolf 2003; Eugster et al. 2003]. *(§30.5.1)*

PUE and WUE — **Power usage effectiveness (PUE)** is the ratio of total energy entering a datacenter facility to the energy delivered to its IT equipment (servers, storage, network) over a period, normally a year. An ideal facility has PUE 1.0. **Water usage effectiveness (WUE)** is the annual site water used for cooling and humidification divided by IT equipment energy, in liters per kWh. Both metrics were defined by The Green Grid [Avelar et al. 2012; The Green Grid 2011]; PUE is also standardized as ISO/IEC 30134-2. *(§51.10.1)*

Q

Qualifying stream — A play that counts toward royalty and chart calculations under the service's rules, typically a play that lasted at least a minimum duration (for example 30 seconds) and passed fraud checks. The definition is contractual: changing it changes who gets paid. *(§54.6.1)*

Queueing system — A model in which **jobs** (requests, messages, packets) arrive at a **service center**, wait in a **queue** if all **servers** are busy, receive service, and depart. The **arrival rate** λ is the average number of jobs arriving per second; the **service rate** μ is the average number of jobs one server can complete per second when it is never idle, so the average **service time** is $S = 1/\mu$. *(§4.10.1)*

Quorum — A set of nodes whose agreement is sufficient for an operation to take effect. A **majority quorum** in a cluster of N voting nodes is any set of more than $N/2$ nodes. The essential **intersection property**: any two majority quorums share at least one node. *(§26.4.1)*

R

Race condition — A bug in which the result of a program depends on the relative timing or interleaving of concurrent operations on shared state. A **data race** is the specific case where two threads access the same memory location concurrently, at least one access is a write, and nothing orders them. *(§6.9)*

Raft term — A logical clock that divides time into consecutive, numbered periods. Each term begins with an election; if a candidate wins, it is the **leader** for the rest of the term, and there is at most one leader per term. Every RPC carries the sender's term; a node that sees a higher term immediately adopts it and becomes a follower; a request with a lower term is rejected. *(§26.7.1)*

Rate limiting — Enforcing an upper bound on how many requests (or how much work) a given **client identity** may submit to a resource over time. Requests beyond the bound are rejected (or, less often, delayed). The bound is usually stated as a **rate** (for example 100 requests per minute) plus a **burst** allowance. *(§22.3.1)*

RDMA (remote direct memory access) — A network capability in which the network interface card (NIC) moves data directly between the memory of an application on one machine and registered memory on another, without the kernel on the data path (**kernel bypass**), without intermediate copies (**zero-copy**), and, for one-sided operations, without involving the remote CPU at all. Applications use it through the **verbs** interface (libibverbs) [InfiniBand Trade Association; NVIDIA RDMA Programming Manual]. *(§49.10.1)*

Read-local/write-global — Every region serves traffic and reads from a local replica, but writes for any record go to a single write location: one global primary region, or the leader of each record's consensus group. *(§44.6.2)*

Read repair and anti-entropy — **Read repair** fixes stale replicas discovered while serving a read: the coordinator writes the newest version back to replicas that returned older ones. **Anti-entropy** is a background process that compares whole replicas, typically with

Merkle trees, and copies the differences [DeCandia et al. 2007; Demers et al. 1987]. *(§27.13.1)*

Read-through — The application asks only the cache; on a miss the *cache* loads the value from the database through a configured loader, stores it and returns it. *(§20.7.3)*

Read-write lock — A lock that allows any number of concurrent readers or exactly one writer, never both; it improves throughput when reads greatly outnumber writes and each read holds the lock long enough for contention to matter (§6.10.5). *(§37.16.4)*

Read-your-writes consistency — After a client writes a value, its own later reads return that value or a newer one. Other clients get no such promise. *(§14.4.3)*

Rebalancing — Moving partitions, or parts of them, between nodes so that data and load stay even as nodes join, leave or fail and as data grows, while staying available and moving no more data than necessary. *(§14.9.1)*

Reconciliation loop (control loop) — A loop that repeatedly reads an object's desired state (`spec`), observes actual state, computes the difference and takes actions to reduce it, then records what it observed (`status`). It is **level-triggered**: it acts on the current state of the world, not on the sequence of events that produced it. *(§42.6.3)*

RED method — For every **service**, monitor **R**ate (requests per second), **E**rrors (failed requests per second) and **D**uration (the distribution of request latency, as a histogram from which percentiles are read). Tom Wilkie proposed it while at Weaveworks as a service-level complement to USE [Wilkie 2018]. *(§23.3.3)*

Reduce-side (sort-merge) join and broadcast (map-side) join — In a **reduce-side join**, both inputs are mapped to `(join key, tagged record)`, shuffled so that all records with the same key meet at one reducer, sorted, and combined there. In a **broadcast join**, the smaller input is copied in full to every map task, loaded into an in-memory hash table, and each record of the larger input is joined locally by lookup, with no shuffle of the larger input. *(§29.4.4)*

Regional evacuation — Deliberately moving all traffic, and where necessary data ownership, out of a region that is failing or under maintenance, onto the remaining regions, without waiting for the region to fail completely. *(§44.11.1)*

Regional independence; static stability — A design is **regionally independent** when each region can serve its users with no synchronous dependency on any other region or on a global service. It is **statically stable** when it keeps working through a failure *without making changes*: no scaling, no reconfiguration and no control-plane calls are needed to survive [Weiss and Furr 2020]. *(§44.10.1)*

Region, availability zone, edge location — A **region** is a geographic area (for example `us-east-1`, `europe-west1`, `West Europe`) containing several isolated data-center groups,

with its own control plane and, by default, its own copy of regional services. An **availability zone (AZ)** is one or more data centers within a region with independent power, cooling and networking, connected to the other zones of the region by redundant, low-latency links, so that a fire, flood or power failure in one zone should not take down another. An **edge location** (point of presence) is a smaller site in a metropolitan area that runs CDN caches, DNS and edge compute close to users, but not general-purpose VMs and databases. *(§41.4.1)*

Region; multi-region system — A **region** is a cloud provider's geographic area containing several isolated availability zones, typically within roughly 100 km of each other, connected by low-latency links (§41.4). A **multi-region system** runs serving capacity, data, or both in two or more regions and has a defined policy for which region handles each request and each piece of data. A **global system** is a multi-region system whose users are spread across continents. *(§44.3.1)*

Register — A tiny, extremely fast storage slot inside a core, typically 64 bits wide for general-purpose registers. x86-64 exposes 16 general-purpose integer registers to programs; ARMv8-A (AArch64) exposes 31. Reading a register costs essentially nothing beyond the instruction that uses it. *(§5.3.2)*

Relation — A **relation** is a named set of **tuples** that share the same **attributes**. Each attribute has a name and a **domain** (the set of allowed values, such as 64-bit integers). In SQL a relation is a **table**, a tuple is a **row** and an attribute is a **column**. The relation's name and attributes together form its **schema**; the set of rows at a moment is its **instance**. *(§11.3.1)*

Relevance score — A number computed for each (query, document) pair that estimates how well the document satisfies the query. A **ranking function** computes it; the engine returns the k highest-scoring documents. *(§16.5.1)*

Reliability, MTBF, MTTR and failure rate — **Reliability** $R(t)$ is the probability that a component operates without failure for a period of length t. The **mean time between failures (MTBF)** is the average operating time from the end of one repair to the next failure (for non-repairable parts the same quantity is called **MTTF**, mean time to failure). The **mean time to repair (MTTR)** is the average time from failure to restored service, including detection, diagnosis and repair. The **failure rate** λ is the average number of failures per unit of operating time. *(§4.15.1)*

Remote procedure call (RPC) — A mechanism that lets a program call a function in another process, usually on another machine, with syntax that resembles a local function call. Generated **stubs** serialize the arguments, send them over the network, and deserialize the result [Birrell and Nelson 1984]. *(§8.8.1)*

Replica recovery — Returning a replica to full membership after a crash or replacement, by **log catch-up** (replaying missed log entries), **snapshot plus log** (installing a copy of

the state, then replaying from the snapshot's position) or **rebuild** (copying all data from peers). *(§27.12.1)*

Replicated state machine (RSM) — A service implemented as a deterministic state machine that is copied onto several nodes. Each node applies the same sequence of commands, taken from a replicated **log**, in the same order, so every node passes through the same sequence of states and produces the same outputs [Schneider 1990]. *(§26.3.2)*

Replication — Keeping a copy of the same data on more than one node. Each copy is a **replica**. In **primary–replica replication**, exactly one node, the **primary** (called the "master" in older documentation), accepts writes and streams its changes to the **replicas**, which apply them in the same order and serve reads. *(§14.3.1)*

Replication lag — The delay between a change committing on the primary and becoming visible on a replica, measured in seconds, bytes of log or transactions. *(§14.4.2)*

Replication log formats — What the log describes: the SQL statements executed (**statement-based**), the changed rows (**row-based**), the storage engine's page-level byte changes (**physical**, or WAL shipping), or decoded, engine-independent row changes per table (**logical**). *(§14.4.5)*

Replication modes — In **synchronous replication**, the primary reports a commit only after at least one designated replica has durably received (or applied) it. In **asynchronous replication**, it reports success after its local commit and ships the change afterwards. **Semi-synchronous replication**, MySQL's middle ground, waits until a replica has *received and logged* the change and falls back to asynchronous mode after a timeout. *(§14.4.1)*

Replication strategy — The rule that decides *which* replicas may accept a write, *in what order* the replicas apply writes, and *when* a write counts as done. The five families are **primary–backup**, **chain replication**, **multi-leader**, **leaderless** and **consensus-based** replication. *(§27.3.1)*

Replication topology — The graph along which leaders forward writes to each other: a **circular** ring, a **star** with a hub, or **all-to-all**. *(§27.6.1)*

Repository — An object that mediates between the domain model and data storage, presenting stored aggregates as an in-memory collection with methods such as `add`, `get` and domain-specific finders, so that domain code never sees SQL, ORM sessions or storage APIs [Fowler 2002; Evans 2003]. *(§37.13)*

Request–response lifecycle — The complete sequence of network and processing steps between a client issuing a request and receiving the full response, including name resolution, connection establishment, routing through intermediaries, application processing, data access and the return path. *(§8.5.1)*

Requirement — A statement of what the system must do (a **functional requirement**, e.g. “a customer can cancel an order before the restaurant accepts it”) or how well it must do it (a **non-functional requirement**, e.g. “99% of order placements complete within 800 ms”). A requirement is **testable** if you could write an automated check or a measurement that proves it is met. *(§2.5.1)*

Reservoir sampling — An algorithm that maintains a uniform random sample of k items from a stream whose length n is not known in advance, using $O(k)$ memory and a single pass: after any number of items, every item seen so far is in the sample with probability k/n [Vitter 1985]. *(§17.12.1)*

Resilient Distributed Dataset (RDD) — A read-only, partitioned collection of records that can be created only by deterministic operations (**transformations** such as `map`, `filter`, `join`) on stable storage or on other RDDs. Each RDD records its **lineage**, the graph of transformations that produced it, so a lost partition can be recomputed from its parents instead of being restored from a replica [Zaharia et al. 2012]. *(§29.5.1)*

REST (Representational State Transfer) — An architectural style for distributed hypermedia systems, defined by Roy Fielding in his 2000 doctoral dissertation as a set of constraints on how components interact [Fielding 2000]. In everyday usage, a “REST API” is an HTTP API that models its domain as **resources** identified by URIs and manipulated with the standard HTTP methods. *(§8.6.1)*

Rmax and Rpeak — The **Top500** list, published twice a year since 1993, ranks systems by **Rmax**, the sustained rate in floating-point operations per second (FLOP/s, 64-bit) achieved on the High-Performance Linpack (HPL) benchmark, which solves a dense linear system $Ax = b$ by LU factorization. **Rpeak** is the theoretical peak: devices × FLOPs per cycle × clock rate. The ratio Rmax/Rpeak is the HPL efficiency [Top500; Dongarra et al. 2003]. *(§49.8.3)*

Rolling deployment — A deployment that replaces the instances of the old version with instances of the new version a few at a time, so that the service keeps serving throughout and, for the duration of the rollout, both versions serve traffic side by side. *(§43.4)*

Round robin (RR) — Send the k-th request to backend $k \bmod N$. **Weighted round robin (WRR)** gives backend i an integer weight w_i and sends it a share $w_i / \sum_j w_j$ of requests in each cycle. *(§19.4.1)*

Round-trip time floor — The **RTT floor** between two points is the minimum time for a signal to travel there and back along the great-circle path in optical fiber, about $2d/v$ with $v \approx 200,000$ km/s. **Route inflation** is the ratio of a measured RTT to that floor; it reflects cable paths that are longer than the great circle, plus equipment, queuing and routing policy. *(§44.4.1)*

Routing and forwarding — **Forwarding** is the per-packet act of choosing an outgoing interface for a packet based on its destination address and the **forwarding table**. **Routing** is the control-plane process of building those tables by exchanging reachability information with other routers. *(§7.5.1)*

RUM conjecture — For any access method, bounding two of **R**ead overhead, **U**pdate overhead and **M**emory (space) overhead forces the third to be worse: you can optimize for at most two [Athanassoulis et al. 2016]. *(§13.11.1)*

S

Safe method — A method whose semantics are read-only: the client does not request, and does not expect, any state change on the server [RFC 9110 §9.2.1]. Logging or metrics side effects are allowed. *(§8.6.3)*

Saga — A long-lived transaction written as a sequence of local transactions $T_1, T_2, \ldots, T_n$, each committed independently, where each T_i has a **compensating transaction** C_i that semantically undoes it. Either $T_1 \ldots T_n$ all complete, or $T_1 \ldots T_j, C_j \ldots C_1$ run [Garcia-Molina and Salem 1987]. *(§28.6)*

Scalability — The ability of a system to handle a growing workload by adding resources, with throughput rising roughly in proportion to the resources added and latency staying within its objective. A system is *not* scalable for a workload if adding resources yields little or no extra throughput, or if the cost per unit of work rises sharply. *(§18.3.1)*

Scale cube — A model by Martin Abbott and Michael Fisher that classifies every scaling technique along three independent axes [Abbott and Fisher 2015]: the **X axis**, cloning identical copies of a service or its data behind a load balancer; the **Y axis**, splitting by function, service or resource so that each part handles different work; and the **Z axis**, splitting by customer, requester or other key so that each part handles the same work for a subset of the data or users. *(§18.10.1)*

Scaling bottleneck — The resource that limits throughput as load or node count grows: the resource with the largest service demand per unit of capacity (§2.6). For a horizontally scaled system, it is usually a resource that *all* nodes share and that cannot itself be scaled out by adding application nodes. *(§18.7.1)*

Scheduling framework — The plugin architecture of `kube-scheduler`. A pod passes through a fixed sequence of **extension points**; each enabled plugin implements one or more of them. A **scheduling cycle** chooses a node for one pod and runs serially; a **binding cycle** applies the choice and may run concurrently with the next pod's scheduling cycle [Kubernetes Docs: Scheduling Framework]. *(§46.6.1)*

Search engine (as a data store) — A system such as Elasticsearch, OpenSearch or Apache Solr that stores JSON documents and builds an **inverted index** — a map from each term to the list of documents containing it — so it can answer full-text, relevance-ranked, faceted and fuzzy queries. *(§12.9)*

Secret — Any value that grants access and must be kept confidential: database passwords, API keys, OAuth client secrets, TLS and signing private keys, encryption keys, webhook HMAC keys. **Secrets management** is the practice of storing, distributing, rotating, auditing and revoking secrets so that they are available to the workloads that need them and to nobody else. *(§10.8)*

Security property — A statement about what must remain true about a system even when an adversary is actively trying to violate it. The classic triad is **confidentiality** (only authorized parties can read data), **integrity** (data and behavior cannot be changed without detection) and **availability** (authorized parties can use the system when they need it), often abbreviated **CIA**. System designers add **authentication** (knowing who is acting), **authorization** (deciding what that actor may do) and **non-repudiation** (an actor cannot credibly deny an action they took). *(§10.3.1)*

Segment — A self-contained, immutable mini-index (its own dictionary, postings, stored fields, norms and doc values) covering a subset of documents. A Lucene index is a set of segments plus a **commit point** file (`segments_N`) listing which segments are live; a search runs over every live segment and combines the results. *(§16.6.1)*

Semaphore — An integer counter with two atomic operations introduced by Dijkstra: **wait** (P, or *acquire*) decrements it and blocks if the result would be negative; **signal** (V, or *release*) increments it and wakes a waiter [Dijkstra 1965]. *(§6.10.2)*

Sequence diagram — An interaction diagram that shows objects or participants as vertical **lifelines** and the **messages** they exchange as horizontal arrows ordered top to bottom in time. **Execution specifications** (activation bars) show when a participant is busy, and **combined fragments** (`alt`, `opt`, `loop`, `par` and others) show conditional, optional, repeated and parallel behavior [OMG 2017]. *(§38.4.1)*

Sequential consistency — A history is **sequentially consistent** if there is a single total order of all operations that is a legal sequential history of the objects and that respects each client's **program order** (the order in which that client issued its own operations). In Lamport's words, "the result of any execution is the same as if the operations of all the processors were executed in some sequential order, and the operations of each individual processor appear in this sequence in the order specified by its program" [Lamport 1979]. *(§25.4.1)*

Serializable snapshot isolation (SSI) — A concurrency-control algorithm that runs transactions under snapshot isolation, tracks anti-dependencies between concurrent

transactions at run time, and aborts a transaction whenever a dangerous structure could form, so every committed history is serializable [Cahill et al. 2008]. *(§45.4.5)*

Serialization (encoding) — Translating an in-memory data structure into a sequence of bytes for storage or transmission; **deserialization (decoding)** is the reverse [Kleppmann 2017, ch. 4]. *(§8.9.1)*

Serverless — An architecture built from **functions as a service (FaaS)**, short-lived functions that the platform runs in response to events, combined with **managed services** (databases, queues, object storage, authentication) that the provider operates, such that the team provisions no servers, capacity scales automatically including **to zero**, and billing is per request and per unit of execution time rather than per running machine [Jonas et al. 2019]. *(§33.9.1)*

Serverless computing — A cloud programming model with three properties: the developer **does not manage resource allocation** (no servers, clusters or capacity plans), the platform **scales automatically, including to zero**, and billing is **in proportion to resources used** rather than resources reserved [Jonas et al. 2019]. In practice it combines **functions as a service (FaaS)**, which run developer code in short-lived sandboxes triggered by events, with **backend as a service (BaaS)**: managed object storage, databases, queues, authentication and so on, which hold all the state. *(§48.3.1)*

Server-Sent Events (SSE) — A W3C/WHATWG-standardized mechanism in which a client opens one long-lived HTTP request and the server streams a sequence of UTF-8 text events down the response body using the `text/event-stream` format; browsers expose it through the `EventSource` API, which parses events and reconnects automatically, resuming from the last received event ID [WHATWG HTML §9.2]. *(§9.5.1)*

Server-side rendering (SSR) — The server produces complete HTML for each request; the browser displays it immediately and then loads JavaScript to make it interactive (**hydration**). *(§8.4.2)*

Service discovery — The mechanism by which a client finds the current network locations of healthy instances of a service. A **service registry** stores instances, locations and health; a **lookup** path lets a client (client-side discovery) or a router (server-side discovery) query it [Richardson 2018]. *(§34.7)*

Service mesh — An infrastructure layer for service-to-service communication. Its **data plane** is a set of proxies through which all service traffic passes (a **sidecar** per workload instance, or shared per-node proxies); its **control plane** configures the proxies, issues certificates and collects state. It provides traffic management, security (mutual TLS, authorization) and telemetry without application changes [Istio Docs: Architecture; Linkerd Docs: Architecture]. *(§34.10.1)*

Service models — **IaaS** (infrastructure as a service): the provider runs physical hardware, the network and the hypervisor; you rent virtual machines, disks and networks and manage the operating system upward (Amazon EC2, Google Compute Engine, Azure Virtual Machines). **PaaS** (platform as a service): the provider also runs the operating system and runtime; you deploy code or containers (Google App Engine, Azure App Service, AWS Elastic Beanstalk, Cloud Run). **SaaS** (software as a service): the provider runs the whole application; you configure it and own your data and users (Gmail, Salesforce, Microsoft 365). **FaaS** (function as a service): a PaaS whose unit of deployment is a function invoked per event, scaled to zero and billed per invocation and duration (AWS Lambda, Cloud Run functions, Azure Functions). *(§41.3.2)*

Service-oriented architecture (SOA) — An enterprise integration style, prominent from roughly 2000 to 2010, in which business capabilities are exposed as coarse-grained, reusable **services** with formal contracts, typically SOAP web services described in WSDL, connected through an **enterprise service bus (ESB)** that routes, transforms and orchestrates messages between them. *(§33.6.1)*

Session — Server-recognized state that links a series of requests to one authenticated user (or anonymous visitor) over time, typically identified by a cookie. *(§8.10.2)*

Session affinity (sticky sessions) — A balancer policy that sends all requests of one client session to the same backend, identified by a cookie, the client's IP address or a request key. *(§19.6)*

Session guarantees — **Read-your-writes (RYW):** if a session writes w and later reads, the read reflects w (or a later write). **Monotonic reads (MR):** if a session reads a value reflecting a set of writes, later reads reflect at least that set; the session never sees time go backwards. **Monotonic writes (MW):** a session's writes are applied at every replica in the order the session issued them. **Writes-follow-reads (WFR):** if a session reads a value produced by write w_1 and then writes w_2, every replica applies w_1 before w_2 (the new write is ordered after what the session saw). *(§25.6.1)*

Set-associative cache — A cache divided into S sets of W slots (**ways**). A line at a given address may be stored in any of the W ways of exactly one set. $W = 1$ is a **direct-mapped** cache; a cache with a single set holding every line is **fully associative**. *(§5.4.4)*

Shared responsibility model — The division of security and operational duties between the provider and the customer. In AWS's phrasing, the provider is responsible for security **of** the cloud (facilities, hardware, hypervisor, global network, the managed services' own software), and the customer for security **in** the cloud (data, identities and permissions, OS and application patching on IaaS, network rules, encryption choices) [AWS: Shared Responsibility Model]. The exact line moves with the service model (Figure 41.1). *(§41.4.2)*

Short polling — A technique in which the client sends an ordinary HTTP request at a fixed interval T to ask whether new data exists; the server answers immediately, either with the new data or with an empty response, and the connection's request ends. *(§9.3.1)*

Shuffle — The all-to-all redistribution of intermediate data between two stages, in which every task of the producing stage writes its output partitioned by key and every task of the consuming stage reads its partition from every producer. It costs serialization, local disk writes and reads, and network transfer, and it is a barrier between stages. *(§29.6.2)*

Silo, pool, bridge and tiered — In the **silo** model each tenant gets dedicated resources: its own stack, account, database or cluster. In the **pool** model tenants share resources and isolation is enforced logically by tenant-aware code, policies and limits. The **bridge** (hybrid) model mixes the two by layer, for example shared services with a database per tenant. A **tiered** deployment applies different models to different customer tiers, typically pooling small tenants and siloing premium ones. *(§47.4.1)*

SIMD (single instruction, multiple data) — CPU instructions that apply the same operation to several data elements packed into one wide **vector register** at once — for example, adding eight pairs of 32-bit floats in a single instruction. *(§5.11.1)*

Simple factory — A function or static method that takes a description of what is wanted (a string, an enum, a config value) and returns an instance of the matching concrete class, behind a common interface. It is an idiom rather than a GoF pattern, but it is the most common factory in practice. *(§37.3.1)*

Simultaneous multithreading (SMT) — A technique in which one physical core runs two (occasionally more) instruction streams at once, interleaving them through the same execution units. Intel markets its implementation as **Hyper-Threading Technology**. Each stream appears to the operating system as a separate **logical CPU** (or **hardware thread**). *(§5.3.6)*

Single-decree (basic) Paxos — A consensus algorithm in which **proposers** suggest values, **acceptors** vote on them and **learners** find out the decided value. A value is **chosen** when a majority of acceptors has accepted it with the same proposal number. Paxos guarantees safety under any message delays, loss or reordering, and makes progress whenever one proposer can run both phases without interference from another. *(§26.6.1)*

Single-page application (SPA) / client-side rendering (CSR) — The server sends a nearly empty HTML shell plus a JavaScript bundle; the JavaScript calls JSON APIs and builds the page in the browser. Navigation afterwards happens without full page loads. *(§8.4.2)*

Single Responsibility Principle (SRP) — A module should be responsible to one, and only one, **actor**, where an actor is a group of people (a role, a team, a stakeholder) who

request changes to the module for the same reasons [Martin 2017]. The earlier formulation is “a class should have only one reason to change” [Martin 2002]. *(§36.3.1)*

Singleton — A class that guarantees it has exactly one instance within a scope and provides a global access point to it [Gamma et al. 1994]. The scope is almost always one process, a fact that matters greatly in distributed systems. *(§37.6)*

Skip list — An ordered linked list augmented with extra levels of “express” pointers. Each node is promoted to the next level with probability p (typically 1/2 or 1/4), so level i contains about a fraction p^i of the nodes. Search, insert and delete take expected $O(\log n)$ time [Pugh 1990]. *(§17.7.1)*

Sliding window counter — A limiter that keeps fixed-window counters for the current and previous windows and estimates the count over the last W seconds by weighting the previous window’s count by the fraction of it that still overlaps the sliding interval. *(§22.7.2)*

Sliding window log — A limiter that stores the timestamp of every admitted request per key and admits a new request only if fewer than L timestamps fall in the interval $(t - W, t]$. *(§22.7.1)*

SLI, SLO, SLA — A **service level indicator (SLI)** is a carefully defined quantitative measure of some aspect of the service as users experience it, best expressed as the ratio of good events to valid events. A **service level objective (SLO)** is a target for an SLI over a time window, for example “99.95% of valid place-order requests succeed, over a rolling 28 days”. A **service level agreement (SLA)** is a contract with a customer that states objectives and the consequences, usually financial service credits, of missing them [Beyer et al. 2016]. *(§39.6.1)*

Sloppy quorum and hinted handoff — In a **sloppy quorum**, a write that cannot reach W of a key’s N home replicas is accepted by the next healthy nodes on the ring instead, and still counts toward W. Each stand-in stores the write with a **hint** naming the intended home replica and **hands it off** when that replica recovers [DeCandia et al. 2007]. *(§27.9.1)*

Slotted page — A page layout in which a **header** is followed by an array of **slots** (also called line pointers or item IDs) that grows from the front, while variable-length **records** (tuples) are packed from the back. Each slot stores the offset and length of one record; free space sits in the middle. *(§13.3.2)*

Snapshot-based start (SnapStart) — A mode in which the platform, when a function version is published, runs its initialization, takes a Firecracker snapshot of the microVM’s memory and disk state, encrypts and caches it, and on each later cold start **restores** the snapshot instead of initializing from scratch [AWS Docs: Lambda]. *(§48.4.3)*

Software architecture — “The set of structures needed to reason about the system, which comprise software elements, relations among them, and properties of both” [Bass et al. 2021]. The international standard for architecture description defines it as the fundamental concepts or properties of a system in its environment, embodied in its elements, relationships, and in the principles of its design and evolution [ISO/IEC/IEEE 42010]. *(§1.4.1)*

Solid-state drive (SSD) — A storage device with no moving parts that stores data in **NAND flash** memory cells, managed by an on-board controller running a **flash translation layer** (FTL). *(§5.6.2)*

Spaced repetition — Reviewing material at increasing intervals, so that each review happens around the time you would otherwise begin to forget it. The underlying finding, that spacing study sessions apart beats massing them together, is the **spacing effect**. *(§3.4.3)*

Speedup — The ratio of the time a job takes on one processor (or node) to the time it takes on N: $S(N) = T(1)/T(N)$. Perfect, **linear** speedup is $S(N) = N$. *(§4.12.1)*

SPIFFE ID and SVID — **SPIFFE** (Secure Production Identity Framework for Everyone) is an open specification for workload identity. A **SPIFFE ID** is a URI of the form `spiffe://<trust-domain>/<path>`, for example `spiffe://quickbite.example/ns/payments/sa/charge-api`. A **SPIFFE Verifiable Identity Document (SVID)** is a short-lived credential carrying that ID: an **X.509-SVID** (a certificate whose URI subject alternative name is the SPIFFE ID, used for mTLS) or a **JWT-SVID** (a signed token, used where TLS cannot be end to end). A **trust bundle** holds the CA certificates that verify a trust domain’s SVIDs [SPIFFE Spec]. *(§50.4.3)*

Split brain — A failure in which two or more parts of a cluster each believe they are the authoritative primary (or leader) and accept conflicting writes, so the system’s state diverges. *(§26.12.1)*

Spot capacity — Spare provider capacity sold at a steep discount (often 60–90% off on-demand, varying by type, zone and time) that the provider can reclaim when it needs the capacity back. AWS **Spot Instances** receive a two-minute interruption notice; Google **Spot VMs** (successor to preemptible VMs, which were limited to 24 hours) and Azure **Spot VMs** receive about 30 seconds’ notice [AWS EC2 docs: Spot; Google Cloud docs: Spot VMs; Azure docs: Spot VMs]. *(§41.8.5)*

SQL — The Structured Query Language, standardized by ANSI/ISO, with sublanguages for defining schema (DDL: `CREATE`, `ALTER`, `DROP`), manipulating data (DML: `SELECT`, `INSERT`, `UPDATE`, `DELETE`) and controlling transactions (`BEGIN`, `COMMIT`, `ROLLBACK`). Every major database implements the core standard plus its own dialect. *(§11.6.1)*

State — An object delegates its behavior to a separate state object and changes behavior by swapping that state object, so it appears to change its class; each state class handles the transitions that are legal from it [Gamma et al. 1994]. *(§37.15.1)*

Stateful service — A service whose instances hold data that must survive between requests and that clients or other instances depend on: a database, a cache node, a WebSocket server holding live connections, or an application server keeping sessions in memory. *(§18.5.1)*

Stateless service — A service that keeps no client-specific data in its own memory between requests. Every request carries, or lets the service look up from a shared store, everything needed to process it. *(§8.3.2)*

State machine diagram — A behavior diagram that shows the **states** one object (or protocol) can be in and the **transitions** between them. A transition is labeled `trigger [guard] / effect`: the **trigger** is the event, the **guard** a Boolean condition that must be true for the transition to fire, and the **effect** an action executed during the transition. A state may declare **entry**, **exit** and **do** behaviors, run on entering, on leaving, and while inside the state [OMG 2017]. *(§38.6.1)*

Static site generation (SSG) — HTML is produced at build time and served as static files, usually from a CDN (Chapter 21). Pages that change per user cannot be fully static. *(§8.4.2)*

Storage tier and lifecycle policy — A **storage tier** (storage class) is a price/performance point for the same data: **hot** (frequent access, highest storage price, no retrieval fee), **warm** or infrequent access (cheaper storage, per-GB retrieval fee, minimum storage duration), **cold** (cheaper again, slower or costlier retrieval) and **archive** (cheapest storage, retrieval in hours). A **lifecycle policy** is a set of rules, usually by prefix, tag or age, that automatically transitions objects between tiers and expires (deletes) them. *(§15.9)*

Strangler fig application — A migration strategy in which a new system is grown around the edges of an old one, taking over one capability at a time while the old system keeps running, until the old system can be retired. Fowler named it after strangler fig vines, which grow around a host tree until they stand on their own [Fowler 2004]. *(§34.13.1)*

Strategy — A family of interchangeable algorithms, each behind a common interface, so that a client can be configured with one at run time without changing its code [Gamma et al. 1994]. *(§37.7)*

Stream processing, event time and processing time — **Stream processing** runs a long-lived computation over an **unbounded** dataset, one that grows forever, producing results incrementally. Each record has an **event time**, when the event actually happened

(stamped by the device or service that produced it), and a **processing time**, when the system observes it. The difference is the record's **event-time skew**, which is variable and unbounded in the worst case. *(§29.8.1)*

STRIDE — A mnemonic for six threat categories, developed at Microsoft in 1999 by Loren Kohnfelder and Praerit Garg and popularized by Shostack [Shostack 2014]: **S**poofing, **T**ampering, **R**epudiation, **I**nformation disclosure, **D**enial of service and **E**levation of privilege. Each category is the violation of one security property. *(§10.3.4)*

Superscalar execution — A core that can issue and complete more than one instruction per cycle by having several execution units working in parallel. *(§5.3.5)*

Symmetric encryption — Encryption in which the same secret key is used to encrypt and decrypt. A **block cipher** such as AES (Advanced Encryption Standard) encrypts fixed 128-bit blocks under a 128-, 192- or 256-bit key; a **mode of operation** turns the block cipher into a scheme for messages of any length. *(§10.4.2)*

Symptom-based alert — An alert on something users experience (errors, latency, unavailability, correctness), ideally expressed against an SLO. A **cause-based** alert fires on a suspected cause (high CPU, a full disk queue, a replica down) that may or may not hurt users [Beyer et al. 2016, ch. 6]. *(§40.10.1)*

Synchronous and asynchronous inter-service communication — In **synchronous** communication the caller sends a request (REST, gRPC) and cannot complete its work until the response arrives, so caller and callee must be available at the same time. In **asynchronous** communication the sender publishes a message (event or command) to a broker or log and continues; the receiver processes it later (§30.3). *(§34.8.1)*

Synchronous communication — An interaction in which the sender waits for the receiver to process a request and return a response before it continues; both parties must be running and reachable at the same time. *(§30.3.1)*

System — A set of interacting **components** (programs, machines, data stores, networks and people) that together deliver a capability no single component delivers alone. Components interact only through **interfaces**: agreed formats and protocols for exchanging requests, responses and data. *(§1.3.1)*

System boundary — The line that separates what you are designing and are responsible for from everything outside it: users, other teams' systems and third-party services. You control what is inside. You can only *depend on* what is outside. *(§2.4.1)*

System call (syscall) — A controlled entry from user mode into the kernel to request a privileged service, such as reading a file, sending on a socket, allocating memory or creating a process. Linux x86-64 has a few hundred system calls, each identified by a number [Linux man-pages: syscalls(2)]. *(§6.7)*

System design — The process of deciding the components of a software system, their responsibilities, their interfaces, how data flows and is stored between them, and how they are deployed — so that the system meets its functional requirements *and* its non-functional requirements (performance, scalability, availability, durability, security, cost and others) under stated assumptions about load and failure. The output of the process is also called the *system design*: a set of decisions, diagrams and documents. *(§1.3.2)*

System design interview — A 45–60-minute interview in which a candidate designs a system from an open-ended prompt (for example, “design a photo-sharing service”) in conversation with an interviewer, who evaluates the candidate’s process, technical judgment and communication rather than a single correct answer. *(§1.11.1)*

System model — A precise statement of what a distributed algorithm may assume about (1) **timing**: bounds on message delay, processing speed and clock drift, and (2) **faults**: how nodes and links may misbehave. Proofs of correctness hold only within the stated model. *(§24.6.1)*

T

TCP — A connection-oriented transport protocol that provides a reliable, ordered, full-duplex **byte stream** between two endpoints identified by (IP address, port) pairs. It achieves reliability with sequence numbers, acknowledgments and retransmission; it protects a slow receiver with **flow control**; and it protects the network with **congestion control**. *(§7.7.1)*

Template Method — A method in a base class that defines the skeleton of an algorithm as a fixed sequence of steps, some of which are abstract **primitive operations** or overridable **hooks** that subclasses supply, so subclasses vary steps without changing the sequence [Gamma et al. 1994]. *(§37.15.2)*

Tenant and multi-tenancy — A **tenant** is the unit of ownership, billing and isolation in a shared system: usually a customer organization in a SaaS product, or a team in an internal platform. **Multi-tenancy** means serving many tenants from shared infrastructure and code while keeping each tenant’s data, performance and failures separate. **Tenant isolation** is the set of mechanisms that enforce that separation. *(§47.3.1)*

Tenant placement directory — A small, highly available mapping from tenant ID to location (cell, shard or dedicated cluster), owned by the control plane and cached by every router. It lets the system place, move and isolate individual tenants, which pure hashing cannot. *(§47.6.1)*

Terraform — A declarative infrastructure-as-code tool from HashiCorp. Configurations are written in the HashiCorp Configuration Language (HCL); **providers** are plugins that translate resources into calls to a platform’s API; a **resource** block declares one infra-

structure object; **state** records which real object each resource corresponds to [HashiCorp Docs: Terraform]. *(§43.9.1)*

The four key metrics — - **Deployment frequency** — how often the organization deploys code to production. - **Change lead time** — the time from a commit being made to that commit running successfully in production. - **Change failure rate** — the percentage of deployments to production that cause a failure needing remediation (a rollback, hotfix, patch or incident). - **Failed deployment recovery time** — how long it takes to restore service after a deployment causes a failure. Earlier reports called this *time to restore service* or mean time to restore (MTTR); the 2023 report narrowed it to deployment-caused failures [DORA 2023]. *(§43.3.3)*

Thread — An independent sequence of execution within a process, with its own program counter, registers and stack, sharing the process's address space, heap, globals and open files with the process's other threads. *(§6.3.5)*

Thread pool — A fixed or bounded set of worker threads that take tasks from a queue and execute them, so the cost of creating threads is paid once and the number of concurrent tasks is capped [Goetz et al. 2006]. *(§37.16.2)*

Threat model — A structured description of a system, the **assets** in it that are worth protecting, the **adversaries** who might attack it and their capabilities, the **threats** (ways a security property could be violated), and the **mitigations** chosen for each threat [Shostack 2014]. *(§10.3.2)*

Three-phase commit (3PC) — A commit protocol that inserts a **pre-commit** phase between voting and committing, so that no participant can commit until every operational participant knows that all voted yes. Under a synchronous system model with reliable failure detection and no network partitions, it lets the surviving participants always reach a decision without the failed coordinator [Skeen 1981]. *(§28.5.1)*

Time-of-day clock and monotonic clock — A **time-of-day** (wall-clock) clock returns the current date and time, for example as seconds since the Unix epoch (Linux `CLOCK_REALTIME`, Python `time.time()`). It is synchronized with other machines and *can jump* forward or backward when corrected. A **monotonic** clock (Linux `CLOCK_MONOTONIC`, Python `time.monotonic()`) only moves forward at a steady rate from an arbitrary starting point. It is meaningless across machines but correct for measuring durations on one machine. *(§24.9.1)*

Timeout and deadline — A **timeout** is a relative duration after which a caller stops waiting for one operation (for example 300 ms). A **deadline** is an absolute point in time by which the *whole* request must complete; it is passed along the call chain so that every downstream call knows how much time remains. *(§22.11)*

Time-series database (TSDB) — A database optimized for sequences of timestamped measurements. Data is organized into **series**, each identified by a metric name plus a set of **labels** (tags) such as `{host="web-3", region="eu"}`, and each series is an append-only list of **samples** `(timestamp, value)`. *(§12.8.1)*

Time to live (TTL) — The maximum time an entry may be served after it was stored. After the TTL the entry is treated as absent (or, with stale-while-revalidate, as stale). Redis removes expired keys lazily when they are accessed and actively by periodically sampling keys that have a TTL [Redis Docs: EXPIRE]. *(§20.8)*

TinyLFU — An **admission policy**: when the cache is full and a new candidate arrives, admit it only if its estimated access frequency exceeds that of the victim the eviction policy would remove. Frequencies are estimated by a small approximate sketch (a Count-Min sketch with 4-bit counters, §17.6) over a sample of recent requests, and **aged** by halving every counter after a fixed number of requests [Einziger, Friedman & Manes 2017]. *(§20.9.3)*

Token bucket — A rate limiter that keeps a counter of **tokens**, refilled continuously at **rate** r up to a maximum **capacity** (burst size) b. Each request consumes one token (or a cost c); a request that finds too few tokens is rejected. The long-run admitted rate is at most r, and up to b requests may be admitted at once. *(§22.4.1)*

Topic, partition and record — A **topic** is a named category of records (for example `orders`). A topic is split into **partitions**, each an independent, ordered, replicated log with its own offsets starting at 0. A **record** carries an optional **key**, a **value** (opaque bytes), a **timestamp** and optional **headers**. Kafka guarantees order *within* a partition, not across partitions of a topic. *(§31.5.1)*

Torn write (torn page) — A page write that is interrupted by a crash so that part of the page on disk is new and part is old. It arises because the database page (8 or 16 KiB) is larger than the unit the device or file system writes atomically (commonly 4 KiB or 512 bytes). *(§13.12.2)*

Total cost of ownership (TCO) — The **total cost of ownership** of an option is every cost it causes over a stated horizon: infrastructure, licences and service fees, the engineering time to build, operate, upgrade and be on call for it, migration in and out, and the expected cost of its failures. **Build** means writing and running your own; **self-host** means running open-source software yourself; **managed** means paying a provider to run it; **buy** means purchasing a finished product or SaaS. *(§51.9.1)*

Trace and span (data model) — A **span** records one timed operation: a trace ID (16 bytes), a span ID (8 bytes), a parent span ID (empty for the **root span**), a name such as `POST /checkout`, a **kind** (server, client, producer, consumer or internal), start and end timestamps, a status, key–value **attributes**, timestamped **events** (for example an exception) and optional **links** to spans in other traces. A **trace** is the set of spans sharing one

trace ID; parent pointers turn it into a tree rooted at the first instrumented operation [OpenTelemetry Specification: Tracing API; Sigelman et al. 2010]. *(§40.6.1)*

Trace, span and context propagation — A **trace** records one request's path through a distributed system under a unique **trace ID**. It is a tree of **spans**, each recording one unit of work (an inbound request, an outbound call, a query) with service, operation, start time, duration, status, its span ID and its **parent span ID**. **Context propagation** passes the trace ID and current span ID from caller to callee (in HTTP headers or message metadata) so the callee's spans join the trace [Sigelman et al. 2010; W3C Trace Context]. *(§34.9.1)*

Trade-off — A situation where improving one desired property of a system makes another worse. Examples: lower latency at higher cost, stronger consistency at lower availability during network partitions, faster delivery at higher operational risk. Every design decision is a trade-off. If you cannot name what an option makes worse, you have not understood it yet. *(§2.8.1)*

Transaction — A sequence of reads and writes that the database treats as one logical unit: either all of its effects become permanent together (**commit**) or none of them do (**abort** or **rollback**), and concurrently running transactions are isolated from each other's intermediate states. *(§11.11.1)*

Transactional outbox — A pattern in which a service writes the events it wants to publish into an **outbox table** in its own database, in the same local transaction as the state change, and a separate **message relay** later reads committed outbox rows and publishes them to the broker, retrying until the broker acknowledges [Richardson 2018]. *(§32.5.2)*

Transcoding — Decoding a video from its uploaded format (the **mezzanine** or source file) and re-encoding it into one or more target formats, each defined by a codec, a resolution, a frame rate and a target bitrate. A set of renditions of one video at increasing bitrates is a **bitrate ladder** (§21.8.1). *(§54.4.1)*

Transport Layer Security (TLS) — A protocol that gives two communicating applications **confidentiality** (eavesdroppers cannot read the data), **integrity** (tampering is detected) and **authentication** (at least the server proves its identity, usually with an X.509 certificate). **HTTPS** is HTTP carried over TLS, on TCP port 443 by default. TLS 1.3 is specified in RFC 8446 (2018). *(§7.10.1)*

Trie (prefix tree) — A tree in which each edge is labeled with a character and each node represents the string spelled by the path from the root; nodes that end a stored key are marked. Looking up a key or a prefix of length L takes $O(L)$ steps, independent of how many keys are stored [Fredkin 1960]. *(§17.11.1)*

TrueTime — Google's clock API that returns time as an interval with a guaranteed error bound instead of a single value. `TT.now()` returns $[earliest, latest]$, guaranteed to contain

the absolute time at which it was called; `TT.after(t)` is true if *t* has definitely passed, and `TT.before(t)` is true if *t* has definitely not arrived. The half-width of the interval is the **uncertainty** *ε* [Corbett et al. 2012]. *(§28.8.1)*

Trunk-based development — A source-control practice in which all developers commit to a single shared branch (the trunk or mainline), either directly or through short-lived branches that live for hours to a day or two, and the trunk is kept releasable at all times [Hammant n.d.]. *(§43.3.2)*

Trust boundary — A line in a system where the level of trust changes: data or requests crossing it come from a party that the receiving side does not fully control or trust. Examples: the internet-to-load-balancer edge, the browser-to-server connection, a service calling a third-party API, a tenant's code running on shared infrastructure. *(§10.3.2)*

Two generals problem — Two armies camped on opposite hills must attack a city in the valley at the same time; either attacking alone is defeated. Their generals can communicate only by messengers who cross the valley and may be captured. The problem is to design a messaging protocol after which both generals are *certain* that they will attack together. No such protocol with a finite number of messages exists. *(§24.3.3)*

Two-phase commit (2PC) — An atomic commitment protocol in which one node, the **coordinator** (also called the transaction manager), first asks every participant (resource manager) to **prepare**, that is, to make its part of the transaction durable while keeping it invisible and to promise to commit on request; and then, only if every participant voted yes, durably records a **commit** decision and tells all participants to commit. Any no vote or timeout leads to abort [Gray 1978; Bernstein et al. 1987]. *(§28.4.1)*

Two-phase locking (2PL) — A protocol in which each transaction acquires locks (shared **S** for reading, exclusive **X** for writing) before accessing data and, once it releases any lock, acquires no new ones: a *growing* phase followed by a *shrinking* phase. **Strict 2PL** holds all X locks until commit or abort. Any schedule produced by 2PL is serializable [Eswaran et al. 1976]. *(§11.15.1)*

U

Ubiquitous language — A rigorous vocabulary built by developers and domain experts for one model and used consistently in conversation, tests and code, so that each term means exactly one thing within that model [Evans 2003]. *(§34.4.1)*

UDP — The User Datagram Protocol [RFC 768] is a connectionless transport protocol that adds only port numbers, a length and a checksum to IP. Its 8-byte header provides process-to-process delivery of individual **datagrams** with no handshake, no acknowledgments, no retransmission, no ordering, and no flow or congestion control. *(§7.8)*

Unified Modeling Language (UML) — A general-purpose graphical language for specifying, visualizing and documenting software systems, standardized by the Object Management Group (OMG). The current version, UML 2.5.1 (December 2017), defines 14 diagram types divided into *structure* diagrams (what the system is made of) and *behavior* diagrams (what it does over time) [OMG 2017]. *(§38.3.1)*

Unit cost and unit economics — A **unit cost** is the cost of delivering one unit of business value: one request, one active user, one order, one GB stored or one model inference. **Unit economics** compares that cost with the revenue the same unit earns. The **contribution margin** of a unit is its revenue minus every cost that varies with it; it is what the unit contributes toward fixed costs and profit. *(§51.4.1)*

USE method — For every **resource**, check **U**tilization (the fraction of time the resource was busy, or the fraction of its capacity in use), **S**aturation (the amount of extra work queued because the resource could not service it) and **E**rrors (the count of error events) [Gregg USE]. A resource is any physical or software component with finite capacity: CPUs, memory, disks, network interfaces, controllers and interconnects, but also locks, thread pools, connection pools and file descriptors. *(§23.3.2)*

V

V8 isolate — An instance of the V8 JavaScript engine's heap and execution state. Many isolates run inside one operating-system process, each with its own memory and globals and no access to another's objects; switching between them costs about as much as a function call, not a process context switch [Bloom 2018]. *(§48.8.1)*

Varint — A variable-length encoding of an unsigned integer in base 128: each byte carries 7 bits of the number, least-significant group first, and the most significant bit (MSB) of each byte is a continuation flag — 1 means "another byte follows" [Protocol Buffers Docs: Encoding]. *(§8.9.2)*

Vector — An ordered list of d numbers, $\mathbf{a} = (a_1, a_2, \ldots, a_d)$, where d is the **dimension**. Geometrically, a vector is an arrow from the origin to a point in d-dimensional space; its **length** (or norm) is $\| \mathbf{a} \| = \sqrt{a_1^2 + \cdots + a_d^2}$. *(§4.9.1)*

Vector clock — With n processes, each process P_i keeps a vector $V_i[1..n]$, initially all zeros. Before each event, P_i increments $V_i[i]$; a send attaches a copy of V_i. On receiving a message carrying V_m, P_i sets $V_i[k] \leftarrow \max(V_i[k], V_m[k])$ for every k, then increments $V_i[i]$. *(§24.11.1)*

Vector database — A data store that indexes high-dimensional numeric vectors (**embeddings** produced by machine-learning models) and answers **approximate nearest neighbor (ANN) search** queries: "the k stored vectors most similar to this query vector", by cosine similarity, dot product or Euclidean distance. *(§12.10)*

Vertical scaling (scaling up) — Increasing the capacity of a single node by giving it more or faster CPU cores, memory, storage or network bandwidth, for example by moving a database from an 8-core to a 64-core machine. *(§18.3.1)*

Virtual memory — A mechanism in which every address a program uses is a **virtual address** that the hardware's **memory-management unit (MMU)** translates, using tables maintained by the kernel, into a **physical address** in RAM, or into a fault if no valid mapping exists. *(§6.6.1)*

Virtual node (vnode) — One of V ring positions belonging to the same physical node, typically obtained by hashing labels such as `db-3#vn17`; also called a **token**. *(§14.8.1)*

Virtual private cloud (VPC) — A logically isolated, software-defined network in a provider's cloud, defined by a private CIDR range (§7.4) and divided into **subnets**. Packets between instances are encapsulated by the provider's virtual network (on Nitro, by the cards) and delivered according to the VPC's **route tables** and firewall rules, regardless of which physical hosts the instances are on. *(§41.10.1)*

Volcano (iterator) model — An execution model in which a query plan is a tree of operators, each implementing the same interface — `open()`, `next()` and `close()` — and each `next()` call pulls one row from the operator's children on demand [Graefe 1994]. *(§11.9.2)*

W

Watermark — A watermark with value t is a statement flowing through the stream: "no more events with event time $\leq t$ are expected." It lets event-time operators decide that a window is complete. A **perfect** watermark is possible only with full knowledge of the sources; real systems use **heuristic** watermarks, such as the maximum event time seen minus a bound δ on out-of-orderness, which can be wrong. Events that arrive with event time behind the watermark are **late data**. *(§29.8.3)*

WebRTC — A set of IETF protocols (overview in RFC 8825 [Alvestrand 2021]) and a W3C browser API [W3C WebRTC] for real-time audio, video and arbitrary data directly between peers. Media travels over SRTP, data over SCTP data channels, both secured by DTLS, typically over UDP; peers discover a working network path using ICE with the help of STUN and TURN servers. *(§9.7.1)*

WebSocket — A protocol, standardized in RFC 6455 [Fette & Melnikov 2011], that starts as an HTTP/1.1 request, *upgrades* the underlying TCP connection, and thereafter carries a full-duplex sequence of framed messages in both directions with 2–14 bytes of framing overhead per frame. URLs use the schemes `ws://` (plain TCP, default port 80) and `wss://` (over TLS, default port 443). *(§9.6.1)*

Wide-column store — A database whose rows are identified by a key, sorted (globally or within a partition) by that key, and contain a sparse, variable set of columns grouped into **column families**; each row may have millions of columns and each cell may hold several timestamped versions. Bigtable, HBase, Cassandra and ScyllaDB belong to this family. *(§12.6.1)*

Write-ahead log (WAL) — An append-only file of **log records** describing every change to the database, written *before* the changed pages themselves reach disk. Each record is identified by a monotonically increasing **log sequence number (LSN)**, usually its byte offset in the log. Also called the redo log (InnoDB) or journal. *(§13.5.1)*

Write-around — Writes go directly to the database and bypass the cache; the cache is populated only by reads (usually cache-aside), and the written key is invalidated or left to expire. *(§20.7.6)*

Write-back — Writes update only the cache and are acknowledged immediately; the cache marks entries **dirty** and flushes them to the database asynchronously, in batches or after a delay. *(§20.7.5)*

Write-through — Every write goes to the cache, which synchronously writes it to the database before acknowledging; the cache is updated and the database is updated as one client-visible operation. *(§20.7.4)*

X

XA — The X/Open Distributed Transaction Processing standard interface between a **transaction manager** (TM, the coordinator) and **resource managers** (RMs: databases, message brokers), with an **application program** (AP) demarcating transactions. Its main calls are `xa_start` and `xa_end` (associate work with a global transaction ID, the XID), `xa_prepare`, `xa_commit`, `xa_rollback` and `xa_recover` (list in-doubt XIDs after a crash) [X/Open 1991]. *(§28.4.6)*

Z

Zero trust — A security model in which network location confers no trust: every request is authenticated, authorized and encrypted based on the identity of the user, the device and the workload, plus contextual signals, regardless of where it originates. NIST SP 800-207 describes it as moving defenses “from static, network-based perimeters to focus on users, assets, and resources” [NIST SP 800-207]. *(§10.10.1)*

Zipf (Zipf-like) distribution — A popularity law in which the item of popularity rank i is requested with probability proportional to $1/i^s$, where $s > 0$ is the **skew exponent**. Breslau et al. found that requests to web proxies follow a Zipf-like law with an exponent below 1

and that, as a consequence, hit ratio grows roughly logarithmically with cache size [Breslau et al. 1999]. *(§20.3.3)*

ZooKeeper — A replicated coordination service that exposes a small, file-system-like tree of data nodes (**znodes**) with linearizable writes, FIFO per-client ordering, ephemeral and sequential nodes, and change notifications (**watches**). Applications build locks, leader election, barriers and configuration management on top of these primitives [Hunt et al. 2010]. *(§26.8.1)*
